ides Cr_2O_3 , MoO_3 , and Fe_2O_3 . The peak denoted OH^- has the same position as oxygen in $\text{Cr}(\text{OH})_3$ and Mo-hydroxide. This peak overlaps with the signal from the OH group of methanol. The third peak represents water as well as oxygen in acetone. The samples polarized at the dissolution potential were treated in acetone only. The passivated samples were rinsed in acetone and methanol. The difference in rinsing treatment can be read from the figure. It appears that the oxygen peaks recorded after passivation are narrower than after dissolution. This shows that methanol completely removes acetone from the surface, but, on the other hand, this also implies that water bonded in the passive film could be removed. In interpretation of the oxygen signals, the intensity of the peaks representing OH^- and H_2O are reduced by the contribution from methanol and acetone. The contribution is estimated to be $2.5 \times I(\text{C})$, where $I(\text{C})$ is the intensity of the corresponding carbon peak ($\text{C}-\text{OH}$ or $\text{C}=\text{O}$). It appears from the figure that Cl^- ions (BE = 198.5) are present in the oxide product. No Na^+ ions were detected; thus, Cl^- ions are not bound as salt crystals on the surface. Later, it will be shown that the Cl^- ions are incorporated in the film.

Figures 7-11 show the results obtained from quantitative evaluation of the ESCA spectra. The data obtained are given for each individual experiment at the dissolution potential -320 mV and the passive potentials -100 and $+500$ mV. The notations MP and IE refer to the pretreatments, mechanical polishing and ion-etching, respectively. The cation contents in Fig. 7 are calculated from the intensities obtained in the as-polarized condition, i.e., before ion etching. Thus they do not take into account any in depth variations of the composition. Furthermore, all oxide states are summed.

The passive films formed at -100 and $+500$ mV (SCE), polarized for 1h (Fig. 7), consist mainly of Cr^{3+} compounds (oxide and hydroxide). The Cr^{3+} content is about 70%. It seems to be constant and does not vary with the potential. The measured Fe^{ox} (Fe^{2+} and Fe^{3+}) content is in the range 20 to 25 atom percent (a/o) at -100 mV (SCE) and slightly higher at $+500$ mV (SCE). The higher Fe^{ox} concentration at $+500$ mV compensates for the lower Mo^{ox} content at this potential. The measured Mo^{ox} is 7-9 a/o at -100 mV

(SCE) and about 5 a/o at the higher potential. It appears from the figure that the cation content is independent of the pretreatment of the surface. It could be expected that the Mo content of the samples pretreated by ion etching should be higher because ion etching causes enrichment of Mo on the surface due to the lower sputtering rate of Mo.

The oxide products formed on the surface during rinsing and transferring of the polarized sample to the dissolution potential, -320 mV (SCE), depend on the pretreatment procedure. Figure 7 shows that the mechanically polished (MP) samples polarized for 5 min at the dissolution potential consist mainly of Fe^{ox} . The Cr^{3+} is only 35 a/o, which is half of the value obtained after passivation. The Mo^{ox} content is about 15 a/o, which is twice as much as obtained after passivation at -100 mV. The samples prepared by ion etching and polarized for 5 min show much higher Cr^{3+} contents (52 and 55 a/o). The Fe^{ox} and Mo^{ox} concentrations are about 35 and 10 a/o, respectively. Polarization for 1h gives about the same result. It is suggested that the high Cr^{3+} content in the film is indirectly an effect of the ion etching. The etching causes enrichment of Mo on the surface and makes it impossible to keep the surface in its active state; instead, it is passivated.

The thicknesses of the surface oxide products are shown in Fig. 8. It appears that the thickness of the passive film increases with the potential. The values at -100 and $+500$ mV (SCE) are 10 and 15 Å, respectively. After treatment at the dissolution potential, the thickness of the oxide formed on the mechanically polished surface is 5 ± 1 Å. The average value of the ion-etched samples is about 40% higher.

Figure 9 shows the measured Cl^- ion content vs. the thickness of the oxide layer. The values are given before and after a slight ion etching. The ion etching was performed to establish whether the Cl^- ions were adsorbed on the surface or bonded in the oxide. The results show that Cl^- ions are found in the oxide. The figure indicates that at the corrosion potential the highest Cl^- content occurs on the surface covered with the thinnest oxide. The content of Cl^- ions increases with the potential in the passive range. The distribution of Cl^- ions through the

Fig. 6. Deconvoluted ESCA spectra of Mo from Fig. 5

passive film, obtained from ion etching, is shown in Fig. 10. Neglecting selective sputtering effects, it appears that the highest Cl^- concentration exists in the outer layer of the film.

Fig. 7. The cation contents of the reaction products formed at -320 mV (SCE) and of the passive films formed at -100 mV (SCE) and at $+500$ mV (SCE).

Fig. 8. Thickness of the oxide product vs. the potential

Figure 11 shows distribution of the ions through the passive film obtained by polarization to $+500$ mV (SCE). All Mo concentrations are multiplied by a factor of 10. The data points are average values from four measurements. Before ion etching, the difference between the total charges of cations and anions is less than 2%. The most characteristic feature of the figure is the high OH^- concentration in the outer layer. After ion etching, the OH^- content decreases and the O^{2-} increases. However, it has been demonstrated above that this is at least partly an artifact due to ion etching. It also appears that the outer layer contains hydration water. The profile shows that Cr^{3+} is the dominating species in the inner layer of the passive film. That this result should be an artifact can be excluded because prolonged sputtering into the bulk of the alloy with oxygen present in the sputtering gas (low pressure) gives a ratio between Fe^{ox} and Cr^{3+} which is almost identical to the alloy composition. The profile shows that Fe^{2+} is mainly present in the outer "hydroxide" phase. The content of Fe^{2+} in the inner layer may be an effect of the ion etching because Fe^{3+} is partly reduced to Fe^{2+} . It is suggested that the low Fe^{2+} content in the inner layer is not due to the fact that Fe^{2+} is reduced to the

Fig. 9. Cl^- ion content vs. the thickness of the oxide product

Fig. 10. Cl^- distribution at -100 mV (SCE) and at $+500$ mV (SCE)

metallic state of Fe because, in our experimental setup, we have never observed reduction of Fe^{3+} via Fe^{2+} to Fe^{met} . The Mo content in the passive film is less than 2%. At this potential, Mo is mainly present in the outer layer as Mo^{6+} , while at low potential Mo^{4+} is dominating. Both Fe and Mo are detected in the inner layer of the oxide.

Due to the fact that the oxide products on the alloy are very thin, it is possible to get information about the composition of the metallic state underneath the oxide. The dots in Fig. 12a mark the calculated (by using the formulas [2] and [3]) composition of the metal phase after polarization to the corrosion potential of the sample. The composition obtained is apparent because the formulas [2] and [3] do not take into account the real distribution of the alloying elements in the surface region. The solid bars show the bulk composition of the alloy. It appears from the figure that the apparent Fe concentration is about 10 a/o units lower than the Fe content of the alloy. It also shows that Ni is markedly enriched in the surface region because the apparent Ni content is about twice as high as the figure given from the chemical analysis of the alloy. Furthermore, Mo is slightly enriched, while Cr is depleted in the surface region.

Above, it has been emphasized that the oxide products present on the surface after polarization to the corrosion potential are mainly formed during rinsing and transferring of the sample. It is suggested that the depletion of Cr in the metal phase is caused by selective oxidation during handling of the sample because the Cr

Fig. 12. The composition of the metal phase during dissolution at active potential. a: The apparent metal content. b: The estimated metal content in the outermost atomic layer (15).

content in the oxide is higher than in the alloy. Iron, on the other hand, shows lower concentration in both the oxide and the metal phases compared to the bulk concentration. This observation shows that Fe is dissolved selectively during dissolution at the corrosion potential. Thereby the alloying elements are enriched on the surface.

The observation that Fe is selectively dissolved during dissolution of stainless steel in the active range of the alloy has been reported earlier (10-12). An extensive analysis of the distribution of the alloying elements in the neighborhood of the surface is given in Ref. (15). In that paper, the cations present in the oxide were converted to their metallic state. Also, it was assumed that the alloying elements differ from the bulk concentration in the three outer atomic planes.

The composition of the outermost atomic plane is shown in Fig. 12b [using the procedure in Ref. (15)]. The solid lines in each bar show the average value, while the white area is the standard deviation. The figure shows that during anodic dissolution the alloying elements Cr, Ni, and Mo are significantly enriched in the surface region.

In Fig. 13, the precision of the quantitative method is demonstrated. The alloy was polished on emery paper in methanol and transferred to the analyzer. It is suggested that no selective dissolution of the alloy occurs during polishing in methanol. The apparent composition is shown in Fig. 13a. The cations in the oxide (8\AA) formed during transfer were converted to their metallic state, and the composition of the outermost layer was calculated (Fig. 13b). The calculated concentration of the alloying elements in the outermost atomic plane in this case is very close to the bulk composition of the alloy. Thus, the enrichment of the alloying elements during active dissolution of the alloy is a real effect.

Discussion

This study confirms the duplex structure of the passive film with an outer layer of hydrated hydroxide and an inner layer of oxide. The thickness of these layers cannot be determined exactly, but the sputtering profiles of oxygen in OH^- and H_2O states show that the hydroxide layer is at least one third of the whole film. Both layers consist of mainly Cr^{3+} compounds. Of the total cation content, the content of Cr^{3+} is at least 70 a/o. Nickel in its oxide state cannot be detected in the passive film. Iron is

Fig. 13. The austenitic steel polished on emery paper in methanol. a: The apparent content b: The estimated composition of the outermost layer (15).

present in its di- and tri-valent states. The molybdenum content in the passive film is low, a few atomic percent. At -100 mV (SCE), the Mo four-valency state is dominant, while at $+500$ mV (SCE) Mo is present mainly as Mo^{6+} . The oxidation states of both Mo and Fe are reduced during ion etching. Considering the above, it can be concluded that the inner oxide layer consists mainly of Cr and Fe in their three-valency states.

The analysis shows that Cl^- ions are present in the surface products. The amount increases with the potential in the passive range. A suggested explanation for this behavior is that the field strength is higher at the high potential, even in spite of the fact that the layer is thicker. The incorporation of Cl^- in the film is completely different from the situation when stainless steel is exposed in sulfuric acid (12). In that case, SO_4^{2-} ions are merely adsorbed on the surface and completely removed by a slight ion etching. The difference in behavior is suggested to arise from the fact that the Cl^- ion is the same size as the OH^- ion and, therefore, can easily be substituted in the outer hydroxide layer.

The role of Mo has been discussed in the literature. Sugimoto *et al.* (6, 16) and Hashimoto *et al.* (8, 9) suggest that the stability of the oxide film in acid chloride solutions is the result of hexavalent molybdenum oxide forming on the surface. Hashimoto explains the fact that Mo alloyed steels show a much lower current in the passive region by a model in which the passive film is not homogeneous; instead, it contains a high density of microcracks through which current can leak. The microcracks are filled with water, and this is responsible for the high current. In the case of Mo-alloyed steels, Mo^{6+} ions are formed in the cracks and thereby decrease the size of the active sites. It was also mentioned that this Mo^{6+} compound is formed on the surface during active dissolution preceding passive film formation. This idea is to some extent contradictory to the results reported in this study. It has been shown that the six-valency state of Mo is obtained at high potential. At low potential, Mo^{4+} dominates. Also, comparing the result from passivation of pure Mo (17) no six-valency Mo compound is found at potentials lower than $+250$ mV (SCE). However, from a thermodynamic point of view (18), Mo^{6+} is expected even at lower potentials; Mo is oxidized to MoO_3 above -182 mV and to MoO_4^{2-} above -242 mV (SCE) (standard conditions). Interpretation of these compounds by ESCA is not an easy task due to the fact that the positions of the signals repre-

senting Mo in the compounds are very close to each other.

Our result indicates that Mo is uniformly distributed through the layer. Support for this statement is that the high energy peak of the complex Mo^{4+} signal is dominating after passivation and that both Mo^{4+} and Mo^{6+} exist through the layer. We suggest that the role of Mo in the passive film is that it stabilizes the oxide products. At least the outer hydroxide layer is influenced. It is known that some Mo complexes [*i.e.*, $\text{Mo}_3\text{Cl}_4(\text{H}_2\text{O})_2(\text{OH})_2 \cdot 6\text{H}_2\text{O}$] are insoluble in acid while corresponding Fe-Cr-compounds are soluble. It has been suggested by Wanklyn (19) that hydrated MoO_2 occurs in the passive film. We conclude that the outer part of the passive film consists of a mixed hydroxide containing Mo, Fe, and Cr. The latter is directly observed in the spectra.

We have reported (12) that in the case of ferritic steels exposed in 0.5M H_2SO_4 the passive film consists almost entirely of Cr_2O_3 in the inner layer. It was suggested that it is this inner oxide layer that is rate determining for the dissolution. The observation that the oxide consists of mainly three-valency cations implies that the defect density of the passive film is low. However, both lower (Fe^{2+}) and higher (Mo^{4+} and Mo^{6+}) valency cations are present in the film. It is suggested that the defects created by Fe^{2+} are canceled by the defects created by Mo^{4+} and Mo^{6+} . Thus, an almost defect-free oxide is formed in which ionic conductivity is extremely low.

It is found that the thicknesses of the passive films formed on this austenitic steel in hydrochloric acid (0.1M HCl) and on a Mo containing ferritic steel (12) in sulfuric acid (0.5M H_2SO_4) follow the same potential dependence. Even the absolute thickness is almost the same. In the case of non-Mo containing steel (12), the film was noticeably thicker at low potential. Thus, the thickness of the passive film seems mainly to be dependent on the Mo content in the alloy.

At the dissolution potential of the alloy, the alloying elements Ni, Cr, and Mo are enriched on the surface in their metallic states. The enrichment is caused by selective dissolution of Fe. The high Ni content is directly observed from the measurements. The contents of Cr and Mo were obtained by converting the cations in the oxide to their metallic states. It was not possible to avoid a slight oxidation of the surface during handling in spite of all precautions taken. It could be argued that Cr in its oxide state is present on the surface even during active dissolution because pure Cr is passive at the dissolution potential of the alloy (Fig. 2). However, even Fe and Mo are present as oxide on the surface after the dissolution treatment. Iron is the dominating cation in the oxide product, but pure Fe is definitely not passive at the corrosion potential of the alloy. A further indication for the statement that most of the oxide is formed after polarization is that the oxide product formed on the surface of an etched sample in the protecting atmosphere of the cell is thicker than the products discovered after polarization to the corrosion potential.

The selective dissolution of Fe is controlled by the interatomic forces over the interface (metal/solution) and between the alloying elements. Earlier (11), it has been suggested that the elements form a surface phase with lower Fe content than the bulk composition of the alloy. The alloy system forms at high temperature intermetallic compounds (σ -, X-, and Laves phases). During active dissolution, corresponding phases are suggested to be formed due to interaction between the atoms. The initiation of the enrichment is described by the model: at the corrosion potential of the alloy, the dissolution rates of Fe and Cr are higher than the dissolution rate of Mo and Ni because Fe and Cr are less noble than Mo and Ni; interatomic forces between Cr and Mo slow down the dissolution rate of Cr, and thereby it is enriched on the surface. After the initiation, a steady state is reached where the overall dissolution rate is lowered.

The analysis shows that the thickness of the passive film increases with the potential in the passive region.

Fig. 14. The apparent metal content of the alloy vs. the potential (SCE).

Because Ni is not present in the oxide (or to only a low extent) and dissolves with a lower dissolution rate than Fe, it is enriched under the passive film. Figure 14 shows the apparent composition of the metal phase. It appears that the apparent Ni content is about twice as high as the bulk composition and that it increases with the potential. Because the excess of Ni atoms is located in a few atomic planes close to the oxide/metal interface, the Ni content of the outermost of these is higher than the value given in the figure.

Because all electrochemical reactions between the metal and the environment take place in the outermost atomic plane, the surface composition and the surface state contribute to the overall reactions and control factors as dissolution rate, overpotential, corrosion potential, and passivability. From the polarization diagram, Fig. 2, it appears the corrosion potential of the alloy is close to the corrosion potential of pure Mo and Ni. It has been emphasized that one beneficial effect of Mo and Ni is the enrichment of these elements on the surface during the anodic dissolution (10, 11, 15) that always precedes passivation. Thereby, the dissolution rate is lowered and the passivation of the alloy is provoked.

Conclusions

The passive film formed on a Mo containing austenitic steel consists of Cr oxide containing Mo and Fe. Chro-

mium is present in hydroxide and oxide compounds. The Ni content of the film is very low. The valency states of Mo are Mo^{4+} at low potentials and Mo^{6+} at high potentials. Chloride ions are incorporated into the oxide passive film. The alloying elements Cr, Ni, and Mo are enriched on the surface during active dissolution. The enrichment is caused by selective dissolution of Fe. The enrichment of the alloying elements provoke passivation of the alloy.

Kinetics and Mechanism of Passive Film Formation on Iron in 0.05M NaOH

T. Zakroczyński,¹ Chwei-Jer Fan, and Z. Szklarska-Smialowska*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Simultaneous electrochemical and ellipsometric studies of the anodic film growth on iron in 0.05M NaOH have revealed that passivation occurs in two stages. During the first stage, which lasts for about 2s, the anodic current is consumed only for film growth, whereas in the second stage ($t > 2s$) release of iron cations into the electrolyte also occurs. The chemical composition of the passive film formed for times longer than 2s corresponds to FeOOH with a constant density and a complex index of refraction of $\tilde{n} = 1.84(1 - 0.075i)$. During the first stage of film formation ($t < 2s$), the film density and the complex index of refraction change from values characteristic of the electrolyte to those of FeOOH, which is probably related to the fact that the amount of water occluded in the passive film decreases with time. The film thickness increases with increasing anodic potential. A major increase in film thickness occurs during the first 0.2-0.5s.

Although numerous papers have been published in the field of iron passivity, there is little comprehension of some fundamental aspects of this phenomenon. This is particularly true of the passive film formation on iron in alkaline solutions, since the major part of research work has been performed in neutral or near-neutral borate electrolytes. Therefore, literature data concerning alkaline solutions are scanty. Foley *et al.* (1) found the passive film on iron in 0.1M NaOH to be γ -Fe₂O₃, but their conclusion was based on electron diffraction studies conducted on dried films. Froelicher *et al.* (2) used Raman spectroscopy to study *in situ* the passivation of iron in various solutions. In a 1M KOH solution, in which oxidation/reduction cycles had been applied to an electrode, only Fe₃O₄ was found. Donnwald *et al.* (3) also studied the passive film on iron in 1M KOH by Raman spectroscopy. In their study, the iron samples were cycled from cathodic to transpassive potentials at a rate of 1 mV/s. From the spectra obtained, the film appeared to be composed of Fe₃O₄. The trivalent compound which came nearest to matching the spectra was amorphous δ -FeOOH. When the cycle rate was increased to 50 mV/s, a weakly attached reddish-brown layer was formed. This layer was thought to be α -FeOOH, which covered the Fe₃O₄ layer. Huang and Ord (4) took ellipsometric measurements on an iron electrode which was cycled galvanostatically in 0.05M NaOH. They concluded that a low density outer layer built up progressively over an inner layer of a compact oxide which was identified as Fe₃O₄. The inner layer reached a maximum thickness of approximately 3.8 nm at oxygen evolution and was removed completely by cathodic reduction, whereas the outer layer thickness grew by more than 10 nm/cycle. According to the authors, the outer layer is not merely a by-product layer but is alternately oxidized and reduced on each cycle, and has different refractive indexes in its oxidized and reduced states. More recently, Sarver and Szklarska-Smialowska (5) have found that, in NaOH solution of pH 12, as in borate solutions (6), the growth of the passive film occurs in four stages. In the first two stages, which last for only approximately 1s, the thickness of the film achieves 60% or more of its final thickness. They conclude that the composition of the film is probably closer to FeOOH than to Fe₃O₄ or Fe₂O₃.

The present paper is the first of a series of works of which the objective is to use electrochemical and ellipsometric techniques to characterize the passivity of iron in alkaline solutions. In particular, efforts are made to elucidate some fundamental aspects, such as (i) the mechanism and kinetics of film growth, (ii) composition, structure, and physical properties of the passive film, and (iii) effects of environmental factors—electrolyte composition (Cl⁻, chelating agents) and potential.

¹ On leave from the Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, 01-224 Warsaw, Poland.

The subject of this study is passivation of iron in 0.05M NaOH solution (pH = 12.0).

Experimental

The material used was pure iron. Its chemical composition is given in Table I. The specimen was machined from a rod of 6.35 mm diam, and was mounted in a Teflon holder. The exposed metal surface, which was perpendicular to the rod axis, had an area of 31.7 mm². The specimen was first ground to a 600 grit finish and then mechanically polished with diamond paste to 1 μ m finish. After polishing, the specimen was ultrasonically cleaned in methanol and placed in the ellipsometric cell. An automatic ellipsometer, Rudolph Model Type 2000, was employed. The wavelength was 546.1 nm. The angle of incidence was 71.0° in most experiments.

Simultaneous ellipsometric and electrochemical measurements were performed. Before each measurement, the specimen was cathodically reduced at $-0.950 V_{NHE}$ for 10-15 min. Next, the electrode potential was rapidly changed (sweep rate 80 V/s) to the desired potential in the passive region and changes in electrochemical and ellipsometric parameters were recorded. A high speed electronic recorder (Bascom-Turner Model 3120 T) was used to collect data during the first 2s, and electromechanical recorders (Bio-Rad Model 1322) were applied to collect data at a slower speed during the entire experiment. All measurements were carried out at $24^\circ \pm 1^\circ C$. A Hg/HgO/0.1M NaOH reference electrode ($\cong 0.160 V_{NHE}$) was used for electrode potential measurements. All potential values given below are in the normal hydrogen electrode scale. The optical constants of iron, the films on its surface, and the film thicknesses were calculated using the McCrackin computer program (7) with some modifications.

Results

Electrochemical data.—Figure 1 shows the potentiodynamic anodic polarization curves measured at four different potential sweep rates. With increasing potential sweep rate, both the maximum current density at the potential corresponding to the active/passive transition and the current density in the passive region increased.

Figure 2 depicts changes in the anodic current density *vs.* time observed when the electrode potential was rapidly changed from $E = -0.950 V$ to the following four potentials in the passive region (E^*): -0.350 , -0.050 , 0.250 , and $0.550 V$. At first, the current density (i_{Total}) increased with time, and after about 0.1s achieved a maximum value. Maximum current density increased when a more positive potential was applied. Afterward, the current decreased quite rapidly, and then much more slowly for times longer than 2s. In this final stage, the log current density was a linear function of log time with a slope of about -0.5 .

Table I. Chemical composition of the iron used in this study (ppm)

C	N	O	Na	Mg	P	S	Cl	K	Co	Ti	Cr	Cu	Zn	Fe

Figure 3 shows changes in the anodic charge density corresponding to changes in the current density taken from Fig. 2. The meaning of i_{film} in Fig. 2 and the method used to determine q_{film} in Fig. 3 are described in the Discussion section.

Ellipsometric data.—The optical parameters of the bare metal after polishing and cleaning measured in air were $n = 2.43$ and $k = 1.36$. After exposure to 0.05M NaOH and cathodic treatment at $E = -0.950V$, the optical parameters changed their values, as shown in Fig. 4. After about 900s, the complex index was $\tilde{n} = 2.72 (1 - 1.27i)$, lower than that reported in the literature for a bare iron surface, for instance, in borate (8, 9) or orthophosphate (10) solutions. During continuous cathodic polarization, the optical parameters n and k continued to change; n decreased, and k increased with time (Fig. 4).

Ellipsometric parameters α and ϵ , which were recorded during anodic polarization, were converted to $\delta\Delta$ and $\delta\psi$, where Δ and ψ are relative phase and amplitude parameters. Relationships between $-\delta\Delta$ and $\delta\psi$ for the four applied potentials are shown in Fig. 5, while changes in $-\delta\Delta$ with time are plotted in Fig. 6.

Discussion

Metal dissolution and passivation.—In the first place, the characteristic relationship between the anodic current density and time shown in Fig. 2 deserves special notice. Generally, a sudden change in the electrode potential from a slightly cathodic to an anodic value may result in changes of the anodic current with time which depend upon the processes occurring at the metal/electrolyte interface. The following three cases of the current vs. time relationship, schematically presented in Fig. 7, can be considered.

Active dissolution: curve A-B-C.—The anodic current increases to a constant level B-C depending upon the applied potential and other experimental conditions. Assuming that all products of the anodic processes

occurring on the metal surface are rapidly transferred into the bulk of solution, no surface impediments take place. The slope of the A-B curve depends upon the potential sweep rate.

Full passivity: curve A-M-O.—Products of the anodic processes accumulate on the metal surface and form a passivating film. The anodic current increases more slowly than in the previous case. The surface film thickens, becomes more dense (or compact), and hinders more and more the anodic processes. At point M, the anodic current reaches a maximum value and begins to decrease when the impeding effect overcomes the ability of the metal to be ionized. If all the anodic reaction products are used for surface film formation with no release of cations to the surrounding electrolyte, the current would finally fall to zero at point O.

Incomplete passivity: curve A-M-N-P.—After reaching some limiting thickness and density at point N, the film does not grow any more and its hindering effect on the anodic current assumes a constant and time-independent level.

Incomplete Passivity: curve A-M-N-Q.—If the film density ρ attains a constant value at point N but the film thickness d still increases or, on the contrary, d assumes a constant value but ρ can still increase, changes in the

Fig. 6. Changes in $-\delta\Delta$ with time at different potentials

anodic current would be represented by line N-Q. Of course, simultaneous changes of d and ρ with time cannot be excluded.

It is obvious that the above model is simplified. However, it seems likely that when the characteristic deflection point N (Fig. 7) is observed after a relatively short period of time, one can presume that up to this moment there is practically no dissolution of the metal in the sense of forwarding metal cations into the bulk of solution.

Comparison of the experimental curves shown in Fig. 2 (coarse lines) with those schematically plotted in Fig. 7 leads to the conclusion that the real course of events ob-

Fig. 7. Schematic representation of possible changes in current density with time as a result of film formation during the anodic polarization of iron.

served in these measurements corresponds to the above case 3b (curve A-M-N-Q in Fig. 7). It is apparent that up to $t = 2$ s there is practically no release of metal cations to the bulk of solution. In this first stage, all reaction products are consumed by the film, which grows thicker and becomes denser. Later on, however, film growth occurs simultaneously with release of metal cations to the surrounding electrolyte.

The next question to be asked is: what share of the total current is consumed by film growth for $t > 2$ s? This share, i_{film} , was estimated by extrapolating the linear parts of M-N curves shown in Fig. 2 (fine lines), which are characterized by a slope of about -1 . The magnitude of this slope suggests that the changes in current density are associated with the film growth, as has been observed for tantalum, aluminum (11, 12), and stainless steel (13). In this manner, the charge consumed for film growth, q_{film} , could be evaluated. The results are represented by fine lines in Fig. 3.

Complex index of refraction, film composition, and thickness.—The complex index of refraction could be calculated from Δ and ψ values. The computer simulation generated the relationship between film thickness, $\delta\Delta$ and $\delta\psi$ for different combinations of n and k . First, certain combinations of n , k , and film thickness (d_{EL}) were selected by matching the experimentally obtained $\delta\Delta$ and $\delta\psi$ values with the computer-generated ones. Second, the film charge density, q_{film} , was used to calculate the thickness, d_{CH} , of the film of an assumed composition, using the following equation

$$d_{\text{CH}} = \frac{q_{\text{film}}M}{zF\rho} \quad [1]$$

where M is the molecular weight of the species formed, z is the number of electrons per elementary reaction, F is the Faraday constant, and ρ is the density of the species formed. The d_{CH} values were calculated for different possible compounds, namely, FeOOH , Fe_3O_4 , $\text{Fe}(\text{OH})_2$, $\text{Fe}(\text{OH})_3$, and Fe_2O_3 , and for $t = 600$ s, during which the film density was believed to attain a constant level. The calculated d_{CH} values and the observed values of $\delta\Delta$ and $\delta\psi$ for the applied anodic potentials and $t = 600$ s are given in Table II and in Fig. 8. The experimental values of $\delta\psi$ vs. $-\delta\Delta$ are plotted in Fig. 8 by open characters, whereas the values of d_{CH} vs. $-\delta\Delta$ are marked by solid ones. The computer-generated relationships $\delta\psi = f(-\delta\Delta)$ and $d_{\text{EL}} = f(-\delta\Delta)$ which fit best to the experimental results are presented by continuous lines. The best fit has been found for the following complex index of refraction: $\tilde{n} = 1.84 (1 - 0.075i)$, which seems to correspond most closely to FeOOH .

Table II. Film charge density (q_{film}), film thickness calculated from charge (d_{CH}) for possible compounds in the film and ellipsometric parameters ($-\delta\Delta$ and $\delta\psi$)
time = 600s

	Potential, E^* (V_{NHE})			
	-0.350	-0.050	0.250	0.550

Fe ₂ O ₃ , $M = 159.7$ $\rho = 5.24 \text{ g/cm}^3$ $z = 3$	4.08	5.41	6.14	7.17
$-\delta\Delta$, degree	4.00	5.68	6.65	8.10
$\delta\psi$, degree	0.54	0.85	1.05	1.26

To ascertain that the ellipsometric data measured were true, additional measurements using different angles of incidence have been carried out. In Fig. 9, the computer-generated relationships $\delta\psi = f(-\delta\Delta)$ for $\tilde{n} = 1.84 (1 - 0.075i)$ and those experimentally observed at two angles of incidence, namely, 71° and 60°, and at $E^* = 0.550V$, are compared. The accordance is very good. Moreover, it can be concluded that the angle of incidence mainly used in this work (71°) has been chosen correctly because it provides significant changes in both the ellipsometric parameters Δ and ψ .

Film growth kinetics.—The kinetics of film growth was estimated on the basis of electrochemical and ellipsometric results as follows. Using Eq. [1], the film charge density vs. time (Fig. 3) was converted into the relationship $d_{CH} = f(t)$, shown in Fig. 10. On the other hand, considering the $-\delta\Delta$ vs. t relationship (Fig. 6), and also that of d_{EL} vs. $-\delta\Delta$ (Fig. 8), d_{EL} could be determined as a function of t , assuming that the film had a constant refractive index of $\tilde{n} = 1.84 (1 - 0.075i)$. The results are shown in Fig. 11.

The above two different calculation methods of film thickness did not lead, however, to satisfactorily consistent results. The film thickness calculated from the charge consumed during the first passivation period was less than that determined ellipsometrically (Fig. 12). Taking into consideration the fact that the film thickness d_{CH} was obtained from the film charge density under the as-

Fig. 8. Relationships between $-\delta\Delta$ and $\delta\psi$ parameters and between $-\delta\Delta$ and film thickness.

Fig. 10. Film thickness calculated from the electric charge vs. time at different potentials.

sumption of M , ρ , and z constancy, the film thickness determined ellipsometrically seems to be more credible.

As is seen in Fig. 11, the film grows in two stages, both being characterized by a linear relationship between the film thickness and the logarithm of time. During the first fast stage, lasting for about 0.5s, the slope of the d_{EL} vs. $\log t$ curve is controlled by the applied potential, E^* , while later on, in the second slow stage, the slope becomes practically independent of E^* . During the first 0.5s, the film attains about 60% ($E^* = -0.350V$) to about 80% ($E^* = 0.550V$) of its final thickness.

Fig. 11. Film thickness evaluated from ellipsometric data vs. time at different potentials.

Fig. 12. Relationship between film thickness determined electrochemically and ellipsometrically.

The fast film growth has proved to be governed by the following empirical equation

$$\frac{d d_{el}}{d \log t} = Z (E - E_{cor}) \quad [2]$$

where d_{el} is the film thickness in angstroms, Z is a constant equal to $1/\epsilon$, where ϵ is the electric field strength, E is the applied anodic potential in volts, E_{cor} is the corrosion potential of iron in the given electrolyte, and t is the passivation time in seconds.

Because the above relation appears to be quite significant, analyses of results obtained in previous studies (6, 14) were carried out and graphically compared in Fig. 13, showing that in all the tested solutions $d d_{el}/d \log t$ is a linear function of the applied anodic potential. The straight lines start from E_{cor} , and their slopes Z range from 18-25 Å/V, depending upon the electrolyte. These results suggest that in all the three solutions indicated in Fig. 13 the film formation begins at the corrosion potential of iron in the given solution and that cations transferred from the metal in its active state participate in film growth.

During the slow stage, the film grows at a rate of about 3 Å per decade of time.

Film density.—The fact that the film thickness determined from charge consumed during the first 2 s is much less than that determined ellipsometrically (Fig. 12) was unexpected. It could be inferred that the film density was time dependent and differed from that used for the calculation of d_{CH} , namely $\rho = 4.28 \text{ g/cm}^3$. Presumably, during anodic polarization both the film thickness and density increase with time. Generally, the film density can be considered to change from a low value characteristic of the liquid phase electrolyte (ρ_{liquid}) to a final value characterizing the solid phase film having an established density (ρ_{solid}). Intermediate stages can be treated as containing a mixture of solid and liquid phases in which the

Fig. 13. Kinetics of film growth on iron in different solutions as a function of the anodic potential.

Fig. 14. The average film density as a function of film thickness

water content decreases with passivation time; consequently, the density increases with time. A similar point of view was expressed by Kruger and Calvert (15).

The actual (average) film density can be calculated from the following equation

$$\rho_{aver} = \frac{d_{CH}}{d_{EL}} (\rho_{solid} - \rho_{liquid}) + \rho_{liquid} \quad [3]$$

The results of these calculations are shown in Fig. 14 and 15. The average film density reaches its final value in about 2 s (Fig. 15), *i.e.*, when the current density *vs.* time curve changes its slope at point *N* (Fig. 2). In turn, inflection points of the average film density *vs.* log time curves are observed after about 0.5 s (Fig. 15), *i.e.*, when the film thickness (d_{EL}) *vs.* log time curves change their slope (Fig. 11).

Further considerations.—As previously concluded, for times longer than 2 s, $\bar{n} = 1.84 (1 - 0.075i)$ fits to the obtained ellipsometric data. However, the exact course of events that occur within the first 2 s of film growth cannot be strictly defined because lower values of \bar{n} , for example, those indicated in Fig. 16, may also fit to the experimental $\delta\psi$ *vs.* $-\delta\Delta$ curve. Assuming that during the first 2 s of anodic polarization the optical parameters of the passive film (n and k) change from values characteristic of the aqueous electrolyte ($n = 1.34$, $k = 0$) to those characterizing FeOOH ($n = 1.84$, $k = 0.075$) and that these changes occur according to Fig. 17, variation of the film thickness *vs.* $-\delta\Delta$ would follow the dotted line in Fig. 18, showing that the film thickness calculated taking into consideration the lower optical parameters is greater than that calculated for $\bar{n} = 1.84 (1 - 0.075i)$. Consequently, for example, at $E^* = 0.550 \text{ V}$, the actual relationships of d_{EL} *vs.* $\log t$ and d_{CH} *vs.* d_{EL} may be represented by "alternative" curves plotted in Fig. 11 and 12, respectively. This means

Fig. 15. The average film density as a function of time

Fig. 16. Relationship between $-\delta\Delta$ and $\delta\psi$ for different complex indexes of refraction.

Fig. 17. Changes in n and k with time

Fig. 18. Film thickness vs. $-\delta\Delta$ for different complex indexes of refraction.

that within the first 2s of film growth the actual film density may be less than that calculated above, and at $E^* = 0.550V$ the ρ vs. d_{EL} relationship may follow the "alternative" curve plotted in Fig. 14.

Conclusions

1. Passivation of iron in 0.05M NaOH at a constant anodic potential occurs in two main stages. During the

first stage, which lasts for about 2s, the anodic current is practically consumed only by the film formation. For times longer than 2s, both the film formation and iron dissolution occur simultaneously.

2. The complex index of refraction of the passive film formed on iron polarized anodically in 0.05M NaOH for times longer than 2s is $\tilde{n} = 1.84 (1 - 0.075i)$. The chemical composition of this film corresponds most closely to FeOOH.

3. During the first 2s, the complex index of refraction and the film density change from the corresponding values of the electrolyte to those of FeOOH, suggesting that the amount of water molecules incorporated in the passive film decreases continuously with time. However, some changes in microstructure further occur in spite of the fact that a constant complex index of refraction and a constant film density are achieved.

4. The film thickness increases rapidly during the first 0.2-0.5s, and then much more slowly. The film is thicker when a higher anodic potential is applied.

5. The fast film growth kinetics (first stage of film growth, $t < 2s$) is governed by the following formula

$$\frac{dd_{el}}{d \log t} = Z(E - E_{cor})$$

During the slow stage, the film grows at a rate of about 3\AA per decade of time.

Passive Film Formation on Iron and Film Breakdown in a Sodium Hydroxide Solution Containing Chloride Ions

T. Zakroczyński,¹ Chwei-Jer Fan, and Z. Szklarska-Smialowska*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The results of measurements of the optical parameters and thicknesses of passive films grown on iron in an alkaline (pH 12) chloride containing solution suggest that these films were composed of FeOOH and that they resisted pitting when water content was sufficiently reduced. The passive film was formed in two distinct stages. During the initial stage, lasting about 2s, the thickness of the film reached about 60-80% of its final value. The film thickness did not appear to affect its pitting resistance significantly. A model for passive film growth and Cl⁻ induced local passivity breakdown is proposed.

Only several papers dealing with pitting of iron in alkaline solutions could be found. Heusler and Fischer (1) reported that iron did not suffer pitting in a borate solution of pH >10.4 when chloride ions were injected after passivation of the specimen. Oranowska and Szklarska-Smialowska (2) studied the behavior of iron in a saturated Ca(OH)₂ solution of pH 12.5 without and with 0.05 or 0.1M CaCl₂ added. They found that, in the presence of Cl⁻, breakdown of passivity occurred by a spontaneous onset of uneven general corrosion. Breakdown took place as the potential of iron attained a critical value. Film thickness in the presence of Cl⁻ was greater relative to that in Ca(OH)₂ solution. Alvarez and Galvele (3) reported pitting of iron in NaOH + NaCl solution above a certain critical potential which was more positive than that found in neutral NaCl solution. In these experiments, the iron sample was in contact with Cl⁻ from the beginning of the tests. Tousek (4) also observed pitting of iron in 0.1M KOH + 0.4M KCl when the metal was kept passive in this solution and the potential was shifted to values situated above the critical pitting potential.

It therefore can be presumed that these changes in the behavior of iron during passivation in alkaline solutions in the absence or presence of Cl⁻ are associated with some variations of the composition and structure of the passive film. It can also be expected that, depending upon the experimental conditions, the thickness and microstructure of passive films will differ even at the same pH of the electrolyte.

The effect of film thickness on the susceptibility of iron to pitting as studied by McBee and Kruger (5). They found that for the thicker passive film the longer time was needed for its breakdown in NaCl solution. Sarver and Szklarska-Smialowska (6) observed pitting of iron in a Na₂SO₄ solution of pH 12 when the protective "barrier layer" of the film was not yet completely formed.

The purpose of this work was to study the effect of chloride ions on passive film growth on iron in NaOH, and to determine the influence of film growth conditions on the vulnerability to pitting.

Experimental

The passivity of iron in 0.05M NaOH solution containing chloride ions was studied using the same pure iron and procedures identical to those described in the previous paper (7).

Results

Electrochemical data.—Anodic polarization curves were measured in 0.05M NaOH without and with an addition of either 0.005 and 0.05M NaCl using different potential sweep rates (PSR). The initial potential was -0.950V, and the final one was 0.550V. The results plotted in Fig. 1 indicate that the presence of chloride ions does not affect

*Electrochemical Society Active Member.

¹On leave from the Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, 01-224 Warsaw, Poland.

the shape of the polarization curves. Examination of the specimen surfaces after measurements did not reveal any indication of general or localized corrosion in either NaOH or NaOH + NaCl solution.

After the final value of potential (0.550V) was achieved, changes in the anodic current density vs. time at this potential were recorded (Fig. 2). It is seen that, irrespective of the PSR employed, in both the 0.05M NaOH and 0.05M NaOH + 0.005M NaCl solutions the current decay curves recorded after the same initial treatment (*i.e.*, the same PSR) are practically identical. However, in the third solution, containing 0.05M NaCl, only one of the four curves shown in Fig. 2 follows the same course as the other two, namely, the curve obtained after application of the slowest PSR of 0.001 V/s. The remaining three curves deviated from the usual course; the higher the PSR previously employed was, the greater the deviation was. After some lapse of time, during which the current density decreased, film breakdown occurred, and the current density began to increase rapidly in an irregular manner, this phenomenon accompanied pitting (or general corrosion in the case of PSR = 0.4 V/s).

Pitting also occurred when the specimen was first passivated at a constant potential of 0.550V for 60, 120,

Fig. 1. Anodic polarization curves for iron in 0.05M NaOH with and without the addition of NaCl at four different potential sweep rates.

Fig. 2. Changes in current density with time for iron in 0.05M NaOH with and without the addition of NaCl at 0.550V. This potential was attained by shifting it at different PSR starting from -0.950V.

180, or 300s in 0.05M NaOH, after which the electrolyte was adjusted to contain 0.05M NaCl. In contrast, pitting did not occur when chloride ions were added after 600s. Specimens treated this way maintained their resistance to localized corrosion during immersion for 160h in 0.05M NaOH + 0.05M NaCl at room temperature. Figure 3 shows changes in the current density with time before and after the addition of chloride ions to 0.05M NaOH. However, the reproducibility of these measurements was not good. For instance, in the case of four consecutive experiments of passivation in 0.05M NaOH lasting 180s, the following induction times for pitting were observed: 10, 12, 240, and 300s.

Figure 4 shows changes in the anodic current density vs. time recorded when the electrode potential was rapidly changed from -0.950V to the following four potentials in the passive region (E^*): -0.350, -0.050, 0.150, and 0.250V. Similarly, as in the case of 0.05M NaOH (7), the current density (i_{total}) increased to a maximum, and then decreased. The maximum current density was higher

Fig. 3. Changes in current density with time caused by the addition of NaCl after different times of film growth in 0.05M NaOH at 0.550V.

Fig. 4. Changes in current density with time for iron anodically polarized at different constant potentials in 0.05M NaOH + 0.05M NaCl. Fine lines show the current consumed for film growth ($t > 2s$).

when a more positive potential was applied. After about 2s (at point N), the slope of the current density vs. time curve decreased and the log current density became a linear function of log time with a slope of about 0.5. However, in contrast with the behavior of iron in 0.05M NaOH (7), in the presence of NaCl the current density in the final stage proved to be potential dependent, i.e. greater at higher anodic potentials. As is seen in these experiments, namely, 0.250V, film breakdown occurred after some 30s, which was followed by pitting.

Changes in charge density with time, corresponding to the current densities given in Fig. 4, are plotted in Fig. 5. In these two figures, extrapolated values of current density (i_{film}) and charge density consumed for film growth (q_{film}) are marked by fine lines [see Ref. (7)].

Ellipsometric data.—The relationships between $-\delta\Delta$ and $\delta\psi$ at four applied potentials for $t = 600s$ are depicted in Fig. 6. The complex index of refraction calculated on the basis of these results is $\hat{n} = 1.76(1 - 0.05i)$. Measurements of $-\delta\Delta$ vs. time have shown that in NaOH + NaCl, as in pure NaOH, $-\delta\Delta$ first increases rapidly with time, but rises much more slowly after some 0.2s.

Evaluation of experimental data.—Based on the results obtained and using the procedure described in detail earlier (7), the most probable film composition and the film thickness were evaluated. The experimental relationships between $-\delta\Delta$ and $\delta\psi$, and d_{CH} (calculated assuming that the film compound is FeOOH) and $-\delta\Delta$ for $t = 600s$ are presented in Fig. 6 by open and closed characters respectively. Correspondingly, the computer-generated relationships of $\delta\psi$ vs. $-\delta\Delta$ and d_{EL} vs. $-\delta\Delta$, which fit best

Fig. 5. Changes in charge density with time corresponding to changes in current density in Fig. 4.

Fig. 6. Changes in $-\delta\Delta$ with time at different potentials

to the experimental results, are also plotted in Fig. 6 as solid lines.

The film thickness evaluated from ellipsometric data, d_{EL} , as a function of time is shown in Fig. 7. The relationship between d_{CH} and time is plotted in Fig. 8. The film thickness, d_{CH} , was calculated from the charge density consumed for film growth.

Discussion

Film composition, thickness, and density.—The complex index of refraction found for the film formed in 0.05M NaOH + 0.05M NaCl is slightly different from that found in 0.05M NaOH. However, there is no reason for assuming a significantly different composition and structure of both those films. The film grown in 0.05M NaOH + 0.05M NaCl, as is that grown in 0.05M NaOH (7), is considered to be FeOOH.

Comparison of the data shown in Fig. 8 with those in Fig. 7 indicates that the film thicknesses measured, either electrochemically or ellipsometrically, after 2s of film growth at the same potential, are identical. However, for shorter growth time periods, the ellipsometric method gives larger values of film thickness than does the electrochemical method, as shown in Fig. 9. Similar results were obtained in 0.05M NaOH (7). Assuming that film thicknesses determined ellipsometrically are close to reality, it can be concluded that in the initial stage of film growth the compound being formed has a significantly lower density than that used for the calculation of d_{CH} , namely $\rho = 4.28 \text{ g/cm}^3$, which corresponds to FeOOH. Figure 10 shows the calculated average density of films formed at different potentials as a function of film thickness determined ellipsometrically. However, a lower complex index of refraction relative to that found in 0.05M

Fig. 7. Film thickness evaluated from ellipsometric data vs. time at different potentials.

Fig. 8. Film thickness calculated from the electric charge vs. time at different potentials.

NaOH (7) suggest a lower film density. Therefore, additional calculations were carried out by using a tentative value of $\rho = 4.00 \text{ g/cm}^3$. The results obtained are also presented in Fig. 10 (fine lines).

The initial low density of the film is thought to be caused by a large content of incorporated water, which decreases continuously as passivation progresses. Hence, in the initial passivation stage, the metal surface appears to be covered by a layer resembling more a supersaturated iron hydroxide solution than a solid substance. Revie *et al.* (8) found that the passivation of iron in chloride containing solutions results in binding a greater amount of water in the film relative to Cl⁻-free borate solutions.

For times longer than 2s the film density is constant and there is only a small increase of film thickness. Therefore, taking into consideration a continuous decrease of the current density during prolonged passivation of iron in NaOH, it can be concluded that some microstructural changes occur in the film, resulting in an improvement of its protective properties towards pitting.

It is also necessary to mention that despite the very good fit of experimental data to the whole $\delta\psi$ vs. $-\delta\Delta$ relationship for $\tilde{n} = 1.76(1 - 0.05i)$, during the first 2s of film growth, when the film density increases very rapidly with time, other, much lower \tilde{n} values may also fit to the experimental data. Accordingly, during the first 2s of film growth its thickness (d_{EL}) may be greater than that presented in Fig. 7 and 9. Consequently, the film densities would be lower than those shown in Fig. 10 (7).

Passive film breakdown.—Films grown in 0.05M NaOH at 0.550V and next subjected to the action of Cl⁻ at the same potential exhibited greater resistance to pitting the

Fig. 9. Relationship between film thickness determined ellipsometrically and electrochemically.

Fig. 10. The average film density as a function of film thickness

longer anodic polarization in absence of chloride ions had previously been applied. On specimens polarized for 1 or 2 min, pitting occurred almost instantaneously when NaCl was added; however, after passivation lasting for 5 min, the induction time for pitting was about 400 min, and after 10 min of passivation pitting did not occur even on exposure to the NaCl containing solution for about 160h (Fig. 3). It was so in spite of the fact that in later passivation stages thickening of the film was insignificant: after 60s of anodic polarization at 0.550V the film was by about only 1 nm thicker than that obtained in 2s, and within the further 20 min its thickness increased by only 0.3 nm. All this indicates that prolonged anodic polarization results in significant changes in the protective properties of the passive film, with little effect on film thickness.

Films grown in 0.05M NaOH + 0.05M NaCl behave differently compared with those grown in 0.05M NaOH, and their behavior depends upon the rate at which the potential is shifted from the cathodic (-0.950V) to the highly anodic value (0.550V) at which the iron electrode is then maintained. Namely, when PSR is high (0.4 V/s), both pitting and general corrosion start within 2-3s after the final constant potential of 0.550V is reached. After application of a lower PSR, for instance 0.01 V/s, pitting starts within about 1000s. A still lower PSR (0.001 V/s) results in a total resistance to any corrosive attack. These results indicate that in the presence of chloride ions in NaOH, consolidation of the passive film on iron to a state of high resistance towards pitting is more difficult relative to that in NaOH.

Reproducibility of the above experiments, especially of measurements of the induction time for pitting, was poor. This suggests a fortuitous character of those events, which was probably related to inhomogeneity of the film. The measured optical and electrochemical properties were averaged for the whole working area of the electrode, while the pitting susceptibility could differ from one point to another. Although in these experiments iron of a relative high purity was used, some "weak" sites in the passive film could probably occur, at which a relatively large amount of Cl^- and water could be agglomerated.

The role of water in the breakdown of passive films on stainless steels was strongly emphasized by Okamoto and Shibata (9, 10). They presumed that from among the three types of oxygen bonding, that of the M-OH type might be the most effective in capturing cations and accelerating repassivation, while the M-OH₂ type could be easily replaced by chloride ions. Consequently, the higher resistance to pitting of steels containing chromium was explained by the high capability of repassivation related to the presence of M-OH bonds in the film (10). Chloride ions, which are adsorbed on the film surface, are thought to migrate into its bulk with assistance of the electric

field and replace the water molecules. In this case, no repair of the film can occur.

Pou *et al.* (11) suggest that water in the passive film on iron facilitates chloride ion penetration. They have found that the thickness of the passive film remains unchanged for various times of exposure to chloride ions before and after breakdown.

On the basis of the results obtained, it is apparent that a compact film composed of FeOOH is much more resistant to pitting than films composed of $\gamma\text{-Fe}_2\text{O}_3$: for example, those formed in borate buffer solutions. However, even a FeOOH film can be destroyed by aggressive anions if it contains incorporated water. Through water "paths" in the film, iron cations can easily migrate to the film/electrolyte interface, while chloride ions move in the opposite direction, reacting with iron cations. As a result of hydrolysis, pH decreases and the metal dissolves locally.

However, the existence of water in the film is not a sufficient condition for pitting. At potentials lower than the pitting potential (E_{np}), water also becomes incorporated into the film, but pitting does not occur. So, under the experimental conditions employed in this study, pitting did not occur at potentials lower than about 0.250V (Fig. 4). Presumably, at potentials lower than E_{np} a sufficiently low pH is not produced within the water paths of the film, because the concentration of chloride ions adsorbed on the film surface is not high enough and/or their migration to water paths is too slow.

Conclusions

The results of this study indicate that pitting of iron can occur in the presence of Cl^- in NaOH solution of pH 12, but only when the passive film is not yet sufficiently consolidated, *i.e.*, when it probably contains a substantial amount of incorporated water. As suggested by ellipsometric data, the film formed either in the absence or presence of Cl^- in NaOH is composed of FeOOH. When fully consolidated, this film is highly resistant to pitting. The thickness of the film does not seem to play an important role in film breakdown.

The Anodic Dissolution of Copper into Phosphoric Acid

I. Voltammetric and Oscillatory Behavior

S. H. Glarum* and J. H. Marshall

AT&T Bell Laboratories, Incorporated, Murray Hill, New Jersey, 07974

ABSTRACT

Anodic electrochemical dissolution of metals is often used in commercial electropolishing, and the copper/phosphoric acid system is a classic example. Surface films are believed essential for polishing, but their composition and role remain elusive. Current oscillations, which may be excited, have been attributed to film formation and breakdown. This study examines the information obtained from voltammetric measurements using rotating disk electrodes. Steady-state currents are limited by a diffusion process whose rate is dependent only upon the solution viscosity and is otherwise independent of its composition. Our results indicate a key role for water and suggest that the film may be a highly viscous, dehydrated surface layer. The oscillations are due to negative impedance surface characteristics.

The anodic dissolution of copper into phosphoric acid solutions represents both a process of technological significance and one with interesting scientific implications. The oscillations which can occur at the onset of the anodic limiting current regime are one of the more intriguing features of this system. These oscillations have been reviewed by Pointu *et al.* (1) and others have studied related aspects of the phenomenon (2-5). A model often invoked to explain this behavior posits the formation and dissolution of a partially soluble, inhibiting surface layer (6, 7). While such a layer may be a necessary condition, it is not sufficient in itself to explain oscillatory behavior. We felt this system might therefore lend itself to a useful impedance study, but first found it advisable to re-examine its voltammetric or steady-state characteristics.

Although the electropolishing region for the $\text{Cu}/\text{H}_3\text{PO}_4$ system has stimulated interest over the years, differences in interpretation remain unresolved. Unanimous agreement exists regarding the diffusional behavior of the limiting current in the electropolishing region, whether based upon transient currents in stagnant solutions or steady-state currents at rotating electrodes (8-14). Contention arises, however, as to the identity of the rate-controlling species. Elmore has proposed Cu^{++} ions (8). With the surface concentration of Cu^{++} fixed by film solubility, dissolution would then be limited by Cu^{++} diffusion into the bulk electrolyte. Several subsequent studies have also favored this interpretation (2, 13, 14).

The principal challenge to this view was first raised by Edwards (10), who examined the influence of bulk Cu^{++} concentration on the dissolution process. Should Elmore's interpretation be correct, the current would be proportional to the difference between a fixed concentration at the electrode surface and a variable concentration in the bulk electrolyte. Edwards found that while addition of Cu^{++} ions to the electrolyte did reduce the dissolution rate, when correction was made for a substantial viscosity increase, the rate was independent of the bulk concentration! Edwards's experiments have been repeated, and his conclusion favored by those making such studies (11-12).

Edwards proposed that phosphate anions, presumably H_2PO_4^- in these acid solutions, were the rate-limiting species. Epelboin and Wagner have called attention to the role of water itself in these concentrated solutions (15, 16). Epelboin has suggested the presence of an anhydrous layer at the electrode, while Wagner has noted the need for water in the hydration of Cu^{++} ions. Scant attention has been paid the role of water in discussions of the copper dissolution process, although it seems evident that significant amounts are required for solvation.

Early interpretations of the copper/phosphoric acid system were based largely on current transient behavior at stagnant electrodes. The intervening development of rotating disk electrode techniques makes more quantitative studies now possible. The importance of diffusion,

*Electrochemical Society Active Member.

concentration, and viscosity has been demonstrated by previous work, and it therefore seemed worthwhile to undertake a more comprehensive examination of this system with the concurrent measurement of these parameters.

To this end, we have employed cyclic voltammetry and rotating disk electrodes. Diffusion coefficients for dilute solutions of cupric ions were determined for a range of phosphoric acid concentrations from cathodic rotating disk limiting currents. Cyclic voltammetric measurements were made for dissolution into these solutions, solutions containing high copper concentrations, and solutions with phosphoric acid replaced by polyphosphoric acid. Viscosities and densities were measured in all cases. Using the rotating disk electrode, we have extended the rate of the dissolution process by an order of magnitude. We also report here on those features of the oscillations revealed by voltammetry - waveforms, frequencies, potential, and current dependence.

Our findings show that the dissolution process is much more complex than dissolving film models would imply. Viscosity gradients and electromigration fields introduce major complications within the diffusion layer. A striking result is that the current, for the solutions explored, depends only upon the viscosity of the electrolyte, and is otherwise indifferent to its composition. This may reflect the importance of water in a fuller understanding of the dissolution process.

Experimental

Voltammetric measurements were made using PAR 173/175/179 components in a potentiostatic configuration. Electrolyte resistance seriously distorts current-voltage plots, and feedback compensation is undesirable for systems prone to oscillation. Uncompensated current and potential signals were first stored in a signal averager and then transferred to diskettes for subsequent analysis. High frequency impedance measurements evaluated the electrolyte resistance. Voltammetric data were then processed to include corrections for electrolyte resistance and plotted in either linear or semilog fashion.

Both 1/16 and 1/4 in. diam copper rotating disk electrodes were used. These were polished to a 15 μm level prior to each series of measurements. Potentials were measured with respect to a calomel electrode isolated from the bath by a capillary bridge. The bath was thermostated at 25°C. Viscosities were measured with suitable Ostwald viscometers, and densities were determined from the weight of 10 cm^3 volumes.

Phosphoric acid (Fisher 85%) and polyphosphoric acid (Aldrich) were used as supplied. Copper phosphate was prepared from CuCO_3 and 30% phosphoric acid. The carbonate was added slowly until effervescence abated. The solution was then filtered and heated to boiling, with a precipitate appearing near 70°. The boiling solution was filtered, giving a fine, bright blue powder which dried rapidly. Although early references are to $\text{Cu}_3(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$

Fig. 1. a (left): Anodic sweep voltammograms at 24 mV/s for a 1/16 in. diam. copper electrode in 85% phosphoric acid. For plots a-e, the disk rotation speeds are 25, 100, 225, 400, and 625 rad/s. b (right): Cathodic sweep voltammograms complementing the plots in Fig. 1a.

(MW = 435) (17), a study by Bassett and Bedwell indicates the correct composition to be $\text{CuHPO}_4 \cdot \text{H}_2\text{O}$ (MW = 179) (18). The apparent molecular weight per Cu atom was found electrochemically by comparison of limiting currents with CuSO_4 solutions in 1M H_2SO_4 . Actual copper concentrations ranged from 10 to 30 mM. Measurements for several preparations gave 150 ± 5 , in agreement with the older formula, and this value was adopted for determining Cu^{2+} concentrations in solutions with added copper phosphate.

Results

Figures 1a and 1b show current-voltage plots derived from cyclic voltammetric measurements for the dissolution of a 1/16 in. diam copper electrode into 85% phosphoric acid. As the applied potential is swept anodically (Fig. 1a), the current rises exponentially until a maximum is reached at $0.2 V_{sce}$. Tafel plots for this portion of the curve have 38 mV/decade slopes over two decades and are independent of disk rotational speed (Fig. 2). Above $0.2 V_{sce}$, the current drops to a nearly constant level, and this plateau extends to ca. $1.5 V_{sce}$. In this constant current regime, we found the current level to vary as the square root of disk rotational speed. The current remains nearly constant during the cathodic retrace, with only a minor maximum at $0.42 V_{sce}$. Below $0.3 V_{sce}$, the current drops rapidly, passing through a zero value because of the buildup of a finite Cu^{2+} concentration in the diffusion layer.

The surface was visually examined *in situ* throughout this potential range with a stroboscopic microscope at magnification ca. 100 \times . In the exponential region of Fig. 1a, the surface first darkened to a ruddy color, and a sharp grain-boundary pattern gradually developed due to surface etching. When the potential was advanced into the limiting current region, the surface returned to a paler complexion and granular features slowly disappeared. After several minutes, the "bright" surface resembled an undulating landscape, with only a few "dark" line segments betraying former grain boundary positions. As the potential was slowly returned to $0 V_{sce}$, the electrode again darkened and etch patterns reappeared. The ruddiness of the surface at etching potentials may be attributed to cuprous oxide (19). However, this coloration disappeared in the polishing region, and we saw no changes which suggested the presence of black cupric oxide (2, 5, 19).

Cyclic voltammetric plots are shown in Fig. 3a and 3b for a 1/4 in. diam copper electrode in 85% phosphoric acid. Although this concentration is identical to that for the Fig. 1 plots, electrical current oscillations now appeared. IR corrections were made after measurements, as for the plots in Fig. 1. The applied sweep range was again $0-1 V_{sce}$, and the difference between the maximum plotted anodic potential and 1V is a measure of this correction.

During the anodic sweep towards more positive potentials, oscillations began ca. $0.42 V_{sce}$. This position was independent of disk rotational speed (current level), although there is a threshold level, and the width of the oscillatory range increases with this level. Oscillations occur at potentials where the I-V plot exhibits a shallow minimum, and not in the nearby region of larger negative slope. Oscillations were also seen during cathodic return traces (Fig. 3b). The current/rotational speed threshold is higher, and the potential range is shifted to $0.38 V_{sce}$, the location of a slight maximum in nonoscillatory plots.

Figure 4 shows several of the diverse waveforms we have observed in these experiments. For these measurements, we used a 1/4 in. electrode in 70% acid solutions. At a rotational speed of 300 rad/s and 0.36V, low amplitude sinusoidal oscillations first appear with a 24 Hz frequency (Fig. 4a). Upon increasing the potential 20-40 mV, a complex 8 Hz waveform develops (Fig. 4b and 4c), and this turns to a sawtooth shape at a slightly higher potential (Fig. 4d). At 0.54V, near the upper limit of the oscillating potential region, a 6 Hz, pulseline waveform is seen (Fig. 4e). With a further potential increase, the period lengthens before oscillations cease altogether (Fig. 4f). When the rotational speed was then raised to 400 rad/s,

Fig. 2. Tafel plots for the exponential region in Fig. 1a for curves c-e.

Fig. 3. a (left): Anodic sweep voltammograms at 24 mV/s for a 1/4 in. diam. copper electrode in 85% phosphoric acid. For plots a-c, the disk rotation speeds are 100, 225, and 400 rad/s. The shaded regions indicate areas swept by oscillations. b (right): Cathodic sweep voltammograms complementing the plots in Fig. 3a.

the waveform shifted to a large amplitude, 11 Hz, distorted sinusoidal oscillation (Fig. 4g). Because of the increase in current level, the potential had dropped to 0.49V. These waveforms were obtained by storing the current signal in a signal averager (one pass). The waveforms are extremely sensitive to small variations in potential and disk rotational speed, but, once established, they were stable and could be maintained unchanged for minutes.

For the oscillations in Fig. 4, the oscillating current amplitude represents a large fraction of the mean current level, with a maximum:minimum ratio of about 2:1. The concomitant surface potential variations because of electrolyte resistivity amount to several hundred millivolts. Integration to find the time-dependent charge/cycle for these waveforms gave values of $2-3 \times 10^{-3}$ C/cm² or, in terms of Cu/Cu²⁺ transitions, $6-9 \times 10^{15}$ at./cm².

As measurements were made under potentiostatic conditions, one may question the potentiostat's contribution to the oscillation waveforms. Anticipating the results of our impedance measurements, oscillations are related to negative impedance characteristics of the electrode interface, and the phase of the potentiostat feedback signal can be reversed. Although a formal analysis suggests a region of conditional stability, an empirical evaluation was

Fig. 4. Oscillation waveforms seen for a 1/4 in. diam copper electrode in 70% phosphoric acid. For curves a-f, the disk rotation speed is 300 rad/s and mean IR-corrected potentials are 0.36, 0.38, 0.40, 0.42, 0.54, and 0.56 V_{sce}. Waveform g was found when the rotation speed was raised to 400 rad/s for the potentiometer setting giving waveform f. The corrected mean potential is 0.49 V_{sce}. The current origin is arbitrary for each plot, but the differential vertical scale is indicated.

made by the insertion of a variable resistance in series with either the working or counterelectrode. In the latter case, no changes in the waveforms were seen for resistance variations 0-500Ω, indicating that the oscillations are independent of potentiostat parameters.

When resistance was inserted in series with the working electrode, however, the waveforms were drastically altered. Under conditions where oscillations were never otherwise seen, they could be induced with a sufficiently large resistance. Formally, one can envision this resistance as equivalent to an increase in electrolyte resistance, apart from nonuniform current distribution effects, and we expect electrolyte resistance to play a major role in shaping the oscillations. While unusual surface behavior is needed for the oscillations to occur, their actual form will depend upon electrolyte conductivity and the electrode configuration. If a is the disk radius, the surface impedance varies as a^{-2} , whereas the electrolyte resistance varies as a^{-1} (20). Consequently, the larger the electrode, the greater the relative importance of electrolyte resistance. A comparison of 1/16 and 1/4, in. diam electrodes shows that oscillatory conditions are more readily established for the latter. The fundamental oscillation frequencies we have encountered fall in the 3-25 Hz range. This range is substantially above that reported in previous studies (≤ 1 Hz) (1, 2, 4). Because of the role of electrolyte conductivity, the size and shape of electrodes are factors in determining oscillatory behavior, and the waveforms are not intrinsic characteristics of the metal-electrolyte interface.

The diffusion-like behavior of the limiting current region has been demonstrated by both rotating disk and transient measurements, but the nature of the current limiting species remains an open question, cupric ions and phosphate anions being most often proposed. The diffusion coefficient of Cu²⁺ in phosphoric acid solutions was obtained from cathodic limiting current measurements for 10-20 mM solutions of copper sulfate for a range of H₃PO₄/H₂O concentrations at a platinum disk electrode. Results for the diffusion coefficient as a function of viscosity are plotted in Fig. 5. Measurements by Krichmar *et al.* based on limiting reduction currents at a microelectrode are also shown (21). Although the viscosity dependence is similar, their absolute values are 50% greater. A least squares fit gives

$$D(\text{cm}^2/\text{s}) = (5.7 \pm 0.1) \times 10^{-6} \nu (\text{cS})^{-1.06 \pm 0.01}$$

For $\nu = 1$ cS, our results extrapolate to the value reported by Tindall and Bruckenstein for Cu²⁺ in 0.2M sulfuric acid (22). The inverse variation with viscosity closely follows Stokes-Einstein behavior, and indicates no change in the size of the diffusing ion over the range studied. The diffusion coefficient is quite small in 85% phosphoric acid, 1.9×10^{-7} cm²/s, because of the high solvent viscosity.

Fig. 5. Variation of the Cu^{++} diffusion coefficient with kinematic viscosity for phosphoric acid solutions. Circles: our results. Triangles: Ref. (21).

Anodic limiting currents were measured at $1.0 V_{\text{sc}}$ and several rotational speeds. Results at 100 rad/s are plotted vs. viscosity in Fig. 6. Data at 25 rad/s had an identical slope. The initial solution was 85% acid, and this was diluted in the course of the experiment.

In a second series of experiments, an 85% acid solution was made 1M in Cu^{++} by addition of copper phosphate. The limiting current decreased 50%, but the viscosity increased from 26 to 50 cS. This solution was then diluted to provide a range of viscosities and Cu^{++} concentrations (0.8-1.0M). These results are also shown in Fig. 6 and lie on the same line as those for Cu^{++} -free solutions, in agreement with Edwards's observation that the limiting current is independent of bulk Cu^{++} concentration when viscosity changes are considered (10).

Edwards has proposed that anion diffusion is the limiting process for anodic dissolution. This hypothesis was tested by substituting polyphosphoric acid/water solutions for the electrolyte. This acid consists of a mixture of species containing predominantly two to five phosphorus atoms per moiety and should have a distribution of anionic entities and diffusion coefficients distinct from those of orthophosphoric acid (23). The electrochemical properties of these solutions were quite similar to those of the simple acid, including oscillatory behavior. When limiting currents were plotted vs. viscosity (Fig. 6), we again found results fitting our previous relationship except that the linear plot was extended to a higher viscosity range. As a further test, the 85% acid was made 1M in Na_3PO_4 . Limiting currents again fell on the common current-viscosity function which characterizes all our results.

Discussion

A satisfactory explanation for the anodic dissolution process should account for those factors determining the limiting current, the potential distribution between metal and electrolyte, and the roles of the diverse chemical species. In addition to the major components, copper, phosphoric acid, and water, ionic forms of Cu^{++} , H_3O^+ , and H_2PO_4^- are certainly present, although their explicit manner of hydration or complexation remains unknown. Copper (I) species also merit serious consideration. Anodic copper dissolution into sulfuric acid, at least near the equilibrium potential, proceeds through a rapid oxidation forming solute Cu^+ ions (24). Some of these escape into the bulk electrolyte, but the majority are converted to Cu^{++} by further electrochemical oxidation. The Cu^+ con-

Fig. 6. Variation of the anodic limiting current density with kinematic viscosity for a disk rotation speed of 100 rad/s. The solutions are phosphoric acid solutions (circles), phosphoric acid solutions containing 0.8-1.0M Cu^{++} (triangles), and polyphosphoric acid solutions (squares).

centration rises exponentially with potential until limited by solubility or disproportionation. The 40 mV/decade Tafel slope, characteristic of dissolution into sulfuric acid, is also seen in Fig. 2 and suggests a similar reaction path.

Proposals for surface films have included cuprous and cupric oxides (1, 2, 4, 5) in addition to "copper phosphate" (7, 13). Lorking reports the appearance of a red-brown film (Cu_2O) at etching potentials (19). For more positive potentials, the "oxide film becomes transparent," and a detaching black film was noted. Our observations of a rotating disk electrode confirm the former feature, but we never witnessed a darkening indicative of black CuO . Its formation may vary with experimental conditions, but its presence does not appear essential to reproduce the characteristic features of the polishing region. Analysis of ellipsometric measurements has indicated film thicknesses > 40 and $< 120\text{\AA}$ (25). The thickness was independent of potential. An electron-diffraction study detected an amorphous layer sufficiently thick, $> 30\text{\AA}$, to obscure diffraction by the metallic substrate (7). This film was soluble in phosphoric acid and crystallized on heating to give a copper phosphate diffraction pattern.

We consider the most important results from voltammetric measurements to be (i) the square root dependence of the anodic limiting current on disk rotational speed, (ii) the appearance of limiting current behavior following establishment of the steady-state diffusion layer, (iii) the apparent dependence of the limiting current only upon solvent viscosity, and its independence otherwise on $[\text{Cu}^{++}]$ or the nature of the phosphate species, and (iv), the occurrence of oscillations when uncompensated electrolyte resistance exceeds a threshold value.

The first pair of results show that steady-state behavior is determined by a gradient or gradients with the hydrodynamic diffusion layer. The valence of dissolution has been established to be 2.0, and the total current can therefore be equated to the flux of Cu^{++} ions (13). Irrespective of the reason for limiting current behavior, the Levich equation

$$I_{\text{lim}} = 0.62 zFD^{2/3} \nu^{-1/6} \Omega^{1/2} c$$

may be used to determine the Cu^{++} surface concentration, c , as the disk rotational speed, Ω , is known, and the viscosity and diffusion constant for Cu^{++} , ν and D , are independently measured. For 85% copper-free acid solutions, we find a value of 0.92M. With 1M Cu^{++} added to the bulk

electrolyte, measurements indicate a concentration difference of 0.82M.

From a least squares analysis of the data plotted in Fig. 6

$$I_{lim} \sim \nu^{-1.13 \pm 0.01}$$

When the viscosity dependence of the diffusion coefficient is substituted in the Levich equation

$$c \sim \nu^{-0.25}$$

The nonzero exponent may reflect either limitations of the Levich equation or a solubility variation with acid concentration.

The Levich equation may overestimate the true concentration because of its neglect of ionic migration effects. At 1M, the Cu^{++} concentration probably exceeds the concentration of hydrogen ions, the dominant ionic current carriers, because of the limited dissociation of phosphoric acid. A potential gradient will then develop in the diffusion layer to assist Cu^{++} migration. By way of illustration, let us consider Cu^{++} , H^+ , and H_2PO_4^- , with concentrations c , h , and a , as the dominant solute species. The Nernst ionic mobility equation for the Cu^{++} ion flux is

$$-J_c = D_c \left(\frac{dc}{dx} + \frac{2e}{kT} c \frac{d\phi}{dx} \right)$$

where ϕ is the electric potential in the diffusion layer. Ultrasonic relaxation measurements show fast dissociation kinetics for H_3PO_4 , $\sim 10^{-8}\text{s}$ (26). We shall therefore assume quasi electroneutrality, rapid dissociation equilibrium for phosphoric acid, and very rapid hydrogen ion diffusion. The latter assumption lets us describe the potential in terms of h

$$e\phi/kT = -h'/h$$

while the former give

$$2c + h = a$$

$$ah = K = h_0^2$$

h_0 being the hydrogen-ion concentration in the bulk, copper-free electrolyte. Combining these equations

$$-J_c = D_c c' [1 + 2c/(c^2 + h_0^2)^{1/2}]$$

and integration across a layer of thickness δ , with c varying from c_0 to 0, results in

$$J_c = (D_c/\delta) [c_0 + 2(c_0^2 + h_0^2)^{1/2} - 2h_0]$$

For $c_0 \gg h_0$, the observed limiting current will be thrice the diffusion value. Suitable estimates for h_0 are difficult to come by. If we adopt a dissociation constant based on the dilute solution value scaled for 14M H_3PO_4 and 14M H_2O , $h_{0\approx} 0.16\text{M}$, and the calculated surface concentration for Cu^{++} is reduced from 0.9 to 0.4M. While this is but an estimate because of assumptions made, it is reasonable to conclude that migration effects should be important and that concentrations will be overestimated when they are neglected. Even if we had assumed a 1M H^+ concentration, c_0 would still be reduced to a 0.6M value.

The Levich equation has a further shortcoming in its assumptions of constant viscosity and diffusion constant throughout the diffusion layer. Empirically, we find that addition of 1M $[\text{Cu}^{++}]$ to 85% acid doubles its viscosity. Across the diffusion layer, therefore, we expect 2:1 variations in both ν and D , with the region of highest viscosity nearest the electrode.

If we forego the possibility of novel migration effects, the dependence of I_{lim} on disk rotation rate and potential says that the surface concentration of Cu^{++} is independent of both potential and the current level. Let us consider the view that this "pinned" value corresponds to the solubility limit for a copper phosphate film. Experimental values range about 1M. We have maintained a stable 1.3M solution in 85% acid for several months. Thus, the magnitude of the limiting current appears consistent with the postulate of a copper phosphate film, although the agree-

ment is less satisfactory when migration is considered. Chemical analysis of the anolyte layer has shown 1.5-2.5M concentrations, with higher values evidently corresponding to supersaturated solutions as precipitates appeared on standing (9). Supersaturation of the surface layer would seem inconsistent with the solubility limit model, for it is difficult to visualize a mechanism whereby the degree of supersaturation would remain independent of ionic fluxes.

If the current is to attain a stationary level, the film must grow with a rate dependent on its thickness until its rate of growth matches its rate of solution. Novak *et al.* found the thickness to be potential independent and postulated mobile cationic vacancies without explaining the limits to film growth (25). The presence of fields within a film should contribute significantly to internal ionic transport rates and hence the steady-state thickness. If transport is purely diffusive, the flux will vary inversely with thickness. The ellipsometric measurements were made at one flux level, 15 mA/cm² (65% acid). At the rotating disk electrode, we find normal limiting current behavior at 300 mA/cm² (60% acid). For a film transport rate varying inversely with thickness, the 40-120Å ellipsometric thickness reduces 20-fold to a rather meaningless value.

A less subtle difficulty with the film solubility model is that, for a given viscosity, the limiting current is independent of the bulk Cu^{++} concentration. The points plotted in Fig. 6 for a 1M solution are coincident with data for copper-free solutions within the 10% scatter. A diffusion model requires an unreasonably high surface concentration, $> 10\text{M}$, to explain this concurrence.

We have shown that migration effects are expected because of the high Cu^{++} concentrations involved. A potential difference of 13 mV across the diffusion layer suffices to generate a current equal to the diffusion-limited value, and this current does not explicitly require a concentration gradient. One may conjure a surface film as a hypothetical injection source, but explaining the dependence of current on hydrodynamic conditions is awkward. For the model analyzed, fixed relationships between the concentrations a , c , and h , lead to a potential gradient proportional to c' . Whether a more intricate chemistry, taking into account, for instance, water variations, would lead to migration currents in saturated solutions remains to be shown. The expressions appear too complex for functional solution, and a surfeit of unknown parameters makes numerical attempts seem unprofitable.

Difficulty in explaining the absence of an influence of $[\text{Cu}^{++}]$ on the limiting current, apart from a viscosity change, has led to proposals that other species must be involved. If we assume diffusion coefficients in the range 10^{-6} - 10^{-7} cm²/s, the Levich equation leads to concentrations 0.6-3M for $z = 1$ in 85% acid, and rules out all but the principal species present. High proton mobility makes hydrogen ions a special case. The product of their diffusion coefficient and concentration can be derived from the electrolyte conductivity. When combined with the Levich equation, one finds the limiting current to be equivalent to a 0.5 mM concentration. The existing concentration is certainly much larger, eliminating H^+ from contention.

The remaining possibilities are H_2PO_4^- , H_3PO_4 , and water. Edwards has suggested a depletion of phosphate anions (10). Anions are required to maintain charge neutrality as cupric ions are added to the solution, but the rapid dissociation of H_3PO_4 provides an ample supply (26). Anion concentration should be greatest at the electrode surface, and, once a stationary profile is established within the diffusion layer, there is no necessity for anion diffusion or the further dissociation of H_3PO_4 in this region.

The consequences of a water depletion region have not had serious consideration, apart from Epelboin's mention of an "anhydrous layer" (15). If the viscosity were determined by a single species, water would be the prime candidate. Water is consumed at the electrode by the hydra-

tion demands of Cu^{++} ions, and the correlation of the limiting current with viscosity suggests that it plays a key role in the dissolution process. When 1 mol of Cu^{++} is added to 1 liter of 85% acid (14M H_2O), the viscosity increases to that for a 9M solution. Formulas for copper phosphate favor one water of hydration per Cu^{++} , and the viscosity increase can simplistically be attributed to the formation of hexa-aquo ions.

The major difficulty with a direct water diffusion model is the need for a diffusion coefficient $< 10^{-7}$ cm^2/s , even assuming $z = 1/3$ ($3\text{H}_2\text{O}/e^-$). Of course, the total water content might not be "free" in the sense of being available for hydration. The water activity in 85% acid, based on vapor pressure measurements, is 0.09 of the value for pure water, whereas the mole fraction is 0.5 (27). The reduced activity shows that Cu^{++} must compete with phosphoric acid for the water present.

As the Cu^{++} concentration builds within the diffusion layer, one may imagine the formation of a region of higher viscosity which hinders subsequent material transport. Additional Cu^{++} ions would tie up most of the remaining water until restricted by the buildup of charge or the amount of water present. In the limit, a dehydrated, amorphous surface film comprised of ions and acid would result. This picture is not dissimilar to a film of limited solubility, and it does bring viscosity more directly into the dissolution process. The steady-state rate, however, would now depend on the rate at which bulk water slakes the viscous layer.

Although oscillation waveforms are difficult to analyze, their existence places constraints on possible interpretations of the polishing region. That the oscillations arise because of negative impedance characteristics of the interfacial region is qualitatively shown by their dependence on external cell loading. Admittance measurements will furnish a quantitative proof. DeLevie has discussed the general aspects of electrochemical negative resistance oscillators (28). Negative resistive behavior can often be associated with a negative slope in current-voltage plots. Figures 1a and 1b, however, show no unusual features in the potential region where oscillations occur. The explanation will appear in admittance measurements which do exhibit negative real values for frequencies below 30 Hz. The admittance goes to zero with frequency, in accord with the slope of the current-voltage curves. For the copper-phosphoric acid system, negative impedance behavior is strictly a dynamic effect. The region of negative slope in Fig. 1a is not a negative resistance region, but a monotonic decay which proceeds independently of potential.

Whether a circuit containing a negative impedance element is stable or oscillatory depends on its loading by other elements. In the electrochemical case, loading is due both to electrolyte resistance and external circuitry. It is the voltage drop across these elements which correlates the behavior of otherwise independent portions of the electrode surface. The formation and breakdown of a surface film is often proposed as a qualitative explanation for oscillatory behavior (4, 5). Negative impedance behavior demands both processes be correlated with potential changes. While one can rationalize an increase in film thickness with potential, it is less evident that a decrease in potential should facilitate breakdown, and a more explicit explanation must be proposed for film thinning.

Under the experimental conditions prevailing in Fig. 4, the copper surface is dissolving at a 2500 $\text{\AA}/\text{s}$ rate. During each cycle, 100-200 \AA are lost, while the charge represented by the oscillating portion of the current amounts to a few copper monolayers. The diffusion distance for Cu^{++} ions in one oscillation period is ~ 1 μm , a fraction of the total diffusion layer thickness. Current oscillations extend both above and below a mean level set by nonoscillatory conditions for the same potential and current.

These parameters may be useful for visualizing the scale of spatial and temporal changes at the electrode, but their meaning is ambiguous. Does the charge per cycle

reflect film thickness? Our result might be so interpreted, but Poncet *et al.* find 500-1000 layers dissolving per cycle (1). The difference reflects our higher oscillation frequencies. The diffusional transit time for Cu^{++} ions through the diffusion layer is about 2s. The oscillations, therefore, do not propagate through this layer, and cannot be explicitly dependent on its thickness. Bidirectional current swings seem to imply a greater inhibition than exists in the nonoscillating steady state.

Mathematical models which have been developed to simulate chemical oscillations involve alternative pathways with mutual catalytic interactions (29). Possible species relevant to the system of interest are Cu^{++} , water, and the "film." In addition to its thickness, the film may involve varying concentrations of Cu(I) and Cu(II) . Apart from the conventional rate constants, it may also be necessary to consider the effects of migration fields and viscosity gradients on the diffusion kinetics.

The anodic dissolution of copper in phosphoric acid solutions is not a simple process. In particular, the view of a surface concentration of cupric ions set by film solubility, with the reaction rate then determined by the diffusion of these ions, provides an inadequate accounting for too many features of the process to be acceptable. Sufficient evidence exists to support the view of a surface film. However, whether the film is a true solid phase with distinct boundaries or a highly viscous layer maintained by water depletion has not been proved. The chemical composition of this region remains uncertain, as does the spatial distribution of the large overpotential present. Voltammetric measurements, by themselves, contain information sufficient to characterize and test only relatively simple electrode reactions. While they may reveal the inadequacies of proposed mechanisms, they primarily set limits for more detailed descriptions to meet. A realistic interpretation of the dissolution reaction awaits more elaborate experimental techniques which can better probe the nature of the interfacial region.

The Anodic Dissolution of Copper into Phosphoric Acid

II. Impedance Behavior

S. H. Glarum* and J. H. Marshall

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Impedance measurements have been used to study the electrochemical dissolution of copper rotating disk electrodes in phosphoric acid as a function of potential and current density. A space-charge layer is formed at large overpotentials. The thickness of this layer is potential dependent, $\sim 100\text{\AA}$ at $+1.0\text{V}$, but independent of current density. Diverse relaxation behaviors are seen at lower potentials. Reactive equivalent-circuit elements are largely independent of current density, while conductive elements are directly proportional to current density, indicating that the structure of the interface is controlled by the electric potential rather than by kinetics. Current oscillations during dissolution reflect a negative impedance relaxation at low frequencies. This impedance is explained by the dependence of the dissolution process on high mobility hydrogen ions and the coupling of $[\text{H}^+]$ with electric fields external to the metal surface.

Current oscillations accompanying electrode reactions have been observed in diverse systems, but their origins remain largely conjectural (1, 2). Few studies have been directed towards the investigation of the phenomenon itself. Impedance measurements would appear to offer a promising avenue for approaching this curious behavior, and their relation to electrochemical oscillations has been discussed by DeLevie (3). Apart from some limited admittance measurements by DeLevie and co-workers on the reduction of In(III) in the presence of SCN^- (4), we are unaware of prior applications of the technique to the study of electrochemical oscillators. Our attention has been attracted to the anodic dissolution of copper metal into phosphoric acid. Oscillations in this system were reported by Jacquet in 1936 (5). Poncet *et al.* have studied this system with voltammetric techniques and proposed that surface oxides are connected with the instabilities (6). The large amplitude oscillations encountered in such experiments are difficult to analyze as they are governed by nonlinear effects. Impedance measurements offer more quantitative information and can be carried out under nonoscillatory conditions.

The copper-phosphoric acid system is well suited for an impedance investigation. Oscillations occur at frequencies $> 1\text{ Hz}$, a range amenable to measurement. Moreover, as the dissolution current is independent of potential over a wide potential range but can still be varied hydrodynamically, rotating disk electrodes make feasible independent evaluations of the influences of potential and current density. We found it desirable to undertake a parallel voltammetric study prior to an extensive impedance investigation, and these findings appear in Ref. 1. In the present paper, we report and discuss impedance behavior in 85% acid solutions at dissolution potentials extending to the oxygen evolution region. The system exhibits an unusually rich range of response functions and data obtained above and below the actual potential range where instabilities appear provide useful insights into the structure of the interfacial region.

The impedance of an electrolytic cell is often best summarized by an equivalent circuit. This is merely a collection of resistive, capacitive, and Warburg elements chosen to mimic the experimental dependence of impedance *vs.* frequency. Inevitably, one requires circuit elements for electrolyte conductivity and double-layer capacitance,

and their interpretation is relatively direct. Faradaic current flow, however, can lead to a complex impedance function in parallel with the double-layer capacitance. Interpretation of this portion of the circuit requires some modeling of possible electrode reactions to relate equivalent circuit elements to functions of chemical interest. Given sufficient equations to define an electrode process, their transformation into a set of perturbation or modulation equations is straightforward although somewhat arcane to the unversed. Because we shall encounter a diversity of response functions in this study, we have relegated to an appendix a generalized procedure for the derivation of impedance function. In discussion, we shall consider equations describing various mechanisms and present their equivalent impedance without digression into the intermediate algebra.

Experimental

General experimental procedures are given in the first part of this paper (1). For impedance measurements, only 1/16 in. diam copper rotating disk electrodes and 85% phosphoric acid solutions were employed. Reported potentials were measured with respect to a saturated calomel electrode and have not been corrected for electrolyte IR drop. The frequency range explored in this work was 1 Hz-200 kHz. This lower limit was deemed adequate because of the rapid rate of electrode dissolution and the fact that complex-plane plots when extrapolated to zero frequency were compatible with the slopes of steady-state current-voltage curves.

A Rockland 5100 Frequency Synthesizer furnished a sinusoidal source for ac measurements (7). This signal passed through a series of variable, active, lead-lag networks into a PAR 173/179 potentiostat system. AC measurements were made with a PAR 129A two-phase lock-in amplifier of the potential difference between the working and reference electrodes and the drop across an external reference resistor in series with the working electrode. The lead-lag networks were adjusted so that the former difference was approximately constant over the frequency range scanned (2 mV , 0°), and the reference resistor was selected so that the latter drop was $\leq 2\text{ mV}$. For optimum bandwidth and minimum noise, the PAR 179 plug-in was kept on the 1A range and its digital circuitry disabled. Both 0° and 90° square-wave reference signals were extracted from the 5100 and used to drive directly

*Electrochemical Society Active Member.

the phase-detector switches, bypassing the lock-in circuitry of the 129A and extending its frequency response. Typically, 500 measurements logarithmically spaced between 200 kHz and 100 Hz were made in 5-10s. At lower frequencies, four sample-and-hold circuits captured the unfiltered output of the phase detectors, permitting two independent measurements per cycle. Accuracy was established with precision RC components chosen to emulate characteristic cell impedances. For a series RC circuit with a 3 kHz relaxation frequency (75Ω , $0.7\ \mu\text{F}$), the series resistance obtained by a deconvolution of the measured admittance was constant to $\pm 0.2\%$ between 200 and 1.5 kHz, while series capacitance values showed a 1% scatter between 30 kHz and 300 Hz. The latter test is especially critical as only a resistive reference was used. Evaluation of a capacitance from voltage measurements is then frequency-dependent and would reflect errors associated with the high sweep rates used.

Results

Figure 1 is a current-voltage plot for the $\text{Cu}/\text{H}_3\text{PO}_4$ interface under conditions typically employed in this study. Distinctive behaviors make it convenient to partition this curve into four regions. In region I, extending to 0.15V, the current rises exponentially. A limiting current level is then established across region II, 0.15-0.35V. The current peak is sweep-rate dependent, being greater for faster rates. In region III, 0.35-0.55V, current oscillations may appear. Here, the current-voltage curve reveals merely a slight minimum/maximum during anodic/cathodic sweeps. Above 0.55V, in region IV, a stable current plateau is maintained until the oxygen evolution region is reached beyond 1.5V.

The electrode was observed *in situ* under $140\times$ magnification during experimentation. As the potential was raised from its open-circuit value, $\sim 0.05\text{V}$, a well-defined etching pattern developed. The polished copper surface first darkened to red-brown, and then sharply demarcated grain boundaries appeared. Individual grains then acquired variegated russet complexions. Crossing regions II and III, the range of tones diminished, with lighter hues favored. A two-tone surface eventually formed and was superseded by a monochrome surface. Grain boundaries remained sharply defined, but the color at this stage was reminiscent of the original bright copper surface. In region IV, these boundaries gradually faded, leaving a featureless surface. When the potential was then lowered, grain boundaries reappeared at $\sim 0.50\text{V}$, and the pattern of coloration was retraced as the potential was further reduced. The etch pattern characterizing region I was stable under open-circuit conditions. At no time was black or dark color observed which might indicate the presence of CuO .

Fig. 1. Voltammetric behavior of the $\text{Cu}/\text{H}_3\text{PO}_4$ interface measured at 20 mV/s sweep rate and 100 rad/s disk rotation. Regions I-IV discussed in the text are shown.

Admittance measurements involved diverse variations of frequency, potential, and current density. Both frequency-sweep measurements at constant potential, $Y_\omega(\omega)$, and potential-sweep measurements at constant frequency, $Y_\omega(\eta)$ proved valuable. The former functions, when plotted in the complex plane, best reveal overall features of relaxation processes. The shapes of these plots are guides to equivalent circuit descriptions. Combinations of $Y_\omega(\eta)$ measurements were used to extract the potential dependence of individual circuit elements after suitable frequencies had been determined from the complex-plane plots.

Complex admittance plots for potentials spanning regions I and II are shown in Fig. 2. Equivalent circuit A in Fig. 3 approximates the response measured in region I. At high frequencies, the admittance is governed by R_0 and C_0 , and the shapes are semicircular. At lower frequencies, plots approach the real axis at 45° . This behavior is better revealed when R_0 and C_0 are deconvoluted from the measured data (Fig. 4). Both G_1 and W increase rapidly with potential in region I. We see, however, clear deviations from the asymptotic slope below 1 kHz. Within region II, these deviations develop into an "inductive" loop which dips below the real axis for frequencies < 300 Hz. Then, rather abruptly, at about 0.25V, this loop is replaced by a capacitive dispersion which approaches the origin at low frequencies. A small but reproducible increase in R_0 is evident in the high frequency intercepts of Fig. 2. The potential dependence of R_0 and C_0 was extracted from $Y_\omega(\eta)$ data at 10 and 100 kHz (Fig. 5). The former function shows a small increase in region II. The latter rises across region I from an initial value of 28 to $35\ \mu\text{F}/\text{cm}^2$ and then plummets abruptly above 0.26V.

Within region III, the low frequency dispersion no longer approaches the origin from the first quadrant but first circles it through quadrants II and III (Fig. 6). The magnitude of this three-quadrant loop is greatest near 0.45V. Plots near this potential but for different electrode rotational speeds show the magnitude of the loop to be proportional to the static current density (Fig. 7). As $\omega \rightarrow 0$, the origin is still approached, but from the third quadrant at an angle $\leq 3\pi/2$. Equivalent circuit B in Fig. 3 can approximate these shapes provided that elements G_2 and C_2 have negative values and $C_1 + C_2 < 0$. The high frequency dispersion, not shown in these figures, remains

Fig. 2. Admittance plots for potentials in regions I-II. For curves a-m, potentials are 0.06-0.30V in 0.02V increments. The frequency range plotted is 50 Hz-200 kHz with 1 kHz (squares) and 10 kHz (circles) points indicated. Disk rotation: 100 rad/s.

Fig. 3. Equivalent circuits A, B, and C discussed in the text

determined by R_0 and C_0 , while the low frequency dispersion is given by G_1 , G_2 , C_1 , and C_2 .

Complex admittance plots at plateau potentials, region IV, show two nearly semicircular dispersions, Figure 8 plots the full dispersion (1 Hz-200 kHz) for a sequence of current densities at 1.00V. The amplitude of the low frequency dispersion is directly proportional to the current density. Figure 9 plots the low frequency dispersion for potentials 0.60-1.50V. The amplitude shows only a slight decrease with potential over this range. The cusp separating the dispersions lies between 100 and 1000 Hz, and is unusually sharp. Above +1.0V, it overlaps itself, forming a closed loop in the first quadrant.

Apart from this loop, the response corresponds to equivalent circuit C in Fig. 3. G_1 and C_1 may be found by analysis of the low frequency dispersion. $Y_w(\omega)$ measure-

Fig. 6. Admittance plots for the low frequency dispersion in region III. Curves a-f correspond to potentials 0.30-0.55V in 0.05V increments. The plotted frequency range is 1-1000 Hz with 1 Hz (triangles), 10 Hz (squares), and 100 Hz (circles) points shown. Disk rotation: 100 rad/s.

ments at 20 and 100 Hz were analyzed assuming that either a semicircle or a depressed circular arc described the low frequency dispersion. Both approximations gave essentially the same results, and those for the former are plotted in Fig. 10. G_1 values are largely independent of potential, even when the analysis is extended into region III, C_1 values decrease with potential from a maximum 3600 $\mu\text{F}/\text{cm}^2$ at 0.65V to 1300 $\mu\text{F}/\text{cm}^2$ at 1.50V. Below 0.65V, C_1 appears to decrease, but the analysis neglects the negative contribution of C_2 which becomes important within region III.

Discussion

Behavior in region I follows the Mattson-Bockris model developed to describe dissolution into surface acid (8)

The dc current rises at 38 mV/decade rate (1). Admittance measurements are empirically represented by equivalent circuit A in Fig. 3. The high frequency resistance, R_0 , equals the value obtained under zero-current conditions and is due to electrolyte resistivity. The high frequency capacitance, C_0 , ranges from 28 to 32 $\mu\text{F}/\text{cm}^2$. This "conventional" double-layer value reveals no unusual surface polarization characteristics. The minor increase may reflect surface roughening.

To model this reaction mechanism, let $c = [\text{Cu}^+]$ and assume that at the interface ($x = 0$)

Fig. 7. Admittance plots for the low frequency dispersion in region III at 0.44V. The plotted frequency range is 1-500 Hz with 10 Hz (squares) and 100 Hz (circles) points shown. For curves a-e, disk rotation speeds are 25, 50, 100, 200, and 400 rad/s.

Fig. 8. Admittance plots in region IV at 1.00V. The plotted frequency range is 1 Hz-200 kHz with 10 Hz (triangles), 10 kHz (squares), and 100 kHz (circles) points shown. 100 Hz and 1 kHz points straddle the minimum. For curves a-e, disk rotational speeds are 25, 50, 100, 200, and 400 rad/s.

$$c = c(\eta) = c_0 \exp(e\eta/kT)$$

$$I_2 = I_{20} [(c/c_0) \exp(\beta e\eta/kT)]$$

$$I_1 - I_2 = -DF (\partial c/\partial x)_{x=0}$$

The last expression accounts for the diffusive escape of Cu^+ from the interface before final oxidation. The reaction admittance is therefore (cf. Appendix)

$$Y = G_1 + (i\omega)^{1/2}W$$

$$G_1 = 2(dI_2/d\eta)$$

$$W = D^{1/2}F(\partial c/\partial \eta)_i = D^{1/2}eFc/kT$$

in accord with circuit A of Fig. 3. Cupric ion diffusion, which in principle would add a Warburg term in series with G_1 , may be ignored in an ac analysis because of the high concentration present.

Numerical values for G_1 and W can be derived from the data in Fig. 4. G_1 is given by the extrapolated low frequency intercept and log plots show a linear increase with potential until a maximum is reached at 0.18V. Presuming D , the Cu^+ diffusion coefficient, scales inversely with viscosity as does the Cu^{++} coefficient (1), we estimate $D = 5.5 \times 10^{-7} \text{ cm}^2/\text{s}$ and obtain Cu^+ concentrations of 1.5, 2.6, and 3.7 mM at 0.04, 0.06, and 0.08V (Fig. 4a-4c) (9). $W(\eta)$ peaks near 0.14V. Calculated $[\text{Cu}^+]$ values appear reasonable, but the peak indicates a leveling off near the 5 mM level. Although Cu^+ diffusion is important in determining the electrode impedance, its contribution to the dc current is $< 1\%$. Surface discolorations are seen well below potentials where deviations from this model appear. Color changes point to formation of Cu_2O , but, evidently, this conductive oxide layer does not affect dissolution in region (1).

The onset of region II is marked by maxima in G_1 and W (circuit A in Fig. 3) and the attainment of the limiting current in static measurements. Admittance plots show the development of a low frequency "inductive" loop dipping below the real axis (Fig. 4g-4i). This loop disappears

Fig. 9. Admittance plots in region IV. For curves a-f, potentials are 0.60, 0.70, 0.80, 1.00, 1.200, and 1.50V. A disk rotation speed of 25 rad/s was used to reveal more clearly the high frequency loop. The plotted frequency range is 1 Hz-1 kHz with 10 Hz (squares) and 100 Hz (circles) points shown.

at 0.24V and is replaced by a capacitive low frequency dispersion at higher potentials (Fig. 4k-4m). Similar behavior has been observed in the anodic dissolution of Fe in H_2SO_4 , and explained by an adsorbed intermediate Fe(I) species (10)

To model this mechanism, assume both partial currents are functions of potential, η , and the degree of surface coverage by a cuprous intermediate, θ

Fig. 10. Variation in region IV of parameters C_1 and G_1 (circuit C of Fig. 3) obtained from 20 and 100 Hz measurements at 37 mV/s sweep rate and 100 rad/s disk rotation.

$$I_1 = I_1(\eta, \theta)$$

$$I_2 = I_2(\eta, \theta)$$

$$Q_{\max} d\theta/dt = I_1 - I_2$$

The last expression accounts for the growth and dissolution of the intermediate layer, with Q_{\max} the charge associated with complete monolayer formation ($\theta = 1$). These expressions lead to the admittance

$$Y = G_1 + (G_2 - G_1)/(1 + i\omega\tau)$$

where

$$G_1 = [\partial(I_1 + I_2)/\partial\eta]_{\theta}$$

$$G_2 - G_1 = [\partial(I_1 - I_2)/\partial\eta]_{\theta} [\partial(I_1 + I_2)/\partial\theta]_{\eta} [\partial(I_2 - I_1)/\partial\eta]_{\theta}^{-1}$$

$$= [\partial(I_1 + I_2)/\partial\theta]_{\eta} (d\theta/d\eta)$$

$$\tau = Q_{\max} [\partial(I_2 - I_1)/\partial\theta]_{\eta}^{-1}$$

G_1 and G_2 are the high and low frequency real axis intercepts. If $G_2 > G_1$, the dispersion appears in quadrant IV. For coverage which increases monotonically with potential, an inductive dispersion corresponds to an increase in coverage with current at constant potential.

Introducing as more explicit functions

$$I_1 = I_{10} (1 - \theta) \exp(e\beta_1\eta/kT)$$

$$I_2 = I_{20} \theta \exp(e\beta_2\eta/kT)$$

we find

$$G_1 = (e\bar{I}/kT) (\beta_1 + \beta_2)/2$$

$$G_2 = (e\bar{I}/kT) [(1 - \theta)\beta_1 + \theta\beta_2]$$

$$\tau = 2\theta (1 - \theta) Q_{\max} \bar{I}$$

where \bar{I} is the dc current level. No dispersion is predicted if either $\beta_1 = \beta_2$ or $\theta = 0.5$. At 0.20V, the low frequency dispersion maximum occurs at 105 Hz ($1/\tau = 2\pi f$), and combining this value for τ with the measured dc current we obtain $\theta(1 - \theta)Q_{\max} = 1.9 \times 10^{14} e^-/\text{cm}^2$. The disappearance of the dispersion at 0.24V implies $\theta \sim 0.5$, and the value for Q_{\max} is consistent with the formation of a monolayer in region II by an electrochemical intermediate.

The expressions for G_2 and G_1 suggest examination of the dimensionless parameter (kTG/eI) as a measure of an anodic transfer coefficient. Taking G_1 from deconvolutions of the high frequency dispersions, we find values decreasing from 2.0 at 0.15V to 0.50 at 0.30V. Over this range, \bar{I} is relatively constant, and the change corresponds to the decrease in size of the low frequency dispersions in Fig. 2. Although values are of order unity, as required for a transfer coefficient interpretation, their dependence on potential implies a more complex mechanism. Limiting current behavior ($G_2 \rightarrow 0$) is only predicted in the limit $\theta \rightarrow 1$ if $\beta_2 \rightarrow 0$, hinting at complications in the second stage of the reaction.

Above 1 kHz, the relaxation is similar to that for region I. The presence of a Warburg contribution is evident in the nonsemicircular appearance of the high frequency dispersions in Fig. 2. W values decrease 50% from their maximum as the potential increases in this region. The high frequency capacitance drops gradually from 32 to 18 $\mu\text{F}/\text{cm}^2$ across region II. The latter decrease is consistent with the formation of a thin insulating layer. A small increase in R_o , $\sim 0.04 \Omega\text{-cm}^2$, may be discerned in the shift of high frequency, real axis intercepts within region II (Fig. 2). When the limiting current level is reached, a large $[\text{Cu}^{++}]$ gradient exists across the diffusion layer. Electro-neutrality forces a corresponding increase in anion concentration which, through the limited dissociation of H_3PO_4 , reduces $[\text{H}^+]$ and consequently electrolyte conductivity in the diffusion layer. In the absence of this effect, we calculate the resistive contribution of the diffusion layer to be $0.013 \Omega\text{-cm}^2$ and the observed change is of a

similar magnitude. Outside region II, R_o values were independent of potential.

We associate region II with the formation of a monolayer of an intermediate Cu(I) species. A transition from low to high coverage is demonstrated by the inductive to capacitive change in the low frequency dispersion and the double-layer capacitance decrease. The latter indicates the monolayer to be a poor electronic conductor. The Cu(I) intermediate cannot be identified with Cu_2O , a good conductor, which is visibly more evident in region I than II.

Although region III is physically the most intriguing, we shall postpone its discussion and pass to region IV. Complex-plane plots show two well-resolved dispersions, each nearly semicircular in appearance (Fig. 7). Apart from the anomalous overlap cusp, the dispersion may be approximated by equivalent circuit C in Fig. 3. At the highest frequencies, response is dominated by R_o and C_o . The former is constant, being fixed by electrolyte resistivity, but the latter exhibits a marked decrease from 18 to 6 $\mu\text{F}/\text{cm}^2$ across regions III and IV. Moreover, C_o is independent of the dc current level. Five measurements at +1.0V for disk rotational speeds ranging between 25 and 400 rad/s yielded values constant to within 3%.

A significant drop in the high frequency capacitance of an electrode can indicate formation of a blocking layer. One interpretation for the origin of limiting current behavior in this system has been the solubility limit of a surface film (11, 12). The rate of dissolution for such a film is proportional to the current density, and film thickness should decrease at higher current levels. The independence of C_o upon current density contradicts this description.

The continuous decrease in C_o with increasing potential suggests trying a Mott-Schottky plot of $1/C^2$ vs. potential (Fig. 11). (Mott-Schottky behavior characterizes a constrained solution of the Poisson-Boltzmann equations and need not imply electronic polarization of a semiconductor interface.) This plot is linear within region IV to 1.2V, at which point C_o begins to increase. The extrapolated intercept of the linear segment lies at +0.35V, the beginning of region III. The simplest model which describes this behavior is a surface layer of thickness l and uniform negative charge density ρ , leading to the Mott-Schottky relations

$$n_d = \rho l^2/2\epsilon$$

$$1/C^2 = (2/\epsilon\rho)\eta_d$$

$$C = \epsilon/l$$

η_d is the potential drop across the layer. From the slope of the plot in Fig. 11, $\epsilon\rho = 5.0 \times 10^{21} e^-/\text{cm}^2$ and $l/\epsilon = 1.3\text{A}$ at +1.2V, the dielectric constant, ϵ , being normalized to its free space value. Physically meaningful parameters imply a high dielectric constant. For 85% H_3PO_4 , $\epsilon = 80$ (13) and for this value $\rho = 6 \times 10^{19} e^-/\text{cm}^3$ and $l = 100\text{\AA}$. The need for a high dielectric constant suggests the charged layer is quasi-aqueous in composition. The layer thickness agrees satisfactorily with previous limits, 13-124 \AA , based on electron diffraction (14), ellipsometry (15), and a reinterpretation of impedance data (16).

The next parameter for consideration is G_1 (circuit C in Fig. 3), a resistive element which determines the initial faradaic current response to a change in potential. G_1 was found to be directly proportional to the limiting current, implying an exponential current-potential relationship. Consider

$$I = I_o(x\dots) \exp(e\beta\eta/kT)$$

where $x\dots$ represents parameters other than the potential. Formally

$$G = (\partial I/\partial\eta)_{x\dots} = (e\beta/kT)\bar{I}$$

with \bar{I} the steady-state current. For data taken at +1.0V, this expression yields $\beta = 0.23 \pm 0.01$ for current densities of 20-80 mA/cm 2 . If β is independent of potential, then, in the limiting current region, so should be G_1 (Fig. 10).

Fig. 11. Mott-Schottky plot for the high frequency capacitance $(1/C_0)^2$ vs. η . C_0

An exponential I - η relation indicates kinetics limited by a barrier whose height is potential dependent. Assume this barrier lies at the metal interface on the inner boundary of the space-charge layer and that the potential drop across this barrier is the difference between the potential of the metal electrode, η , and the potential drop across the space-charge layer, η_d . Thus

$$I = I_0 \exp [e\beta(\eta - \eta_d)kT]$$

where β is the barrier transfer coefficient. The hydrodynamic dependence of the limiting current shows that the steady-state current is determined by concentration gradients external to the surface layer. Consequently, following a potential perturbation, there must be a relaxation of η_d until the injection and dissolution currents are again equal. This relaxation is reflected in the low frequency dispersion seen in Fig. 7 and 8. The semicircular shapes indicate that this relaxation may be approximated by an RC circuit, with the dispersion involving the capacitance, C_1 (Fig. 3C).

For a given potential, C_1 is only slightly dependent on the current density. At +1.0V and rotational speeds of 25, 50, 100, 200, and 400 rad/s, we obtain values of 1600, 1800, 2000, 2100, and 2500 $\mu\text{F}/\text{cm}^2$. In contrast, G_1 ranged 0.5 to 1.9 mho/cm^2 . Against potential, however, C_1 values decrease from 3000 $\mu\text{F}/\text{cm}^2$ at +0.55V to 1300 $\mu\text{F}/\text{cm}^2$ at +1.5V (100 rad/s, Fig. 10). The magnitude of C_1 indicates the associated charge must be faradaic. Between 0.55 and 1.5V, $\int C_1 d\eta$ gives an injected charge of $2 \times 10^{-3} \text{ C}/\text{cm}^2$. This amount is too large to correspond to uncompensated space charge, and we propose that it represents Cu^{++} ions required for growth of the surface layer.

Let us examine growth relaxation for a layer requiring Q coulombs per unit thickness

$$dQ/dt = (dQ/dl) (dl/dt) = I(\eta - \eta_d) - I_d$$

with the rate of change of film thickness proportional to the difference between the electrode current and an unmodulated dissolution current, I_d . The response is that of a conductance, G_1 , and a capacitance, C_1 in series

$$Z = 1/G_1 + 1/(i\omega C_1)$$

$$G_1 = (\partial I/\partial \eta)$$

$$C_1 = (dQ/dl) (\epsilon/\rho l)$$

The capacitance is directly proportional to the high frequency capacitance, assuming a constant density.

Crystallographic data for the compounds CuO , $\text{Cu}_3(\text{PO}_4)_2$, and $\text{CuHPO}_4 \cdot \text{H}_2\text{O}$ give respective molar volumes of 12.4, 85, and 56 cm^3 (17, 18). The $2 \times 10^{-3} \text{ C}/\text{cm}^2$ of integrated charge corresponds to respective layer thicknesses of 13, 29, and 56 \AA . All values are less than the 100 \AA thickness deduced from C_0 . Both C_0 and C_1 decrease similarly with increasing potential. At +0.55V, their ratio is 240, while at +1.0V it is 285. If we suppose that both re-

flect a common surface layer, then from the space-charge density of $6.0 \times 10^{19} e^-/\text{cm}^3$, we deduce molar volumes (Cu^{++}) of 70-80 cm^3 . The molar volume of H_3PO_4 in the electrolyte is also 70 cm^3 . This density is less than that of crystalline $\text{CuHPO}_4 \cdot \text{H}_2\text{O}$. The lower density, together with the high dielectric constant inferred from C_0 values, suggests an amorphous structure containing a high density of dipoles able to reorient in the internal electric fields present.

The most interesting electrical behavior lies in the negative impedance region, III. Here complex admittance plots show a low frequency dispersion circling the origin through three quadrants (Fig. 6, 7). As $\omega \rightarrow 0$, the origin is approached from the third quadrant at an angle $\sim 3\pi/2$, corresponding to a negative capacitance. Current-voltage curves in region III show a small dip/rise in anodic/cathodic sweeps. The magnitude of these changes is sweep-rate dependent, and offers independent confirmation for a negative capacitance. Phenomenologically, any circuit exhibiting the observed response can be made to oscillate by insertion of a series resistance sufficient to shift the negative real axis intercept to the origin. Equivalent circuit B in Fig. 3 can simulate the observed dispersion provided elements R_2 and C_2 are negative and $|C_2| > C_1$. Let us examine its stability with respect to a current fluctuation, $\delta I(t)$, under potentiostatic control ($\delta V(t) = 0$). For simplicity, we drop the high frequency capacitance, C_0 , and combine R_0 and R_1 into a single resistance, R . In addition to depending upon the electrolytic cell, this parameter includes any external resistance we might choose to insert in series with the working electrode. The impedance function $Z(i\omega, R, R_2, C_1, C_2)$ is readily found algebraically. Under constant applied potential the time-dependent current fluctuation is obtained by replacing $i\omega$ with d/dt

$$\delta V(t) = 0 = Z(d/dt, R, R_2, C_1, C_2) \delta I(t)$$

or

$$\{RR_2C_1C_2 \frac{d}{dt^2} + [R(C_1+C_2) + R_2C_2] \frac{d}{dt} + 1\} \delta I(t) = 0$$

Circuit stability depends on the sign of the second term. If positive, fluctuations decay exponentially. If negative, they grow until limited by nonlinearities in the circuit elements. We have assumed R_2 and C_2 to be negative. For R sufficiently small, the circuit is stable, but by increasing R we may always achieve an unstable condition. As the critical point is approached, small amplitude oscillations will occur at a frequency, $\omega = RR_2C_1C_2^{-1/2}$ [cf. Fig. 4a, Ref. (1)]. This is the frequency at which the admittance plot crosses the negative real axis. As experimentally verified (1), larger electrodes are more prone to oscillation because of the greater contribution of electrolyte resistance to the cell impedance. For $C_2 < 0$ but $C_1 + C_2 > 0$, the circuit is unconditionally stable, and complex-plane plots approach the origin at an angle $\pi/2$.

A negative differential capacitance implies a net decrease in the charge stored in the interfacial region following a potential increase. Integration of this capacitance across the negative impedance region gives a drop of $2 \times 10^{-3} \text{ C}/\text{cm}^2$. The magnitude indicates a faradaic charge too large to be accommodated by the thin surface layer present at these potentials. Rather, the charge must be associated with a modulation of the flow of ions into the diffusion layer. We have previously shown that electric fields significantly enhance Cu^{++} fluxes in this quasi-neutral region (1), and we believe these fields are closely related to the instabilities. There is an empirical resemblance between electrochemical behavior and the semiconductor Gunn effect (19). Both involve instabilities in systems with large static fluxes. In semiconductors, the effect is explained by a decrease in carrier drift velocity with an increase in the local electric field. Soliton charge density waves can form within a bulk phase. Instabilities at injecting contacts have also been analyzed, and calculated current-voltage curves bear a marked resem-

blance in shape and position of the negative impedance region to the electrolytic curves (20, 21).

The Gunn effect depends upon a change in band structure with field. Electrolytes lack this option, but offer possibilities arising from a multiplicity of charge bearing species. If we neglect anion migration, our system contains mobile hydrogen and copper ions. We have measured diffusion coefficients in phosphoric acid for the latter and, based upon conductivities, we infer a mobility ratio as high as 10^3 (1). A mechanism by which the balance between high mobility H^+ and low mobility Cu^{++} is shifted towards the latter in high field regions could lead to a direct Gunn analog. We have not been able to rationalize such an ionic field effect, but can construct a potential parallel. Assume behavior in the diffusion layer is expressed by the equations

$$\partial c/\partial x = +(ze/kT) cE - J_c/D_c$$

$$\partial h/\partial x = (e/kT) hE - J_h/D_h$$

$$\partial E/\partial x = (F/\epsilon) (zc + h - a)$$

where c , h , and a are concentrations, E the electric field, and J and D fluxes and diffusion coefficients. For rapid proton diffusion [H^+] follows a local Boltzmann relation

$$h(x) = h_0 \exp[-e\eta(x)/kT]$$

The rapid dissociative equilibrium of phosphoric acid ($ha = h_0^2$) implies (22)

$$a(x) = h_0 \exp[+e\eta(x)/kT]$$

even though anions have been assumed immobile. Copper phosphates are very insoluble in neutral and alkaline solutions and an equilibrium maintained by a reaction such as

may be imagined. Hypothesize a bulk phase in which [—] represents trapped Cu^{++} ions. A local increase in [Cu^{++}] leads to an increase in [H^+] and hence a drop in the local potential. The consequent change in electric field tends to drive neighboring Cu^{++} ions towards the center of the fluctuation. Should this force be sufficient to overcome diffusional spreading, the fluctuation will grow.

While the feasibility of a bulk instability may be conjectural, a dissolution interfacial analog offers one explanation for negative impedance behavior. If [—] represents the surface layer, the dissolution current can be written as

$$I_d = k^+ [H^+] - k^- [Cu^{++}] [H_2PO_4^-]$$

or

$$I_d = h_0 \{k^+ \exp(-e\eta_2/kT) - k^- \exp(+e\eta_2/kT) [Cu^{++}]\}$$

with η_2 the potential at the boundary of the surface and diffusion layers. Although the dissolution reaction does not involve charge transfer *per se*, its potential dependence is similar to a charge transfer reaction, save for the sign reversal in the exponents. Negative impedance behavior follows from the fact that the current decreases with an increase in local potential. Although hydrogen ions are a minor constituent of the system, they are strongly coupled to the dissolution reaction and the electric potential. An increase in potential drives these ions away from the interface, thereby decreasing the rate of dissolution.

To find the impedance of the diffusion layer, we must first consider electric field effects on Cu^{++} migration. Given

$$dc/dt = \partial \frac{\partial}{\partial x} (\partial c/\partial x + (zec/kT)\partial \eta/\partial x)$$

and assuming quasi neutrality with $zc = a \gg h$, this equation simplifies to

$$dc/dt = (z + 1)D_c \partial^2 c/\partial x^2$$

In regions where H^+ is a minority carrier, migration leads to an apparent threefold enhancement of the diffusion coefficient. The "diffusion" current is then given by

$$I_d = -z(z + 1)FD_c (\partial c/\partial x)_{x=0}$$

and the diffusion layer impedance becomes

$$Z_d = \eta_2^*/I_d^* = 1/G_d + [i\omega]^{1/2}W_d]^{-1}$$

with

$$G_d = (\partial I_d/\partial \eta_2)$$

$$W_d = zF(i\omega(z + 1)D_c)^{1/2} (\partial c/\partial \eta_2)_1$$

Both G_d and W_d have negative values, and the equivalent circuit consists of a negative resistance and a negative Warburg element in series.

The extent to which this negative impedance is reflected in measured impedances depends upon an additional relationship connecting changes in η_2 with those of η or η_1 . For thin surface layers, we expect the coupling to be large, whereas for thicker layers it should become negligible. The measured negative impedance is about an order of magnitude larger than Z_d calculated assuming $c \sim 1M$. An analysis of ellipsometric data has suggested the presence of a 2000-3500Å viscous region adjacent to the electrode (15). Although such a region would conveniently account for a greater negative impedance, its existence is not revealed by other parameters dependent upon the diffusion layer.

Negative impedance behavior also appears in region IV in the loop separating the two principal dispersions. An interpretation using the model proposed for region III can be forced by an ad hoc relationship between η_2 and η or η_1 , but an alternative explanation can be positive charge injection into a negatively charged space-charge region. Discussion of region IV has been based on the control of injected current by a barrier at the metal interface with a height dependent on the potential difference between the metal and the adjacent surface layer, $\eta - \eta_1$. The potential in the layer, η_1 , is not zero by virtue of negative space-charge within the film, *i.e.*

$$\eta_1 = -\rho l^2/2\epsilon$$

with $\rho < 0$. The low frequency dispersion arises from an increase in layer thickness with potential. Following an increase in η , the current rises, the film thickens, and η_1 also rises until $\eta - \eta_1$ is restored to its original value. If, however, prior to growth, the injected charge reduces the negative charge density, a small negative capacitance develops. For

$$I = I(\eta - \eta_1)$$

$$\eta_1 = -ql/2\epsilon$$

$$dq/dt = I$$

with q the charge in the layer, we find

$$Z = 1/G + 1/i\omega C)$$

$$G = \partial I/\partial \eta$$

$$C = -2\epsilon/l$$

The magnitude of the negative capacitance is comparable with the high frequency interfacial capacitance. Over longer periods of time film growth leads to a much larger positive capacitance, but, for frequencies well above those characterizing the growth process, this mechanism may account for the high frequency loops.

Questions unresolved concern the role of Cu^+ ions in regions III and IV, and those factors determining the space-charge density. It was concluded in Ref. (1) that a water depletion layer was important in determining the steady-state current. Water has not entered into this discussion, except perhaps implicitly in the rate constants in expressions for I_d . Cu^+ defects in the surface layer might account for the space-charge polarization. The ratio of [Cu^{++}] to the

space-charge density, $C_i/C_0 \approx 250$, is close to the $[\text{Cu}^{2+}]/[\text{Cu}^+]$ ratio expected for the solution phase. Independent experiments, e.g., ring disk studies, sensitive to the Cu^+ dissolution current may resolve some of these uncertainties.

Conclusions

Four stages describe the dissolution of copper into phosphoric acid. Initially, a two-step oxidation process involving soluble Cu^+ occurs. A surface monolayer forms when $[\text{Cu}^+]$ reaches a 5 mM level. At higher potentials, a negatively charged surface layer develops, reaching a thickness $\sim 100\text{\AA}$ at +1.0V. Current injected into this layer is limited by a barrier at the metal interface. The layer grows until the injection rate matches the hydrodynamically determined dissolution rate. Thickness is determined by potential, not current density, indicating it is the space-charge rather than a kinetic IR drop which controls the barrier height. During the initial phase of layer growth, a negative impedance develops which is responsible for current oscillations. As a mechanism, it is proposed that electric fields external to the barrier lower $[\text{H}^+]$ with increasing potential and therewith reduce the dissolution rate.

Manuscript submitted Nov. 21, 1984; revised manuscript received June 24, 1985. This was Paper 256 presented at the New Orleans, Louisiana, Meeting of the Society, Oct. 7-12, 1984.

At&T Bell Laboratories assisted in meeting the publication costs of this article.

APPENDIX

Assume as given a set of equations sufficient to describe a time-dependent electrode process. Time-dependent variables will include the current, I , the total applied potential, η , and a sequence of other variables, x_i , specific to the model. The steady-state value of each variable is subject to an arbitrarily small sinusoidal modulation so that

$$I(t) = \bar{I} + I^* \exp(i\omega t)$$

$$dI/dt = i\omega I^* \exp(i\omega t)$$

and similar expressions follow for η^* and x_i^* . For each of the equations describing the model, there is an equivalent modulation expression obtained from a first-order perturbation expansion about the steady state. If, for example

$$I = I(\eta, x_i)$$

then

$$I^* = (\partial I / \partial \eta)_{x_i} \eta^* + (\partial I / \partial x_i)_{\eta} x_i^*$$

The impedance is obtained by solving this set of linear equations for the ratio η^*/I^* . The admittance is the reciprocal of this ratio. Diffusional equations are frequently encountered, and the modulation counterpart of

$$dc(x,t)/dt = Dd^2c(x,t)/dx^2$$

is

$$i\omega c^*(x) = Dd^2c^*(x)/dx^2$$

with the Warburg solution

$$c^*(x) = c^*(0) \exp[-(i\omega/D)^{1/2}x]$$

The alternative solution with positive exponent becomes important for finite width diffusion regions at low frequencies ($\omega < D/l^2$).

The Study of the Anodic and Cathodic Corrosion Process of Coated Iron with the Electrochemical Impedance Technique

J. Hubrecht and J. Vereecken*

Department of Metallurgy and Electrochemistry, Faculty of Applied Sciences, Vrije Universiteit Brussel, 1050 Brussels, Belgium

ABSTRACT

In order to study the anodic and cathodic corrosion process of painted iron separately, two similar specimens are mounted as a differential aeration couple. Application of the electrochemical impedance measurement technique, scanning electron microscopy, and x-ray analysis demonstrate a different paint-degradation rate according to the anodic or cathodic polarization. The blistering phenomenon is shown to be a consequence of the anodic process. The electrochemical impedance points out diffusion control in the cathodic cell and charge transfer control in the anodic cell.

The study of the quality of organic corrosion inhibiting coatings assumes an investigation of the interaction between the corrosive environment, the coating itself, and the metal substrate. More particularly, the course of the subcoating corrosion process and the mechanism of the coating deterioration are important topics. Interaction means that one should investigate the metal/coating/environment system preferably as an integral one. Furthermore, the system is time dependent, so one should be able to monitor it *in situ*. Since the underlying corrosion phenomenon has an electrochemical nature, first of all electrochemical techniques provide a proper method.

The electrochemical impedance technique is especially useful in examining interface processes, and coating performance (1-10). Two important advantages of this technique are that: (i) it often displays the constituting characteristics of the system separately (surface layers, charge transfer, mass transfer, etc.) and (ii) there is no pronounced perturbation of the system, since one usually works with small amplitude signals.

Still, the interpretation and modeling of electrochemical impedance data is not an easy matter.

In order to evaluate what role oxygen plays in corrosion of the integral metal/coating/environment system, an attempt is made to subdivide the system artificially into the oxidation and reduction process. Impedance data, together with scanning electron microscopy and x-ray analysis, are used to investigate the paint degradation and to determine the corrosion mechanism under the coating.

Experimental

After polishing with 600 grit paper, cleaning ultrasonically, and degreasing with ethanol each ARMCO iron plate is coated with a water-base emulsion paint, consisting of ERCUSOL AS250 (a styrene-acrylic polymer) with red iron oxide and strontium chromate pigments.

As described elsewhere (5), the coated specimen is mounted as the bottom plate of a glass cylinder, which is filled with an aqueous 0.5M NaCl solution. The circular surface of the exposed part has an apparent area of 19.6 cm². The experiment runs at room temperature.

For the application of the electrochemical impedance technique, a platinum grid is used as a counterelectrode and an SCE as a reference electrode. The metal substrates of two identical cells are connected electrically, and the cell solutions are connected electrolytically. Pure oxygen is supplied continuously in cell 1, pure nitrogen in cell 2. In this way, a differential aeration couple is created, and the net current between both cells can directly be measured, as can the mixed potential of the metal substrate *vs.* a SCE.

Cell 1 has an average coating layer thickness of 220 μm , and cell 2 190 μm . To have some idea about the reproducibility, the experiment has been repeated with a similar pair of cells (cells 3 and 4) over a shorter time period. Table I presents the cell specifications.

* Electrochemical Society Active Member.

The electrochemical impedance of the separate cells is measured after first disconnecting both cells and holding them potentiostatically at the latest measured mixed potential.

The electrochemical impedance measurement mounting consists of a 1250 frequency response analyzer (FRA) and a 1186 electrochemical interface (potentiostat) both from Solartron/Schlumberger. The FRA is controlled by a Tektronix 4051 desktop computer to perform automatic measurements, data transmission, and data output. The frequency range of the applied voltage sine wave ranges from 65.5 kHz to 10 mHz, and the amplitude is 20 mV.

After a 92 day test period, cells 1 and 2 are dismantled. The coated plates are rinsed with distilled water and ethanol, dried, and embedded in a cold mounting epoxy resin. A cross section is made with a diamond saw. The samples are then polished with 600 grit paper, rinsed with ethanol, coated with carbon, and subsequently analyzed with scanning electron microscopy (SEM) and x-ray analysis (JEOL JSM-50A and ORTEC 6200).

Results

Figure 1 represents the net corrosion current directly measured between cells 1 and 2, and cells 3 and 4. The current between cells 1 and 2 shows an almost linear increase during the first 15 days of the immersion and finally reaches a kind of plateau of about 200 nA. Cells 3 and 4, however, show a much steeper current increase, and the plateau is situated at 500 nA.

The mixed potential of the connected cells 1 and 2, or corrosion potential (Fig. 2), drops by 200 mV in about 4 days; thereafter, the decrease is much slower. The latter trend is very similar to, if somewhat faster than, the corrosion potential behavior of a single cell (called no. 5 in Table I) with 190 μm of the same paint in 0.5M NaCl under air atmosphere (5) (Fig. 2).

Similarly to the current variation of the couple cell 3/cell 4, their potential variation is also faster than for the couple cell 1/cell 2 (Fig. 2).

After an immersion time of 11 days, the cell 1/cell 2 couple is cut for about 10 min. The potential of cell 2, nitrogen supplied, is found to fall by 57 mV; the potential of cell 1, oxygen supplied, rises by 32 mV.

Typical impedance data of cell 1 and cell 2 after 26 days are depicted in a Cole-Cole plot in Fig. 3. The impedance is expressed in $\Omega\text{-cm}^2$ of the apparent area. It is explained elsewhere (5) that the impedance response of a sub-

mersed coated iron sheet, as specified above, contains three distinct sections according to the frequency domain. The flattened semicircle which is found at high frequencies (HF) is known to reflect the physical behavior of the coating. At intermediate frequencies (IF), the impedance follows the impedance of the electrochemical double layer and charge transfer at the metal substrate, and at low frequencies (LF) the impedance of the mass transfer.

It is noticed from Fig. 3 that the impedance curve of cell 2, and more particularly its HF part, extends over a much wider area than the one of cell 1. If R is taken as the diameter of the HF flattened semicircle, or otherwise as the abscissa of the HF minimum in the curve, then R is $1.29 \times 10^6 \Omega\text{-cm}^2$ for cell 2 and $6.43 \times 10^5 \Omega\text{-cm}^2$ for cell 1 after 26 days.

Further, cell 1 shows a charge transfer response and a mass-transfer response, whereas the data of cell 2 comprise a charge transfer response and no mass-transfer response.

Viewing the impedance data of cell 2 after 11, 26, and 46 days (Fig. 4), one can see that the same behavior is maintained, although the size of the curve is markedly decreasing. The same holds for cell 1 (Fig. 5); still, one can object that the mass transfer becomes increasingly determining with immersion time.

Figure 6 (oxygen-supplied cells no. 1 and 3) and Fig. 7 (nitrogen-supplied cells no. 2 and 4) demonstrate that the experiment is reproducible as for the shape of the impedance curve, but not for its magnitude (Table II). Moreover, going from cell 1 to cell 3 (Fig. 6), the real part of the lowest frequency impedance does not decrease in the same proportion as R . The same is observed in going from cell 2 to cell 4 (Fig. 7).

In the case of the cell 2 sample, the coating shows a blistered surface and can easily be removed after the immersion experiment. The blisters have a maximum diameter of about 1 mm, and an approximate density of 80

cm⁻². The blisters are not cracked. During optical inspection of the coating/metal interface, voluminous light brown products are observed at the blister sites alternated with a thin uniform dark brown layer. During the immersion test, no products are visible on top of the coated sample and the bulk solution pH fluctuates around 6. In the case of the cell 1 sample, the coating shows an intact surface and no blisters at all, and is still uniformly attached to the substrate; at any place where the coating is pushed off, the metal surface is blank. The bulk solution pH is about 8 during the immersion test.

Figure 8 shows a cross section of the cell 2 sample with an accumulation of oxidation products at a blister. Those products contain Fe, O, and Cl; in the surrounding organic coating, Cr is detected, but it is not in the anodic products. SEM and x-ray microanalysis do not reveal any reaction products at the coating/metal interface of the cell 1 sample.

Discussion

The similarity between the corrosion potential behavior of the single cell and the mixed potential behavior of the differential aeration couple demonstrates that the latter experiment is a good simulation of the real corrosion process. Moreover, the oxygen-supplied cells no. 1 and 3 must behave as cathodes, and the nitrogen-supplied cells no. 2 and 4 as anodes. There are more arguments in favor of those statements: the measured net current, the spontaneous shift of the potential of cell 1 to more positive values and of cell 2 to more negative values when they are disconnected, and the intact condition at the metal/coating interface of cell 1 and the oxidation products at the metal/coating interface of cell 2. The simulation also points out that differential aeration may be one factor determining the anodic and cathodic sites of a corroding coated metal.

Fig. 8. SEM picture of a cross section of the cell 2 sample. Above: Coating layer. Under: Iron plate. Right: Oxidation products.

Relying on the model proposed earlier for the metal/coating/electrolyte system (10), the quantity R may be a measure for the resistance of the immersed coating layer, or pore resistance, as conduction is ensured via pores in the coating. The R values for both the cell 1 and cell 2 specimen have been drawn as a function of the immersion time (Fig. 9). The reduction of the coating resistance as a consequence of penetration by the conducting solution and coating degradation is a known phenomenon. Nevertheless, the resistance of the cell 1 coating is lower than that of cell 2, although the slight difference in average thickness (Table I) points in the reverse sense, and although the immersion conditions are the same. This fact is repeatable (Fig. 10). The active section A of the coating available for permeation of electrolyte, reacting and reaction products is only a small fraction of the apparent surface area A_a of the coating. A measure for A can be calculated from the measured resistance R and the thickness l of the coating and the specific resistance ρ of the solution which is 23 Ω -cm for cell 1 and cell 2, according to

$$\frac{R}{A_a} = \rho \frac{l}{A}$$

Figure 11 is a plot of the active section A vs. the immersion time for both cell 1 and cell 2. One finds that the active coating section of the cell 1 sample increases linearly with immersion time, whereas the slope for the cell 2 sample is markedly smaller.

At this point, it may be convenient to discuss the appearance of the samples after the immersion test. It is shown by visual and SEM inspection and x-ray analysis that the anodic process in cell 2 is responsible for the formation of products which contain Fe, O, and Cl. As a result of iron oxidation under the coating, hydrolysis (and thus decrease of the solution pH), Cl⁻ penetration

Fig. 9. Immersed coating resistance R vs. immersion time t . o: Cell 1. +: Cell 2.

through the coating, and Cl^- contribution to the oxidation process, oxidation products are formed and precipitated. They are much more voluminous than the iron itself, and push up the coating. Blister formation is the consequence, which also makes the coating easily detachable.

On the other hand, during the cathodic process in cell 1 oxygen penetrates the coating and is reduced to OH^- , which is proved by the rising of the pH in the bulk solution. One would expect cathodic delamination to occur (11-17), but under the present circumstances no such delamination is detected after 92 days of continuous immersion. An explanation may be found in the rather good performance of the styrene containing copolymer in alkali environment (11) due to the evacuation of OH^- from the metal/coating interface through the water-base emulsion coating, of which the permeability is even increased by the chromate pigment (5).

The better performance of the cell 1 coating is only seemingly contradictory with the R behavior as determined by impedance measurements. Indeed, it is supposed that the coatings of cell 1 and cell 2 behave in the same way as long as only movement of dissolved substances through the coating is occurring. Voluminous deposits, however, as formed by the anodic process in cell 2 cannot move through the coating and actually block the pores. The consequence is that the R drop is slowed down in the anodic cell. This enforces the insight that blister formation in the anodic case is caused by mechanical action of the oxidation products at the coating/metal interface.

Also, the steepest active section increase for cell 2 seems to occur during the first 15 days. It is striking that, as soon as the rate of increase in A in cell 2 slows down, the current reaches its maximum value.

Another system characteristic is that, at a frequency of 10 mHz, the impedance shows the reduction process to be controlled by the diffusion of electroactive species (Fig. 3), and that the longer the immersion the stronger becomes the latter effect (Fig. 5). On the other hand, the oxidation process is still controlled by the charge transfer.

From the low frequency data of the repeated experiment (Table II), it is clear that the rate of the faradaic process in the case of the cell 3/cell 4 couple is much higher than in the case of the cell 1/cell 2 couple, although the difference in coating behavior as reflected by the R value read from the impedance curve is not so drastic as that.

Table II. Maximum real impedance part at 10 mHz in $10^6 \Omega\text{-cm}^2$ (see Fig. 6 and 7)

Cell 1 (11 days)	Cell 3 (10 days)	Cell 2 (11 days)	Cell 4 (10 days)
3.0	1.0	4.2	2.5

The difference in net measured currents for both couples, presented in Fig. 1, confirms the above corrosion rate observations. Still, a nice mathematical relation between the impedance values and the net current is not obvious. It is supposed that perhaps impedance data at frequencies lower than 10 mHz may supply additional information. The problem is, however, that measurements at lower frequencies are disturbed by the spontaneous change of the system.

Conclusion

The simulation of the corrosion process of coated iron with the aid of a differential aeration couple led to some interesting findings concerning the separate action of the anodic and cathodic reaction. Electrochemical impedance measurements show that the pore resistance decreases more rapidly in the coating of the cathodic sample than in the one of the anodic sample. But visual inspection, scanning electron microscopy, and x-ray analysis show that at the anodic metal/coating interface oxidation products are formed which deposit, accumulate, block the coating pores, and cause blistering. Also as revealed by the impedance, the cathodic kinetics seem to be controlled by diffusion phenomena and the anodic kinetics by the charge transfer.

The Stern-Geary theory seems to be respected, as the real part of the 10 mHz impedance of the separate cells is inversely related to the net measured current.

Simplified Calculation of pH and Ion Concentrations in High Temperature Phosphate Solutions and Phosphate-Hydroxide Mixtures

Sidney Barnartt*

Consulting Chemist, Monroeville, Pennsylvania 15146

ABSTRACT

A simplified method is developed for calculating pH and ion concentrations in dilute alkali phosphate-alkali hydroxide mixtures. It is an approximate method which assumes that all of the phosphate is present as H_2PO_4^- and HPO_4^{2-} ions. Comparisons with more general calculations, based on four phosphate species and activity coefficients derived from the Debye-Hückel theory, show good agreement over the temperature range 25°-250°C and Na/P ratios of 1.5-9.

Sodium phosphates have been used extensively as alkali additives to water to mitigate corrosion in high pressure boilers and steam generators. Knowledge of solution pH at operating temperature and of the effect of strong alkali additions is important for corrosion control (1-3). A simplified method of calculating pH and concentrations of phosphate ions in dilute solutions made from sodium phosphates and sodium hydroxide is presented in this paper. The method is shown to yield good precision over a wide range of Na/P ratios at elevated temperatures.

Solutions made from sodium salts of orthophosphoric acid can contain three phosphorus-based ions plus undissociated H_3PO_4 . The following equilibria exist between the dissolved species

where a denotes activity and K the equilibrium constant. There is an additional equilibrium constant for water ionization

Here $a_{\text{H}_2\text{O}}$ is assumed to be unity in dilute solutions.

The pH of a phosphate solution depends upon what combination of alkali hydroxide and phosphoric acid or phosphate salts is used to make the solution. At a fixed temperature, total phosphate molality m_p , and overall atomic ratio Na/P fix the pH of the solution and the concentrations of the dissolved phosphorus containing species.

Equilibrium constants for reactions [1]-[4] are known as a function of temperature within the range 25°-300°C (4-6). These can be used, with the Debye-Hückel theory for evaluating activity coefficients, to calculate pH as a function of temperature.

*Electrochemical Society Emeritus Member.

tion of temperature. A computer program for this calculation is available (7); data in that reference show very good agreement between calculated pH values and published experimental measurements.

A simplified approximation yielding pH and ion concentrations is described below. The concentration ranges and temperatures over which the simplified method provides adequate precision are determined by comparison with the general Debye-Hückel method.

The data base used to generate the temperature dependence of the four equilibrium constants needed for these calculations is given in Table I. Standard Gibbs free energy of reaction values are listed here as a function of temperature. As described in the Appendix, the seven reactions listed provide an internally consistent set of values of ΔG° , the standard free energy of formation from elements at a given temperature, for the seven dissolved species of interest. Convenient polynomials were developed to yield the ΔG° values over the temperature range 25°-300°C. The polynomials are presented in Table II. Equilibrium constants for reactions [1]-[4] are readily obtained from the free energy data in Table II.

Computational Procedures

General method.—The four equilibrium constants, Eq. [1]-[4], are used with the following relations expressing mass balance and electrical neutrality

$$m_p = m_{\text{H}_3\text{PO}_4} + m_{\text{H}_2\text{PO}_4^-} + m_{\text{HPO}_4^{2-}} + m_{\text{PO}_4^{3-}} \quad [5]$$

$$m_{\text{H}^+} + r(m_p) = m_{\text{H}_2\text{PO}_4^-} + 2(m_{\text{HPO}_4^{2-}}) + 3(m_{\text{PO}_4^{3-}}) + m_{\text{OH}^-} \quad [6]$$

Here m_p is the total phosphate molality and r is the atomic ratio Na/P, both known quantities. The sodium ion molality is $r(m_p)$ assuming Na^+ forms no significant amount of ionic complex or neutral molecule in the solutions considered.

An initial set of molalities is obtained by setting the activity coefficient of each dissolved species equal to unity, then solving Eq. [1]-[6] to get the concentrations of the six

dissolved species. A second (improved) approximation is obtainable by inserting values for activity coefficients in Eq. [1]-[4].

The Debye-Hückel theory of ionic interaction (11-13) is used to calculate the activity coefficients of ions, while the activity coefficient of undissociated H₃PO₄ is assumed to be unity. For an ion of charge z_i (positive or negative) in a solution of ionic strength I , the Debye-Hückel theory gives the ionic activity coefficient γ_i for dilute solutions as

$$\ln \gamma_i = - \frac{(z_i e)^2 \kappa}{2DkT(1 + \kappa a_i)} \quad [7]$$

with

$$\kappa = (8\pi e^2 N_A I / 1000 D k T)^{1/2} = BI^{1/2}$$

where ionic strength is defined in terms of molarity c as $I = 1/2 \sum c_i z_i^2$. Here a_i is the ion-size parameter and is taken to be 4Å. D is the dielectric constant of the solution and is taken to be that of water at temperature. Also, N_A is Avogadro's number, k is the Boltzmann constant, e is the charge of an electron, and κ^{-1} is the thickness of the ionic atmosphere of excess charge around ion i . Equation [7] is usually rewritten as

$$-\log \gamma_i = Az_i^2 I^{1/2} / (1 + Ba_i I^{1/2}) \quad [7']$$

where A and B are temperature-dependent constants which have been tabulated (12, 14). This equation with $z_i = 1$ yields the value of $\gamma_{H^+} = \gamma_{OH^-} = \gamma_{H_2PO_4^-}$ and $z_i = 2$ yields $\gamma_{HPO_4^{2-}}$, while $z_i = 3$ gives $\gamma_{PO_4^{3-}}$.

Insertion of these values of γ into Eq. [1]-[4] leads to a new set of molality values from Eq. [1]-[6], which in turn yields a second set of γ values, and the cycle is repeated until unchanging m and γ values result.

With the use of the Debye-Hückel theory in unextended form (Eq. [7]), the calculation should give a good approximation up to the maximum concentrations employed in this report, namely, 0.001*m* total phosphate. Therefore, this method is used in the present study as the standard against which the simplified method, described next, is quantitatively evaluated.

Simplified method.—The basis of the simplified calculation to be described is the deduction that alkaline phosphate solutions over a wide range of pH and temperature contain two phosphate species primarily (> 99%). This is clearly revealed by a plot of activity ratio as a function of pH, shown in Fig. 1 for 25°C and 300°C. These lines are described by Eq. [1]-[3], which can be expressed in the general form

$$\log(\text{activity ratio}) = \log K + pH \quad [8]$$

Thus the line labeled H₂PO₄⁻/HPO₄²⁻ gives the activity ratio of these two ions at a given pH. Line location depends only on the numerical value of the equilibrium constant K .

The pH range $P'P''$ shown in Fig. 1 includes all solutions in which the sum of the H₂PO₄⁻ and HPO₄²⁻ activities exceed 99% of the total phosphate activity. At 25°C, a third species, H₃PO₄, exceeds 1% of phosphate activity be-

Fig. 1. Activity ratios of phosphate solutions as a function of pH at 25° and 300°C.

low pH 4.1, whereas PO₄³⁻ becomes the third species at significant concentration above pH 10.3. Figure 1 shows that the range $P'P''$ shifts in the direction of higher pH when the temperature is raised to 300°C.

From plots similar to Fig. 1 at intermediate temperatures, the pH ranges for two-species solutions, defined by the 99% limits imposed above, yield the limit curves of Fig. 2. The bottom curve gives the low pH limit and the

Fig. 2. pH of solutions dominated by the two phosphate ions H₂PO₄⁻ and HPO₄²⁻.

top curve gives the high pH limit for two-species solutions. The upper shaded zone gives the pH range over which 99-100% of the phosphate activity is due to the single ion HPO_4^{2-} . Similarly, H_2PO_4^- makes up 99-100% of the phosphate activity within the lower shaded zone.

Included for comparison as the broken curve in Fig. 2 is the pH of pure water as a function of temperature (4). At room temperature, the two-species solution range includes neutral solutions and extends into the acid region down to pH 4.1 before undissociated H_3PO_4 builds up to a concentration of 1% of the phosphate activity. Neutral solutions remain within the two-species range up to a temperature of about 225°C. As the temperature is raised from 225° to 300°C the neutral solution contains an increasing fraction of undissociated H_3PO_4 .

The broad pH range for two-species solutions over the whole temperature interval 25°-300°C suggested a simplified procedure for calculating pH and ion concentrations which involves two assumptions: (i) ionic activities are established by only two equilibria, namely, water ionization (Eq. [4]) and H_2PO_4^- dissociation (Eq. [2]); (ii) ionic activity coefficients can be approximated by unity. Under these conditions, Eq. [2], [4]-[6] become

$$K_2 = (m_{\text{H}^+})(m_{\text{HPO}_4^{2-}}) / m_{\text{H}_2\text{PO}_4^-} \quad [2']$$

$$K_w = (m_{\text{H}^+})(m_{\text{OH}^-}) \quad [4']$$

$$m_p = m_{\text{H}_2\text{PO}_4^-} + m_{\text{HPO}_4^{2-}} \quad [5']$$

$$m_{\text{H}^+} + r(m_p) = m_{\text{H}_2\text{PO}_4^-} + 2(m_{\text{HPO}_4^{2-}}) + m_{\text{OH}^-} \quad [6']$$

A given solution fixes total phosphate molality m_p and Na/P ratio r , and the temperature specifies numerical values of K_2 and K_w . Thus, these four equations can be solved to obtain the molalities of the four ionic species. To that end, a convenient equation for m_{H^+} , obtained by substitution into Eq. [6'], is

$$m_{\text{H}^+} - K_w/m_{\text{H}^+} + m_p[r - 2 + (1 + K_2/m_{\text{H}^+})^{-1}] = 0 \quad [9]$$

Equation [9] may be solved by trial by application of the Newton-Raphson method for stepwise improvement of the trial value of m_{H^+} . This method uses

$$x_2 = x_1 - f(x_1)/(df/dx) \quad [10]$$

where x_1 is the initial approximation to m_{H^+} , x_2 the improved approximation, and f is the function of m_{H^+} (left-hand side of Eq. [9]). Successive improvements are continued until m_{H^+} is evaluated with the desired precision. Then m_{H^+} is substituted into Eq. [2'], [4'], and [5'] to evaluate the other three molalities.

Results

Single salt solutions of disodium phosphate and of trisodium phosphate were used in an initial comparison of the simplified and general calculation methods. Figure 3 presents pH variations with temperature for Na_2HPO_4 and Na_3PO_4 solutions at concentrations of 10^{-5} , 10^{-4} , and $10^{-3}m$. For 10^{-5} and $10^{-4}m$ solutions, the two calculation methods are in very good agreement over the entire range 25°-300°C. At $10^{-3}m$, the two methods agree within 0.1 pH unit at temperatures up to 250°C, but at 300°C the deviation begins to exceed 0.1 pH.

The set of solutions compared in Fig. 3 conforms to the pH limits of Fig. 2 for two-component solutions, except for the uppermost portion of the top Na_3PO_4 curve (broken section) which is outside those limits. The good agreement revealed in Fig. 3 between the two methods of calculation demonstrates that the simplified method yields pH with sufficiently high precision.

Figure 3 shows that heating from 25° to 300°C raises the H^+ concentration in these solutions, just as it does for pure water. What is not revealed is the fact, which emerges from the computed values of m_{OH^-} , that heating also raises the OH^- concentration. This is true for all of these phosphate solutions. The ratio of m_{OH^-} to total phosphate (m_p) can be used to illustrate the effect. For $10^{-3}m$ Na_2HPO_4 , the ratio m_{OH^-}/m_p increases from 0.0116

Fig. 3. pH of dilute Na_2HPO_4 and Na_3PO_4 solutions

at 25°C to 0.793 at 300°C, and for $10^{-3}m$ Na_3PO_4 it increases from 0.949 to 1.616 for the same temperature change. In the latter case, the molalities of the three dominant ions at 300°C are ($\times 10^3$) $m_{\text{OH}^-} = 1.616$, $m_{\text{H}_2\text{PO}_4^-} = 0.623$, and $m_{\text{HPO}_4^{2-}} = 0.377$. Here, the most abundant ion is OH^- . This can be significant for accelerated alloy corrosion in boilers or steam generators, if the corrosion mechanism involves a passivating phosphate film which suffers localized breakdown when OH^- exceeds a critical concentration.

Phosphate ion concentrations in the solutions of Fig. 3 are plotted in Fig. 4. The ordinate is the concentration of the divalent ion HPO_4^{2-} as a percentage of total phosphate. At low temperatures, the divalent ion is the dominant species in either Na_2HPO_4 or Na_3PO_4 solutions. As the temperature is raised, the divalent ion converts gradually to the monovalent ion by reaction [2], and at 300°C the monovalent ion is the dominant one in these dilute solutions. The simplified method yields concentrations in good agreement with those generated by the general method over the whole temperature range at 10^{-5} and $10^{-4}m$. For $10^{-3}m$ solutions, the two methods of calculation begin to deviate noticeably at 200°C and the deviation increases with increasing temperature.

Similar calculations of pH and ion concentrations were performed for a wide variety of Na/P ratios ranging from monosodium phosphate, Na/P = 1, to solutions made with Na_3PO_4 and added NaOH up to a molar ratio $\text{NaOH}/\text{Na}_3\text{PO}_4 = 6$ (or Na/P = 9). Ion concentration results are collected in Table III for $10^{-3}m$ total phosphate, which is the highest concentration examined. This concentration yields maximum deviations between the simplified and general computational methods. The blocked case at the upper right corner of Table III represents the only solution in which H_3PO_4 exceeds 1% of total phosphate (general calculation). The enclosed block at the lower left includes all of the solutions examined which contained $\text{PO}_4^{3-} \geq 1\%$ of total phosphate. Within the latter block, deviations of the simplified method from the general method increase with increasing Na/P ratio but decrease with increasing temperature. Solutions outside of the two blocked areas are those in which the two ions, H_2PO_4^- and HPO_4^{2-} , account for more than 99% of the total phosphate molality. Within this group, the deviation of the simplified calculation (Method 1) increases with increasing Na/P ratio and with increasing temperature.

Fig. 4. Conversion of divalent to monovalent phosphate ion with increasing temperature in dilute Na_2HPO_4 and Na_3PO_4 solutions.

Although a few of the concentration deviations listed in Table III are relatively large their effect on pH is minimal, as revealed by the parallel pH listing in Table IV. Throughout the lower left block, agreement between the simplified and general methods remains very good. Even at the lowest temperature and highest Na/P ratio, where the pH of 11.8 is well outside the limits given by Fig. 2,

Fig. 5. Effect of Na/P ratio on pH variation with temperature in 10^{-4} and 10^{-3} m phosphate solutions.

the deviation does not exceed 0.07 pH unit. The good agreement in that blocked section results mainly from two compensating errors in the simplified calculation, namely (i) activity coefficients too high (set at unity) and (ii) PO_4^{3-} concentration too low (set at zero). The calculated H^+ concentration tends to be too small from the first error and too large from the second. For all of these solutions, the net result is that the H^+ concentration from the simplified calculation remains close to but always slightly smaller than the value given by the general method.

The largest pH deviation in Table IV is seen to occur for monosodium phosphate solution at 300°C (upper right block), where undissociated H_3PO_4 appears although only at 1.2% of total phosphate. In the whole of Table IV, the pH deviation exceeds 0.1 unit only in the temperature range 150°C - 300°C for monosodium phosphate and only at 300°C for the other solutions.

The temperature variation of pH given in Table IV for 10^{-3} m phosphate solutions is shown graphically in Fig. 5, together with similar curves for 10^{-4} m solutions. These data were generated by the simplified method. The curves illustrate that the pH rise from an NaOH addition,

e.g., to a solution made from Na₂HPO₄, is relatively small at 200°-300°C compared to the pH rise at room temperature from the same addition.

Variations of pH with total phosphate concentration are shown by the plots in Fig. 6, which compare pH at 300°C with that at room temperature. Each plot shows an almost linear increase of pH with log (concentration) over the range covered, 10^{-5} - $10^{-3}m$. At 25°C, the pH shift on increasing the Na/P ratio from 1.5 to 9 becomes larger as concentration increases, but at 300°C the curves tend to be parallel.

Although sodium was used as the alkali cation in the solutions discussed, other alkali cations such as Li⁺ or K⁺ should yield the same ion concentrations if salts of these cations can be assumed to remain completely dissociated in dilute solutions.

Conclusions

1. Dilute solutions of monosodium, disodium, or trisodium phosphate or their mixtures contain mainly two dissolved phosphate species: H₂PO₄⁻ and HPO₄²⁻ ions.

2. A simplified calculation of pH and ion concentrations is developed, considering only equilibrium between

these two of the four dissolved phosphate species. It yields pH within 0.1 pH unit over the temperature range 25°-250°C.

3. In solutions of disodium phosphate only and of trisodium phosphate only, almost all the phosphate is present as the divalent ion HPO₄²⁻ at room temperature. On heating, this gradually converts to the monovalent ion by the reaction

accompanied by an increase in H⁺ concentration, and at 300°C the monovalent ion predominates.

4. In solutions of monosodium phosphate only, almost all the phosphate is present as H₂PO₄⁻ throughout the temperature interval 25°-300°C.

5. The two ions H₂PO₄⁻ and HPO₄²⁻ predominate also in solutions of Na₃PO₄ with added NaOH. As NaOH is gradually added, the PO₄³⁻ ion does appear in increasing although low concentrations. Nevertheless, the simplified pH calculation remains valid within 0.1 pH unit for a wide range of compositions: Na/P ratios from 1.5 to 9.0 over the temperature range 25°-250°C.

Manuscript submitted April 8, 1985; revised manuscript received Aug. 9, 1985.

APPENDIX

Free Energies of Formation at Elevated Temperatures

The following seven constituent substances are involved in phosphate solution equilibria: H₂O, H⁺, OH⁻, H₂PO₄⁻, HPO₄²⁻, PO₄³⁻, and undissociated H₃PO₄. Maximum use was made of experimental high temperature thermodynamic data from the literature in calculating standard Gibbs free energies of formation from the elements for the seven substances. Literature data for phosphate equilibria and water ionization are given in Table I, reactions [1-A]-[4-A], as standard free energies of reaction.

Similar data were needed for three additional reactions, and the formation reactions for substances H₂O, H⁺, and HPO₄²⁻ were chosen: reactions [5-A]-[7-A] in Table I. These free energies were calculated from molar heat capacities of reaction, Δc_p , by use of the well-known thermodynamic relation

$$\Delta G_T^0 = \Delta G_{298}^0 - \Delta S_{298}^0 (T - 298) + \int_{298}^T \Delta c_p dT - T \int_{298}^T \frac{\Delta c_p}{T} dT \quad [\text{A-1}]$$

Fig. 6. Effect of Na/P ratio on pH at 25° and 300°C as a function of concentration.

where ΔS° is the standard entropy change for the reaction. The method of Kubaschewski and Alcock (10) was followed, in which Eq. [A-1] is utilized in the following equivalent form for easy evaluation of the integrals

$$\Delta G_r^\circ = \left[\Delta H_{298}^\circ - \int_0^{298} \Delta c_p dT \right] - T \left[\Delta S_{298}^\circ - \int_0^{298} \Delta c_p d \ln T \right] + \int_0^T \Delta c_p dT - T \int_0^T \Delta c_p d \ln T \quad [\text{A-2}]$$

Since Δc_p is available in the general form

$$\Delta c_p = e + fT + gT^2 + hT^{-2}$$

where e , f , g , and h are tabulated constants (10, 15), the integrals become

$$\int_0^T \Delta c_p dT = eT + 1/2 fT^2 + 1/3 gT^3 - hT^{-1} \quad [\text{A-3}]$$

$$\int_0^T \Delta c_p d \ln T = e \ln T + fT + 1/2 gT^2 - 1/2 hT^{-2} \quad [\text{A-4}]$$

It should be noted that the term $e \ln$ (zero), which formally should be included in Eq. [A-4], can be omitted since it cancels out in Eq. [A-2]. Molar heat capacities for ions H^+ and HPO_4^{2-} were obtained by the method of Criss and Cobble (9) based on their entropy correspondence principle.

Free energies of reaction listed in Table I yield free energies of formation for all of the ions and compounds involved. Then for each substance the free energy as a function of temperature was fitted, by multiple linear regression analysis on a computer, to the cubic polynomial

$$(\Delta G_r^\circ)_T = (\Delta G_r^\circ)_{298} + a(\Delta T) + b(\Delta T)^2 + c(\Delta T)^3 \quad [\text{A-5}]$$

with $\Delta T = T - 298$. Table II gives values of the polynomial coefficients for each of the species. This tabulation is a useful and internally consistent set of numerical data for calculating equilibrium constants of high temperature phosphate solutions.

Changes in Oxide Films on Nickel during Long-Term Passivation

B. MacDougall,* D. F. Mitchell, and M. J. Graham

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

The nature of the long-term anodic currents observed when nickel is potentiostatically polarized in the passive potential region has been investigated. Passive oxide films are formed in O^{18} (or O^{16}) solutions and then exposed to O^{16} (or O^{18}) solutions for continued anodic polarization. The change in the O^{18} (or O^{16}) content of the film is determined by SIMS using the polyatomic species $^{58}\text{Ni}^{16}\text{O}_2^-$ and $^{58}\text{Ni}^{16}\text{O}^{18}\text{O}^-$. The extent of oxygen replacement in the passive film increases with increasing time of exposure to the new solution and eventually complete replacement occurs. The kinetics of replacement are highly dependent on the conditions of pretreatment in the O^{18} (or O^{16}) solution, *i.e.*, on the defect state of the oxide and on the aggressiveness of the exposure solution. The results can best be interpreted in terms of a model where the passive oxide film is locally breaking down and being replaced by new oxide formed in the fresh solution. The current efficiency for local repassivation is only $\sim 20\%$, the rest of the charge going towards metal dissolution. Transformation of a passive oxide film, via local breakdown-repair events, occurs at essentially the same rate in Cl^- as in SO_4^{2-} solutions, suggesting that the important role of Cl^- in pit initiation is to interfere with local repassivation rather than to directly break or thin the film.

A fundamental question in the field of passivity concerns the nature of the electrochemical processes giving rise to the long-term anodic currents, i_a 's, observed upon potentiostatic polarization in the passive potential region. For nickel in sulfate and borate solutions, i_a decreases with time (at constant potential) according to a linear $\ln i_a$ - $\ln t$ relationship, and may eventually reach a steady value (1, 2). Results of this kind are often interpreted in terms of high field growth of an oxide film with the rate of growth eventually decreasing to the point where it is comparable to the rate of chemical dissolution of the oxide (3, 4); this situation would result in the constant i_a frequently observed after long times of anodic polarization. However, for nickel in sulfate and borate solutions the majority of the anodic current is not associated with ox-

ide film growth, even in the region of linearity between $\ln i_a$ and $\ln t$, since the current efficiency (c.e.) for metal dissolution is $> 80\%$ (1). In addition, the limiting NiO film thickness of 12\AA is the same over the pH range 2.0-8.4, which also suggests that the simple high field oxide growth model is inappropriate for explaining the measured i_a 's. Anodic processes which might be contributing to the measured i_a include (i) nickel dissolution through the passive oxide film driven by a high electric field (5, 6) (ii) general chemical dissolution of the oxide (7-9) with the outer layer dissolving and reforming, and (iii) localized chemical dissolution of the passive film with patches of oxide breaking down completely and being replaced by new patches formed as a consequence of local film repair (1, 2, 10-13). A better understanding of which process gives rise to the long-term i_a 's observed in non-

* Electrochemical Society Active Member.

aggressive solutions may also throw light on the highly localized pitting corrosion observed in Cl^- and Br^- solutions.

In the present work, experiments have been designed to determine whether passive oxide films on nickel undergo changes during long-term passivation, *i.e.*, to correlate i_a with changes in the oxide film. To this end, passive oxide films are formed in H_2O^{18} (or H_2O^{16}) solutions and then exposed to H_2O^{16} (or H_2O^{18}) solutions for continued passivation. SIMS is used to determine the change in the O^{18} (or O^{16}) content of the film and the distribution of O^{18} and O^{16} throughout the thickness of the film (14). The results are discussed in terms of the mechanism of breakdown of passive oxide films in sulfate solutions. Data are also presented which allow a comparison to be made between the influence of Cl^- and SO_4^{2-} on oxide film breakdown.

Experimental

Polycrystalline nickel specimens were prepared as described previously (15). Potentials are referred to the saturated calomel electrode, $\text{Hg}/\text{Hg}_2\text{Cl}_2$. Experiments were conducted at 25°C in deaerated solutions of pH 7.65 borate buffer and 0.15N Na_2SO_4 solutions with pH's 1.0, 1.5, and 3.0. The borate solution was 23% oxygen-18 isotope enriched, and samples which were passivated in this solution were subsequently polarized in nonenriched pH 1.0 and 1.5 Na_2SO_4 solutions. Samples were also passivated in 10% oxygen-18 isotope-enriched pH 3.0 Na_2SO_4 solutions and then transferred to nonenriched pH 1.0, 1.5, and 3.0 Na_2SO_4 solutions. The extent of oxygen replacement was followed as a function of prior electrode treatment, aggressiveness of the exchange solution and time in this solution. The extent of O^{18} incorporation into passive oxide films formed on electropolished nickel was also studied.

The O^{18} content in the oxide films was determined by secondary ion mass spectrometry (SIMS) using a PHI 590 Auger system with a PHI SIMS II attachment and a PHI differentially pumped ion gun (14, 16). Sputtering was performed with a 1 keV xenon ion beam at 33° off normal at a rate of $\sim 4 \text{ \AA}/\text{min}$. The ion species analyzed were the polyatomic species $^{58}\text{Ni}^{16}\text{O}_2^-$ (mass = 90) and $^{58}\text{Ni}^{16}\text{O}^{18}\text{O}^-$ (mass 92); the $^{60}\text{Ni}^{16}\text{O}_2^-$ species also contributes to mass 92, but this is always subtracted prior to calculating the ^{18}O content in the film. The sputter profiles give the depth distribution of ^{18}O throughout the passive oxide film.

Results and Discussion

Determination of O^{18} in oxide films.—An electropolished nickel electrode was cathodically reduced and then anodized in pH 7.65 borate buffer solution with 23% oxygen-18 at 0.4V for 5 min. SIMS analysis of the sample is given in Fig. 1; the mass 16 and 18 signals are given along with the mass 90 and 92 signals. The O^{18} content in the film ($x\%$) can be determined from the signal ratio $92/90 + 92$, taking into account that the probability for mass 90 is $(1 - x)^2$ and that that for 92 is $2x(1 - x)$. Analysis of the data indicates, as would be anticipated, a constant O^{18} composition of 23% throughout the passive film. The mass 18 and 16 signals also indicate a 23% enrichment factor, after sputtering away the outer layer of oxide. The atomic signals have an enhanced sensitivity for surface hydroxyl species, probably picked up during air transfer to the UHV chamber, which is not reflected in the polyatomic mass 90 and 92 signals. The subsequent advantages of using the polyatomic species for quantitative SIMS analysis have been discussed in detail previously (14).

Transfer of samples from O^{18} to O^{16} solutions.—SIMS was used to determine the O^{18} content of films formed in 23% O^{18} borate buffer (pH 7.65) and then transferred to pH 1.0 Na_2SO_4 (no O^{18}) for continued potentiostatic polarization. With increasing time of exposure to the latter solution, the O^{18} content is found to decrease from the initial 23% to only 1.5% after 1h (Table I and Fig. 2). The SIMS sputter profiles indicate a constant O^{18} level through the oxide film, independent of the total amount of O^{18} in the

Fig. 1. Percentage of SIMS signals [$\text{mass } 18 \times 100/\text{mass } (18 + 16)$], [$\text{mass } 16 \times 100/\text{mass } (18 + 16)$], [$\text{mass } 92 \times 100/\text{mass } (90 + 92)$], and [$\text{mass } 90 \times 100/\text{mass } (90 + 92)$] for nickel anodized in a 23% oxygen-18 electrolyte. Mass 90 is $^{58}\text{Ni}^{16}\text{O}_2^-$, mass 92 is $^{58}\text{Ni}^{16}\text{O}^{18}\text{O}^-$ (the $^{60}\text{Ni}^{16}\text{O}_2^-$ signal contribution to mass 92 was subtracted prior to calculation), mass 18 is $^{18}\text{O}^-$, and mass 16 is $^{16}\text{O}^-$. Sputtering was by 1 keV xenon at a rate of $\sim 4 \text{ \AA}/\text{min}$.

Fig. 2. Increase of anodic current, i_a , with time for nickel prepassivated in pH 7.65 borate buffer solution (23% O^{18}) at 0.4V for 5 min and then transferred to a pH 1.0 Na_2SO_4 (100% O^{16}) solution for continued polarization at 0.4V. Also shown is the percentage of O^{18} detected in the oxide film by SIMS at various times of exposure to the pH 1.0 Na_2SO_4 solution.

film. This suggests that the O^{18} is being replaced by O^{16} throughout the entire thickness of the film, not just in the outer layer. The results show that the passive oxide film, formed in O^{18} is slowly breaking down and subsequently reforming in the O^{16} solution so that eventually

Table I. Influence of nickel pretreatment in pH 7.65 borate buffer solution, containing 23% O^{18} , and subsequent extent of exposure to pH 1.0 Na_2SO_4 (100% O^{16}) on the O^{18} content in the oxide film. O^{18} contents determined by SIMS. All pretreatments involved electropolishing (EP) and cathodic reduction (CR), with the exception of the last one, where no CR was employed

Electrode pretreatment	Exposure conditions in pH 1.0 Na_2SO_4	Percentage of O^{18} in oxide film
5 min at 0.4V	—	23.0
5 min at 0.4V	1 min at 0.4V	22.5
5 min at 0.4V	10 min at 0.4V	17.0
5 min at 0.4V	20 min at 0.4V	12.5
5 min at 0.4V	1h at 0.4V	1.5
1h at 0.65V	20 min at 0.4V	22.0
EP + 5 min at 0.4V	—	7.5

the entire previously formed film will have broken down and been reformed in the new solution. This breakdown is most probably local in nature, *e.g.*, associated with oxide chemical dissolution at film defects (2). The rate of replacement of O^{18} with O^{16} is much slower for a film previously formed at 0.65V for 1h in the 23% O^{18} borate solution (Table I). This result is consistent with the less defective nature of that film and therefore with the smaller number of breakdown sites.

Influence of solution aggressiveness on rate of oxygen replacement.—To determine the influence of aggressiveness of the breakdown solution on the rate of oxygen replacement, samples pretreated in 23% O^{18} borate solution at 0.4V for 5 min were exposed to pH 1.5 Na_2SO_4 at 0.4V for 60 and 150 min. During these times, the O^{18} content of the film decreased from 23 to 13 and 7.5%, respectively. However, if the standard passive film with 23% O^{18} was exposed to a pH 3.0 Na_2SO_4 solution at 0.4V for 90 min, the O^{18} level falls to only 20.5%. The rate of replacement is thus significantly lower the higher the pH of the exposure solution (*cf.* Table I), supporting the view that local chemical dissolution of the oxide is responsible for film breakdown. The local nature of the breakdown and repair of the film ensures that the O^{18} content in the oxide remains constant throughout the film.

Samples were also passivated in nonenriched pH 3.0 Na_2SO_4 solutions at 0.4V for various times, after which the passivation was continued at the same potential in a similar solution which was 10% enriched in O^{18} . SIMS was then used to determine the rate of uptake of O^{18} into the oxide film. The results, given in Table II, indicate that the film formed exclusively in the enriched solution contains 10% O^{18} . The films formed for 5 min in the O^{16} solution pick up an increasing amount of O^{18} with time of exposure to the O^{18} solution. Eventually, the oxide would contain 10% O^{18} , *i.e.*, the amount obtained when the film is formed from the beginning in the enriched solution, since all elements of the prior passive film will break down if the time is sufficiently long (5). The rate of O^{18} uptake is much less after a longer prepassivation treatment, *i.e.*, 75 min at 0.4V, since the oxide film is substantially more stable and therefore more resistant to breakdown.

Also given in Table II are the results for O^{18} uptake, with time, after immersion of electropolished (EP) nickel into the 10% O^{18} solution at 0.4V. The initial (60s) value of 4.1% is probably at least partly due to an increase in thickness of the oxide film from 7 to 10Å (15); any additional amount would be due to dissolution and reformation of the oxide in the 10% O^{18} solution. [Note that the increase for a similar experiment in 23% O^{18} borate solution is 7.5% (Table I), consistent with 30% of the film being formed in the O^{18} solution.] The SIMS results again indicate that in all cases the O^{18} is distributed uniformly throughout the oxide film, suggesting that the additional 3Å of NiO does not form on top of the original 7Å thick EP film. Instead, it appears that the oxygens of the EP film are incorpora-

Table II. O^{18} content of films initially formed on nickel in pH 3.0 Na_2SO_4 solution (100% O^{16}) and then transferred to 10% O^{18} -enriched pH 3.0 Na_2SO_4 solution for continued polarization at the same potential of 0.4V. Also given are the O^{18} contents of films formed by immersing electropolished (EP) Ni into 10% O^{18} solution at 0.4V, both with and without cathodic reduction (CR) of the prior oxide. O^{18} contents determined by SIMS

Electrode treatment	Percentage of O^{18} in oxide film
EP + CR, $V_A \rightarrow 0.4V$ in H_2O^{18}	10.0
EP, $V_A \rightarrow 0.4V$ in H_2O^{18} (60s)	4.1
EP, $V_A \rightarrow 0.4V$ in H_2O^{18} (25 min)	7.4
5 min at 0.4V in H_2O^{16} ; 60s in H_2O^{18}	0.2
5 min at 0.4V in H_2O^{16} ; 15 min in H_2O^{18}	0.8
5 min at 0.4V in H_2O^{16} ; 95 min in H_2O^{18}	4.1
75 min at 0.4V in H_2O^{16} ; 15 min in H_2O^{18}	0.3

ted into the new passive film, *i.e.*, that there is a reorganization of the EP film upon anodic polarization.

Nature of anodic currents, i_a 's.—When the rate of replacement of O^{18} with O^{16} is correlated with the anodic charge passed (Fig. 2), quantitative information can be obtained about the nature of the long-term i_a 's flowing in the passive potential region. The results in Fig. 2 suggest that only 20-25% of the measured i_a is associated with actual dissolution and reformation of the oxide film, *i.e.*, $NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$ and $Ni + H_2O \rightarrow NiO + 2H^+ + 2e$. The measured charges are four to five times greater than those required to bring about a particular degree of replacement, assuming 100% efficiency for oxide repair. The other 75-80% of the anodic charge must be associated with inefficient film repair (after local breakdown) via parallel nickel dissolution, *i.e.*, $Ni \rightarrow Ni^{2+} + 2e$. The results thus indicate that the i_a 's after a long-term anodization are not a direct measure of the rate of oxide chemical dissolution [*cf.* Ref. (2)]. From this work, the model which explains the anodic passive currents is one where the oxide film is dissolving locally and immediately reforming with a *c.e.* < 100% because of parallel nickel dissolution. This process occurs at random points on the surface, the number of sites involved at any instant in time depending on the state of the oxide (which determines the defect density) and the aggressiveness (pH) of the solution.

Influence of Cl^- on i_a .—The change of i_a with time in pH 1.0 Na_2SO_4 at 0.4V, for a sample prepassivated in pH 3.0 Na_2SO_4 at 0.6V for 15 min, is shown in Fig. 3. There is a steady increase of current with time in the lower pH solution until a steady state is reached after about 40 min. The final current is identical to that obtained if the anodizing had been in the pH 1.0 solution from the start, *i.e.*, the new state of the oxide film is that associated with long-term passivation at 0.4V in pH 1.0 Na_2SO_4 . The oxide film formed in the pH 3.0 Na_2SO_4 solution is obviously undergoing a conversion to a more defective form in the pH 1.0 solution. This conversion at the lower pH is probably related to the fact that the limiting stability of the oxide film is highly pH dependent and it is not possible to reach the same stable state at pH 1.0 as could be achieved at pH 3.0 (1). The conversion again involves localized, random breakdown of the film produced at pH 3.0 and its subsequent local replacement in pH 1.0 solution. The time needed to reach a steady state in pH 1.0 solution is highly dependent on the prior passivation treatment, this time being ~ 5h for a sample pretreated for 18h at 0.6V in pH 3.0 Na_2SO_4 . This result is consistent with a rate of film breakdown which is directly dependent on the state of perfection (*i.e.*, the defect state) of the prior oxide film as well as the aggressiveness of the breakdown solution. The rate of increase of i_a with t is thus a measure of the rate of film breakdown and can be used to check the

Fig. 3. Increase of anodic current i_a with time for nickel prepassivated in pH 3.0 Na_2SO_4 at 0.6V for 15 min and then exposed to a pH 1.0 Na_2SO_4 solution at 0.4V (circles). Also shown is the influence of 0.003M Cl^- in the pH 1.0 Na_2SO_4 on the change of i_a with time (squares).

influence of added Cl^- on the breakdown (*i.e.*, conversion) rate of the oxide. The *i/t* profile for a film formed in pH 3.0 Na_2SO_4 at 0.6V for 15 min and then transferred to a pH 1.0 Na_2SO_4 solution with 0.003M Cl^- solution at 0.4V is also shown in Fig. 3. The eventual current is somewhat higher than that observed for breakdown in pH 1.0 Na_2SO_4 , but this is simply due to Cl^- incorporation into the oxide film making the film more defective, *i.e.*, producing more sites at which breakdown will occur at any instant in time (17-19). When this is taken into account, the kinetics of conversion of the prior film are similar in the presence or absence of Cl^- ion, *i.e.*, the Cl^- does not appear to accelerate the process of film breakdown. This is consistent with the model, which suggests that Cl^- has no direct influence on breakdown of the passive oxide film but simply interferes with local repassivation events which are continuously occurring at numerous sites on the oxide surface (12, 18). It is also in agreement with the observation that addition of Cl^- to a solution in which a passivated sample is held potentiostatically does not result in any measurable increase in i_a until $t > t_{\text{ind}}$, the induction time at which pitting begins (20).

When the $[\text{Cl}^-]$ used in the experiment indicated in Fig. 3 is 0.015M instead of 0.003M, pitting begins ~ 16 min after immersion in pH 1.0 Na_2SO_4 solution, as indicated by a sharp increase in i_a . Before this time, however, the *i/t* profile is almost identical to that observed with 0.003M Cl^- , indicating that even when sufficient Cl^- is present to cause pitting (and V_a is therefore above the pitting potential), the film is dissolving at more or less the same rate as that observed in SO_4^{2-} solution. These results again suggest that the aggressive Cl^- ion has no direct influence on localized passivity breakdown but instead modifies the local repair kinetics so as to greatly decrease the c.e. for film repair, *i.e.*, that Cl^- interferes with repassivation.

In conclusion, the results obtained from the $\text{O}^{16}/\text{O}^{18}$ experiments in this work support the model of the passive oxide film wherein local breakdown/repassivation events are constantly occurring at selected sites on the metal surface.

Screening Design Test for Cyclic Voltammetric Evaluation of Zinc Sulfate Electrolyte

R. K. Singh and T. J. O'Keefe*

Materials Research Center, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

A statistical screening design program was conducted to determine the effects of certain operating parameters in the cyclic voltammetric evaluation of zinc sulfate electrolyte. The variables studied included solution temperature, sulfuric acid and zinc concentrations, and scan rate. Solution temperature was found to be the most significant factor affecting the initial potential, followed by scan rate and zinc concentration. Based on screening design data, mathematical equations were developed to predict polarization behavior of addition-free zinc sulfate electrolytes. A few preliminary tests on the effect of impurities and organic additives, such as Sb(III) and glue, on potential, deposit morphology, and crystal orientation were also made.

Cyclic voltammetry techniques have been used successfully to monitor the electrolyzability of zinc electro-winning solutions (1, 2). By measuring the zinc deposition polarization effects, a definite correlation has been shown to exist between the cathode polarization, deposit morphology, and current efficiency of zinc electrodeposition for a number of systems (3-6). Most of these studies have concentrated on the role of impurities and organic additives in the solutions. However, the activation overpotential and deposit morphology are also affected by other operating variables such as temperature, zinc

concentration, sulfuric acid concentration, and parameters for conducting the test. Therefore, before using this technique for determining an optimum overpotential, it is necessary to delineate the effect of these processing variables if the impurity and organic additive concentrations are to be properly evaluated.

Systems with many independent variables lend themselves to more efficient study by varying several factors at once in a statistical experimental design. The relative importance of independent or factor variables can be ascertained from a Plackett-Burman screening design. A Plackett-Burman design is based on a simplified first-

* Electrochemical Society Active Member.

x_7 Dummy			

order empirical model, but will also yield information indicating overall curvature, or deviations from the linear model, and give an indication of the presence of interaction effect among variables.

The object of the present study was to determine by means of a screening design, the individual effects and interactions, if any, of temperature, zinc and sulfuric acid concentrations, and scan rate on the nucleation potential of zinc electrodeposition. The conditions chosen were similar to those employed in commercial zinc electro-winning operations. In addition, other tests were made to determine the effects of Sb(III) and glue addition on polarization behavior and deposit morphologies.

Experimental

Screening design.—An eight-run Plackett-Burman screening design was chosen to investigate the importance of parameters listed in Table I. Other types and sizes of statistical design are available (7, 8), and each has its merits and drawbacks, depending on the type of information that is desired.

The design procedure employed follows closely that described by Murphy (7), which lists in tabular form the high and low (+ and -) test level arrangement to be used. As explained in the article, the choices for the screening design result from using only a specific fraction of the 2^p factorial design.

Variables considered in the present study included zinc concentration, sulfuric acid concentration, electrolyte temperature, and voltammetric scan rate. The high, low, and intermediate values of the factor levels are listed in Table I. The choice of factor level was based on pre-screening tests and conditions appropriate to industrial zinc electro-winning practice.

Table II shows the matrix of the design, with each variable at two levels, a plus symbol denotes the high level, and a minus symbol low level. Although seven variables can be studied in this design, only four variables were studied, leaving three variables as dummies to estimate the presence of interaction among variables. To estimate curvature effects and experimental error, three center-point runs were added to the design runs. To guard against systematic trends in uncontrolled (or unknown) variables during execution of the design, the order in which the runs were made was randomized. The center points were evenly spaced over experimental run orders, i.e., as the first, middle, and last run of the design.

Solution preparation.—Tests were conducted using both synthetic zinc sulfate solution and an industrial zinc electrolyte for each design point. Synthetic zinc sulfate solution was prepared by dissolving high purity French Process zinc oxide in reagent-grade sulfuric acid. Industrial zinc electrolyte was obtained from Cominco Limited (Trail, Canada). For a given design run, solution compositions were adjusted by adding reagent-grade sulfuric acid and deionized water to give a desired zinc and sulfuric acid concentration. When studying the effect of impurity and/or glue additions, the required amounts were added from the respective stock solutions. Sb(III) stock solution was prepared by dissolving potassium-antimony tartarate [K(SbO)C₄H₄O₆ · ½ H₂O] in deionized water. Glue stock solution was prepared by dissolving Pearl Glue (obtained from Cominco Limited, Trail, Canada) in deionized water and stored in a refrigerator to avoid its degradation.

Cyclic voltammetry.—The cyclic voltammetry experiments were conducted in a Pyrex "H" cell employing an

$$= +0.040$$

aluminum working electrode (area 1 cm²), a titanium/manganese dioxide counterelectrode, and a mercurous sulfate reference electrode (+0.667V vs. SHE). A constant-temperature bath was used to maintain the desired temperature and a Petrolite Potentiodyne Analyzer (Model M-4100) was used to record the cyclic voltammogram. The polarization behavior was recorded as a log current vs. potential plot.

The working electrode was prepared by wet polishing on 600 grit paper. The electrode was washed in an ultrasonic cleaner after polishing and then rinsed with deionized water and dried with hot air. The electrode was then placed in the H cell and allowed to come to the test temperature.

After reaching the test temperature, a voltammogram was obtained by varying the potential from -0.633V vs. SHE to a more cathodic potential where the total current was 50 mA. At this point, the scan was reversed and driven to the original starting potential. The test was terminated after reaching the starting potential.

Deposit examination.—For a given set of experimental conditions, the zinc deposits were obtained by scanning up to a current of 50 mA and holding the potential constant at this point for 2 min. The electrode was taken out of solution and washed thoroughly with deionized water and dried in hot air. The deposits were examined by x-ray diffraction to determine their orientations and scanning electron microscopy was used for surface morphology evaluations.

Results and Discussion

Addition-free electrolyte.—A cyclic voltammogram typical of those obtained for the solutions investigated is shown in Fig. 1. The reactions occurring at various points on the polarization curve have been discussed previously (9). In brief, the reactions occurring are: in region AB, hydrogen gas evolution; in region BC, hydrogen gas evolution and zinc deposition on the aluminum substrate; in region CD, hydrogen gas evolution and zinc deposition on zinc; in region DEF, zinc dissolution and hydrogen gas evolution; and in region FG, hydrogen gas evolution on aluminum substrate.

The response variable chosen was the front scan potential of the working electrode at a current density of 10 mA-cm⁻² (i.e., point Y in Fig. 1). Table II shows the values

Fig. 1. Cyclic voltammogram for industrial electrolyte (60 g-liter⁻¹ Zn, 175 g-liter⁻¹ H₂SO₄); 35°C, 1.25 mV-s⁻¹.

of the response (Y) observed for each of the 11 runs (eight design runs + three center-point runs) for the synthetic and industrial solutions.

In any screening design, the calculated factor effect establishes the best estimate of the relative importance of a factor. The precision of the estimate is generally stated in the form of a confidence interval, which is an interval said to include the "true" effect at a stated confidence level. Factor effects whose confidence interval passes through zero are considered to be statistically insignificant at the chosen confidence level. Calculation of factor effects and confidence interval, based on a 95% confidence level, for the present study is listed in Tables II and III. The three center points of each design were used to estimate the response error for the given design.

Because the way response variable is defined in this case, factor effects with positive values indicate depolarization while negative values indicate increased polarization (or potential changing in a more negative or cathodic direction) when the independent variable is changed from low to high level. As can be seen from Table III, within the range of factor levels considered in the design, solution temperature is the most significant factor followed by test scan rate and zinc concentration. Sulfuric acid concentration is not a significant factor in either of the designs. Increased temperature and zinc concentration cause depolarization (2 mV-°C⁻¹ and 0.65 mV-g⁻¹-liter for industrial electrolyte, and 2.5 mV-°C⁻¹ and 0.60 mV-g⁻¹-liter for synthetic electrolyte), whereas increased scan rate results in polarization (14.7 mV-mV⁻¹-s for industrial electrolyte, and 15.3 mV-mV⁻¹-s for synthetic electrolyte) of the measurements. The fact that the sulfuric acid concentration was not significant is interesting, because a few prescreening tests at 50 g-liter⁻¹ and 100 g-liter⁻¹ acid concentrations had indicated a considerable depolarization as compared to the 150 g-liter⁻¹ acid level. The reason for the nonsignificance of sulfuric acid concentration may be due to its optimum level being already available at the low factor level of 150 g-liter⁻¹. For the given level of variables, there is a measurable difference in the response of the two types of solutions. This can be attributed to the differences in the basic makeup (i.e., presence of residual impurities) of the two solutions. Impurities like Sb, Ge, Pb, Cd, etc., are known to effect the polarization behavior of the system even at very low concentrations (1). This also indicates the importance of preliminary screening of a given electrolyte.

The effect of dummy factors is also shown in Table III. These factors are a measure of any interaction among independent variables in the system. Since all three dummy factor estimates are found to be statistically insignificant, it can be concluded that there are no interactions among variables within the boundaries of this study.

If the system is linear, the centroid of all the design points and the average response from the center points

Table III. Summary of factor effect intervals at 95% confidence limit

Variable	Industrial solution	Synthetic solution
x ₁ Zn concentration	+0.013 ± 0.009 ^a	+0.012 ± 0.009 ^a
x ₂ H ₂ SO ₄ concentration	+0.003 ± 0.009	+0.003 ± 0.009
x ₃ Temperature	+0.040 ± 0.009 ^a	+0.050 ± 0.009 ^a
x ₄ Scan rate	-0.022 ± 0.009 ^a	-0.023 ± 0.009 ^a

x ₆ Dummy	-0.002 ± 0.009	+0.003 ± 0.009
x ₇ Dummy	+0.003 ± 0.009	+0.001 ± 0.009

^a Denotes factor effects which are statistically significant at 95% confidence level.

$$\text{Confidence interval} = \text{factor effect} \pm \frac{ts}{\sqrt{N/4}}$$

at 95% confidence limit and $\nu = 2$, $t = 4.303$, where t is the student's t variable, N is the number of design point runs (eight), s is the standard deviation from center points (0.003 for both types of solutions), and ν is the degrees of freedom.

Table IV. Estimation of curvature effects

	Industrial solution	Synthetic solution
Center point average	-0.850	-0.863
Design point average	-0.848	-0.859
Curvature effect ^a	-0.002	-0.004
Confidence interval (at 95% confidence level) ^b	-0.002 ± 0.009	-0.004 ± 0.009

^a Curvature effect = center point average - design point average.

^b Confidence interval = curvature effect ± $ts\sqrt{1/N + 1/C}$ where t is the student's t variable, s is the standard deviation, N is the number of design point runs, and C is the number of center-point runs.

should be equal. If, however, the system deviates from the linear model, overall curvature can be estimated as the difference between the average response of the center points and the average response of the design points. Table IV shows the calculation of the curvature effect for both designs. At 95% confidence level, the confidence intervals on curvature are -0.002 ± 0.009 for industrial solution and -0.004 ± 0.009 for synthetic solution, values which are not statistically significant.

When responses and factors are continuous in scale, it is useful to consider the factor-response relationship in terms of a mathematical model. Since the overall curvature and interaction among variables are insignificant in both designs, a first-order linear model, as given below, was considered to predict the responses at a given level of the variables

$$\hat{Y} = \bar{Y} + m_1x_1 + m_2x_2 + \dots + m_ix_i$$

where \hat{Y} is the predicted response (potential of working electrode at 10 mA-cm⁻² of current density in front scan region), Y the average measured response from the design points, $m_i = (1/2)$ (factor effect of x_i), and

$$x_i = \frac{\text{factor level} - (\text{high level} + \text{low level})/2}{(\text{high level} - \text{low level})/2}$$

where the factor level is the value of interest between the high and low levels.

Neglecting statistically insignificant factor effects, the predicted equations (see the Appendix for calculations) are as follows

Industrial solution: $\hat{Y} = -0.939 + 0.0007 [\text{Zn}] + 0.0020 (T) - 0.015 (S)$

Synthetic solution: $\hat{Y} = -0.964 + 0.0006 [\text{Zn}] + 0.0025 (T) - 0.0153 (S)$

where [Zn] is the zinc concentration in grams per liter, (T) the temperature in degrees Centigrade, and (S) the test scan rate in millivolts per second.

Using the above equations, calculated potential values were obtained for the values of the factors used in this study. Figures 2 and 3 compare the calculated potential values and those obtained experimentally for industrial and synthetic solutions, respectively. The fit of the model is quite good, and an "F" test showed that the variability between the predicted and experimental potential values is within the experimental error of the system for both types of solutions.

Effect of impurities and organic additives.—Impurities like Sb, Ge, Sn, Cu, Pb, etc., and organic additives like glue gelatin, and gum are known to influence the zinc deposition overpotential, deposit morphology, and orientation (3-6, 10, 11). The results of a few preliminary tests carried out with Sb(III) and glue additions are given in Table V. It is clear that when experimental variables are fixed for a given electrolyte, the addition of Sb(III) causes strong depolarization (column C and column D in Table V), and addition of glue results in a strong polarization (column A and column B in Table V) of the zinc electrodeposition process.

V at 10 mA/cm ²	-0.815	-0.840	-0.880	-0.847

Fig. 4. SEM photomicrograph for the deposit obtained from industrial electrolyte ($Zn = 70 \text{ g-liter}^{-1}$, $H_2SO_4 = 150 \text{ g-liter}^{-1}$, 44°C , $0.5 \text{ mV}\cdot\text{s}^{-1}$). Potential at $10 \text{ mA}\cdot\text{cm}^{-2} = -0.815\text{V}$.

Fig. 6. SEM photomicrograph for the deposit obtained from industrial electrolyte with Sb(III) addition ($Zn = 50 \text{ g-liter}^{-1}$, $H_2SO_4 = 150 \text{ g-liter}^{-1}$, $Sb(III) = 0.040 \text{ mg-liter}^{-1}$, 25°C , $2 \text{ mV}\cdot\text{s}^{-1}$). Potential at $10 \text{ mA}\cdot\text{cm}^{-2} = -0.847\text{V}$.

Fig. 5. SEM photomicrograph for the deposit obtained from industrial electrolyte ($Zn = 50 \text{ g-liter}^{-1}$, $H_2SO_4 = 150 \text{ g-liter}^{-1}$, 25°C , $2 \text{ mV}\cdot\text{s}^{-1}$). Potential at $10 \text{ mA}\cdot\text{cm}^{-2} = -0.880\text{V}$.

Fig. 7. SEM photomicrograph for the deposit obtained from industrial electrolyte with glue addition ($Zn = 70 \text{ g-liter}^{-1}$, $H_2SO_4 = 150 \text{ g-liter}^{-1}$, $\text{glue} = 10 \text{ mg-liter}^{-1}$, 44°C , $0.5 \text{ mV}\cdot\text{s}^{-1}$). Potential at $10 \text{ mA}\cdot\text{cm}^{-2} = -0.840\text{V}$.

disposed. The morphology obtained with the Sb(III) addition (Fig. 6) is most marked by larger crystal facets as compared to those for addition-free solution. The effect of $10 \text{ mg}\cdot\text{liter}^{-1}$ glue additions on the deposit morphology is shown in Fig. 7. The deposit appears more compact and of finer grain size than the deposit from addition-free electrolyte. The dominant feature is the appearance of zinc platelet edges with the basal plane lying more perpendicular to the substrate.

The x-ray diffraction studies on deposits for the determination of preferred crystal orientations were not conclusive. Very weak effects of antimony or glue additions to the electrolyte were observed. It is felt that, because of short duration of electrodeposition period in these tests, crystal orientations of the deposits were affected by the aluminum substrate. This substrate influence on the crystal orientation diminishes gradually as the thickness of the electrodeposit increases.

Previous studies on zinc electrocrystallization (3, 4) have shown a correlation between the deposit morphology/orientation and zinc deposition overpotential. The trends observed in the present study are in agreement with these investigations. However, a point of clarification is also indicated from the present data. A comparison of Fig. 6 and 7 shows that, although the overpotential values for the two deposits are similar, the morphologies and crystal orientations are not. Similarly, from the data in Table V, it is seen that two solutions

(Table V, B and D) with entirely different impurities and/or organic additives may also indicate a false similarity on their respective voltammograms because of differences in the operating parameters and test conditions used to generate the curves. A practical implication borne out of this is that it might be incorrect to relate a given overpotential value to a characteristic morphology/orientation unless other parameters and test conditions are also fixed in the system.

Conclusions

The screening design tests showed that the temperature is the most significant variable in cyclic voltammetric evaluation of zinc electrolytes. The test scan rate and zinc concentration are also important variables, whereas sulfuric acid concentration (in the range of $150\text{--}200 \text{ g-liter}^{-1}$) is not.

In addition to illustrating the importance of various factors, the statistical design permits the development of a model which can be used to predict the potential, and hence the polarization or depolarization behavior, of a given electrode/electrolyte system. The predicted equations have given a good fit to the experimental data within the range of variables in this study. However, its sensitivity can further be improved by using a full response surface design such as the Box-Behnken or the more elaborate Box-Wilson design.

One other very important fact that is evident from the data is that the deposit morphology is a function not only of the magnitude of the overpotential measured, but also of the conditions used in generating the polarization curve and the type of species in the electrolyte that is dominant in the growth. As indicated in previous research, for any fixed operating parameters and electrolyte system, increases in antimony or glue amounts give depolarizing and polarizing effects, respectively, in proportion to their concentrations. In turn, the morphologies that result can be correlated with the overpotential changes. However, it has been shown that, for example, a polarizing effect can be caused by lowering the temperature and zinc content. Even though the magnitude of increase in overpotential noted is nearly identical to that produced by adding glue, the morphologies will be different. No particular problem results from this feature, but it should be pointed out that it would be risky to try to characterize an unknown electrolyte by polarization techniques alone. A base reference must first be established prior to making evaluations of impurity and/or organic contents based on the overpotential measurement.

APPENDIX

Calculation of Predicted Response for Industrial Solution

$$\hat{Y} = \bar{Y} + m_1x_1 + m_2x_2 + \dots + m_jx_j$$

where \hat{Y} is the predicted potential at 10 mA/cm², \bar{Y} the average measured potential at 10 mA/cm² = -0.848, $m_j = 1/2$ (factor effect for variable x_j), and

$$x_j = \frac{\text{factor level} - (\text{high level} + \text{low level})/2}{(\text{high level} - \text{low level})/2}$$

where the factor level is the value of interest between the high and low levels.

Significant main factor effects are

$$\begin{array}{ll} x_1: \text{Zn concentration} & FE_1 = +0.013 \\ x_3: \text{temperature} & FE_3 = +0.040 \\ x_4: \text{scan rate} & FE_4 = -0.022 \end{array}$$

	High	Low		Notations
x_1 : Zn concentration	70	50	(g/liter)	[Zn]
x_3 : temperature	45	25	(°C)	(T)
x_4 : scan rate	2	0.5	(mV/s)	(S)

Now, these values can be substituted into the equation for \hat{Y}

$$\hat{Y} = -0.848 + \left[\left(\frac{0.013}{2} \right) \frac{[\text{Zn}] - (70 + 50)/2}{(70 - 50)/2} \right] + \left[\left(\frac{0.040}{2} \right) \frac{(T) - (45 + 25)/2}{(45 - 25)/2} \right] + \left[\left(\frac{0.22}{2} \right) \frac{S + (2 + 0.5)/2}{(2 - 0.5)/2} \right]$$

Simplifying yields

$$\hat{Y} = -0.848 + [0.00065([\text{Zn}] - 60)] + [0.002(T - 35)] - [0.01466(S - 1.25)]$$

$$\begin{aligned} \hat{Y} &= -0.848 + 0.00065 [\text{Zn}] - 0.039 + 0.002(T) \\ &\quad - 0.07 - 0.01466(S) + 0.0183 \\ &= -0.939 + 0.0007[\text{Zn}] + 0.002(T) - 0.015(S) \end{aligned}$$

Ionic Electrodeposition of II-VI and III-V Compounds

I. Development of a Simple, Butler-Volmer Equation-Based Kinetic Model for $M_1X_1(\text{CdTe})$ Electrodeposition

ABSTRACT

A simple kinetic model has been developed for the electrodeposition of CdTe and other 12-16 (II-VI) or 13-15 (III-V) compounds from solutions containing reducible ions of both constituents and is based upon a generalized Butler-Volmer equation that considers ion transport limitations near the cathode. Although the deposition itself is a non-equilibrium process, the reaction between the plated cadmium and tellurium is assumed sufficiently rapid that any infinitesimally small volume in the deposit remains in quasi-chemical equilibrium, as defined by the equilibrium constant-mass action expression involving the activities of the solid constituents and conservation of mass, as invoked by a unity mole fraction sum. Exponential activity coefficients are postulated consistent with "regular" solution models. Although neglecting second-order effects such as hydrogen generation, IR and space-charge voltage drops within the deposit, and possible phase segregation, the model yields a convenient algorithm to numerically simulate voltammetric (j - E) curves and calculate the mole fractions and activities of cadmium, tellurium, and cadmium telluride existing at the deposit surface for any deposition potential.

The electrodeposition of binary chalcogenides (1-12) such as CdTe (13-31, 47) and CdSe (32-37) from solutions containing both the metal and chalcogen in reducible ionic form has been a topic of recent experimental research. The major problems associated with compound semiconductor electrodeposition are, first, producing stoichiometric, nondegenerate material, and, second, achieving large-grained, nonamorphous deposits.

Unfortunately, there has not been extensive published theoretical work on the ionic "alloy" (22) electrodeposition of compound semiconductors (31, 48). Noteworthy is Kroger's (38) work describing the equilibrium state of a compound electrodeposit. Although similar in some respects to metallic alloy electroplating, as described in the works of Brenner (39), the very negative Gibbs free energies of formation for 12-16 (II-VI) and 13-15 (III-V) compounds, the possible semiconducting nature of the deposits, the large differences in the standard reduction potentials (E°) of selenium, tellurium, arsenic, and antimony and most metal ions, the changing nature of the deposit during deposition, and the presence of metastable states present complexities to any theoretical description.

This paper presents a simple model for the kinetics corresponding to ionic electrodeposition of M_1X_1 compounds, as originally developed in detail in Ref. (15) and disseminated in abbreviated form in Ref. (16, 17). The model will be developed in terms of CdTe electrodeposition from acidic solutions of Cd^{2+} and HTeO_2^+ but could be applied to any M_1X_1 compound. Although several simplifying assumptions have been made, the model allows for the simulation of the electrodeposition process and leads to potentially useful predictions about the electrodeposition and associated voltammetric sweeps of such compounds.

Experimental Environment and Assumptions Corresponding to the Model

The primary cathode reactions are

and

and occur at a bare inert (C, Pt, etc.) potentiostat-con-

*Electrochemical Society Active Member.

trolled cathode immersed in an aqueous ($\text{pH} \approx 2.5$) solution containing CdCl_2 , CdSO_4 , etc., and TeO_2 . The reaction at an inert, cadmium, or tellurium anode could be O_2 evolution, Cd^{2+} dissolution, or HTeO_2^+ dissolution, respectively, but has no direct effect upon the cathode kinetics. The volume of the solution is large so that the electrochemical reactions produce negligible changes in pH and cadmium and tellurium ion activities (concentrations). Any hydrogen current is assumed to have no direct effect on the cadmium and tellurium current densities and the resultant deposit surface stoichiometry. Hydrogen is not bound or occluded in the "pure" Cd_xTe deposit. However, the hydrogen ion concentration will affect the tellurium current density through its effect on the tellurium Nernst potential and exchange current density. The total current densities discussed will be the sum of only the cadmium and tellurium current densities and will not include the approximately exponential H_2 current-voltage component.

Telluride or polytelluride anion formation from the six- or ten-electron reduction of Te(IV) ions is assumed negligible with the deposition voltages used. The deposit is formed by the solid-state reaction of plated cadmium and tellurium atoms rather than precipitation of Te_2^{2-} , Te^- , HTe^- , or H_2Te and Cd^{2+} .

The solution is stationary with no stirring and negligible thermal convection currents to avoid dependence of the cathodic diffusion-limited current density upon the agitation-dependent diffusion layer thickness. Any anodic diffusion-limited current, corresponding to cadmium and tellurium dissolution and ion hydration, is very large and not encountered at voltages considered in this paper.

The cathode-reference voltage is assumed to be completely dropped across the double (primarily Helmholtz) layer at the deposit-electrolyte interface. This implies that the electrolyte is very conductive, that voltage drops in the deposit bulk or surface space-charge regions are compensated or insignificant, that the electrochemical reactions and/or ion mass transport are the rate-determining steps, and that the current densities are described by Butler-Volmer kinetics. Because of large concentrations of surface states at a semiconductor surface due to irregularities, defects, and adsorbed electrolyte species, semiconducting electrodes do often behave quasi-metallically with a Tafel-like current-voltage characteristic (46). Furthermore, the deposit will be a nondegenerate semiconductor over a very small x range in Cd_xTe due to native dopants such as atomic vacancies and interstitials.

The deposit is assumed to be homogeneous over its surface area but may change in composition with depth into the deposit. Any nonhomogeneities caused by different grain orientations, grain boundaries, etc., are negligible, and the deposit is best considered an amorphous "gel" that grows complete layer by layer with a layer thickness approaching that of a monolayer. Kinetic parameters for cadmium and tellurium, such as rate constant and transfer coefficients, are assumed constant and independent of the deposit surface composition or structure.

Any small volume in the deposit is assumed to always be in quasi-chemical equilibrium described by

$$\frac{a_{\text{CdTe}}}{a_{\text{Cd}}a_{\text{Te}}} = \exp\left[\frac{-\Delta G^\circ_{\text{CdTe}}}{RT}\right] = K \quad [4]$$

and

$$\sum_1 x_i = 1 \quad [5]$$

Atomic migration within the deposit is assumed negligible, and, therefore, phase segregation and solubility limitations are ignored, consistent with the low temperature deposition system. The deposit exists as a homogeneous, metastable Cd_xTe material with $0 \leq x \leq \infty$ and x dependent upon the cadmium and tellurium current densities.

This model corresponds only to the deposition of material onto a bare inert substrate, as occurs with a negatively sweeping deposition potential, and not to the dissolution of material. Thus, it would not describe the anodic "backsweep" of a voltammetric measurement.

The Generalized Butler-Volmer Equation

The cathodic current densities are described by a generalized Butler-Volmer equation (40)

$$j_i = \frac{z_i F k_i^\circ \left[\left[\prod_m a_{\text{rm}}^{\nu_m} \right]^{\bar{\alpha}_i + \bar{\alpha}_i} \exp\left[\frac{-z_i F \bar{\alpha}_i}{RT} (E - E_i^\circ)\right] - \left[\prod_m a_{\text{pm}}^{\nu_m} \right]^{\bar{\alpha}_i + \bar{\alpha}_i} \exp\left[\frac{z_i F \bar{\alpha}_i}{RT} (E - E_i^\circ)\right] \right]}{1 + \frac{z_i F k_i^\circ}{j_{c,l_i}} \left[\left[\prod_m a_{\text{rm}}^{\nu_m} \right]^{\bar{\alpha}_i + \bar{\alpha}_i} \exp\left[\frac{-z_i F \bar{\alpha}_i}{RT} (E - E_i^\circ)\right] \right]} \quad [6]$$

where z_i is the number of electrons required to reduce the cadmium ($z_i = 2$) or tellurium ($z_i = 4$) ions, k_i° is a rate constant ($\text{mol}/\text{cm}^2\text{-s}$), a_{rm} is the cathode surface activity of reactant m (Cd^{2+} , HTeO_2^+ , H^+) in the formation of solid constituent, i , a_{pm} is the deposit surface activity of product m (Cd , Te , H_2O) in the reaction, ν_m is the stoichiometric coefficient, j_{c,l_i} is the cathodic diffusion-limited current density for ion i (Cd^{2+} or HTeO_2^+), and the other symbols have their standard meanings and/or are defined in the List of Symbols.

The k_i° value is temperature activated

$$k_i^\circ = k_{0i} T \exp\left[-\frac{E_{A_i}}{RT}\right] \quad [7]$$

where E_{A_i} is an activation energy and k_{0i} is a constant that includes any zeta potential drop (assumed small and constant) in the diffuse Gouy-Chapman layer. The units for k° are ($\text{mol}/\text{cm}^2\text{-s}$), rather than the usual (cm/s), because dimensionless activities rather than concentrations (mol/cm^3) have been used in the Butler-Volmer equations. Both $\bar{\alpha}_i$ and $\bar{\alpha}_i$, the transfer coefficients, can take on any value but normally $\bar{\alpha}_i + \bar{\alpha}_i = 1$. Note that z_i is not necessarily the charge (z') on ion i ; for example, $z_{\text{Te}} = 4$ but the tellurium ion is HTeO_2^+ .

The diffusion-limited current density, neglecting convection, can be described by (41)

$$j_{c,l_i} = z_i F D_i \left[\frac{c_{0i}}{(1 - t_{+i})\delta} \right] \quad [8]$$

if the mass transport of the ion i is rate determining, D_i , the diffusion coefficient, ($\sim 10^{-5} \text{ cm}^2/\text{s}$) is directly proportional to temperature, and δ , the diffusion layer thickness,

is normally 10^{-5} - 10^{-2} cm . If γ_i is an insensitive function of concentration over concentrations from 10^{-6} to $0.1M$, then ($a_{0i}^{z_i}/1000\gamma_i$) can be substituted for c_{0i} in Eq. [8]. Even though the above equation relates c_{0i} , $a_{0i}^{z_i}$, and j_{c,l_i} , j_{c,l_i} is taken as an independent, adjustable parameter because of uncertainty in D_i , t_{+i} , γ_i , and δ .

Butler-Volmer Eq. [6] (one for each constituent) reduces to Nernst-like, open-circuit (reversible) potential equations

$$E_{\text{Nernst}_i} = E_i^\circ - \frac{RT}{z_i F} \ln \left[\frac{\prod_m a_{\text{pm}}^{\nu_m}}{\prod_m a_{\text{rm}}^{\nu_m}} \right] = E_i, (E_{\text{Cd}}, E_{\text{Te}}) \quad [9]$$

for $j_i = 0$. If the electrochemical reactions [1]-[3] are reversible, this equation corresponds to the Nernst equation. Indeed, j_i can be zero for all components only at equilibrium, and this zero current condition for all constituents can be used to define the deposit activities at equilibrium (15, 38).

Equation [6] also predicts that $j_i(E \rightarrow -\infty) = j_{c,l_i}$ and can be easily manipulated into a form involving exchange currents, j_0 , and overpotentials, η

$$j_0 = z F k_i^\circ \prod_m (a_{\text{rm}}^{\nu_m})^{\bar{\alpha}_i} \prod_m (a_{\text{pm}}^{\nu_m})^{\bar{\alpha}_i} \quad [10]$$

and

$$\eta = E - E_i \quad [11]$$

It also corresponds to (42)

$$\begin{aligned} a_i^{z_i} &\approx a_{0i}^{z_i} \left[1 - \frac{j_i}{j_{c,l_i}} \right] \\ \text{cathode} & \\ \text{surface} & \end{aligned} \quad [12]$$

when γ_i is nearly constant over the range of concentrations normally used. When $j_i \rightarrow j_{c,l_i}$, ion i becomes depleted at the cathode surface and negative (anodic) j_i causes a buildup of ion i .

The electrochemical reactions [1] and [2] are assumed to occur in a single step. Although neglecting the possible multiple-step nature of both reactions, this assumption simplifies the model and sidesteps a lack of conclusive information about the individual steps and equilibrium constants of all but the rate-determining step. The transfer coefficients, $\bar{\alpha}_i$, could, however, take into account the multiple-step nature of the reactions in a semiempirical, phenomenological manner.

Mass Conservation and Thermodynamic Considerations

It can be shown that

$$\frac{n_{\text{Cd}}}{n_{\text{Cd}} + n_{\text{Te}}} = \frac{\frac{j_{\text{Cd}}}{z_{\text{Cd}}}}{\frac{j_{\text{Cd}}}{z_{\text{Cd}}} + \frac{j_{\text{Te}}}{z_{\text{Te}}}} = x_{\text{icd}} = x_i \quad [13]$$

where x_{icd} is the total (gross) mole fraction (total number of cadmium atoms in an infinitesimal deposit volume divided by the sum of the total number of cadmium and tellurium atoms in the same volume) and n_i is the number of moles of constituent i in the volume. Similarly

$$x_2 = x_{\text{Te}} = \frac{\frac{j_{\text{Te}}}{z_{\text{Te}}}}{\frac{j_{\text{Cd}}}{z_{\text{Cd}}} + \frac{j_{\text{Te}}}{z_{\text{Te}}}} \quad [14]$$

and

$$x_{\text{Cd}} + x_{\text{Te}} \equiv 1 \quad [15]$$

Since these quantities involve all cadmium and tellurium atoms, both those "free" and those bound in CdTe molecules, they correspond to initial values that exist before the rapid reaction of the atoms that results in Eq. [4] being satisfied. Values of x , n , a , etc., that exist after the reaction which produces this equilibrium are designated by the subscript f to denote final values.

The activity coefficients of M_iX_i compounds such as CdTe are modeled by

$$\gamma_{\text{Cd}} = \exp \left[\frac{\beta}{RT} x_2^2 \right] \quad [16]$$

$$\gamma_{\text{Te}} = \exp \left[\frac{\beta}{RT} x_1^2 \right] \quad [17]$$

and

$$\gamma_{\text{CdTe}} = \exp \left[\frac{\beta}{2RT} (1 - 4x_1x_2) \right] \quad [18]$$

where β is a compound-dependent constant. $\gamma_{\text{CdTe}} \rightarrow 1$ as $x_{1,2} \rightarrow 0.5$ at perfect CdTe stoichiometry and $\gamma_{\text{Cd,Te}} \rightarrow 1$ as $x_{2,1} \rightarrow 0$. Equations [16]-[18] can be shown to satisfy the Gibbs-Duhem relation and are suggested by the Guggenheim model (43) for the "regular" solid solution and the regular associated solution (RAS) model of Jordan (44, 45). β , although theoretically dependent upon bonding or interchange energies between the metal and nonmetal atoms, is best considered an adjustable, potentially measurable, and semiempirical parameter. Based upon Jordan's measurements (45), β_{CdTe} is probably between -10^4 and -10^5 J/mol. $\beta = 0$ corresponds to an ideal solid solution and unity activity coefficients.

One can define an effective mole fraction equilibrium constant, K'

$$K' \equiv \frac{x_{\text{CdTe}}}{x_{\text{Cd}}x_{\text{Te}}} \quad [19]$$

Using the above activity coefficient expressions and the fact that $x_1 + x_2 \equiv 1$, one finds that

$$K' = K \exp \left(\frac{\beta}{2RT} \right) = \exp \left[\frac{1}{RT} \left(\frac{\beta}{2} - \Delta G^\circ \right) \right] \equiv \exp \left(\frac{\beta'}{RT} \right) \quad [20]$$

where

$$\beta' \equiv \frac{\beta}{2} - \Delta G^\circ \quad [21]$$

Since 1 mol of CdTe requires 1 mol of cadmium and 1 mol of tellurium for its formation

$$n_{\text{CdTe}} = n_{\text{Cd}} - n_{\text{Cd}} = n_{\text{Te}} - n_{\text{Te}} \quad [22]$$

Now

$$K' = \frac{x_{\text{CdTe}}}{x_{\text{Cd}}x_{\text{Te}}} = \frac{n_{\text{CdTe}}}{n_{\text{Cd}}n_{\text{Te}}} [n_{\text{Cd}} + n_{\text{Te}} + n_{\text{CdTe}}] \quad [23]$$

Therefore, by use of Eq. [22] and [23]

$$n_{\text{Cd}} = n_{\text{Cd}} + \frac{K' n_{\text{Cd}} n_{\text{Te}}}{n_{\text{Cd}} + n_{\text{Te}} + n_{\text{CdTe}}} \quad [24]$$

Substitution of

$$n_{\text{Te}} = n_{\text{Te}} + n_{\text{Cd}} - n_{\text{Cd}} \quad [22]$$

and

$$n_{\text{CdTe}} = n_{\text{Te}} - n_{\text{Te}} \quad [23]$$

into Eq. [24] and manipulation yield

$$n_{\text{Cd}} = n_{\text{Cd}} + \frac{K' n_{\text{Cd}} (n_{\text{Te}} + n_{\text{Cd}} - n_{\text{Cd}})}{n_{\text{Cd}} + n_{\text{Te}}} \quad [25]$$

Solving for the positive, physically permissible value of n_{Cd} yields

$$n_{\text{Cd}} = \frac{n_{\text{Cd}} - n_{\text{Te}}}{2} + \left[\left(\frac{n_{\text{Cd}} - n_{\text{Te}}}{2} \right)^2 + \frac{n_{\text{Cd}} n_{\text{Te}}}{1 + K'} \right]^{0.5} \quad [26]$$

Since

$$x_{\text{Cd}} = \frac{n_{\text{Cd}}}{n_{\text{Cd}} + n_{\text{Te}} + n_{\text{CdTe}}} \quad [27]$$

and

$$n_{\text{CdTe}} = n_{\text{Te}} - n_{\text{Te}} \quad [22]$$

$$x_{\text{Cd}} = \frac{n_{\text{Cd}}}{n_{\text{Cd}} + n_{\text{Te}}} = \frac{1}{1 + \frac{1}{\left(\frac{n_{\text{Cd}}}{n_{\text{Te}}} \right)}} \quad [28]$$

By defining

$$\frac{n_{\text{Cd}}}{n_{\text{Te}}} \equiv h = \frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}}, \quad \left(b_i = \frac{1}{z_i} \right) \quad [29]$$

one obtains

$$\frac{n_{\text{Cd}}}{n_{\text{Te}}} = \frac{h - 1}{2} + \left[\left(\frac{h - 1}{2} \right)^2 + \frac{h}{1 + K'} \right]^{0.5} \quad [30]$$

and

$$\begin{aligned} x_{\text{Cd}} &= \frac{1}{1 + \frac{1}{\frac{h - 1}{2} + \left[\left(\frac{h - 1}{2} \right)^2 + \frac{h}{1 + K'} \right]^{0.5}}} \\ &= \frac{h - 1 + \left[\left(\frac{h - 1}{2} \right)^2 + \frac{h}{1 + K'} \right]^{0.5}}{h + 1 + \left[\left(\frac{h - 1}{2} \right)^2 + \frac{h}{1 + K'} \right]^{0.5}} \\ &= \frac{\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}} - 1 + \left[\left(\frac{\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}} - 1}{2} \right)^2 + \frac{\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}}}{1 + K'} \right]^{0.5}}{\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}} + 1 + \left[\left(\frac{\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}} - 1}{2} \right)^2 + \frac{\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}}}{1 + K'} \right]^{0.5}} \end{aligned} \quad [31]$$

Since Eq. [19] is symmetrical with respect to x_{Cd} and x_{Te} , one can derive a similar expression for x_{Te} by an interchange of Cd and Te subscripts

$$\begin{aligned} x_{\text{Te}} &= \frac{\frac{b_{\text{Te}} j_{\text{Te}}}{b_{\text{Cd}} j_{\text{Cd}}} - 1 + \left[\left(\frac{\frac{b_{\text{Te}} j_{\text{Te}}}{b_{\text{Cd}} j_{\text{Cd}}} - 1}{2} \right)^2 + \frac{\frac{b_{\text{Te}} j_{\text{Te}}}{b_{\text{Cd}} j_{\text{Cd}}}}{1 + K'} \right]^{0.5}}{\frac{b_{\text{Te}} j_{\text{Te}}}{b_{\text{Cd}} j_{\text{Cd}}} + 1 + \left[\left(\frac{\frac{b_{\text{Te}} j_{\text{Te}}}{b_{\text{Cd}} j_{\text{Cd}}} - 1}{2} \right)^2 + \frac{\frac{b_{\text{Te}} j_{\text{Te}}}{b_{\text{Cd}} j_{\text{Cd}}}}{1 + K'} \right]^{0.5}} \end{aligned} \quad [32]$$

By defining

$$M \equiv \frac{b_{\text{Cd}} j_{\text{Cd}} - 1}{b_{\text{Te}} j_{\text{Te}}} = \frac{2j_{\text{Cd}} - 1}{j_{\text{Te}}} \quad [33]$$

one obtains

$$\frac{b_{\text{Cd}} j_{\text{Cd}}}{b_{\text{Te}} j_{\text{Te}}} = \frac{2j_{\text{Cd}}}{j_{\text{Te}}} = 2M + 1 \quad [34]$$

$$\frac{b_{Te}j_{Te}}{b_{Cd}j_{Cd}} = \frac{j_{Te}}{2j_{Cd}} = \frac{1}{2M+1} \quad [35]$$

$$x_1 = \frac{2M+1}{2M+2} \quad [40]$$

$$\frac{\frac{2j_{Cd}}{j_{Te}} + 1}{2} = M+1 \quad [36]$$

$$\gamma_{Cd} = \exp \left[\frac{\beta}{RT} \left(\frac{1}{2M+2} \right)^2 \right] \quad [41]$$

$$\frac{\frac{j_{Te}}{2j_{Cd}} + 1}{2} = \frac{M+1}{2M+1} \quad [37]$$

$$\gamma_{Te} = \exp \frac{\beta}{RT} \left[\left(\frac{2M+1}{2M+2} \right)^2 \right] \quad [42]$$

and

$$\frac{\frac{j_{Te}}{2j_{Cd}} - 1}{2} = \frac{-M}{2M+1} \quad [38]$$

and x_{iCd} and x_{Te} expressed as functions of M .

The Nernst equations for the electrochemical Eq. [1] and [2] are

$$E_{Cd} = -0.403 - \frac{RT}{2F} \ln \left(\frac{a_{Cd}}{a_{Cd^{++}}} \right) \quad [43]$$

and

$$E_{Te} = 0.551 - \frac{RT}{4F} \ln \left(\frac{a_{Te}}{a_{HTeO_2^+}} \right) - \frac{3RT}{4F \log_{10}(e)} [pH] \quad [44]$$

Equations [33]-[38], in conjunction with Eq. [13], [14], [16], and [17], yield

$$x_2 = \frac{1}{2M+2} \quad [39]$$

Substitution of all of the above-derived terms into the individual Butler-Volmer Eq. [6] yields

$$j_{Cd} = \frac{2Fk_{Cd}^{\circ} \left[a_{Cd^{++}}^{\bar{\alpha}_{Cd} + \bar{\alpha}_{Cd}} \exp \left[\frac{-2F\bar{\alpha}_{Cd}(E+0.403)}{RT} \right] - \exp \left[\frac{2F\bar{\alpha}_{Cd}(E+0.403)}{RT} \right] \right] \exp \left[\frac{\beta}{RT} \left(\frac{1}{2M+2} \right)^2 \right]}{\left[1 + \frac{2Fk_{Cd}^{\circ}}{j_{Cd}} a_{Cd^{++}}^{\bar{\alpha}_{Cd} + \bar{\alpha}_{Cd}} \exp \left[\frac{-2F\bar{\alpha}_{Cd}(E+0.403)}{RT} \right] \right]} \left[\frac{M + \left[\frac{M^2 + \frac{2M+1}{1 + \exp \left(\frac{\beta'}{RT} \right)} \right]^{0.5}}{M+1 + \left[\frac{M^2 + \frac{2M+1}{1 + \exp \left(\frac{\beta'}{RT} \right)} \right]^{0.5}} \right] \right]^{\bar{\alpha}_{Cd} + \bar{\alpha}_{Cd}} \quad [45]$$

$= f_{Cd}(E, M)$

$$j_{Te} = \frac{4Fk_{Te}^{\circ} \left[(a_{HTeO_2^+} \cdot a_{H^+}^3)^{\bar{\alpha}_{Te} + \bar{\alpha}_{Te}} \exp \left[\frac{-4F\bar{\alpha}_{Te}(E-0.551)}{RT} \right] - \exp \left[\frac{4F\bar{\alpha}_{Te}(E-0.551)}{RT} \right] \right] \times \dots}{\left[1 + \frac{4Fk_{Te}^{\circ}}{j_{Te}} (a_{HTeO_2^+} \cdot a_{H^+}^3)^{\bar{\alpha}_{Te} + \bar{\alpha}_{Te}} \exp \left[\frac{-4F\bar{\alpha}_{Te}(E-0.551)}{RT} \right] \right] \times \dots} \times \dots$$

$$\dots \times \left[\exp \left[\frac{\beta}{RT} \left(\frac{2M+1}{2M+2} \right)^2 \right] \left[\frac{\frac{-M}{2M+1} + \left[\frac{\left(\frac{-M}{2M+1} \right)^2 + \frac{1}{(2M+1) \left[1 + \exp \left(\frac{\beta'}{RT} \right) \right]} \right]^{0.5}}{M+1 + \left[\frac{\left(\frac{-M}{2M+1} \right)^2 + \frac{1}{(2M+1) \left[1 + \exp \left(\frac{\beta'}{RT} \right) \right]} \right]^{0.5}} \right] \right]^{\bar{\alpha}_{Te} + \bar{\alpha}_{Te}} \right] \quad [46]$$

$\dots \times$

1

Further manipulation reduces j_{Te} to Eq. [47]

$$j_{Te} = \frac{4Fk_{Te}^{\circ} \left[(a_{HTeO_2^+} \cdot a_{H^+}^3)^{\bar{\alpha}_{Te} + \bar{\alpha}_{Te}} \exp \left[\frac{-4F\bar{\alpha}_{Te}(E-0.551)}{RT} \right] - \exp \left[\frac{4F\bar{\alpha}_{Te}(E-0.551)}{RT} \right] \right] \times \dots}{\left[1 + \frac{4Fk_{Te}^{\circ}}{j_{Te}} (a_{HTeO_2^+} \cdot a_{H^+}^3)^{\bar{\alpha}_{Te} + \bar{\alpha}_{Te}} \exp \left[\frac{-4F\bar{\alpha}_{Te}(E-0.551)}{RT} \right] \right] \times \dots} \times \dots$$

$$\dots \times \left[\exp \left[\frac{\beta}{RT} \left(\frac{2M+1}{2M+2} \right)^2 \right] \left[\frac{-M + \left[\frac{M^2 + \frac{2M+1}{1 + \exp \left(\frac{\beta'}{RT} \right)} \right]^{0.5}}{M+1 + \left[\frac{M^2 + \frac{2M+1}{1 + \exp \left(\frac{\beta'}{RT} \right)} \right]^{0.5}} \right] \right]^{\bar{\alpha}_{Te} + \bar{\alpha}_{Te}} \right] \quad [47]$$

$\dots \times$

1

$= f_{Te}(E, M)$

[47]

Computational Algorithm

There now exist two equations with two unknowns (j_{Cd} , j_{Te}) for a specified E value. To solve the equations for the unknowns, division of Eq. [45] by Eq. [47] is required to yield

$$f(E, M) = \frac{j_{Cd}(E, M)}{j_{Te}(E, M)} = \frac{j_{Cd}}{j_{Te}} = \frac{2M + 1}{2} \quad [48]$$

which can be interpreted as a single equation in M for a specified E value or a single equation in E for a specified M value.

One can iterate through E and solve for the M value required to satisfy Eq. [48] or iterate through M and solve for the required E value. M can range from $-1/2$ to ∞ if $j_{Cd,l} \rightarrow \infty$, and will saturate at a value

$$\frac{2j_{Cd,l} - 1}{j_{Cd,l} - 1}$$

otherwise. $M = 0$ corresponds to "perfect stoichiometry" with $j_{Cd} = j_{Cd,l}/2$ since

$$x_{iCd} = \frac{1}{1 + \left[1 + \exp\left(\frac{\beta'}{RT}\right) \right]^{0.5}} = x_{iTe} \quad [49]$$

and

$$\gamma_{Cd} = \exp\left(\frac{\beta}{4RT}\right) = \gamma_{Te} \quad [50]$$

Hence

$$a_{iCd} = x_{iCd}\gamma_{Cd} = a_{iTe} = x_{iTe}\gamma_{Te} \quad [51]$$

Once the (E , M) points are calculated, substitution into the individual j_{Cd} and j_{Te} equations (Eq. [45] and [47], respectively) yields j_{Cd} , j_{Te} , and their sum, j_{total} (neglecting hydrogen generation). Thus, it is possible to calculate curves of j_{total} vs. E as approximations to voltammograms conducted with the solutions.

Subsequently, x_{iCd} , x_{iTe} , γ_{Cd} , γ_{Te} , a_{iCd} , and a_{iTe} , existing at the deposit surface for a given deposition potential, can be calculated by substituting M into Eq. [31], [32], (by replacing the current density ratios by the appropriate M containing term), [41], and [42], and then multiplying x_i by γ . Then x_{iCdTe} is obtained from

$$x_{iCdTe} = 1 - x_{iCd} - x_{iTe} \quad [5]$$

Use of Eq. [18] for γ_{CdTe} with x_1 and x_2 defined by Eq. [39] and [40] yields

$$a_{iCdTe} = \gamma_{CdTe} x_{iCdTe} \quad [52]$$

At this point, all partial current densities, mole fractions, and solid-state activities are known as functions of deposition potential. Furthermore, f_{Cd} and f_{Te} can be considered functions of $a_{Cd^{2+}}$, $a_{HTeO_2^+}$, T , $j_{Cd,l}$, $j_{Te,l}$, k_{Cd}^0 , k_{Te}^0 , α_{Cd} , and α_{Te} , and the effects of these parameters upon the current densities and stoichiometries can be also explored. Calculated j - E and x - E curves and subsequent interpretation and discussion will be presented in the second part of this sequence (49) for a representative set of equation parameters.

Conclusions

An analytical model/computational algorithm has been developed for the calculation of constituent current densities, mole fractions, and activities as functions of deposition potential for the electrodeposition of CdTe or other M_iX_i compounds onto bare, inert cathodic substrates from solutions containing metal and nonmetal ions. The model utilizes a generalized Butler-Volmer equation that includes the cathodic diffusion-limited current density. The deposit is assumed to remain in quasi-chemical equilibrium as described by the conventional equilibrium

constant expression and a unity mole fraction sum. An exponential form for the solid-state activity coefficients is assumed, as suggested by various "regular" solution models, but this development could utilize other activity coefficient-mole fraction relationships. The model does not take into account second-order effects such as hydrogen generation or impurity reduction, the possible semi-conducting nature of the deposit over a narrow stoichiometry range, and incomplete or slow metal-nonmetal reactions, but does allow computer simulation of the electrodeposition process for metal selenides, tellurides, arsenides, and antimonides and leads to several interesting predictions, as will be discussed in the next paper (49).

Acknowledgments

Derald Morgan, Dr. Jack Boone, Dr. Bruce Poling, Dr. Burns Hegler, Dr. Yildirim Omurtag, and Mr. Alok Berry at the University of Missouri-Rolla for their help, comments, and discussion, and Sherry Engelken, Maxine Smith, and Betty Minton at Arkansas State University for the manuscript preparation.

Manuscript submitted March 8, 1985; revised manuscript received Aug. 20, 1985. This was Paper 430 presented at the New Orleans, Louisiana, Meeting of the Society, Oct. 7-12, 1985.

LIST OF SYMBOLS

a_i	activity of constituent or ion i
a_o	bulk ion activity
b_i	reciprocal of number of electrons required to reduce ion i , defined in conjunction with Eq. [29]
c_o	bulk ion concentration (mol/cm ³)
c_i	ion i concentration (mol/cm ³)
D	diffusion coefficient
e	electron or exponential base
E	deposition potential
E_A	activation energy, defined in Eq. [7]
E_i	reversible, open-circuit, or Nernst potential of constituent i (Cd, Te)
E^0	standard reduction potential
f	general functional expression or final value
F	Faraday's constant
ΔG^0	Gibbs' free energy
h	dimensionless molar ratio, defined by Eq. [29]
i	general subscript variable, species, initial value indicator, or current (obvious from context)
j_i	current density of constituent i
$j_{Cd,l}$	diffusion-limited current density
j_o	exchange current density
k^0	fundamental rate constant, defined in Eq. [7]
k_o	pre-exponential rate constant multiplier
K	activity equilibrium constant, defined in Eq. [4]
K'	mole fraction equilibrium, defined in Eq. [19]
m	summation or product subscript, or general metal
M	general metal, or dimensionless current ratio variable, defined in Eq. [33]
$n_{i,i}$	number of moles of constituent i before solid-state reaction
$n_{f,i}$	number of moles of constituent i after equilibrium
p	chemical product indicator
q	electronic charge indicator
r	chemical reactant indicator
R	universal gas constant
t_+	transference number
T	temperature (K)
x	general stoichiometry indicator (e.g., Cd, Te)
x_i	mole fraction of constituent i
$x_{1,2}$	total (gross) mole fraction of constituent 1 or 2 (Cd or Te)
X	general Group V or VI element
z_i	number of electrons required to reduce ion i to the element
z'_i	charge on ion i
α	cathodic transfer coefficient
α	anodic transfer coefficient
β	solid-state activity coefficient parameter, defined in Eq. [16]-[18]
γ	activity coefficient
δ	diffusion layer width
ν	stoichiometric coefficient

Σ general summation indicator
 Π general product indicator

Ionic Electrodeposition of II-VI and III-V Compounds

II. Calculated Current Density and Stoichiometry vs. Deposition Potential Curves for Parameter Values Representative of CdTe and with One Partial Current Density Diffusion Limited

ABSTRACT

This article presents the results of a computer simulation of the kinetic model, developed in the first part of this paper for the electrodeposition of 13-15 (III-V) and 12-16 (II-VI) (notably CdTe) compounds from solutions containing reducible ions of both deposit constituents. The simulation utilized parameter values approximating those of CdTe. The calculated graphs of current density and constituent mole fractions vs. deposition potential indicated that the potential of perfect stoichiometry (PPS), the potential at which $x_{\text{Cd}} = x_{\text{Te}}$ and $x_{\text{CdTe}} \approx 1$, can lie positive of the pure cadmium Nernst potential (E_{Cd}) at the sharp positive shoulder of a nearly constant current plateau. This plateau corresponds to cadmium underpotential depositing on a nearly 1:1 basis with tellurium only because of the reduction in cadmium activity associated with compound formation. This is named conventional underpotential deposition (CUD). n-CdTe can be deposited within this plateau region, but native p-CdTe can be deposited only within a very small potential range positive of the PPS. When the cadmium and tellurium ion concentrations are of the same order of magnitude, the PPS can be shifted negative of E_{Cd} and onto the steep portion of the cadmium current curve. If the diffusion-limited current densities are matched so that equal molar fluxes occur at the cathode, the PPS shifts onto the diffusion-limited, nearly-constant current region negative of E_{Cd} so stoichiometric CdTe (MX) can be plated over a broad potential range. This is named matched diffusion-limited current (MDLC) deposition. The activity coefficient parameter, β , has negligible effect on the PPS during CUD, but varies the width of the plateau region. Less negative $\Delta G_{\text{MX}}^{\circ}$ values shift the PPS negative and decrease the plateau width. A discussion of various experimental measurements and differences with and similarities to the calculated results is also presented.

Because of recent interest in the electrodeposition of electronic-grade compound semiconductor films from solutions of the constituent ions, and the shortage of published theoretical work on the subject (2-5, 14, 16, 17), the first part of this paper (1) presented a simple model/computational algorithm to simulate the ionic electrodeposition of 13-15 (III-VI) and 12-16 (II-VI) compounds, notably CdTe, through the calculation of the cadmium and tellurium current densities, mole fractions, and activities corresponding to a given deposition potential. The present paper presents the results of such a computer simulation for parameters representative of CdTe.

These calculated results lead to several interesting predictions. Among these are the following.

First is the existence of an underpotential cadmium current density (j_{Cd}) plateau structure several hundred millivolts wide over which n-type CdTe can be plated.

Second is the existence of a corner, at the positive shoulder of this plateau, which corresponds to the potential (point) of perfect stoichiometry (PPS) at which intrinsic CdTe (MX) can be plated.

Third is the electrodeposition of native nondegenerate p-CdTe only over an extremely narrow range in potential positive of the PPS.

Fourth is the shifting of the PPS negative of the cadmium Nernst potential (E_{Cd}) and the disappearance of the plateau structure for nearly equal and usually small cadmium and tellurium ion concentrations (c_{Cd} , c_{Te}) and diffusion-limited current densities, (j_{Cd} , j_{Te}), and the deposition of stoichiometric CdTe by the matched diffusion-limited current (MDLC) deposition mode.

Fifth is the lack of sensitivity of the PPS upon β , the activity coefficient parameter, when the PPS lies on the positive shoulder of the plateau during conventional underpotential deposition (CUD).

Representative Parameter Values and Computational Technique

Table I presents the parameter values used in the calculations discussed in the first part of this paper (1). In several cases, these values were derived or extrapolated from

*Electrochemical Society Active Member.

incomplete, questionable, or widely varying data and the kinetic parameters k° , E_{A} , α , and $j_{\text{C},l}$ are best considered as only order of magnitude estimates. Reference (6) was useful in the determination of these representative values.

Even though $k_{\text{CdTe}} > k_{\text{Cd}}$, it includes the factor $(a_{\text{H}^+})^{-3\alpha_{\text{Te}}}$ and is based upon a much smaller exchange current density than for cadmium. In both cases, $\alpha + \bar{\alpha} = 1$; this simplifies the calculations but $\bar{\alpha}_{\text{Te}}$ may be considerably smaller than 0.45 for small cathodic currents.

The activity coefficient parameter, β , corresponding to a regular solid solution model, was typically $-67,800$ J/mol, an ad hoc value not too different from $-12,970$ J/mol found by Jordan (13) for liquid CdTe near its freezing point, but only an estimate for β_{CdTe} which probably lies between -10^4 and -10^5 J/mol. In conjunction with $\Delta G_{\text{CdTe}}^{\circ} \approx -9.97 \times 10^4$ J/mol, the mole fraction equilibrium constant parameter, β' , was calculated to be $\beta' = \beta/2 - \Delta G^{\circ} \approx 6.58 \times 10^4$ J/mol.

The $j_{\text{C},l}$ values were estimated from

$$j_{\text{C},l} \approx \frac{z_i \text{FD}c_{\text{oi}}}{\delta} \quad [1]$$

However, due to uncertainty in δ , $j_{\text{C},l}$ was taken as an adjustable parameter but generally "tracks" $c_{\text{Cd}^{++}}$ or $c_{\text{HTeO}_2^+}$.

In addition to the rate constant equation

$$k_i^{\circ} = k_{\text{oi}} T \exp[-E_{\text{A},i}/RT] \quad [2]$$

temperature corrections were also applied to E_{oi} and D_i through

$$E_{\text{Cd}}^{\circ}(T) \approx -0.403 - 9.3 \times 10^{-5}(T - 298.16 \text{ K}) \quad [3]$$

$$E_{\text{Te}}^{\circ}(T) \approx 0.551 - 3.7 \times 10^{-4}(T - 298.16 \text{ K}) \quad [4]$$

and

$$D_i = D_i(298.16 \text{ K}) \times (T/298.16 \text{ K}) \quad [5]$$

The D_i correction implies that

$$j_{\text{C},l}(T) \approx j_{\text{C},l}(298.16) \times (T/298.16 \text{ K}) \quad [6]$$

neglecting any possible change in $c_{o,i}$ with temperature (avoiding saturated solutions).

The "standard" operating values were $T = 25^\circ\text{C}$, $a_{Cd^{++}} = 0.019$ ($c_{Cd^{++}} = 0.1\text{M}$), $a_{\text{H}_2\text{TeO}_3} = 2.51 \times 10^{-5}$ ($c_{\text{H}_2\text{TeO}_3} \approx 2.51 \times 10^{-5}\text{M}$), $\text{pH} = 2.5$, $j_{c,l_{Te}} = 100 \mu\text{A}/\text{cm}^2$, $j_{c,l_{Cd}} = 200 \text{mA}/\text{cm}^2$, and $\beta = -6.78 \times 10^4 \text{J}/\text{mol}$.

The computer program was written in Harris REAL*12 (Quadruple Precision) FORTRAN 77 and was executed on a Harris H-800 computer system at Arkansas State University. In the root finding routines, the absolute value of a function at a "root" had to be $\leq 10^{-18}$.

As discussed in the first part of the paper, the program involved finding the

$$M = \frac{\left(\frac{2j_{Cd}}{j_{Te}}\right) - 1}{2} \quad [7]$$

value that satisfied Eq. [48] of that article (1)

$$\frac{j_{Cd}}{j_{Te}} = \frac{2M + 1}{2} = \frac{f_{Cd}(E, M)}{f_{Te}(E, M)} = f(E, M) \quad [8]$$

for a specified E value. This was done by starting at $M = -1/2$ and iterating positively through M until the root was crossed, and then using the conventional bisection method to "chop" in on the correct M .

This M value was reinserted into separate equations for j_{Cd} , j_{Te} , $j_{Cd} + j_{Te}$, x_1 , x_2 , x_{Cd} , x_{Te} , γ_{Cd} , γ_{Te} , and γ_{CdTe} to calculate these values. After this, $a_{Cd} = x_{Cd}\gamma_{Cd}$, $a_{Te} = x_{Te}\gamma_{Te}$, $x_{CdTe} = 1 - x_{Cd} - x_{Te}$, and $a_{CdTe} = \gamma_{CdTe}x_{CdTe}$ were obtained. At this point, the deposition current densities and associated deposit surface stoichiometries were specified as functions of deposition potential.

Calculated Data and Associated Discussion

Figure 1 exhibits calculated voltammetric curves for various temperatures. The "experimental" parameter values used are indicated on the graph. The cathodic cur-

Fig. 1. Plots of total current density vs. deposition potential with temperature as a parameter. Note the underpotential cadmium current density plateau structure and sharp corner at its positive edge. This corner potential is the potential of perfect stoichiometry (PPS).

rent density (j) increases above zero at the tellurium Nernst potential, E_{Te} , ($\approx 0.37\text{V}$ [SHE] at 25°C) and increases nearly exponentially for $E < E_{Te}$. After a 0.1V potential decrease, $j = j_{Te}$ begins to saturate and asymptotically approaches $j_{c,l_{Te}}$. Since the "sweep rate" is infinitesimally slow, the capacitive current is zero and there is no peak at the j_{Te} shoulder due to a transient decrease in $c_{\text{H}_2\text{TeO}_3}$ at the cathode surface.

After a further 0.3-0.5V decrease in potential along the nearly constant $j = j_{Te} \rightarrow j_{c,l_{Te}}$ curve, another distinct increase in j occurs between -0.1 and -0.3V . This new current component exhibits an abrupt but continuous shoulder. Negative of this shoulder exists a current plateau with a relatively small slope.

This second structure is due to the underpotential electrodeposition of cadmium caused by $a_{Cd} < 1$ due to bonding of the plated cadmium with tellurium in the Cd_xTe deposit as described by

$$\frac{a_{CdTe}}{a_{Cd}a_{Te}} = \exp\left[\frac{-\Delta G^{\circ}_{CdTe}}{RT}\right] = K \quad [9]$$

and

$$\frac{a_{Cd}}{\gamma_{Cd}} + \frac{a_{Te}}{\gamma_{Te}} + \frac{a_{CdTe}}{\gamma_{CdTe}} = 1 \quad [10]$$

where $a_{Cd}/\gamma_{Cd} = x_{Cd}$ and $a_{Te}/\gamma_{Te} = x_{Te}$ are functions of j_{Cd}/j_{Te} as described by Eq. [31] and [32] of Ref. (1).

The sharp shoulder at the positive end of the underpotential j_{Cd} plateau occurs exactly at the potential of perfect stoichiometry (PPS), the potential at which $x_{Cd} = x_{Te}$, $a_{Cd} = a_{Te}$, $x_{CdTe} = a_{CdTe} = 1$, and $2j_{Cd} = j_{Te}$. The PPS for the room temperature curve is -0.300V (SHE) and is indicated by a box and an arrow. At the PPS, nearly intrinsic CdTe should be plated and $a_{Cd} = a_{Te} = [1/K]^{0.5}$, since $a_{CdTe} = x_{CdTe} = 1$.

Within the current density plateau, j_{Cd} is controlled by j_{Te} ; that is, because $E > E_{Cd}$, cadmium can plate only when it can react with tellurium. Any cadmium-rich regions will quickly redissolve due to $a_{Cd} \rightarrow 1$, causing a large anodic term in Eq. [45] of Ref. (1), the cadmium Butler-Volmer equation.

Within the plateau, the material is slightly cadmium rich and corresponds to n-CdTe doped by cadmium interstitial atoms. After an approximately 0.1V decrease in potential within the plateau region, the potential is near enough E_{Cd} (-0.454V at 25°C) that the cathodic exponential term in Eq. [45] in Ref. (1) becomes large and j_{Cd} begins its conventional exponential rise. At extremely negative voltages, it would approach its diffusion-limited value of $202.1 \text{mA}/\text{cm}^2$.

The PPS shifts positively with increasing temperature (T). This, in conjunction with a negative shift in E_{Cd} with T , widens the plateau. Thus, higher values for T widen

the voltage range over which CdTe can be plated as well as increasing the grain size.

Figure 2 plots PPS vs. $(1000/T)$ with the same conditions as for Fig. 1 except for just slightly larger $j_c, l_{Te} = 124.0 \mu A/cm^2$ and $j_c, l_{Cd} = 247.1 mA/cm^2$. The graph is nearly linear, indicative of the $1/RT$ containing terms appearing as arguments of the deposition voltage and rate constant terms

$$\exp\left(\frac{\pm 2F\alpha_{Cd}(E - E^0_{Cd})}{RT}\right)$$

and

$$k^0 = k_0 T \exp\left[\frac{-E_A}{RT}\right] \quad [2]$$

The slight bow is due to the minor temperature dependences of j_c, l_{Te} and E^0_{Cd} . Precise temperature control is indicated during electrodeposition to avoid shifting of the PPS and the resultant increase in native doping due to cadmium vacancies or interstitial atoms.

Figure 3 logarithmically plots x_{Cd} , x_{Te} , and x_{CdTe} vs. deposition potential for the room temperature curve in Fig. 1. With a PPS of $-0.300V$, the "free" cadmium and tellurium mole fractions are very small ($x_{Cd} \approx x_{Te} \approx 1.6 \times 10^{-6}$), equal, and changing very rapidly. x_{CdTe} approaches unity ($\approx 1 - 3.2 \times 10^{-6}$). For $E > PPS$, x_{CdTe} decreases and x_{Cd} continues its rapid decrease, while x_{Te} increases rapidly as the deposit becomes nearly pure tellurium at $-0.2V$. At $-0.27V$, x_{Te} becomes larger than x_{CdTe} and indicates a $0.03V$ range in which native p-CdTe is the predominant constituent. These rapid changes are a consequence of a sharply decreasing j_{Cd} for $E > PPS$ in Fig. 1.

For $E < PPS$, x_{CdTe} falls off relatively slowly and remains approximately unity for $0.04V$. CdTe is the dominant deposit constituent until $-0.41V$ where $x_{Cd} > x_{CdTe}$. Near $-0.46V$, $x_{Cd} \rightarrow 1$, $x_{CdTe} < 10^{-2}$, and $x_{Te} \approx 10^{-12}$. The -0.30 to $-0.34V$ range represents a $40 mV$ plateau width in which $x_{CdTe} > 0.97$. This corresponds to the j_{Cd} plateau in Fig. 1 in which j_{Cd}/j_{Te} is changing relatively slowly. Thus, CdTe is predominant over $0.14V$.

Figure 4 plots the logarithm of $3.11 \times 10^{22} (\text{MAX}[x_1, x_2] - 0.5)$ vs. deposition potential corresponding to Fig. 3. The ordinate is a measure of

$$\frac{A_{Cd}(E) - A_{Cd}(E = PPS)}{\text{volume}} \quad [11]$$

Fig. 2. Plot of the deposition potential required for perfect stoichiometry (PPS) vs. reciprocal temperature for conditions similar to those in Fig. 1. The PPS shifts positively with increasing temperature.

Fig. 3. Logarithmic plots of constituent mole fractions vs. deposition potential for curve 3 in Fig. 1. Note the rapid transitions at the PPS and relatively slow decline in x_{CdTe} negative of the PPS.

for $E < PPS$ and the same expression with Cd replaced by Te for $E > PPS$. A_i is the number of atoms of i . These quantities represent a measure of the native doping density as defined as the per volume number of atoms of constituent i minus the number existing at perfect stoichiometry. Since cadmium vacancies and tellurium interstitial atoms are thermodynamically equivalent, the tellurium excess will be a measure of the acceptor density due to singly ionized cadmium vacancies, and the cadmium excess is a measure of the cadmium interstitial donor density.

Although neglecting multiple ionized vacancies and interstitials and self-compensation effects, Fig. 4 indicates

Fig. 4. Plot of approximate native doping density vs. deposition potential corresponding to the curves in Fig. 3. The native doping density, as defined as the number of cadmium or tellurium atoms per cm^3 in excess of that number at perfect stoichiometry, undergoes a dramatic and sudden decline at the PPS.

that the voltages range over which nondegenerate, electronic-quality CdTe can be electrodeposited is probably very narrow. The intrinsic carrier density for CdTe is approximately $10^6/\text{cm}^3$ at 300 K while Fig. 4 indicates that the native doping density is less than $10^{19}/\text{cm}^3$ only between -0.2997 and -0.3046V . Furthermore, the excess cadmium density remains less than $10^{20}/\text{cm}^3$ over a reasonably broad 0.02V range (-0.30 to -0.32V), corresponding to the plateau, while the tellurium excess (cadmium deficiency) is less than $10^{20}/\text{cm}^3$ over less than a millivolt positive of -0.29974V , the PPS. Thus, the electrodeposition of nondegenerate native p-CdTe would be difficult and require extremely stringent potential control, while nondegenerate n-CdTe might be plated over a critical but controllable $5\text{-}10\text{ mV}$ range.

Figure 5 shows the calculated voltammograms as a function of $a_{\text{Cd}^{2+}}$. The plateau width decreases with decreasing $a_{\text{Cd}^{2+}}$ and the plateau and associated abrupt shoulder at the PPS disappear when $a_{\text{Cd}^{2+}}$ decreases to 10^{-4} . As $a_{\text{Cd}^{2+}}$ decreases, E_{Cd} and the PPS become more negative. In fact, the PPS becomes negative of E_{Cd} for $a_{\text{Cd}^{2+}} = 2.56 \times 10^{-4}$ because small $a_{\text{Cd}^{2+}}$ do not produce enough underpotential deposition to match j_{Te} . For $a_{\text{Cd}^{2+}} \leq 10^{-4}$, j_{Cd} comes on scale.

Figures 6 and 7 exhibit the effect of $a_{\text{HTEO}_2^+}$ upon the voltammograms. For large enough ($a_{\text{HTEO}_2^+}/a_{\text{Cd}^{2+}}$), no distinct j_{Cd} plateau structure appears and the PPS is shifted onto the steep, nearly exponential portion of the j_{Cd} plot. When $a_{\text{HTEO}_2^+} \ll a_{\text{Cd}^{2+}}$, the j_{Cd} value is sufficiently small that the underpotential j_{Cd} can match it and shift the PPS positive of E_{Cd} .

For example, in Fig. 6, with $a_{\text{HTEO}_2^+}$ values of 15.2×10^{-3} and 4.64×10^{-3} , the PPS's are both negative of E_{Cd} (-0.454V) and are on the steep portion of the j_{Cd} curve. In Fig. 7, with $a_{\text{HTEO}_2^+}$ values of 1.00×10^{-4} and 2.51×10^{-5} , the PPS's have increased positive of E_{Cd} and the sharp inflection becomes apparent at the onset of the plateau structure.

Thus, too large a ($a_{\text{HTEO}_2^+}/a_{\text{Cd}^{2+}}$) value erases the plateau structure, shifts the PPS onto the exponential portion of the j_{Cd} curve, and makes the electrodeposition of electronic-quality CdTe very difficult. Smaller ($a_{\text{HTEO}_2^+}/a_{\text{Cd}^{2+}}$) values result in $2j_{\text{Cd}} \equiv j_{\text{Te}}$ being satisfied at $E > E_{\text{Cd}}$, and the occurrence of the underpotential j_{Cd} plateau within which a CdTe-rich deposit can be plated. This mode of binary compound electrodeposition involving a constant, diffusion-limited current density for the more noble component, a larger concentration of the ion of the less noble constituent, an underpotential current plateau, and a sharp shoulder (PPS) at the positive side of the plateau is named conventional underpotential deposition (CUD) and corresponds to the Class I compounds discussed by Kroger (3). CUD is inherently a voltage-controlled process

Fig. 5. Plots of total current density vs. deposition potential with cadmium ion activity as a parameter. Note the disappearance of the plateau structure and shifting of the PPS negative of the cadmium Nernst potential for the smallest $a_{\text{Cd}^{2+}}$.

Fig. 6. Plot of total current density vs. deposition potential with tellurium ion activity as a parameter. Note the disappearance of the plateau structure and shifting of the PPS negative of the cadmium Nernst potential for the largest $a_{\text{HTEO}_2^+}$.

with nondegenerate CdTe being plated only within a narrow and precisely controlled voltage range about a PPS dependent upon j_{Cd} , l_{Te} and temperature. For random potential variations about the PPS due to noise, shifts in the PPS due to temperature fluctuations and depletion of the tellurium ions, or the selection of a slightly incorrect deposition potential, the chances of depositing n-CdTe are much greater than depositing p-CdTe, as evidenced by Fig. 4. Films deposited with $E > \text{PPS}$ would likely exhibit p-type behavior as a result of the p-nature of excess tellurium, rather than due to true nondegenerate p-CdTe (15). The most useful voltage should lie slightly positive of the center of the plateau where n-CdTe could be plated with noise immunity because of the small $|dj/dE|$ value.

Matched Diffusion-Limited Current (MDLC) Deposition Mode

In Fig. 6, the PPS lies on the steep exponential portion of the j_{Cd} curve for the largest ($a_{\text{HTEO}_2^+}/a_{\text{Cd}^{2+}}$) values. Because of the large $|dj/dE|$ and dx/dE values at these PPS's, the electrodeposition of electronic-grade CdTe would be difficult and require exact knowledge and stability of the PPS.

However, it is also possible to electrodeposit perfectly stoichiometric CdTe with a vanishing dx/dE value by increasing ($a_{\text{HTEO}_2^+}/a_{\text{Cd}^{2+}}$) until $[j_{\text{Cd}}, l_{\text{Te}}/z_{\text{Te}}] = [j_{\text{Cd}}, l_{\text{Cd}}/z_{\text{Cd}}]$ ($C_{\text{HTEO}_2^+} \approx C_{\text{Cd}^{2+}}$) and then choosing a potential where $j_{\text{Cd}} \approx j_{\text{Cd}}$ and $j_{\text{Te}} \approx j_{\text{Cd}}$. This will ensure nearly equal molar ion fluxes at the cathode for all potentials negative of the shoulder occurring when $j_{\text{Cd}} \rightarrow j_{\text{Cd}}$. The advantage of this deposition mode is that the deposit stoichiometry (as determined by $j_{\text{Cd}}/j_{\text{Te}}$) is nearly independent of potential.

Figure 8 is j - E plot with ($a_{\text{HTEO}_2^+}/a_{\text{Cd}^{2+}}$) deliberately chosen slightly less than unity. The PPS ($\approx -0.53\text{V}$), just positive of the j_{Cd} shoulder, still corresponds to a large $|dj/dE|$ value. Figure 9 logarithmically plots x_{Cd} , x_{Te} , and x_{CdTe} vs. deposition potential for the voltammogram of Fig. 8. The x_{CdTe} and x_{Cd} values fall off rapidly for $E > \text{PPS}$, while x_{Te} rapidly approaches unity. For $E < \text{PPS}$, x_{CdTe} approaches the constant, voltage-independent value of 0.858 while x_{Cd} and x_{Te} approach the constant values of 0.142 and 1.79×10^{-11} , respectively. At the PPS, $x_{\text{Cd}} = x_{\text{Te}} = 1.72 \times 10^{-6}$ while $x_{\text{CdTe}} = 1$ ($\equiv 1 - x_{\text{Cd}} - x_{\text{Te}}$).

Increasing $C_{\text{HTEO}_2^+} \approx a_{\text{HTEO}_2^+}$ to equal $C_{\text{Cd}^{2+}} \approx a_{\text{Cd}^{2+}} = 1.2 \times 10^{-5}$ would increase $j_{\text{Cd}}, l_{\text{Te}}$ to $30.98 \mu\text{A}/\text{cm}^2 \approx 2j_{\text{Cd}}, l_{\text{Cd}}$ assum-

Fig. 7. As in Fig. 6 for different $a_{\text{HTeO}_2^+}$ values

ing nearly equal D_i . This would shift the PPS of Fig. 8 negative of the voltammogram shoulder onto the horizontal section of the curve. A unique PPS would still exist but due to the nearly zero $|dj/dE|$ value, one could define a broad potential range over which x_{CdTe} is greater than some number near unity. In Fig. 9, x_{CdTe} would remain just slightly less than unity (0.999966 at the PPS) for all $E < \text{PPS}$.

To maintain a small but experimentally adjustable $|dj/dE|$ value at the PPS, $j_{c,\text{Cd}}/j_{c,\text{Te}}$ could be chosen just slightly greater than one so that the PPS was just negative of the voltammogram shoulder. This would allow one to deposit both n- and p-CdTe over broad potential ranges negative and positive, respectively, of the PPS. If $j_{c,\text{Cd}} \equiv j_{c,\text{Te}}$, only p-CdTe could be plated; perfectly stoichiomet-

Fig. 8. Plot of total current density vs. deposition potential for nearly equal cadmium and tellurium ion activities and nearly matched diffusion-limited current densities. Note that the PPS is almost on the horizontal diffusion-limited cadmium current density region.

Fig. 9. Logarithmic plot of constituent mole fractions for the curve in Fig. 8. The cadmium telluride mole fraction does not appreciably decrease for potentials negative of the PPS.

ric CdTe would occur only at $E \rightarrow -\infty$. This voltage range expansion for both n- and p-CdTe is the advantage of having matched diffusion-limited currents, given the narrow deposition potential range corresponding to p-CdTe in the CUD mode (Fig. 4).

This deposition involving small $c_{o,i}$'s, nearly equal and matched $j_{c,l}$'s, PPS's negative of the metal $j_{c,l}$ shoulder, and small $|dj/dE|$ values is named the matched diffusion-limited current (MDLC) deposition mode. In principle, MDLC deposition could be used with large $c_{o,i}$ and $j_{c,l}$ values, but would be complicated by the limited solubility of TeO_2 in aqueous solutions and the possible formation of $\text{Te}^=$, $\text{Te}_2^=$, HTe^- , or H_2Te for $E < -1\text{V}$, as required to make $j_{\text{Cd}} \rightarrow j_{c,\text{Cd}}$. MDLC can, however, be implemented with small $c_{\text{Cd}^{++}}$ and $c_{\text{HTeO}_2^+}$ values.

As opposed to CUD, MDLC deposition is inherently a current-controlled process since $|dj/dE|$ is very small. The ratio ($j_{c,\text{Cd}}/j_{c,\text{Te}}$) must not drop below unity or n-CdTe will never be produced. If ($j_{c,\text{Cd}}/j_{c,\text{Te}}$) is too much greater than unity, the PPS will be shifted positive of the $j_{c,\text{Cd}}$ shoulder to a region of large $|dj/dE|$ and dx_i/dE in which deposition of perfectly stoichiometric material would require precise voltage control.

Unfortunately, $j_{c,\text{Cd}}$ and $j_{c,\text{Te}}$ vary with temperature due to changes in D_i and, more importantly, changes in complex dissociation (e.g., CdCl_2^{2-x}) and TeO_2 solubility with changing temperature and pH. Increasing stirring or cathode rotation rates (or increasing thermal convection currents with increasing temperature) decrease δ at the cathode surface and increase both $j_{c,\text{Cd}}$ and $j_{c,\text{Te}}$. Depletion of small unsaturated $c_{o,i}$ with prolonged deposition also decreases both $j_{c,l}$ values. These factors tend to complicate effective MDLC deposition. A large volume, stationary electrolyte at room temperature containing no excess undissolved TeO_2 or cadmium salt would be desirable. Potentials just negative of the $j_{c,\text{Cd}}$ shoulder and $j_{c,\text{Cd}}$ values just slightly greater than $j_{c,\text{Te}}$ would result in a still small but nonzero $|dj/dE|$ value that would allow one to compensate for small drifts in the $j_{c,l}$ values by changes in the deposition potential.

Effect of the Activity Coefficient Parameter, β , Gibbs Free Energy, ΔG° , and Metal Standard Reduction Potential, E° , upon the Calculated Voltammograms

As described by Eq. [16]-[18] in Ref. (1), the activity coefficients used in this model were

$$\gamma_{Cd} = \exp \left[\frac{\beta}{RT} x_2^2 \right] \quad [12]$$

$$\gamma_{Te} = \exp \left[\frac{\beta}{RT} x_1^2 \right] \quad [13]$$

and

$$\gamma_{CdTe} = \exp \left[\frac{\beta}{2RT} (1 - 4x_1x_2) \right] \quad [14]$$

Figure 10 demonstrates that the PPS does not depend sensitively upon the activity coefficient parameter, β . In fact, the PPS visually appears as the same point, and the total currents for $E >$ PPS visually coincide for all curves.

However, β does have a strong effect upon the j_{cd} plateau for $E <$ PPS. The apparent plateau width ranges from slightly greater than 0.1V for $\beta = -1$ J/mol to little more than an inflection for $\beta \cong -10^5$ J/mol. Thus, the more "ideal" ($\beta \cong 0$, $\gamma_i \cong 1$) the solid metastable Cd_xTe solution, the larger will be the potential range over which reasonably pure n-CdTe can be electroplated. It might be possible to use carefully performed voltammetric studies (in the absence of hydrogen or Te(-II) generation) to determine β for solid CdTe from experimental plateau widths. Fortunately, if accurate k_i and $\bar{\alpha}_i$ are known, the PPS can be calculated even with large uncertainties in β and the lack of PPS dependence upon β implies the PPS's insensitivity to the functional forms used for γ_i . Thus, the PPS is a distinct and important quantity characterizing the electrodeposition of M_1X_1 when $j_x = j_c, l_x$.

Figure 11 shows the effect of the Gibb's free energy of formation, ΔG_{MX}^0 , for the imaginary compound M_1X_1 having the same parameter values as CdTe except for β , which was set to zero to accent the plateau structure. The voltammetric curves for $\Delta G^0 = -10^5$ and -10^6 J/mol coincide within the resolution of the graph and possess pronounced j_{cd} plateau structures with a PPS near -0.31 V (SHE). There is substantial underpotential cadmium deposition beginning near -0.2 V because of the strong bonding between M and X . However, as ΔG^0 is positively increased to -10^4 J/mol, the plateau structure disappears, the PPS shifts from -0.31 to -0.43 V (still positive of E_m , -0.454 V), and the metal M does not begin to plate to any

Fig. 10. Plots of total current density vs. deposition potential with the activity coefficient parameter, β , as a parameter. Note that the PPS is insensitive to β , but the plateau width increases with less negative β values.

Fig. 11. Plots of total current density vs. deposition potential with ΔG_{MX}^0 , the free energy of formation of compound MX , as a parameter. With small $|\Delta G^0|$, the plateau structure disappears as the two partial current densities become nearly independent.

extent until -0.35 V. The PPS lies on the steep quasi-exponential portion of the metal current curve.

As ΔG^0 increases to -10 J/mol, the PPS shifts to -0.441 V, very close to E_m . There is no significant underpotential deposition until $E = -0.4$ V. The small $|\Delta G^0|$ value indicates weak interconstituent bonding and electrodeposits more like mechanical mixtures than compounds.

The rapid increase in equilibrium a_M (equals x_M for $\beta = 0$) in the deposit as ΔG^0 changes from -10^5 to -10^4 J/mol causes the distinct differences in the curves. The mole fraction equilibrium constant [Eq. [20] in Ref. (1)] is

$$\frac{x_{MX}}{x_M x_X} = K' = \exp \left[\frac{1}{RT} \left(\frac{\beta}{2} - \Delta G^0 \right) \right] \equiv \exp \left(\frac{\beta'}{RT} \right) \quad [15]$$

For $\beta = 0$ and $T = 25^\circ\text{C}$, K' is 3.30×10^{17} with $\Delta G_{MX}^0 = -10^5$ J/mol, but is only 56.5 with $\Delta G_{MX}^0 = -10^4$ J/mol. The much larger x_M and a_M with the smaller $|\Delta G^0|$ value result in a larger anodic pre-exponential multiplier in the cadmium Butler-Volmer equation [Eq. [45] of Ref. (1)], thus, greatly diminishing the underpotential deposition.

Although this model assumes that the solid-state reaction between plated cadmium and tellurium is sufficiently rapid (a rate constant approaching infinity) that the deposit is always described by Eq. [9], [10], and

$$a_i = \gamma_i x_i \quad [16]$$

with γ_i given by Eq. [12]-[14], a finite rate of reaction might be phenomenologically accounted for by a less negative $\Delta G_{eff}^0(t)$, the time varying effective free energy. As plated cadmium and tellurium react toward equilibrium, x_{Cd} , x_{Te} , a_{Cd} , and a_{Te} will decrease and x_{CdTe} and a_{CdTe} will increase until equilibrium is reached. At all previous times

$$\left[\frac{a_{CdTe}}{a_{Cd} a_{Te}} \right] (t) \equiv K_{eff}(t) \equiv \exp \left[\frac{-\Delta G_{eff}^0(t)}{RT} \right] \quad [17]$$

where $\Delta G_{eff}^0(t)$ drifts negatively with time and approaches ΔG^0 .

Thus, the calculated voltammograms for $\Delta G_{MX}^0 > -9.97 \times 10^4$ J/mol might approximate the behavior of experimental current-voltage curves if cadmium and tellurium react more slowly than assumed. As $\Delta G_{eff}^0(t) \rightarrow +\infty$, no

solid-state reaction occurs and the j_i are totally independent. The effects of incomplete reaction between the cadmium and tellurium atoms near the deposit surface include a negative shift in the PPS and a reduction or disappearance of the plateau region.

Figure 12 exhibits the effect of the metal standard reduction potential E_m^0 , upon the voltammograms for imaginary compounds with the same free energy as CdTe. If $j_x \rightarrow j_c, l_x$ at the potential where significant underpotential metal deposition begins to occur, the voltammograms are identical except for the horizontal offset due to different E_m^0 values. This similarity is a consequence of $\Delta G_{MX}^0 = -9.97 \times 10^4 \text{ J/mol}$ being used for all three curves. Since only the term $(E - E_m^0)$, and never E alone, occurs in the metal Butler-Volmer equation and the pre-exponential multipliers depend only upon ΔG^0 , β , $\alpha_{x(\text{IV})}$, $\alpha_{M^{++}}$, j_c, l_x and j_c, l_M , and not E , the j_i 's are always functions of the relative potential $(E - E_m^0)$ rather than the absolute potential E , as long as $j_x \approx j_c, l_x$. When $j_x < j_c, l_x$ at voltages where significant underpotential metal deposition can occur, as when $E_m^0 \approx E_x^0$, the voltammetric structure differs from that exhibited in this paper and perfectly stoichiometric M_xX_1 can be plated at voltages positive of both E_m and E_x . This mode of deposition is named pure underpotential deposition and corresponds to Class II compounds in Kroger's work (3).

Figure 12 indicates that it is not necessary to have $E_m^0 \approx E_x^0$ to electrodeposit the stoichiometric alloy or compound, as is sometimes assumed. The underpotential j_M plateau with its small $|dj/dE|$ values should occur for most base metal chalcogenides. CdTe should be as easy to plate as PbTe or SnTe. At very negative voltages where H_2Te or HTe^- can be generated, the film growth mechanism could change to a precipitation-like reaction such as

and change the observed voltammetric structure for ZnTe or MnTe electrodeposition.

Comparison of Theoretical Results with Experiment

Other workers investigating CdTe electrodeposition have observed plateau-like structures in voltammograms. These often exhibited characteristics different from those of the calculated curves, probably because of the pres-

Fig. 12. Plots of total current density vs. deposition potential with E_m^0 , the standard reduction potential of the metal in compound MX , as a parameter. The shapes of the curves are independent of E_m^0 as long as the tellurium current density is diffusion limited.

ence of second-order effects such as hydrogen generation and nonideal voltammetric characteristics of tellurium (multiple steps, very low transfer coefficients, and large overpotentials). These last factors could shift the j_c, l_{Te} peak negative of the calculated shoulder voltage. It is possible that, in some instances, substantial cadmium begins to plate before j_{Te} becomes diffusion limited. In this case, to be discussed later in this sequence of articles, the voltammograms would not be as simple to interpret as those curves calculated in this paper.

Figure 13 exhibits a voltammogram obtained by the authors with a graphite cathode in an aqueous solution ($pH = 2.6$, $T = 90^\circ C$, sweep rate $\approx 50 \text{ mV/s}$) saturated in TeO_2 , $0.24 M$ in Cd^{++} , and containing a graphite anode and Ag/AgCl reference electrode. At $25^\circ C$, the potentials of the standard calomel (SCE) and Ag/AgCl reference electrodes are 0.242 and $0.222 V$, respectively, vs. the standard hydrogen electrode (SHE).

Near $0.1 V$ (Ag/AgCl), a shoulder appears in the current, possibly due to $j_{Te} \rightarrow j_c, l_{Te}$. The current (i) is nearly constant with a slight decrease for about $0.3 V$, and a strong rise and a peak occur near -0.2 and $-0.35 V$, respectively. The current only slowly increases within the apparent plateau until i_{Cd} rapidly increases near $-0.7 V$.

Three strong anodic peaks occur in Fig. 13. There appears to be a correlation between these peaks and the three cathodic structures. The negative-most anodic peak is due to dissolution of cadmium metal plated at the end of the cathodic sweep, which, when stripped, leaves a Cd_xTe deposit. When the potential becomes sufficiently positive, cadmium will strip from the surface $CdTe$ layers according to

thus producing the middle anodic peak and leaving a tellurium surface that is stable until the voltage reaches a more positive critical potential where tellurium and any remaining CdTe is quickly stripped.

The above interpretation is supported by the cathodic photocurrent behavior of the sweeps. On the initial negative going sweeps, photocurrents commence at the apparent underpotential i_{Cd} shoulder (the middle cathodic wave) and remain until pure cadmium deposition begins. On the anodic backsweep, the cadmium dissolution peak appears and photocurrent reappears at the peak's positive foot. Photocurrent remains strong until voltages just negative of the center anodic peak, corresponding to CdTe dissolving into Cd^{++} and tellurium. Between the middle anodic peak and the large tellurium dissolution peak, there is negligible photocurrent.

The photocurrent's sudden disappearance at the middle anodic peak is probably due to the transformation of remaining surface layers from semiconducting CdTe to

Fig. 13. Experimental voltammetric data for acidic aqueous solutions of cadmium and tellurium ions and a graphite cathode. Three cathodic waves and three anodic peaks appear and may correspond to the plating and dissolution, respectively, of tellurium, cadmium telluride, and cadmium.

quasi-metallic tellurium. The photocurrent onset on the shoulder of the center cathodic wave is probably due to the sudden onset of nondegenerate CdTe deposition (near the PPS).

The apparent PPS's, as determined from the shoulder of the second cathodic wave, the middle anodic peak, and the photocurrent onset, were in the -0.2 to $-0.4V$ (SHE) range, consistent with those values calculated. Much of the middle cathodic wave is probably due to hydrogen and possibly enhanced tellurium reduction, and this is probably why there is such a large difference in the apparent magnitudes of i_{Te} and i_{Cd} . Furthermore, the initial tellurium reduction appears sluggish, probably indicating transfer coefficients and rate constants smaller than assumed in the calculations. It is possible that the first cathodic wave is due to reduction of Te (VI) to Te (IV), as speculated by Bhattacharya and Rajeshwar (7) (discussed below), and that significant tellurium plating does not occur until within the second wave. However, the shoulder or inflection point of the middle cathodic wave is almost certainly the potential at which CdTe deposition commences and should be near the PPS.

Other workers have made observations qualitatively substantiating the authors' analytical model. AMFTEK (8) found that a deposition voltage of -578 mV (Ag/AgCl) led to electronic-grade CdTe in a solution with a temperature of $80^\circ C$, a pH of 2, a Cd^{++} concentration of $1.2M$, and a tellurium ion concentration of $1.6 \times 10^{-4}M$. The resistivity of the films varied from 10^3 to $10^6 \Omega\text{-cm}$ as the deposition potential varied over less than a 20 mV range about -578 mV. This range is consistent with Fig. 4 showing the approximate native doping density, while -578 mV (Ag/AgCl) is consistent with the calculated PPS's.

The Rockwell group (9) determined that a potential of -725 mV (SHE) produced near-stoichiometric CdTe in a $1M$ HCl, $0.1-1M$ Cd^{++} , and $10^{-3}M$ TeO_2 -based solution at temperatures from room temperature to boiling. This potential was critical with a 2-6% change in the cadmium/tellurium ratio per millivolt change in potential noted. The calculated PPS with $a_{HTeO_2^+}$ of order 10^{-3} is between -0.4 and $-0.5V$ (SHE), qualitatively agreeing with Rockwell's value. Rockwell alluded to the existence of an underpotential cadmium current plateau.

The Monosolar group (10) found that the cadmium/tellurium ratio could be varied from 0.75 to 0.82 by varying the deposition potential from -300 to -700 mV (SCE). Evidently, this ratio did not exceed unity until voltages negative of E_{Cd} . The high temperatures ($\approx 95^\circ C$) probably resulted in a large TeO_2 solubility that led to large values of j from 200 to $500 \mu A/cm^2$. Thus, it is reasonable that the PPS was negative of E_{Cd} , consistent with Fig. 6. The largest CdTe grain sizes ($5.7 \mu m$) occurred with a potential of -400 mV (SCE). They could not grow p-type material, even with arsenic, antimony, and gold acceptors, consistent with the narrow potential range calculated for nondegenerate p-CdTe.

Panicker *et al.* (11) found that electrodeposited CdTe films changed from n- to p-type for potentials between -0.45 and $-0.5V$ (SCE) with a solution ($T = 85^\circ C$, pH = 3.4, stir rate = 160 rpm) $1.2M$ in Cd^{++} and saturated in TeO_2 . A plateau-like region beginning between -0.4 and $-0.5V$ (SCE) was observed at $25^\circ C$ and various acidic pH's, was approximately 200 mV wide, and ended with the deposition of pure cadmium. The onset of the plateau at $25^\circ C$ correlates with the n-p transition at $85^\circ C$.

Llabres (12) found an apparent PPS of -660 mV (SCE) for CdTe electrodeposition on stainless steel and ITO from a solution ($T = 82^\circ C$, pH = 2.0-3.5) $1M$ in $CdSO_4$ and saturated with TeO_2 . Plots of bulk resistivity *vs.* deposition potential indicated that the value at $-0.66V$ (SCE) ($\approx 2 \times 10^3 \Omega\text{-cm}$) was several hundreds times that at $-0.58V$ (SCE) ($\approx 5 \times 10^2 \Omega\text{-cm}$). The potential range for single-phase (lacking segregated tellurium) p-CdTe electrodeposition ranged from -0.62 to $-0.66V$, a narrow 40 mV range but considerably larger than that implied in Fig. 4. The tellurium and cadmium atomic percentages decreased and increased, respectively, as the cathodic po-

tential was made more negative. Although not explicitly mentioned, it is likely that n-CdTe was plated over a narrow range of voltages negative of $-0.66V$, a value close to E_{Cd} .

Takahashi *et al.* (5) deposited CdTe from aqueous solutions $1M$ in $CdSO_4$, $10^{-3}M$ in TeO_2 , and $0.05M$ in H_2SO_4 . They observed diffusion-limited currents with voltages between -0.3 and $-0.65V$ (Ag/AgCl) and a strong current increase at $-0.65V$. A linear relationship between this limiting current and $c_{HTeO_2^+}$ was noted, but c_{CdSO_4} had little effect. An increase in the strength of the separate tellurium x-ray diffraction peaks occurred for more positive potentials, and no free cadmium peaks were observed for potentials between -0.2 and $-0.6V$. The films transformed from p- to n-type at $-0.45V$, possibly the PPS.

Plots of photocurrent of already deposited films *vs.* applied voltage indicated that maximum photocurrent occurred for films deposited at $-0.40V$ (Ag/AgCl). No photocurrents were observed for initial potentials positive of $-0.20V$ or negative of $-0.55V$. Thus, the PPS is probably between -0.40 and -0.45 , and the range of potential corresponding to nondegenerate CdTe electrodeposition is approximately $0.35V$. They argue that during deposition of pure CdTe

$$i_{total} = \frac{6D_{Te}Fc_{HTeO_2^+}}{\delta} \quad [20]$$

while

$$i_{Te} = \frac{4D_{Te}Fc_{HTeO_2^+}}{\delta} \quad [21]$$

where D_{Te} is the diffusion coefficient of $HTeO_2^+$. Thus, at perfect stoichiometry, i_{total} equals $1.5i_{Te}$, as corroborated by the authors' current model and calculations.

Bhattacharya and Rajeshwar (7) conducted voltammograms with platinum microelectrodes in acidic aqueous solutions $\approx 5.0 \times 10^{-4}M$ in TeO_2 . They observed a tellurium ion reduction wave near $0.4V$ (SCE) and verified the diffusion-limited nature of i_{Te} from the linear wave peak *vs.* (sweep rate)^{0.5} characteristics. They attributed this wave to the reaction

Another reduction wave began near $-0.1V$ (SCE) and peaked near $-0.25V$, as shown in Fig. 3 of their article. The current dipped slightly near $-0.3V$ and increased near $-0.4V$, the negative end point of that particular sweep. Near $-0.4V$, a black deposit, speculated to be tellurium, was formed and was stripped near $0.55V$ during the anodic back sweep.

CdTe films were deposited at potentials from -0.65 to $-0.85V$ (SCE) (potentials probably negative of E_{Cd}), with current densities ranging from 0.3 to 0.5 mA/cm², a pH of 2.5-3.0, and a temperature of 40° - $50^\circ C$ from aqueous solutions $1M$ in $CdSO_4$ and 10^{-5} - $10^{-3}M$ in TeO_2 . The Cd:Te ratio for films grown on titanium averaged 45:55, consistent with tellurium-induced p-type conductivity in the as-deposited films. Annealing at $\approx 600^\circ C$ increased the Cd:Te ratio and changed the films to n-type, as corroborated by photoelectrochemical measurements. Addition of copper to the solutions and films resulted in extrinsic p-type conductivity (15).

Although there are significant variations in the apparent tellurium deposition onset potential, PPS, plateau structure, etc., among the various workers previously discussed, several general trends emerge.

1. For large tellurium ion concentrations (10^{-4} - $10^{-3}M$) and subsequent large j_c, i_{Te} , as occur at low pH's and high temperatures, the apparent PPS lies very near or even slightly negative of E_{Cd} ($E^0 = 0.403V$ [SHE]).

2. Underpotential cadmium deposition does occur, as evidenced by apparent PPS's up to 200 mV positive of E_{Cd} .

3. The range of deposition potential over which electronic-grade CdTe can be plated is relatively narrow (20-400 mV).

4. The apparent tellurium deposition onset potential ($\cong E_{Te}$) lies negative of that predicted from the kinetic parameters assumed in the authors' calculations, and j_{Te} may not always become diffusion limited before significant underpotential j_{Cd} occurs. There may exist a large overpotential for tellurium deposition, and the α_{Te} value may be much smaller than 0.5. The large cathodic reduction wave that commonly occurs a few hundred millivolts positive of E_{Cd} is partially due to underpotential cadmium deposition, as analytically predicted and substantiated by various microanalysis, x-ray diffraction, and photocurrent measurements, but is probably partially due to enhanced tellurium deposition and hydrogen generation.

5. Tellurium may exist as Te (VI) and Te (-II) in addition to the Te (IV) and Te (0) assumed in the authors' model.

6. Tellurium segregation does occur for sufficiently large Te:Cd ratios, as evidenced by x-ray diffraction data.

7. CdTe exhibiting native p-type conductivity can be deposited over a reasonably broad range of potential. However, due to the probable existence of separate p-tellurium phases, it is unclear if this is due to p-CdTe or tellurium.

Except for trend 6, and possibly 7, these trends are consistent with the results of the authors' model and calculations, but would require parameter value changes and model expansions to precisely incorporate. Indeed, the simulated voltammograms were originally intended to be only approximately analogous to CdTe. It would be interesting to conduct voltammograms in organic solutions of N-N dimethylformamide or dimethylsulfoxide, $TeCl_4$, and $CdCl_2$. $TeCl_4$ is extremely soluble ($> 10^{-3}M$), does not undergo hydrolysis, and exists as yellow $TeCl_3^+$ and $TeCl_5^-$ ions in these solvents. The key advantage of the organic baths is the absence of hydrogen generation and ion hydrolysis. Thus, their use in voltammetric measurements should more conclusively prove the validity of the authors' model and calculations.

Conclusions

This paper has presented the results of a computer simulation of the model, developed in the first part of the paper (1), corresponding approximately to CdTe (or M_2X_3) electrodeposition from solutions containing both cadmium and tellurium ions in a reducible form.

The calculated graphs lead to the following conclusions.

1. For diffusion-limited tellurium current densities, there exists an underpotential cadmium current density plateau over an approximately 100 mV range in potential which occurs because cadmium can plate at potentials negative of its pure element Nernst potential (E_{Cd}) only on a nearly 1:1 basis with tellurium. This is because a solid-state reaction between the cadmium and tellurium is required to reduce the cadmium activity enough that the anodic term in the cadmium Butler-Volmer equation is small. This activity reduction and underpotential cadmium current is enhanced by more negative β and ΔG_{MX}^0 values.

2. At the sharp positive shoulder of this plateau lies the potential of perfect stoichiometry (PPS), where $x_{Cd} \cong x_{Te}$, $a_{Cd} \cong a_{Te}$, $x_{CdTe} \cong a_{CdTe} \cong 1$, and the material is nearly intrinsic, neglecting self-compensation effects in the native doping. The PPS shifts positively with increasing temperature and $\alpha_{Cd^{++}}$ (assuming $\alpha_{HTeO_2^+}$ remains constant). If $\alpha_{HTeO_2^+}$ increases with temperature due to enhanced TeO_2 solubility, the PPS may shift negatively with temperature due to larger tellurium diffusion-limited currents.

This mode of deposition, involving PPS's positive of the Nernst potential of the more electronegative deposit constituent, occurring at the positive edge of this constituent's current plateau, and occurring when the more noble constituent's current is diffusion limited, is named conventional underpotential deposition (CUD).

3. With CUD, cadmium-rich, n-type, and probably nondegenerate CdTe is deposited within a several hundred millivolt wide potential range between the PPS and

E_{Cd} . High resistivity p-CdTe ($x_{CdTe} > x_{Te}$) can be deposited only within a very narrow potential range positive of the PPS.

4. For cadmium and the tellurium ion concentrations (activities) sufficiently close together, the PPS may shift negative of E_{Cd} and the plateau structure may disappear. Under these conditions, the PPS can lie on the steep, quasi-exponential portion of the cadmium current density curve and cause a strong dependence of deposit mole fractions on deposition potential.

5. In the CUD mode, the PPS is nearly independent of β , the activity coefficient parameter. This makes the PPS a key quantity for characterizing ionic MX electrodeposition. However, less negative β values broaden the plateau region, with a maximum plateau width occurring with $\beta = 0$ (ideal solid solution) because less negative β values increase γ_{Cd} and a_{Cd} and delay the onset of quasi-exponential cadmium currents. The plateau width decreases and the PPS shifts negatively with less negative ΔG_{MX}^0 values because a smaller MX equilibrium constant and larger free M mole fraction (activity) increase the anodic current density in the M Butler-Volmer equation.

6. If the ion concentrations are very nearly equal, the two diffusion-limited current densities are close together, and the molar fluxes are equal, the PPS may shift onto the nearly constant current region corresponding to both ions being diffusion limited. In this case, the dj_{total}/dE and, hence, dx_i/dE values are very small, so electronic-grade CdTe can be deposited over a broad potential range. This method of deposition is named the matched diffusion-limited current (MDLC) mode.

7. Experimental voltammetric and stoichiometry vs. potential measurements by various workers have differed but have shown that underpotential cadmium deposition does occur with apparent PPS's (based upon microanalysis measurements, maximum photocurrent, or n-p transitions) in qualitative agreement with the calculated results. Plateaulike structures appear, but these may be experimentally complicated by hydrogen and enhanced tellurium deposition. Careful voltammetric, composition, photocurrent, and conductivity-type measurements should be performed as a function of deposition potential with organic solvents such as N-N dimethylformamide or dimethylsulfoxide containing a tellurium halide ($TeCl_4$) and cadmium salt. These baths should avoid hydrogen generation and allow large tellurium ion concentrations and temperatures above 100°C to be used, thus, leading to more general and easy-to-interpret data and better corroboration of the analytical model and calculated results.

Coupled Electrocatalysis and Gas Phase Diffusion in a Stabilized-Zirconia Tubular Flow Oxygen Pump

L. M. Rincon-Rubio, B. C. Nguyen,* and D. M. Mason**

Department of Chemical Engineering, Stanford University, Stanford, California 94305

ABSTRACT

A tubular electrochemical reactor constructed from a 10 mole percent Y_2O_3 -stabilized ZrO_2 electrolyte tube with porous Au electrodes on its inner and outer surfaces was operated as an oxygen pump in the temperature range 650°-850°C. Gas mixtures with different O_2 content were circulated through the inside cathodic wall of the tube, where O_2 was electrochemically reduced and pumped out through the outer anodic wall of the tube to an annular chamber. The current-overpotential behavior of the cell was found to be dominated by catalytic rate processes at the cathode. The electrochemical kinetics can be described by a modified Butler-Volmer expression. The behavior of the tubular flow reactor in the integral mode of operation was studied by numerically solving the convective-diffusion equation of change for O_2 molecules in the gas phase, incorporating both radial and axial diffusion and electrochemical reaction on the tube wall. The finite-difference method of successive over-relaxation was used to solve the governing mass-transfer equation. When the axial change in O_2 concentration at the tube wall is accounted for, the computed integrated currents agree very well with the experimentally measured values, allowing the prediction of total ionic current and fractional reactant conversion for a given set of flow and physical variables. Under certain conditions, axial diffusion is found to be quite pronounced, with concentration disturbances penetrating the region well upstream of the inlet to the reaction zone ($\xi = 0$), and significantly decreasing the O_2 concentrations at $\xi = 0$ from values in the entering feed stream.

There has been considerable interest in recent years in employing solid-oxide electrolytes in practical devices such as oxygen sensors, oxygen pumps, electrolysis cells, and fuel cells. Among the oxygen anion conductors, those compounds based on ZrO_2 with the fluorite structure, so-called stabilized ZrO_2 , have been the most widely investigated (1, 2). The ionic conduction is due to the migration of oxygen ions via a vacancy mechanism. The vacancies involved are oxygen vacancies, V_{O}^{oo} , with an effective charge of +2, which are created in order to preserve the electrical neutrality of the solids when ZrO_2 is doped with metal oxides containing cations with valence lower than +4, such as CaO, MgO, Y_2O_3 , or Sc_2O_3 (3, 4). In all these devices, a region of solid stabilized ZrO_2 of a particular desired geometry is used to separate a pair of compartments containing gases with different O_2 activities. In most cases, metals such as Ag, Au, Pd, or Pt are employed as electrodes. At equilibrium, there is no current flowing through the cell and the theoretical open-circuit potential of the cell is given by the Nernst equation, which for a predominantly ionic conductor can be written as

$$E_o = \frac{RT}{4F} \ln \frac{P_{O_2}^{II}}{P_{O_2}^I} \quad [1]$$

where 4 is the total number of electrons transferred in this particular electrode reaction involving O_2 .

When a stabilized ZrO_2 electrochemical cell is operating as an oxygen pump, O_2 can be removed from gas mixtures at any predetermined rates by applying an appropriate external voltage to the cell. As a result of a finite current I circulating through the closed circuit, the cell potential E needed to drive the system is increased above the theoretical value, E_o , because of potential losses asso-

ciated with ohmic resistance of the electrolyte and electrodes and also with nonohmic rate processes such as charge transfer, adsorption, slow gas phase and/or surface diffusion of reactants or products. In order to increase cell efficiencies, it is necessary to identify the major sources of these so-called polarization overpotentials and to determine the functional relationship between overpotential and current density. Electrode polarization phenomena in these solid oxide electrolyte cells are strongly influenced by factors such as gas composition, temperature and total current, electrode morphology, adsorption of reactants and/or products on the solid electrolyte and/or on the electrode. In recent years, even though significant progress has been made in the field of electrode kinetics, it is still very difficult in the case of ZrO_2 -stabilized cells to derive unambiguous general current-overpotential relationships for a particular reacting system.

The reduction of O_2 which takes place at the cathode of a stabilized ZrO_2 electrochemical cell involves species from three different phases and the overall reaction can be written

A variety of physical-chemical processes have been proposed as rate-determining steps for the above reaction, including diffusion of O_2 through the electrode (5), dissociation of O_2 or electron transfer (6), surface diffusion of adsorbed O on ZrO_2 (7), mass transport in the gas phase (8, 9), electronation of O_2 (10), surface diffusion of adsorbed O on the metal electrode (11, 12), and gaseous diffusion in electrode pores (13). Much of the disagreement among the investigators is found actually to arise due to differences in electrode morphology, operating conditions, and cell geometries. Recently, the effects of electrode morphology (11, 14), electrode particle size, and

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

type of electrolyte on the nature of the electrode polarization have been emphasized (15, 16).

Cell geometries employed in most of the previous studies have not been amenable to analysis employing fluid mechanics theory, and in cases where gas phase diffusion has arisen as the rate-determining step a simple linear driving force relationship of the type below has been used

$$\frac{i}{nF} = \frac{D_j}{\delta} (C_{jb} - C_{js}) \quad [3]$$

where i is the current density, n is the total number of electrons transferred in the reaction, F the Faraday constant, D_j is the effective diffusion coefficient of species j in the gas phase, δ is the thickness of the diffusion layer next to a solid surface, and C_{jb} and C_{js} represent the concentration of species j in the bulk and at the electrode surface, respectively (17, 18). This so-called lumped mass-transfer model is useful in correlating data in complicated geometries not amenable to analytical attack. With the simple tubular geometry under consideration, the gas phase diffusion process near the electrode/electrolyte surface can be more exactly described by the distributed mass-transfer model (19)

$$\frac{i}{nF} = D_j \left. \frac{\partial C_j}{\partial y} \right|_{y=0} \quad [4]$$

where $(\partial C_j/\partial y)|_{y=0}$ represents the concentration gradient of species j at the electrode/electrolyte surface. The value of this gradient is obtained either by solving the convective mass-transfer equation for component j for the entire cell or by using empirical mass-transfer correlations if available for the given cell geometry. Most previous studies have been devoted to unraveling the complicated kinetics occurring in solid-oxide electrolyte reactors. No study has been made of the effects of combined fluid mechanics and electrochemical kinetics on the optimal design and operating conditions of cells in practical devices.

A tubular cell was constructed and operated as an oxygen pump, both in a differential mode to study electrochemical kinetics, and then in an integral mode to obtain the high conversion data encountered in practice. The analysis of the experimental results obtained for the cathodic reduction of O_2 on porous Au electrodes have been presented elsewhere (20). For high inlet O_2 concentration ($P_{O_2} > 9.9 \times 10^{-3}$ atm), the current-overpotential data were correlated with a modified Butler-Volmer expression

$$I = I_{\text{app}} \left[e^{\frac{3}{2} \frac{F\eta_c}{RT}} - e^{-\frac{1}{2} \frac{F\eta_c}{RT}} \right] \quad [5]$$

where I_{app} is an apparent exchange current density which is only a function of temperature and inlet P_{O_2} and η_c is the cathodic overpotential assumed to be constant over the whole electrode surface. When $P_{O_2} < 1.0 \times 10^{-3}$ atm, the experimental results no longer obey Eq. [5]. In the region of low P_{O_2} , the cell was found to operate as an integral reactor with high overall conversion (20). The decrease in the O_2 wall concentration along the length of the cell reduced the gas phase mass-transfer rates as well as the reaction rates. Correspondingly, there was a large decrease in I_{app} with downstream position which is not accounted for by Eq. [5]. The purpose of this paper is to investigate whether Eq. [5] can be employed as a boundary condition in a more general convective-diffusion model to correlate the experimental data in the region of low P_{O_2} . The mathematical equations derived from this model were solved numerically using the method of successive over-relaxation (SOR). It is hoped that the results obtained here with the relatively simple O_2/Ar system will permit a better understanding of the dynamic behavior of other chemical systems such as hydrocarbon gas mixtures reacting in a tubular solid-electrolyte fuel cell reactor.

Theory

Convective-diffusion equation and boundary conditions.—The combined effects of gas phase mass-transfer

Fig. 1. Tubular flow geometry

and electrochemical kinetics on the O_2 concentration profiles and overall conversions were investigated for different operating variables. The tubular stabilized-zirconia cell employed in the present study is schematically shown in Fig. 1. It is assumed that gas mixtures of initial oxygen composition C_F flow through the inner tubular chamber of the reactor with a fully developed laminar velocity profile $V(z)$. Furthermore, it is assumed that the flow is incompressible and isothermal. Oxygen molecules diffuse from the bulk gas phase to the tube wall, where they undergo an electrochemical reaction at a rate given by a modified form of Eq. [5]

$$i(\xi) = K(T) \theta^{1/2}(\xi, \rho) \Big|_{\rho=1} \left[e^{\frac{3}{2} \frac{F\eta_c}{RT}} - e^{-\frac{1}{2} \frac{F\eta_c}{RT}} \right] \quad [6]$$

where $\rho = r/R_0$, $\xi = z/R_0 N_{pe}$, $\theta = C/C_F$, F is Faraday constant, and N_{pe} is the Peclet number, defined as $N_{pe} = R_0 \langle V \rangle / D$ with R_0 the tube radius, $\langle V \rangle$ the average flow velocity, and D the diffusion coefficient of O_2 . In Eq. [6], the local current density $i(\xi)$ is a function of ξ and the dimensionless O_2 concentration $\theta(\xi, \rho)$ is allowed to vary with both ξ and ρ inside the reactor, with $\theta|_{\rho=1}$ being its value at the tube wall at a given axial position ξ . Moreover, $K(T)$ is the experimentally determined rate constant defined as $K(T) = A(T) P_F$, where P_F is the partial pressure of O_2 in the feed stream; the values of $A(T)$ are given in Table II. At steady state, the convective-diffusion equation for gaseous O_2 can be written in dimensionless form as

$$(1 - \rho^2) \frac{\partial \theta}{\partial \xi} = \frac{\partial^2 \theta}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial \theta}{\partial \rho} + \frac{1}{N_{pe}^2} \frac{\partial^2 \theta}{\partial \xi^2} \quad [7]$$

The boundary conditions for Eq. [7] and the matching conditions at $\xi = 0$ are

$$\xi \rightarrow -\infty \quad \text{for all } \rho \quad \theta = 1 \quad [8a]$$

$$\infty < \xi < 0 \quad \text{for } \rho = 0 \quad \frac{\partial \theta}{\partial \rho} = 0 \quad [8b]$$

$$\text{for } \rho = 1 \quad \frac{\partial \theta}{\partial \rho} = 0 \quad [8c]$$

$$0 < \xi < \frac{L}{R_0 N_{pe}} \quad \text{for } \rho = 0 \quad \frac{\partial \theta}{\partial \rho} = 0 \quad [8d]$$

$$\text{for } \rho = 1 \quad \frac{\partial \theta}{\partial \rho} = \frac{-R_0}{C_r D} \frac{i(\xi)}{4F} \quad [8e]$$

$$\xi = \frac{L}{R_0 N_{pe}} \quad \text{for all } \rho \quad \frac{\partial \theta}{\partial \xi} \rightarrow 0 \quad [8f]$$

$$\xi = 0 \quad \theta \rightarrow \text{continuous} \quad [8g]$$

$$\frac{\partial \theta}{\partial \xi} \rightarrow \text{continuous} \quad [8h]$$

Boundary condition [8a] states that far upstream from the reactor entrance, the O₂ concentration is uniform ($C = C_r$), whereas boundary condition [8f] is a simplifying approximation which has been shown to be valid for any finite value of the mass diffusivity particularly when the concentration gradients in the radial direction are not extremely large anticipating the results, as seen in Fig. 3b, 4b, and 5b (21). That $\partial\theta/\partial\xi$ approaches zero at $\xi = L/R_0 N_{pe}$ (or $z = L$) is borne out by the behavior depicted in Fig. 3a, 4a, and 5a.

In order to evaluate the point-to-point change in the O₂ concentration at the tube wall, Eq. [7] must be solved together with boundary conditions Eq. [8a]-[8h]. The values of the wall O₂ concentration thus obtained can then be introduced into Eq. [6] to evaluate $i(\xi)$ as a function of ξ along the reactor. The total ionic current can be calculated according to

$$I = \frac{2\pi R_0 L}{R_0 N_{pe}} \int_{\xi=0}^{\xi=L/R_0 N_{pe}} i(\xi) d\xi \quad [9]$$

where L is the active cell length of the Au electrodes. If Eq. [6] is valid, then the computed values of I should agree with the measured values of the current circulating through the cell at steady state. The radially averaged bulk or mixing cup O₂ concentration at any given axial position is calculated in accordance with

$$C_{Av}(z) = \frac{\int_0^{R_0} 2\pi r v C(z, r) dr}{\int_0^{R_0} 2\pi r v dr} \quad [10]$$

which reduces for the case of fully developed laminar flow to

$$\theta_{Av}(\xi) = \int_0^1 \rho (1 - \rho^2) \theta(\xi, \rho) d\rho \quad [11]$$

Numerical methods.—The behavior of tubular reactors with catalytic walls in which chemical reaction as well as diffusion processes play important roles has been the subject of many investigations. Previous investigators have made simplifying assumptions such as neglecting the effect of axial diffusion (22-25) to facilitate the mathematical analysis of the problem, and the solutions have generally been given in terms of orthogonal eigenfunction expansions (24, 26-27). However, in the present case as well as other important situations in electrochemistry, the mass diffusivity is large and the axial velocity is low. Under solid-electrolyte working temperatures (600°-1000°C), mass diffusivities are high and ignoring axial diffusion leads to incorrect solutions to the problem, especially near the entrance of the reactor. On the other hand, the inclusion of an axial-diffusion term changes the nature of the governing equations from parabolic to elliptic type. Walker (28) studied the tubular-reactor problem with axial diffusion and first-order homogeneous and heterogeneous reactions and obtained asymptotic results for the far downstream region. Dang (29-30) presented an exact analysis of a similar problem for the entire domain $-\infty < z$

$< \infty$. In this analysis, the eigenvalues and eigenfunctions in the upstream region ($z < 0$) and positive downstream ($z > 0$) region are first obtained separately and then both solutions are matched at the reactor entrance $z = 0$. It has been shown that, for the case of a first-order heterogeneous reaction, the error arising in the inlet dimensionless concentrations if axial diffusion is not included can be as large as 50% for small N_{pe} , and with the error increasing when either N_{pe} decreases or the heterogeneous reaction rate constant increases (29). When the heterogeneous rate expressions are not first order, boundary condition [8e] becomes nonlinear, and one usually has to resort to numerical methods in order to obtain complete solutions to the problem. Because of the simple geometry of a tubular reactor, finite-difference schemes have been used in the past to analyze heat- or mass-transfer problems in such systems. Cleland and Wilhelm (25) used a finite-difference approach to study diffusion and reaction in a viscous-flow reactor but did not consider axial diffusion. Poirier (31) used a similar technique to extend the results of Cleland to second-order reactions. In the field of heat transfer, investigators have frequently used numerical techniques to approximate solutions to the classical Graetz problem with constant wall temperature and uniform heat-flux density boundary conditions (32-33).

In the present work, first and second derivatives are approximated by central difference operators resulting in a leading error of the order of $(\Delta\xi)^2$ and $(\Delta\rho)^2$ for derivatives in the axial and radial direction, respectively (34). The finite difference equation corresponding to Eq. [7] is

$$[1 - (j - 1)^2(\Delta\rho)^2] \frac{\theta_{i+1,j} - \theta_{i-1,j}}{2\Delta\xi} = \frac{\theta_{i,j+1} - 2\theta_{i,j} + \theta_{i,j-1}}{(\Delta\rho)^2} + \frac{1}{(j - 1)\Delta\rho} \frac{\theta_{i,j+1} - \theta_{i,j-1}}{2\Delta\rho} + \frac{1}{N_{pe}^2} \frac{\theta_{i+1,j} - 2\theta_{i,j} + \theta_{i-1,j}}{(\Delta\xi)^2} \quad [12]$$

where $\theta_{i,j}$ is the dimensionless O₂ concentration at the (i, j) mesh point with $i = 1, 2, \dots, M$ and $j = 1, 2, \dots, N$. Due to the elliptic nature of Eq. [7], boundary conditions are assigned around the complete domain of integration. As a result, it is not possible to use a simple marching procedure to obtain the solution. Therefore, the large system of equations that arises after applying Eq. [12] at every mesh point has to be solved simultaneously. Fortunately, the number of zero elements in the coefficient matrix associated with this system of equations is much greater than the number of nonzero elements. For this type of matrix, iterative methods of solution are in general found to be more efficient than direct methods, since no computation is required with zero coefficients and considerably fewer numbers need to be stored in the computer (34-36). It is convenient when working with iterative methods to express the finite-difference equation [12] in the form of a five-point difference equation (34)

$$\theta_{i,j} = \frac{1}{A_j} [B_j \theta_{i,j+1} + C_j \theta_{i-1,j} + D_j \theta_{i,j-1} + E_j \theta_{i+1,j}] \quad [13]$$

with

$$A_j = A = \frac{2}{(\Delta\rho)^2} + \frac{2}{N_{pe}^2 (\Delta\xi)^2}$$

$$B_j = \frac{1}{(\Delta\rho)^2} + \frac{1}{2(j - 1)(\Delta\rho)^2}$$

$$C_j = \frac{1}{N_{pe}^2 (\Delta\xi)^2} + \frac{1 - (j - 1)^2(\Delta\rho)^2}{2\Delta\xi}$$

$$D_j = \frac{1}{(\Delta\rho)^2} - \frac{1}{2(j - 1)(\Delta\rho)^2}$$

$$E_j = \frac{1}{N_{pe}^2 (\Delta\xi)^2} - \frac{1 - (j - 1)^2(\Delta\rho)^2}{2\Delta\xi}$$

Fig. 2. A: Grid configuration (2:1): two axial zones and one radial zone. B: Grid configuration (4:1): four axial zones and one radial zone. C: Grid configuration (4:2): four axial zones and two radial zones. D: Details of the rectangular grids used in the numerical computations.

The three grid configurations which were used in this study are schematically shown in Fig. 2a-2c. Each of the axial regions contains $M \times N$ mesh points, where N is the number of points along the radial direction and M is the number of points in the axial direction as shown in Fig. 2d. For all internal points, Eq. [13] is applicable. The equations describing the points at the boundaries of each region are obtained by combining Eq. [13] with the appropriate boundary conditions Eq. [8a]-[8f] as shown in the Appendix. A FORTRAN computer program based on the SOR method together with a ten-step Newton linearization loop (34, 35) was written to solve the resulting system of nonlinear algebraic equations. The algorithm for the SOR scheme can be written for internal mesh points as

$$\theta_{i,j}^{(n+1)} = \frac{1}{A} [B_j \theta_{i,j+1}^{(n)} + C_j \theta_{i,j-1}^{(n+1)} + D_j \theta_{i,j-1}^{(n+1)} + E_j \theta_{i+1,j}^{(n)}] W - (W-1) \theta_{i,j}^{(n)} \quad [14]$$

when n represents the previous n^{th} iterative step and the expression in square brackets is seen to contain some terms calculated earlier in the present $(n+1)^{\text{th}}$ iteration and W is the acceleration parameter characteristic of the SOR method, usually in the range $1 < W < 2$. The numerical procedure involved assuming initial values of the concentration at all mesh points, usually 0.90 for θ in the region $\xi < 0$ and 0.10 for θ in the region $\xi > 0$. These initial guess values were then iteratively improved with Eq. [13] and Eq. [A-1]-[A-11] until the difference in the dimensionless concentrations between successive approximations reached a termination condition. The criterion used for terminating the computation was

$$\sum_{i=1}^M \sum_{j=1}^N [|\theta_{i,j}^{(n+1)} - \theta_{i,j}^{(n)}| + |\theta_{i,j}^{(n+1)} - \theta_{i,j}^{(n)}|] < 10^{-5} \quad [15]$$

Experimental Procedures

The reactor was constructed with a 10 mole percent Y_2O_3 -stabilized ZrO_2 tube (15 cm long and 2.5 cm od). Working and reference Au electrodes were made from unfluxed Engelhard gold paste no. A-3156. The working electrodes (10 cm long) have a superficial area of 80 cm^2 and an average thickness of $5-8 \mu\text{m}$. All experimental runs were carried out at atmospheric pressure and in the temperature range $650^\circ-850^\circ\text{C}$. Certified standard O_2/Ar mixtures and research-grade O_2 from Matheson were used. The cell was operated as an oxygen pump in which O_2 mixtures circulated in the inner chamber and air circulated in the outer chamber. In order to avoid reducing the zirconia electrolyte, the external voltage applied to the cell never exceeded 1.5V. Additional details regarding the apparatus and procedures are given elsewhere (20).

Numerical Results and Discussion

In order to check the accuracy of the numerical scheme, the FORTRAN computer program was employed to investigate a similar mass-transfer problem which involves a simple first-order heterogeneous reaction at the tube wall as well as a first-order homogeneous reaction. The numerical results obtained for the dimensionless oxygen concentration θ at the reactor entrance ($\xi = 0$) and at the reactor outlet ($\xi = 1.125$) are then compared with semianalytical results available in the literature (30). Three different grid configurations were tested as depicted in Fig. 2a-2c, and the results are given in Table II. As expected, subdividing the basic configuration into four axial regions (4:1) increased the computing time as compared with two axial regions (2:1), but the accuracy was significantly improved as a result of a finer mesh size around $\xi = 0$ where a step change occurs in the wall boundary condition. Further subdivision into two radial regions with finer step size near the wall (4:2) increased the computing time but did not considerably improve the accuracy of the solution. The grid configuration (4:1) with four axial zones and one radial zone was thus chosen on this basis for all standard runs. Different radial step sizes were tested with this grid configuration. As shown in Table II, increasing the number of radial or axial steps from 2 to 3 more than doubled the computing time but did not improve the solution significantly. Based on these results, values of $M = 21$ and $N = 21$ were used throughout this work.

Complete concentration profiles were obtained for experimental conditions with Peclet numbers ranging from 1 to 20, temperatures from 650° to 850°C , O_2 feed concentrations from 0.009 to 21 volume percent (v/o), and cathodic overpotentials from 50 to 1000 mV. Over-relaxation parameters in the range 1.7-1.9 were found to be the most appropriate, with the larger values corresponding to runs with Peclet numbers $N_{pe} < 2$. For higher N_{pe} , smaller relaxation parameters had to be used in order to avoid divergence or oscillations in the rate of convergence Q

$$Q = \frac{\sum_i \sum_j [|\theta_{i,j}^{(n+1)} - \theta_{i,j}^{(n)}| + |\theta_{i,j}^{(n+1)} - \theta_{i,j}^{(n)}|]}{\sum_i \sum_j [|\theta_{i,j}^{(n)} - \theta_{i,j}^{(n-1)}| + |\theta_{i,j}^{(n)} - \theta_{i,j}^{(n-1)}|]} \quad [16]$$

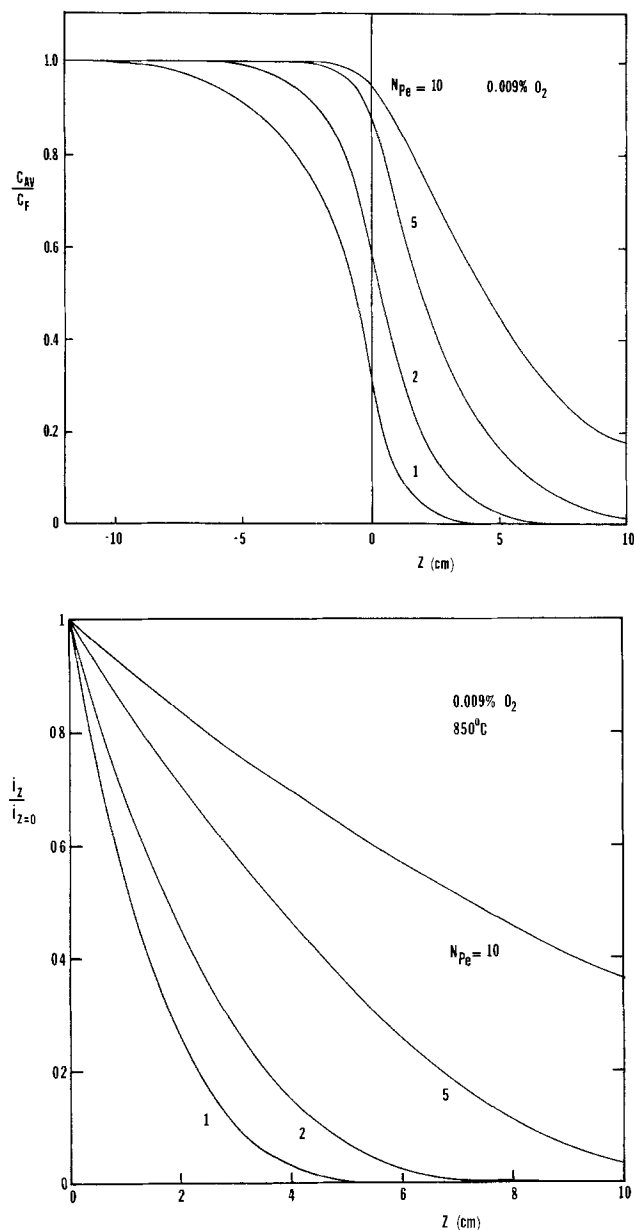

Fig. 3. a(top left): Dimensionless average oxygen concentration vs. axial position with Peclet number as a variable. ($T = 850^\circ C$, $\eta_c = 700$ mV, $C_F = 0.009$ v/o). b(above): Dimensionless oxygen concentration vs. dimensionless radial position at $Z = 0$ (solid curves) and $Z = L$ (dashed curves) with Peclet number as a variable. ($T = 850^\circ C$, $\eta_c = 700$ mV, $C_F = 0.009$ v/o). c(left): Dimensionless local ionic current vs. axial position with Peclet number as a variable. ($T = 850^\circ C$, $\eta_c = 700$ mV, $C_F = 0.009$ v/o).

By choosing the appropriate value of W , the rate of convergence Q was significantly improved and the total number of iterations necessary to reach the termination condition Eq. [15] was reduced to about one-quarter of those necessary when $W = 1$, which corresponds to the Gauss-Seidel iterative scheme. The rate of convergence increased with increasing N_{Pe} and η_c . In the first case, the faster convergence was related to a smaller dimensionless axial step size, while increasing η_c resulted in a larger concentration gradient at the wall. In general, the number of iterations required for termination ranged from about 150 for $N_{Pe} = 20$, high η_c and $C_F = 0.009$ v/o to about 500 for $N_{Pe} = 1$, low η_c , and $C_F = 21$ v/o. The local ionic currents are calculated according to Eq. [6]; Simpson's rule for integration was used to evaluate the averaged bulk concentrations according to Eq. [11].

As expected, the shape of the concentration profiles was highly influenced by the magnitude of N_{Pe} as shown in Fig. 3a. As the convective velocity, and thus N_{Pe} , decreases, backmixing increases owing to the effect of axial diffusion penetrating further into the region upstream from the reactor entrance causing the dimensionless average concentration at $\xi = 0$ to depart significantly from unity. As seen in Fig. 3b, when N_{Pe} decreases, the radial concentration profiles become somewhat flatter due to the increasing importance of the mixing effect of radial diffusion. The expected decrease in the local ionic-

current ratio flowing through the electrolyte as a function of axial position is evident in Fig. 3c for different N_{Pe} .

The concentration and current profiles obtained for different inlet O_2 concentrations C_F is shown in Fig. 4a-4c. For a given η_c , the average amount of O_2 that reacts at the wall relative to the concentration in the feed C_F increases with decreasing C_F , tending to increase the effect of axial diffusion as seen in Fig. 4a. From Fig. 4b, it can be seen that the radial concentration profiles become steeper at lower values of C_F as well as flatter downstream from the entrance because of the effect of convective mass transport. The expected decrease in $i(\xi)$ with axial position is shown in Fig. 4c for different C_F , and the growing importance of the electrochemical reaction at the wall is evident at lower concentrations.

The influence of the overpotential η_c upon the concentration profiles is shown in Fig. 5a-5b. An increase in η_c causes a significant increase in the electrical driving force term of the rate expression Eq. [6] in such a way that the reaction rates at the wall become much higher. As seen in Fig. 5a, this increase in the reaction rates causes backmixing to become more pronounced, with the O_2 concentrations at $\xi = 0$ deviating further from unity as η_c is increased. The overall conversions also increase with increasing η_c in such a way that, in two cases, conversions on the order of 99.99% are attained at moderate values of η_c , as seen in Fig. 5a. In these cases, further increases in

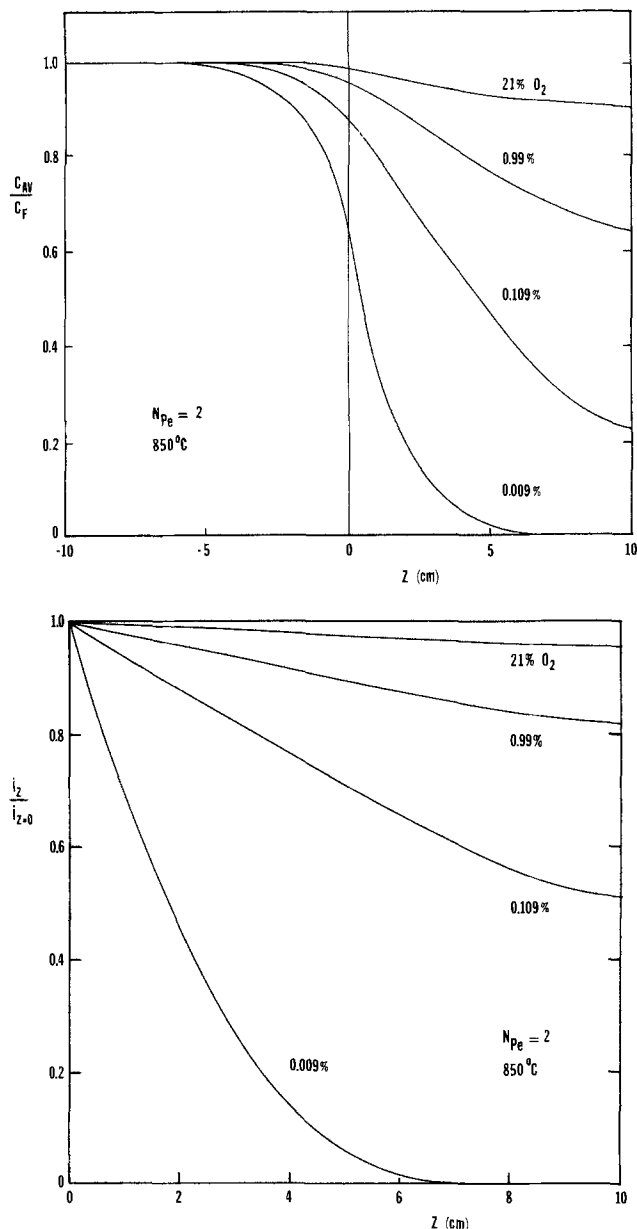

Fig. 4 a(top left): Dimensionless average oxygen concentration vs. axial position with oxygen concentration in the feed as a variable. ($T = 850^\circ C$, $N_{Pe} = 2$, $\eta_c = 700$ mV.) b(above): Dimensionless oxygen concentration vs. dimensionless radial position at $Z = 0$ (solid curves) and $Z = L$ (dashed curves) with oxygen concentration in the feed as a variable. ($T = 850^\circ C$, $N_{Pe} = 2$, $\eta_c = 700$ mV; A = 21 v/o O_2 , B = 0.99%, C = 0.109%, and D = 0.009%.) c(left): Dimensionless local ionic current vs. axial position with oxygen concentration in the feed as a variable. ($T = 850^\circ C$, $N_{Pe} = 2$, $\eta_c = 700$ mV.)

η_c do not lead to an appreciable increase in the overall conversion and the calculated total currents approach limiting values. These limiting values of current correspond to the current plateaus experimentally observed at low P_{O_2} (20). Figure 5b shows that as η_c is increased the radial concentration profiles become steeper, owing to the presence of a high slope of concentration at the wall and the high reaction rate (see Eq. [4]).

The variation of the current density (based on electrode superficial area) with respect to axial position is shown in Fig. 6a-6d for four different inlet O_2 concentrations. At a given η_c , the area under the $i(z)$ vs. z curves determines the value of the total ionic currents. It is seen in Fig. 6a that when air is circulated through the inner chamber, a nearly uniform current distribution results along the reactor for all applied potentials investigated and the reactor is operating in a differential regime. However, when gas mixtures of lower O_2 content are circulated through the oxygen pump, the reactor departs significantly from the differential regime. At moderate to high values of η_c , there is a substantial drop in $i(z)$ with axial position along the reactor. As shown in Fig. 6b and 6c, corresponding respectively to $C_F = 0.99$ and 0.109 v/o, this situation becomes evident when η_c is in the proximity of 1000 mV. For lower inlet O_2 concentrations, the marked decrease in $i(z)$ at high η_c as seen in Fig. 6d indicates that the applied potential E has reached a point beyond which any further increase in E does not give rise to an increase in current.

In these cases, the local current density $i(z)$ drops to negligibly small values at a distance before the end of the active cell region. The length of reactor effectively used is then significantly less than the actual total cell length as evidenced in Fig. 6d. In this particular case, when η_c reaches 1000 mV, most of the ionic current originates in an effective reaction zone corresponding to approximately one-third of the total cell length. The length of the cell being effectively used can be increased by increasing the flow rates and keeping the overall conversion at around 99.99%. During this process, the total ionic current will also increase. Eventually, the gas flow rate reaches a value at which the effective cell length is equal to the total cell length. Beyond this point, further increases in the flow rate will lead to a decrease in the overall conversion.

The effect of temperature on the axial concentration profiles is summarized in Fig. 7. The general trend can be interpreted in terms of an increase in the rate of the electrochemical reaction with increasing temperature as would be expected from the Arrhenius rate expression.

In order to test the validity of the above convective-diffusion model and the accuracy of the numerical solutions, the total ionic currents obtained numerically from Eq. [9] for different values of temperature, inlet O_2 , η_c , and flow rate were compared with the experimentally measured values. For intermediate and high O_2 concentrations ($C_F \geq 0.99$ v/o), the reactor was operating effectively in the differential mode with low overall conversion

Fig. 5. a(left) Dimensionless average oxygen concentration vs. axial position with cathodic overpotential as a variable. ($T = 850^{\circ}\text{C}$, $N_{\text{Pe}} = 2$, $C_{\text{F}} = 0.009$ v/o). b: Dimensionless oxygen concentrations vs. dimensionless radial position at $Z = 0$ (solid curves) and $Z = L$ (dashed curves) with cathodic overpotential as a variable. ($T = 850^{\circ}\text{C}$, $N_{\text{Pe}} = 2$, $C_{\text{F}} = 0.009$ v/o; A = 200 mV, B = 400 mV, C = 700 mV, and D = 1000 mV.)

throughout the complete overpotential range. As a result, Eq. [6] can be directly used to correlate the current-overpotential data because the change in the O_2 concentration at the tube wall along the reactor is negligible as shown from the above results. However, for lower O_2 concentrations ($C_{\text{F}} < 0.109$ v/o), the reactor enters the integral mode of operation as η_{c} is increased. In this case, it is seen in Fig. 8 and 9 that when changes in O_2 concentration at the tube wall with respect to axial position along the reactor are computed, the resulting total currents obtained from numerical integration of Eq. [9] agree very well with the measured curves of the steady-state current circulating through the cell, indicating that Eq. [6] still provides a valid description of the electrode kinetics associated with the cathodic reduction of O_2 . That the reactor is operating in the integral mode is confirmed by mixing cup fractional conversions ranging from 0.7 to 0.99 in these figures.

The analysis developed here for a tubular solid-electrolyte flow reactor is flexible enough to be applicable with appropriate modifications to any complex form of heterogeneous rate expression. Thus, the investigation of the electrochemical kinetics and/or overall reactor performance for a wide variety of reacting systems, including the decomposition of oxygen bearing species (37), oxidative dehydrogenation of hydrocarbons (38), and the anodic oxidation of gaseous hydrocarbons (39), is amenable to analyses by the numerical scheme presented herein. This model is currently being applied to the electro-oxidation of hydrocarbon gas mixtures such as produced from coal to produce electrical energy as well as valuable chemicals in the so-called "chemical cogeneration" mode of operation. For such fuel cell systems operating with large overall conversions, the assumption of isothermal flow might not be adequate due to thermal effects of the reaction on the wall, and it might be necessary to include an energy balance. The energy balance would then need to be solved numerically together with the convective-diffusion equation. Finally, in cases where large concentration gradients arise in the radial direction, boundary condition Eq. [8f] is less valid, and it might become necessary to recast the mass-transfer problem in the region $L/R_0 N_{\text{Pe}} < \xi$

$< +\infty$ by employing the exact boundary condition $\partial\theta/\partial\xi \rightarrow 0$ as $\xi \rightarrow \infty$. These two additional complexities are currently being incorporated into the numerical scheme.

Conclusions

It has been shown that by solving a general convective-diffusion equation which incorporates axial as well as radial diffusion and a complex electrochemical reaction at the wall, the performance of a tubular stabilized-ZrO₂ oxygen pump operating in the integral mode can be satisfactorily described. The electrochemical kinetics associated with the cathodic reduction of O_2 at the wall was correlated with a modified Butler-Volmer equation. The resulting system of nonlinear equations was numerically solved by the method of successive overrelaxation (SOR). The numerical results indicate that axial diffusion exerts the greatest influence on the concentration profiles at low N_{Pe} , low inlet P_{O_2} , and high values of η_{c} . The total ionic currents computed from these concentration profiles are consistent with those observed experimentally.

APPENDIX

To obtain the equations describing the points on the grid boundaries, Eq. [13] must be combined with the appropriate boundary condition as follows.

(i) For points at $\xi = -\infty$, Eq. [8a] is used

$$\theta_{i,j} = 1 \quad [\text{A-1}]$$

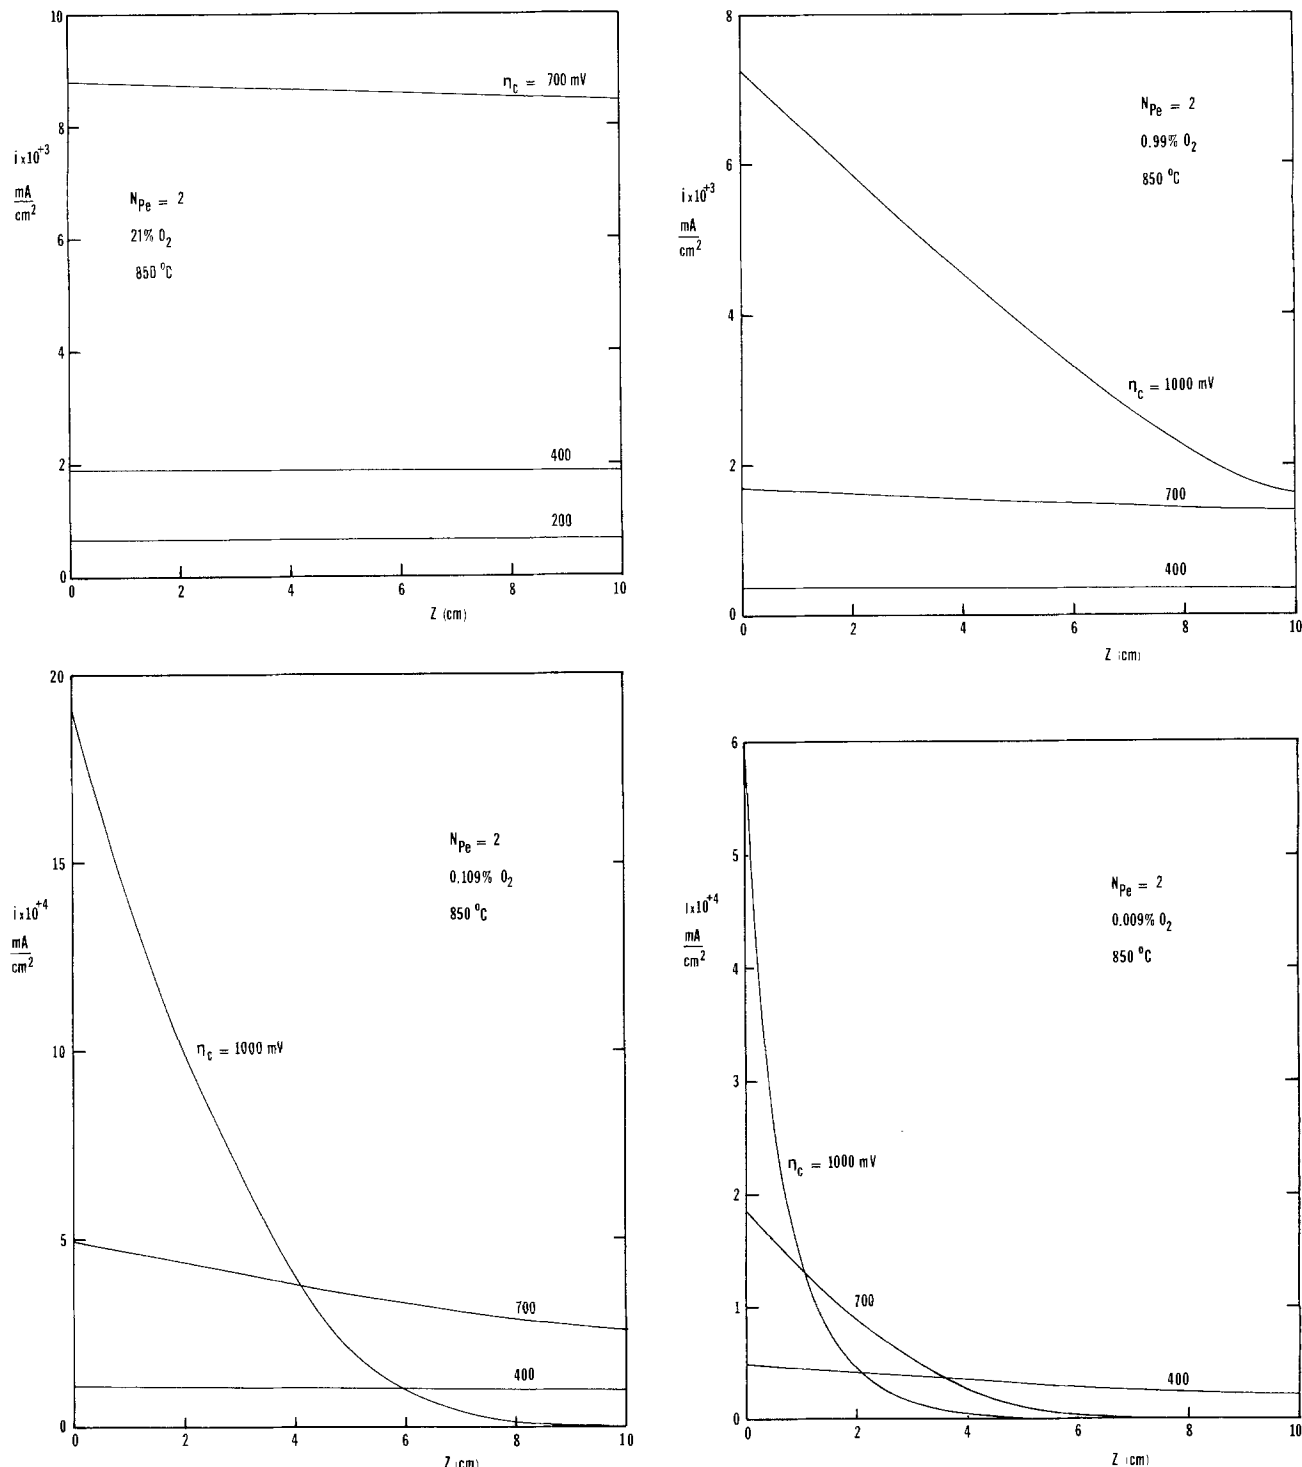

Fig. 6. a(top left): Local ionic current vs. axial position with cathodic overpotential as a variable. ($T = 850^\circ\text{C}$, $N_{Pe} = 2$, $C_F = 21$ v/o.) b(top right): Local ionic current vs. axial position with cathodic overpotential as a variable. ($T = 850^\circ\text{C}$, $N_{Pe} = 2$, $C_F = 0.99$ v/o.) c(bottom): Local ionic current vs. axial position with cathodic overpotential as a variable. ($T = 850^\circ\text{C}$, $N_{Pe} = 2$, $C_F = 0.109$ v/o.) d: Local ionic current vs. axial position with cathodic overpotential as a variable. ($T = 850^\circ\text{C}$, $N_{Pe} = 2$, $C_F = 0.009$ v/o.)

with lengths corresponding to $\xi = -\infty$ at which boundary condition Eq. [A-1] is satisfied being found by trial and error.

(ii) In order to use a central difference operator for points at the wall, it is usual to introduce a "fictitious" concentration θ_{i,N^*+1} at the external mesh point ($i, N^* + 1$) (26). From Eq. [8c], it is then obtained that

$$\theta_{i,N^*+1} = \theta_{i,N-1} \quad [\text{A-2}]$$

If Eq. [13] is written for all points at the wall, i.e., for $i = N$ and then all the terms involving θ_{i,N^*+1} replaced with Eq. [A-2], the following equation is obtained for points at the wall in the region $\xi < 0$

$$\theta_{i,N} = \frac{1}{A} [C_N \theta_{i-1,N} + D_N \theta_{i,N-1} + E_N \theta_{i+1,N}] \quad [\text{A-3}]$$

with

$$C_N = \frac{1}{N_{Pe}^2 (\Delta\xi)^2} \quad D_N = \frac{2}{(\Delta\rho)^2} \quad E_N = \frac{1}{N_{Pe}^2 (\Delta\xi)^2}$$

(iii) Similarly, for points at the wall in the reaction zone ($0 < \xi < L/R_0 N_{Pe}$), the finite difference form of Eq. [8e] becomes

$$\theta_{i,N^*+1} = \theta_{i,N-1} - 2(\Delta\rho) \frac{R_0}{C_F D} \frac{K(T)}{4F} \theta_{i,N^{*+1/2}} [e^{\frac{3}{2} \frac{F\eta_c}{RT}} - e^{-\frac{1}{2} \frac{F\eta_c}{RT}}] \quad [\text{A-4}]$$

Fig. 7. Dimensionless average oxygen concentration vs. axial position with temperature as a variable. ($N_{Pe} = 2$, $C_F = 0.009$ v/o, $\eta_c = 700$ mV.)

and combining Eq. [A-4] with Eq. [13] to eliminate the unknown $\theta_{i,N+1}$ yields

$$\theta_{i,N} = \frac{1}{A} [C_N \theta_{i-1,N} + D_N \theta_{i,N-1} + E_N \theta_{i+1,N}] - 2B_N(\Delta\rho)$$

$$\frac{R_o}{C_F D} \frac{K(T)}{4F} \theta_{i,N}^{1/2} \left[e^{\frac{3}{2} \frac{F\eta_c}{RT}} - e^{-\frac{1}{2} \frac{F\eta_c}{RT}} \right] \quad [A-5]$$

with

Fig. 8. Plot of $\log I$ vs. η_c for low P_{O_2} at 750°C showing comparison with numerical results (points).

Fig. 9. Plot of $\log I$ vs. η_c for low P_{O_2} at 850°C showing comparison with numerical results (points).

$$B_N = \frac{1}{(\Delta\rho)^2} + 0.5 \quad C_N = \frac{1}{N_{Pe}^2(\Delta\rho)^2}$$

$$D_N = \frac{2}{(\Delta\rho)^2} \quad E_N = \frac{1}{N_{Pe}^2(\Delta\xi)^2}$$

(iv) By combining Eq. [8b] or [8d] with Eq. [13], the following equation is obtained for the points at the centerline ($i = 1, 2, \dots, M$ and $j = 1$)

$$\theta_{i,1} = \frac{1}{A} [B_1 \theta_{i,2} + C_1 \theta_{i-1,1} + E_1 \theta_{i+1,1}] \quad [A-6]$$

with

$$B_1 = \frac{2}{(\Delta\rho)^2} \quad C_1 = \frac{1}{N_{Pe}^2(\Delta\xi)^2} \quad E_1 = \frac{1}{N_{Pe}^2(\Delta\xi)^2} - \frac{1}{2\Delta\xi}$$

(v) Proceeding in a similar fashion with Eq. [8f] and Eq. [13] yields the equation for the internal mesh points at the far right boundary ($i = M$ and $j = 2, 3, \dots, N - 1$)

$$\theta_{M,j} = \frac{1}{A} [B_j \theta_{M,j+1} + C_j \theta_{M-1,j} + D_j \theta_{M,j-1}] \quad [A-7]$$

with

$$B_j = \frac{1}{(\Delta\rho)^2} + \frac{1}{2(j-1)(\Delta\rho)^2} \quad C_j = \frac{2}{N_{Pe}^2(\Delta\xi)^2}$$

$$D_j = \frac{1}{(\Delta\rho)^2} - \frac{1}{2(j-1)(\Delta\rho)^2}$$

(vi) To obtain the equation for the single point located at the wall of the far right boundary ($i = M$ and $j = N$), Eq. [8e], [8f], and [13] are used together

$$\theta_{M,N} = \frac{1}{A} [C_N \theta_{M-1,N} + D_N \theta_{M,N-1}] - 2B_N(\Delta\rho)$$

$$\frac{R_o}{C_F D} \frac{K(T)}{4F} \theta_{M,N}^{1/2} \left[e^{\frac{3}{2} \frac{F\eta_c}{RT}} - e^{-\frac{1}{2} \frac{F\eta_c}{RT}} \right] \quad [A-8]$$

with

$$B_N = \frac{1}{(\Delta\rho)^2} + 0.5 \quad C_N = \frac{1}{N_{pe}^2(\Delta\xi)^2} \quad D_N = \frac{1}{(\Delta\rho)^2}$$

(vii) Finally, Eq. [8d], [8f], and [13] are used to obtain the equation for the point located at the centerline of the far right boundary ($i = M$ and $j = 1$)

$$\theta_{M,1} = \frac{1}{A} [B_M \theta_{M,2} + C_M \theta_{M-1,1}] \quad [A-9]$$

with

$$B_M = \frac{2}{(\Delta\rho)^2} \quad C_M = \frac{2}{N_{pe}^2(\Delta\xi)^2}$$

The basic grid configuration used in this study contains four axial regions and one radial region (Fig. 2b). Whenever this layout was used, Eq. [13] was applied at all internal mesh points and Eq. [A-1]-[A-9] to boundary points as indicated. Matching conditions Eq. [8g] and [8h] were used to solve for the values of the concentration at $\xi = 0$

$$\theta_{M,j^I} = \frac{(\Delta\xi)^j}{(\Delta\xi)^{II}} \theta_{2,j^{II}} + \theta_{M-1,j^I} / 1 + \frac{(\Delta\xi)^j}{(\Delta\xi)^{II}} \quad [A-10]$$

$$\theta_{1,j^{II}} = \theta_{M,j^I} \quad [A-11]$$

where superscripts I, II denote the values of θ in the region $\xi < 0$ and $\xi > 0$, respectively.

Toward an Understanding of the Adhesion of PVA-Deposited MP1 Phosphor DVST Screens

Gordon Sletmoe

Tektronix, Incorporated, Beaverton, Oregon 97077

ABSTRACT

MP1 is an MgO surface-modified version of in-house prepared P1 phosphor ($Zn_2SiO_4:Mn$). Reports of "loose phosphor" at CRT Test for a particular lot of this material prompted the present study. Before determining why adhesion varied from lot to lot, it first was necessary to discover the factors governing MP1 adhesion. Contrary to expectations, the surface magnesium was found to exist in two forms: (i) free MgO, which is bad for adhesion, and (ii) $MgSiO_3$, which is beneficial. Process modifications could, however, turn MgO to an advantage by first causing the dissolution of much of this material and then later the redepositing of a small but important portion of it at the phosphor/phosphor and phosphor/substrate interfaces.

In-house P1 phosphor has long been used in our direct-view storage tubes (DVST's) because of its high luminescent efficiency for low voltage bombardment (i.e., 130-300V). More recently, phosphor life was improved roughly four times, with minimal loss of efficiency, by coating the P1 with fine particle MgO, followed by subsequent firing in air at 800°C. This temperature was thought to be high enough to cause chemical combina-

tion of the coating with the underlying silicate material of the P1, while not degrading the basic crystalline properties of the P1 structure. The morphology of the underlying P1 structure as well as that of the magnesium-rich surface nodules are apparent in Fig. 1.

Because of the low voltage operation, DVST screens are not aluminized but rely on an indium-tin oxide (ITO) coating on the glass (together with conductive collectors)

Fig. 1. SEM photographs of MP1 phosphor particles. Figure 1b (bottom) is a ten times enlargement of the center of Fig. 1a (top).

to maintain the phosphor potential and to collect secondary electrons. Without an aluminum overcoat, individual phosphor grains experience significant coulombic attraction under certain operating conditions, as when the nearby wall bands are at a potential of +150V and the screen is suddenly switched to +300V.

To prevent phosphor from covering the collector dots, the polyvinyl alcohol/ammonium dichromate (PVA/AD) photodeposition process is used for depositing phosphor. Exposure is through the glass, with the collectors serving as their own photomask. A slurry version of this process is used to prepare the devices under study. The slurry, consisting of phosphor suspended in a solution of PVA and AD in a mixture of water and an organic solvent, is settled for 20 min before exposure. This permits most of the phosphor to settle to the bottom of the fluid. After exposure through the glass, a controlled fraction of the phosphor is immobilized by the gelled PVA, while the remainder may be decanted off. Remaining unreacted material is then removed by extensive water rinsing in the spray rinser. Finally, the screen is dried and then sent on for bakeout.

In the case of spherically curved screens (as with the 19 and 25 in. devices), slurry depth—and hence ultimate phosphor loading—is kept uniform by the centrifugal effect of slow rotation of the screens during the settling and exposure steps.

Experimental

During the initial phase of this project, Production Engineering had developed a "blow-off" type of adhesion tester, the results of which correlated well with loose

phosphor at test. This would allow the evaluation of adhesion on coated face plates rather than on completed CRT's, thereby greatly increasing the number of tests which could be evaluated. It was a simple arrangement of a glass tube positioned at a fixed distance from the substrate under test. Dry nitrogen flow rate was controlled by a variable pressure regulator. Pressure was advanced in a regulated manner until a massive blow off was experienced. With an arbitrary adhesion value of 10 units, the standard deviation was of the order of 1 unit. If ten samples of the same type were measured, the uncertainty of the mean value at the 95% confidence level would be $\pm 2/3$ of a unit.

Now the most interesting findings of this study pertained to the complex interaction between the deposition process and the surface composition of the phosphors. Before discussing this, however, let us first consider some information concerning the influence of substrate type as well as phosphor particle size upon adhesion.

Figure 2 depicts several adhesion effects related to the substrate. The production problem was experienced on ITO-coated, curved 19 in. screens (with a relatively rough, stippled surface). For comparison the adhesion of the same material (Lot no. 18A) on other substrates is shown. Also shown is how these data compare to the adhesion of another lot of material (Lot no. B17). To obtain the 19 in. data, two panels were specially modified to have four different kinds of surfaces on the same panel (i.e., naturally stippled and specially smoothed, both coated by ITO as well as uncoated). By repeated deposition of phosphor, measurement of adhesion, removal of phosphor, and redeposition, etc., a fairly strong and internally consistent data base was built up. For convenience in this and most subsequent adhesion experiments, the normal collector dots were omitted.

The greatest adhesion difference here was that between curved 19 in. screens and flat 5 in. screens, regardless of surface coating or roughness. A second significant, although less striking, observation was that adhesion was better to specially polished 19 in. screens as compared to those with the regular texture. Whereas ITO vs. uncoated had little effect on 19 in. targets or with Lot no. B17 on 5 in. targets, there was a substantial ITO effect for Lot no. 18A on 5 in. screens.

The most plausible explanation for this data is thought to be (i) that smooth substrates are more favorable than rough, (ii) Lot no. 18A is generally better adhering than Lot no. B17, and finally, (iii) although the process was held as constant as possible between flat and curved substrates, there were unavoidable differences which led to the improved adhesion of the flat screens. Some of the experimentation to be discussed was aimed at discovering which process variables were responsible for this. More important to the remainder of the program is that the adhesion of various lots of MP1 on flat screens generally paralleled their adhesion on curved screens. This

Fig. 2. Adhesion vs. CRT type, surface coating, and phosphor lot

Fig. 3. Adhesion vs. particle size for various lots and treatments

made it possible to use the more convenient flat screens for the remaining experimentation.

Figure 3 shows some results due primarily to the nature of the phosphor. Lot no. B17 was the poorly adhering lot of MP1 noted in Fig. 2. P1 (Lot no. 58C) was the lot of P1 phosphor used in the preparation of this MP1. Because the MP1 Lots no. 18A and 12B exhibited nearly identical adhesion behavior, their results were combined in this figure.

The three groups of materials were each fractionated by two techniques: (i) sedimentation in water, and (ii) air classification in a commercial air fractionator. In every case, the fines had better adhesion than the coarse material. Although of interest, this is of little practical value, as fines do not generally have the efficiency or other performance characteristics required. Especially with the MP1's, note also the regular difference between the water-settled and the corresponding air-fractionated samples. Now as determined from particle size analyses of the various fractions, air fractionation was found to be much more efficient than water settling. Thus, the better adhesion of water-settled particles was not because they were finer than the air-classified material. The most likely reason for the better adhesion of water fractionated MP1's is that their surfaces were favorably modified by this exposure to water. This will be examined in detail below.

Although the PVA process is of primary interest to this work, it was possible to gain valuable insight from the following nonstandard screen deposition technique. Large beakers or battery jars were affixed with side arms and stopcocks near the base, to draw off fluid when required. Clean, flat face plates were then placed horizontally near the bottoms of the containers (but above the location of the drain line). After the covering of the substrates to be coated to a depth of several inches with the fluid of interest (the selection of fluids is discussed below), a phosphor slurry in the same fluid was uniformly sprinkled into the container. Phosphor was then allowed to settle onto the face plate. After suitable settling time, fluid was carefully drained off, leaving only a thin meniscus of fluid on the horizontal plate. This was then evaporated to dryness before removing the coated target.

In one test, we utilized an organic solvent, methyl ethyl ketone (MEK), as the settling fluid, to avoid hydrolysis of the magnesium surface coating. In further experiments, DI water was used as the settling medium, allowing for the possibility of simple hydrolysis, without the influence of acidity or residual chromium (as the AD) or organic residues (from the PVA). To eliminate extraneous variables, targets processed as above were given the same PVA bakeout treatment and subsequent warm/dry handling after bake until adhesion measurement was carried out, as were the standard PVA targets.

Figure 4 compares the adhesion of two lots of MP1, settled in the two fluids just described as well as deposited by the standard PVA process. Several conclusions may be drawn. Water settling results in substantially more adhesion than does MEK settling. The most probable cause

Fig. 4. Adhesion vs. settling technique for two phosphor lots

of this is related to hydrolysis of the magnesium surface coating by the water. Also, note the substantial improvement for Lot no. 18A but not for Lot no. B17 in going from water settling to the PVA reaction. Additional experimentation was called for to understand this.

With the settling technique just described, we could incorporate the PVA chemicals—one at a time—into the aqueous system, to see if we could trace adhesion differences to any one factor. Results from such work are shown in Fig. 5. Here, we see minor differences resulting from the addition of AD or straight PVA. For reference, the standard PVA data are also given. The most important result here was the great improvement resulting from the addition of acetic acid (HAc). HAc was utilized in this case as a prototype of a weak acid such as AD but without any residual chromium.

The great improvement with HAc led us to try to capitalize on this by incorporating HAc in the PVA slurry. Results were disappointing; there was only slight improvement in adhesion of the PVA samples upon addition of HAc. To understand this, we must first consider the acid/base reaction occurring between the HAc and the phosphor surface, as illustrated in the following pH study.

The pH of a solution of 1 ml glacial acetic acid in 100 ml water was about 2.7. When 10g of an MP1 were added to this solution (with continuous stirring), the pH jumped almost instantly to 6.93. Over the first 20 min, it further rose to a value of 7.19, which was close to the value of 7.22 at which it leveled off. Thus, not only was virtually all of the HAc neutralized by the MP1 phosphor, but the time required for this was within the time frame available during normal PVA processing.

Fig. 5. Adhesion as a function of additive type, in modified water settling.

Assuming this reaction resulted in the formation of soluble ions such as Mg^{++} (an assumption amply validated by the results to follow), then the fate of these soluble ions is thought to explain the observed differences between the two systems.

In the PVA system, most of the soluble ions generated in the above acid/base reaction are thought to be rinsed away during the extensive spray rinse step. In the water settling process, however, there is no analogous rinse step. Instead, whatever ions remain in the meniscus of fluid on the plate after draining are allowed to evaporate to dryness on the settled phosphor coating. Upon subsequent bakeout, Mg^{++} and Ac^- or OH^- ions would react to leave a residue of MgO . Because of capillary effects during evaporation, this material would tend to be located at the interstices between, phosphor/phosphor and phosphor/substrate—right where it would be most effective in promoting adhesion of the subsequent dry film.

At this point, it seemed possible that the various lots of MP1 owed their differing adhesion tendencies to variable concentrations and/or reactivity of magnesium compounds on their surfaces. This led us to attempt to render all of the MP1 lots the same by etching with HAc. This effort was unsuccessful, most likely because HAc is too reactive, attacking the P1 underlayer as well as the magnesium-rich surface coating. This led to the use of the more gentle AD to etch these materials. Before looking at the results of this, let us first consider why AD should react with MgO at all

As shown in Eq. [1], chromate ion from the AD hydrolyzes to bichromate ion. The equilibrium constant is of the order of unity. Bichromate ion then can dissociate to protons plus chromate ion, as in Eq. [2]. At the same time, as shown in Eq. [3] and [4], MgO hydrolyzes to magnesium hydroxide, which, in turn, sparingly dissociates to magnesium and hydroxide ions. The net effect is as shown in Eq. [5]. Because the dissociation constant of water is many orders of magnitude less than the dissociation constant of chromate ion or the solubility constant of magnesium hydroxide, Eq. [5] is shifted far to the right.

In practice, with finely divided MgO in a typical PVA/AD slurry, this reaction will go nearly to completion in the 20 min settling time employed. This has been observed in pH vs. time experiments similar to the one described above. By way of comparison, reagent $MgSiO_3$ powder is scarcely attacked by AD under these conditions (i.e., the slightly acidic pH caused by the AD remains unchanged, and there is a very low level of solubilized Mg^{++} in the reaction fluid).

Figure 6 illustrates the effect of processing upon residual magnesium levels. (All magnesium is reported here as MgO .) Starting with a typical level of 5.5 weight percent (w/o) on the incoming phosphor, roughly one-third of this is lost in preparing samples for MEK settling. Clearly, this fraction is loosely adhering and is of little value to subsequent adhesion. Additional MgO fails to survive water settling. Presumably, the removal of this loosely adhering or readily hydrolyzable material accounts for the improved adhesion of water-settled vs. MEK-settled targets. Additional MgO is lost in going to the PVA'd targets. Some or all of this increment is from solubilization by AD (as discussed above). Finally, etching of the MP1 with excess AD results in removal of still more MgO . The remainder is probably $MgSiO_3$.

Figure 7 shows the resulting adhesion by removing all of this loose as well as dissolvable MgO from a variety of lots of varying intrinsic performance. Points above and

Fig. 6. Residual percentage of MgO as a function of MP1 treatment

Fig. 7. The effect of AD etching upon adhesion of various MP1 lots

to the left of the diagonal benefited by this treatment, whereas points below and to the right were degraded. What was observed (except for the special case of Lot no. B17DF) was a leveling. Poorly adhering materials were helped while good adhering materials were degraded. This suggests that the principal difference in lots has to do with the amount and kind of loose and/or soluble MgO on the surface, whereas the underlying $MgSiO_3$ has the same adhesion in all cases. Lot no. B17DF was a refined version of the poorly adhering Lot no. B17. Here, presumably, a substantially higher fraction of the total magnesium had become chemically bound to the silicate structure. (Unfortunately, double firing degraded other performance characteristics, so this was not a practical solution. Nevertheless, it pointed in the right direction.)

To see if adhesion could be improved through PVA process optimization, the study represented by Fig. 8 was performed. The shaded area represents the somewhat reciprocal combination of exposure times and AD

Fig. 8. Residual percentage of MgO and acceptable target weight envelope as a function of PVA variables.

Fig. 9. Adhesion as a function of PVA variables

Fig. 10. Adhesion as a function of residual percentage of MgO

concentrations which yielded acceptable target weights per unit area. Screens within this "process window" would be expected to give us acceptable performance. Note the decreasing residual percentage of MgO with increased AD level. Figure 9 shows the results of this reduced percentage of MgO, where adhesion was dramatically improved. The individual data points of this array showed an excellent correlation of increasing adhesion *vs.* decreasing percentage of MgO, as shown in Fig. 10. An adverse consequence of the high AD recipe is increased residual chromium on the final target, which results in some loss of efficiency. This trade-off would have to be considered carefully in going to this new recipe.

Figure 11 is a composite, comparing the advantages of a high AD recipe to the removal in advance of MgO by AD etching. In both cases, we see a leveling effect for bad and good lots. In both cases, much of the loose and/or soluble MgO has been removed. Why, then, was the high AD recipe so much more beneficial to adhesion than the pre-etch? The best answer seems to be as follows.

1. Pre-etch removes most of the soluble magnesium, making all the samples roughly similar. Differences in amounts of unetchable MgSiO_3 account for the resulting adhesion differences.

2. The high AD recipe also has the effect of removing a substantial portion of the soluble magnesium, although not as completely as with the pre-etch treatment.

3. Unlike with the pre-etch, however, the solubilized ions are formed right in the PVA slurry. Whereas many of these ions are removed during the subsequent spray rinse step (hence the low residual percentage of MgO with this treatment), a small but important amount of

Fig. 11. The effect upon adhesion of the "high AD" recipe *vs.* AD etching of various MPI lots.Fig. 12. Adhesion improvement via postdeposition MgAc_2 soak

magnesium ions is left on the phosphor to dry in the interstices and subsequently to be converted on bakeout back to MgO. To this small but effectively located amount of MgO is attributed the improved adhesion of this group relative to the pre-etched samples.

4. But why does extra AD improve adhesion, whereas added HAc in the PVA system (as discussed earlier) resulted in only slight adhesion improvement? The answer seems to be related to the fact that, in the high AD recipe, extra chromium is bound by the gelled PVA (as evidenced by high residual chromium levels in the baked targets). This bound chromium electrostatically holds an equivalent amount of Mg^{++} ions, preventing them from being rinsed away. Although small on a percentage weight basis, this strategically placed amount of material has a profound effect upon adhesion.

In support of this hypothesis. Fig. 12 indicates a group of targets, both 5 and 19 in., which were prepared in the normal manner. However, before bakeout they were soaked briefly in magnesium acetate solutions of the indicated concentration. After drying and bakeout, the magnesium acetate would have been converted to MgO. SEM studies at the highest MgAc_2 concentrations clearly showed residual MgO "glue" at the interfaces. Intermediate levels of this treatment caused minimal negative impact on luminescent efficiency, while substantially improving adhesion.

Conclusions

1. The magnesium in MPI is present in two forms: (i) MgO—soluble in AD; much of it loosely adhering, and (ii) MgSiO_3 (or related silicate)—insoluble in AD; tenaciously adhering to the phosphor.

2. Adhesion is favored by: (i) removal of MgO, (ii) the presence of MgSiO_3 , (iii) the formation of Mg deposits at

the phosphor/phosphor and phosphor/substrate interfaces, (iv), small particle size, and (v) smooth substrate.

3. Processes to improve adhesion include (i) high AD recipe in the PVA process, and (ii) postdeposition soaking in MgAc_2 solution. (In both cases, there is some fall off in efficiency with improved adhesion.)

4. Better phosphor lots presumably have less loosely adhering and/or soluble MgO deposits. This is achieved by more rigorous MgO firing conditions. (Again, care must be taken so as not to degrade efficiency.)

Photoelectrochemical Properties of Ferrites with the Spinel Structure

L. G. J. de Haart and G. Blasse

Department of Solid State Chemistry, Physics Laboratory, Utrecht University, 3508 TA Utrecht, The Netherlands

ABSTRACT

The diffuse reflection spectra and the photoelectrochemical properties of the ferrites ZnFe_2O_4 , MgFe_2O_4 , and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ with spinel structure are presented. A marked difference between the reflection spectra and the photocurrent action spectra is discussed. The onset wavelength of the photocurrent lies at about 550 nm. Steady-state photocurrents are severely limited by a relatively low absorptivity in the visible region and by surface recombination at low potentials. From an admittance spectra analysis, a value for the flatband potential of ZnFe_2O_4 was obtained, *viz.*, -0.5V vs. SCE in 1M NaOH.

The use of n-type semiconducting materials in photoelectrochemical (PEC) cells for solar energy conversion has been studied extensively in the last decade (1). In this period, much attention has been paid to iron(III)-oxide, $\alpha\text{-Fe}_2\text{O}_3$. With its bandgap of 2.2 eV, $\alpha\text{-Fe}_2\text{O}_3$ is quite suitable for solar energy conversion (2-12).

Stoichiometric $\alpha\text{-Fe}_2\text{O}_3$ is an insulator. It can be made n-type semiconducting by doping with higher valent ions. Shinar and Kennedy (10) studied extensively the way in which the performance of doped $\alpha\text{-Fe}_2\text{O}_3$ anodes depends on the nature and the concentration of the dopant. Doping with lower valent ions can lead to p-type semiconducting $\alpha\text{-Fe}_2\text{O}_3$, which acts as a photocathode in a PEC cell (13, 14).

$\alpha\text{-Fe}_2\text{O}_3$ can also be made n-type semiconducting by reduction. However, reduction treatments result mainly in the formation of a conducting Fe_3O_4 layer on the surface of the electrode. It has been proposed that recombination occurs in this layer (10, 15). This inhomogeneity after the reduction treatment is assumed to be due to the inability of the corundum structure ($\alpha\text{-Fe}_2\text{O}_3$) to tolerate large concentrations of spinel (Fe_3O_4) inclusions [Ref. (15)].

In view of this, we studied the photoelectrochemical properties of ferrites with the spinel structure. Many of these ferrites show n-type semiconducting behavior. Since these ferrites and Fe_3O_4 have the same crystal structure, they can form solid solutions. This prevents segregation on the surface.

The spinels $\text{CO}_{0.90}\text{Fe}_{2.10}\text{O}_4$ and $\text{CoFe}_{1.86}\text{Ti}_{0.14}\text{O}_4$ were investigated for use as photoanodes by Archer *et al.* (16). These materials show an almost uniform spectral response in the wavelength region from 400 to 760 nm. The quantum yield is, however, very low. A large bias had to be applied to obtain significant steady-state photoresponse.

For our investigations, we selected the spinels ZnFe_2O_4 , MgFe_2O_4 , and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$. The Zn^{2+} ion has $3d^{10}$ configuration, and the Mg^{2+} ion and the Li^+ ion both have noble gas configuration. These ions do not give rise, therefore, to optical absorption in the near-UV and visible regions. Absorption and photoeffects observed in these spectral regions must then be accounted for by transitions in which the iron ions are involved. In this way, a comparison can be made with $\alpha\text{-Fe}_2\text{O}_3$.

ZnFe_2O_4 has the normal spinel structure (17), $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ is an inverse spinel (18), and in MgFe_2O_4 the degree of inversion is around 0.9 (19), depending on the quenching temperature. The occupation of the tetrahedral and octahedral positions in the spinel structure for these compounds is thus: $\text{Zn}[\text{Fe}_2]\text{O}_4$, $\text{Fe}[\text{Li}_{0.5}\text{Fe}_{1.5}]\text{O}_4$, and $\text{Mg}_{0.1}\text{Fe}_{0.9}[\text{Mg}_{0.9}\text{Fe}_{1.1}]\text{O}_4$. In this sequence, there is a decrease in the number of iron ions on the octahedral positions. This enables us to investigate the effect of this occupancy on the photoelectrochemical properties.

Experimental

Samples were prepared by usual ceramic techniques using high purity oxides and carbonates as starting materials. Firing was performed between 1050° and 1200°C in air.

Samples were checked by x-ray powder diffraction. Diffuse reflection spectra were recorded at room temperature on a Perkin-Elmer Lambda 7 UV/VIS spectrophotometer.

For the preparation of the electrodes, stoichiometric amounts of the thoroughly mixed oxides and/or carbonates were pre-fired at 600°-700°C in air. After regrinding, the mixture was pelletized at 120-150 kg/cm². The pellets were sintered at 1150° ($\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$), at 1200° (ZnFe_2O_4), and at 1270°C (MgFe_2O_4) for 3-4h in air and cooled slowly to room temperature. The density ratio of the pellets was about 90% for the MgFe_2O_4 samples and more than 95% for the ZnFe_2O_4 and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ samples. The surfaces of the pellets were polished using emery paper (grain size: 40 μm).

By heating the pellets in a stream of nitrogen at around 700°C for 2-2.5h, they became n-type conducting. The resistivities of the pellets (~ 1 mm thick) dropped to 1-2 k Ω for the $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ pellets, to 3-5 k Ω for the ZnFe_2O_4 pellets, and 8-10 k Ω for the MgFe_2O_4 pellets. A silver paste (Degussa, leitsilber) was applied to the back of each pellet to provide electrical contact.

The surfaces of the electrodes were examined for their structure and composition with a Cambridge Stereo Scan 150 electron microscope, equipped with an energy dispersive elementary analysis system (Link Systems, Cambridge, England).

The PEC cell arrangement and photoelectrochemical measurement procedures for steady-state conditions have been described previously (20). All photocurrent densities have been corrected for variations in the light intensity by normalizing them to the number of photons at $\lambda = 470$ nm. Current-voltage scans with hand-chopped illumination were recorded on a Bryans X-Y recorder 29000 A3. Electrode potentials are referred to the saturated calomel electrode (SCE). All photoelectrochemical measurements were performed in 1M NaOH.

The admittance spectra of a PEC cell with a ZnFe_2O_4 anode were studied in the frequency range from 25 mHz to 10 kHz using a Solartron 1172 frequency response analyzer. The ac signal amplitude was kept at 20 mV (rms). Representative admittance spectra were analyzed using a computer program for nonlinear least squares fitting to complex data (21). This procedure has been applied before to analyze admittance spectra of PEC cells with TiO_2 and SrTiO_3 anodes (22, 23).

Results and Discussion

Diffuse reflection spectra.—In Fig. 1, the diffuse reflection spectra of the composition $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$ and of the compound ZnFe_2O_4 are shown. The spectrum of $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$ shows an intense absorption band around 275 nm. Around 500 nm, a shoulder can be observed. Going from the composition $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$ to ZnFe_2O_4 , a marked increase of the absorption strength in the short-wavelength part of the visible region is observed. At about 800 nm, a separate band is observed.

The Fe^{3+} ion has $3d^5$ configuration, which in an octahedral as well as a tetrahedral crystal field gives rise to a 6A_1 ground state. Since this is the only sextet state, all crystal-field (CF) transitions are both spin and, octahedral symmetry, parity forbidden. In tetrahedral symmetry, the latter selection rule is slightly relaxed. Nevertheless, these transitions are extremely weak.

Fig. 1. Diffuse reflection spectra of $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$ and of ZnFe_2O_4 .

The shoulder around 500 nm in the spectrum of $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$ can be assigned to the CF transition ${}^6A_1 \rightarrow {}^4A_1$, ${}^4E(G)$ on octahedral Fe^{3+} (24-26). The band around 800 nm in the spectrum of ZnFe_2O_4 can be assigned to the CF transition ${}^6A_1 \rightarrow {}^4T_1(4G)$ on octahedral Fe^{3+} (24). This CF transition is not observed in the spectrum of $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$. The position of this transition depends strongly on the crystal-field strength. With increasing crystal field, the transition shifts to lower energy. In the case of $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$, the Fe^{3+} ion occupies a relatively small lattice site, resulting in a stronger crystal field than in ZnFe_2O_4 . For $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$, the CF transition ${}^6A_1 \rightarrow {}^4T_1$ is expected at a lower energy, which is beyond the limit of the instrument used.

In the wavelength region between 300 and 450 nm, additional CF transitions on octahedral Fe^{3+} are expected. In the spectrum of $\text{ZnFe}_{0.02}\text{Al}_{1.98}\text{O}_4$, these are, however, masked by the tail of the strong absorption band around 275 nm. This band must be assigned to the $\text{O}^{2-} \rightarrow \text{Fe}^{3+}$ charge transfer (CT) transition. In $\text{Al}_2\text{O}_3:\text{Fe}^{3+}$, this CT transition is situated around 260 nm (27).

The spectrum of ZnFe_2O_4 shows a very strong absorption in the wavelength region from 200 to 500 nm compared to the absorptivity of the CF transitions. Around 300 nm, this is not unexpected, because the $\text{O}^{2-} \rightarrow \text{Fe}^{3+}$ CT transition is situated in this region. However, neither this CT transition nor the CF transitions can account for the intensity of the absorption in the wavelength region from 350 to about 500 nm. It should be noted that the absorption strength decreases in the region from 200 to 500 nm (28), a fact which the present type of spectra does not reveal.

The diffuse reflection spectrum in the visible region of ZnFe_2O_4 is again shown in Fig. 2, now together with the diffuse reflection spectra of MgFe_2O_4 and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$. Both latter compounds show the same relatively strong absorption as ZnFe_2O_4 in the region from 350 to about 500 nm. Around 620 nm, shoulders can be observed in the spectra of MgFe_2O_4 and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$. For these two com-

Fig. 2. Diffuse reflection spectra in the visible region of ZnFe_2O_4 , of MgFe_2O_4 , and of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$.

pounds, containing Fe^{3+} on tetrahedral sites, these shoulders can be assigned to the CF transition ${}^6A_1 \rightarrow {}^4T_1(4G)$ on tetrahedral Fe^{3+} (25).

We will return to the strong absorption observed in the region from 350 to 500 nm below in relation with the photocurrent action spectra observed for these ferrites.

Photocurrent measurements.—The steady-state photocurrent action spectra of the ferrites are shown in Fig. 3. The photocurrents start around 550 nm, but remain rather low in the visible region. Only with UV irradiation, a reasonable efficiency is obtained. For ZnFe_2O_4 with $\lambda = 300$ nm and at $V = +0.5\text{V}$, the quantum efficiency amounts approximately 25%. The spectra resemble closely the photocurrent action spectra reported for $\alpha\text{-Fe}_2\text{O}_3$ (2, 3, 6, 10). Note that for the three ferrites the photocurrent action spectra are similar (see Fig. 3). From this we conclude that the photoeffects occur on the Fe^{3+} ions on octahedral sites. This makes it tempting to relate the decrease in efficiency, observed in Fig. 3 going from ZnFe_2O_4 to MgFe_2O_4 , to the number of Fe^{3+} ions on octahedral sites in these spinels. We will show below, that care has to be taken with such an interpretation.

A comparison between the photocurrent action spectra and the diffuse reflection spectra shows, that there is a great difference between these spectra in the wavelength region from 350 to 500 nm. This will be discussed below.

In Fig. 4 a current-voltage scan is shown for a $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ anode. The insert shows the low potential part scanned with a 10-fold enlargement of the current axis. At these low potentials the photocurrents are highly transient. The transients near -0.3V are still anodic. This indicates that the flatband potential is situated at a more cathodic potential.

Significant steady-state photocurrent response starts only at $+0.3\text{V}$. Above this potential, the transients decrease and above $+0.6\text{V}$ they vanish. The dark current starts to increase steeply at $+0.6\text{V}$ due to oxygen evolution. After long-term polarization at these high anodic potentials in the dark, gas bubbles could be observed on the electrode surface. The same has been observed for $\alpha\text{-Fe}_2\text{O}_3$ electrodes (2, 4, 7).

Figure 5 shows the steady-state photocurrent-voltage curves for the three ferrites, measured with monochromatic irradiation at 300 nm. The curves measured at 380

Fig. 3. Variation of the steady-state photocurrent density with irradiation wavelength for ZnFe_2O_4 , MgFe_2O_4 , and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$.

Fig. 4. Photocurrent-voltage scan obtained for a $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ anode by scanning from left to right at 0.66 mV/s with hand-chopped irradiation ($\lambda = 300\text{ nm}$) at 1 min intervals. The insert shows the low potential region scanned with a tenfold increase in the current axis.

Fig. 5. Variation of the steady-state photocurrent density with applied potential (vs. SCE) for ZnFe_2O_4 , MgFe_2O_4 , and $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$.

and 460 nm show the same voltage dependence. In the potential region from -0.3V to about $+0.3\text{V}$ a low photocurrent is observed, which increases very slowly. Above $+0.3\text{V}$, the photocurrent increases steeply with increasing potential and tends to reach saturation above $+0.7\text{V}$. For some electrodes, however, the photocurrent showed a maximum value around $+0.7\text{V}$ followed by a fast decrease with increasing potential. This feature was also observed for $\alpha\text{-Fe}_2\text{O}_3$, by Ono *et al.* (29).

Photocurrent-voltage curves reported for $\alpha\text{-Fe}_2\text{O}_3$ (2, 5, 7, 9, 12) show a similar behavior as reported here for the ferrites. In several cases, however, the onset potential of the photocurrent (*i.e.*, the potential at which the photocurrent starts to rise steeply) was situated at more cathodic potentials, although the measurements were performed in the same electrolyte (2, 5, 12). Transients were also observed for $\alpha\text{-Fe}_2\text{O}_3$ electrodes (4, 9, 12, 30). These features, as well as the low steady-state photocurrent in the potential region from -0.3 to $+0.3\text{V}$, can be explained in terms of surface recombination or back reaction of the photogenerated species (30). Oxygen (or a hydroxyl radical) produced by the photogenerated holes produces a back reaction and a cathodic current component by reacting with an electron at the surface. This is equivalent to a surface electron-hole recombination (31). This cathodic current component decreases as the potential is made more positive (30).

The steady-state photocurrent in the saturation region is higher for the $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ anode than for the ZnFe_2O_4 anode. This shows that care has to be taken in relating the observed efficiency to the number of Fe^{3+} ions on octahedral sites in these spinels, as the photocurrent action spectra attempt to do.

Capacitance measurements.—The admittance spectra of the PEC cell with the ZnFe_2O_4 anode were measured in the potential region from -0.4 to $+1.0\text{V}$ at regular intervals. At high anodic potentials ($V \geq +0.6\text{V}$, high dark currents were observed and gas evolution on the electrode surface could be observed, similar to the behavior of the $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ anode at these potentials (see Fig. 4). The results of the analysis of the ac response data obtained at these potentials were not reliable. We limited the analysis, therefore, to the data obtained between -0.4 and $+0.4\text{V}$. In this potential region, the dark current was less than $1 \mu\text{A}/\text{cm}^2$. The admittance spectra measured between -0.4 and $+0.4\text{V}$ could all be accurately fitted to the equivalent circuit given in Fig. 6. This circuit can be represented by $Q_{\text{SC}}R_{\text{F}}PC_{\text{A}}R_{\text{A}}SPQ_{\text{B}}R_{\text{B}}PSR_{\text{S}}S$, following the notation presented in Ref. (21-23) (P stands for parallel and S for series). The Q element represents a constant-phase-angle (CPA) admittance of the form (21).

$$Y_Q = k_j (i\omega)^\alpha \quad [1]$$

For $\alpha = 1$, this Q element represents the admittance of a capacitor, while for $\alpha = 0$ this element reduced to a resistor. The Q element is usually attributed to current inhomogeneities (32).

The equivalent circuit of Fig. 6 is adopted from the one Tomkiewicz (33) used to model the n-TiO₂/electrolyte in-

Fig. 6. The equivalent circuit to which the ac response data obtained for the PEC cell with a ZnFe_2O_4 anode were fitted. The symbols are explained in the text.

terface. We inserted the branch $Q_{\text{B}}R_{\text{B}}P$ and replaced C_{SC} by a Q_{SC} element. Dare-Edwards *et al.* (12) used the circuit after Tomkiewicz to fit the ac response data of a PEC cell with a Fe_2O_3 electrode. A circuit similar to the one we used, with capacitances and Q elements exchanged, was used by 't Lam *et al.* (22) to model the ac response data of a PEC cell with a TiO_2 anode.

In the branch $Q_{\text{B}}R_{\text{B}}P$, the Q element approaches the behavior of a pure capacitance ($0.91 \leq \alpha_{\text{B}} \leq 0.98$). The values of the elements in the part $Q_{\text{B}}R_{\text{B}}P R_{\text{S}}S$ of the equivalent circuit are independent of the applied potential. This part can be related to processes in the bulk of the semiconductor and in the electrolyte (22, 23).

The other part of the circuit, $Q_{\text{SC}}R_{\text{F}}PC_{\text{A}}R_{\text{A}}SP$, must then be representative for processes at the semiconductor/electrolyte interface. The resistance R_{F} can be related to the faradaic dark current. The values of R_{F} are quite large ($> 1 \text{M}\Omega$). This agrees very well with the low dark currents observed ($< 1 \mu\text{A}/\text{cm}^2$). The values of C_{A} show a marked voltage dependence. At -0.4V , C_{A} is around $10 \mu\text{F}$, but this value decreases rapidly with increasing potential and approaches a constant value above $+0.2\text{V}$. Dare-Edwards *et al.* (12) found the same voltage dependence for the capacitance C_{SS} in their analysis. The branch $C_{\text{SS}}R_{\text{SS}}S$ in their equivalent circuit, which is analogous to the branch $C_{\text{A}}R_{\text{A}}S$, models surface states of a particular energy.

The element Q_{SC} is related to the space-charge capacitance C_{SC} . The values of α_{SC} are between 0.91 and 0.94, showing that Q_{SC} approaches closely a pure capacitance. Therefore, we may relate the values of k_{SC} to the actual C_{SC} values (23).

In the depletion region the relation between the space-charge capacitance C_{SC} and the potential V is given by the Mott-Schottky equation (34)

$$C_{\text{SC}}^{-2} = \frac{2}{\epsilon\epsilon_0 e N_{\text{D}} A^2} \left(V - V_{\text{FB}} - \frac{kT}{e} \right) \quad [2]$$

where ϵ is the relative dielectric constant, ϵ_0 the permittivity of free space, e the electronic charge, N_{D} the donor density, A the interfacial surface area, and V_{FB} the flatband potential. We have used the values of k_{SC} to construct a Mott-Schottky plot (k_{SC}^{-2} vs. V). This is shown in Fig. 7. From the V axis intercept, a value for the flatband potential V_{FB} was obtained, *viz.*, $V_{\text{FB}} = -0.5\text{V}$ vs. SCE. From the slope, a value for N_{D} can be derived. With $\epsilon = 20$ for ZnFe_2O_4 (35), and $A = 50 \text{nm}^2$, this yields $N_{\text{D}} = 5.6 \times 10^{21} \text{cm}^{-3}$. This value is rather high compared with the number of Fe^{3+} ions on octahedral sites in ZnFe_2O_4 ($2.7 \times 10^{22} \text{cm}^{-3}$).

According to Schoonman *et al.* (36), surface roughness can account for this high value of the donor density. Rough electrodes have acutal interfacial areas ($A = A_0 + \Delta A$), which are greater than the geometrically determined surface areas (A_0). The edge of the depletion layer inside the electrode follows the surface roughness for small values of the electrode potential. Only for large values the edge of the depletion layer will approach A_0 (37).

In Fig. 8, an electron micrograph of the surface of the ZnFe_2O_4 electrode is shown. This picture reveals that we are indeed dealing with a rough surface.

Goodman (37) modified the MS equation to account for surface roughness. However, for small band bending the MS plot will still be linear and may be used to determine V_{FB} . A reliable value for N_{D} will be hard to obtain. The value found by applying Eq. (2) is usually too high (36).

Values of the flatband potential for $\alpha\text{-Fe}_2\text{O}_3$, which are mentioned here for comparison, have been reported by several authors. The ac response data analysis of Dare-Edwards *et al.* (12) resulted in a nonlinear MS plot. This could, however, be extrapolated to $V_{\text{FB}} = -0.5\text{V}$ vs. SSE (1M KOH) ($\text{SSE} = -0.02\text{V}$ vs. SCE). These authors limited the analysis to a five-component equivalent circuit and used only pure capacitances, although their electrode surface was unpolished. This might explain the nonlinear MS plot.

Quinn *et al.* (3) reported a value of -0.67V vs. SCE (2M NaOH) for a single crystal. Kennedy and Frese (6) re-

Fig. 7. Mott-Schottky plot of the k_{sc} data obtained for the PEC cell with α - $ZnFe_2O_4$ anode.

ported $-0.73V$ vs. SCE ($2M$ NaOH) for a reduced polycrystalline electrode and $-1.00V$ vs. SCE ($1M$ NaOH) for a Ti-doped polycrystalline electrode. Curran and Gissler (7) reported $-0.95V$ vs. SCE ($1M$ NaOH) for both a sintered Fe_2O_3 electrode and the thin Fe_2O_3 layer of flame-oxidized iron. All these authors used monofrequency impedance measurements to obtain these values. Unfortunately, they are little coherent, which makes a comparison with our value for $ZnFe_2O_4$ difficult.

General Discussion

In relation to the photoeffects observed for α - Fe_2O_3 and for the ferrites reported here, the question arises of which optical transitions generate the charge carriers. Particularly for the visible region, where a marked difference between the diffuse reflection spectra and the photocurrent action spectra is observed, this is of interest. The CF transitions of Fe^{3+} , which cannot account for the intensity of

Fig. 8. Scanning electron micrograph of the surface of the $ZnFe_2O_4$ electrode.

the absorption in this region, are excluded beforehand. The localized nature of these transitions make carrier generation improbable, *i.e.*, they will not give rise to photocurrents of any importance. The relatively large absorption coefficient in the visible region might indicate another type of charge transfer transition, *i.e.*, metal to metal, which can be schematically envisaged as $2Fe^{3+} \rightarrow Fe^{2+} + Fe^{4+}$ (A). Kennedy and Frese (5) came to the same conclusions. Also Pollert *et al.* (38) discussing the photoelectrochemical properties of the magnetoplumbite $PbFe_{12}O_{19}$ arrived at this assignment. This metal-to-metal CT transition starts around 2.2 eV, *i.e.*, the onset wavelength of the photocurrent. In the UV part of the photocurrent action spectra, the already mentioned ligand-to-metal CT, *i.e.* $O^{2-} + Fe^{3+} \rightarrow O^- + Fe^{2+}$ (B) accounts for the electron-hole pair generation.

The total photocurrent consists of two contributions: one from carriers generated in the depletion layer, and another from carriers generated in the bulk which diffuse into the depletion layer before recombining (1). The diffusion current depends on the minority carrier diffusion length, which is usually quite short for metal oxide semiconductors. For a small absorption coefficient, the light will penetrate deep into the semiconductor bulk, where most of the photogenerated charge carriers will recombine before reaching the depletion layer. With increasing absorption coefficient, the charge carrier generation in the depletion layer increases, as does the photocurrent efficiency. A higher absorption coefficient for UV radiation than for visible radiation (*cf.* the diffuse reflection spectra section) accounts, therefore, for the higher efficiency observed in the UV region.

We have summarized the results of this consideration in schematic band-structure diagram shown in Fig. 9. This is adopted from a semi-empirical energy-level diagram for α - Fe_2O_3 (39). Since we excluded the CF transitions on Fe^{3+} , the excited-state levels originating from the $Fe^{3+}:3d^5$ configuration have been omitted in this diagram. The two CT transitions responsible for the electron-hole pair generation are indicated (A and B, respectively, see Fig. 9).

From Fig. 9 it can be seen that we are left with two types of holes, each at a different energy level. Upon irradiation with visible light, the holes are in the Fe_e^{3+} band. Under UV irradiation, the holes are created in the oxygen

Fig. 9. Schematic band structure of ferrites with spinel structure. A and B indicate the CT transitions discussed in the text.

valence band. The photocurrents measured for 300, for 380, and for 460 nm irradiation show the same voltage dependence. This indicates, that the conduction path for the holes is the same, whether irradiation is performed with visible light or with UV light. The low hole mobility reported for p-type $\alpha\text{-Fe}_2\text{O}_3$ (40) indicates that the hole migrates in the $\text{Fe}_{0^{3+}}$ band rather than in the oxygen valence band. Dare-Edwards *et al.* (12) arrived at a similar conclusion for $\alpha\text{-Fe}_2\text{O}_3$.

The value for V_{FB} (-0.5V vs. SCE) obtained from the admittance spectra analysis agrees with the value expected from the photocurrent-voltage curves observed. The values obtained for the capacitance C_A , which can be associated with surface states, clearly show the decreasing importance of these surface states with increasing band bending. This strongly supports the explanation given before for the transients and the low steady-state photocurrent observed in the low potential region.

In conclusion, we have shown that ferrites with the spinel structure can be used as photoanodes in a PEC cell. Photocurrents are observed up to around 550 nm, but the efficiency in the visible region is limited by a relatively low absorptivity. The flatband potential lies close to, but anodic of, the hydrogen evolving level. However, in the region of low band bending, steady-state photocurrents are severely limited because of surface recombination of the photogenerated electron-hole pairs.

Polarization Relaxation in Electrodeposited Polyphenylene-Oxide Films

S. H. Glarum* and J. H. Marshall

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Impedance measurements of electrodeposited polyphenylene-oxide films, $\sim 250\text{\AA}$ thick, show a polarization relaxation for the metal/polymer/electrolyte interface. The initial polarization following a potential perturbation is distributed across the film. Relaxation follows to a much larger polarization characteristic of a bare metal/electrolyte interface. Kinetics are controlled by ion transport within the film and relaxation times range between 1 and 10^{-4} s. Results are reported for films in strong acids and bases. In the former case, ionic permeability can be reversibly altered by factors $> 10^3$.

Electrochemical syntheses of thin polymer films and their electric properties are topics of increasing importance given the growing interest in microelectrochemical applications. Polymerizations which proceed through oxidative coupling mechanisms are especially attractive for electrochemical studies because the reaction is localized at the electrode surface by fixed electron-transfer requirements for monomer addition (1). Polymer films can be formed in this manner from phenols (2), pyrroles (3), and anilines (4). The latter polymers are electronic conductors under polymerization conditions, and thick films can be produced electrochemically. In contrast, polyphenylene-oxides are insulators and the reaction is quickly quenched when thicknesses of 10^2 - 10^3\AA are reached. This dimension, shared with both Langmuir-Blodgett films and biologic membranes, introduces possibilities for a variety of studies of both fundamental and practical interest. Transport processes too slow to be macroscopically significant occur quite expeditiously on this scale. From a practical viewpoint, such processes may set lower limits for the scaling of macrodesigns.

In a series of papers, Dubois and co-workers have characterized many of the chemical and physical properties of polyphenylene oxide films (5). They propose that the initial polymerization step is the oxidation of a phenolate ion to a radical species. This radical has large spin densities at its *ortho* and *para* ring positions, and, if these sites are not blocked by substituents, the radical adds to an oxygen atom at the end of a growing polymer chain with the removal of H^+ and a second electron.

In this paper, we report on studies of the electric properties of electrodes coated with polyphenylene oxide films in aqueous electrolytes. When a potential difference is applied across the metal/polymer/electrolyte interface, the polymer layer is initially polarized. This polarization decays because of charge transport through the film, and we have used ac techniques to measure this relaxation. Polymers of 2,6-dimethylphenol (DMP) and 4-*t*-butylphenol (TBP) have been examined in detail. The *ortho* positions are blocked in DMP and coupling should take place at the *para* position, leading to a "linear" polymer. The *ortho* and *para* roles are reversed for TBP. Bruno *et al.* report that polymerization does not take place when the *para* and one of the *ortho* positions are blocked (5). We have observed that 2,4-dimethylphenol does form passivating layers when oxidized in aqueous base and, the TBP polymers may contain branching points.

Experiment

Platinum rotating disk electrode, 1/16 in. diam, were used for this work. Prior to polymer deposition, they were polished with $0.05\ \mu\text{m}$ alumina. Unless otherwise indicated, films were grown potentiostatically for 20 min at $\pm 0.25\ V_{\text{sc}}$ (DMP) or $+0.35\ V_{\text{sc}}$ (TBP). These potentials lie just above the monomer oxidation threshold and well below the oxygen evolution region. On one occasion, it was

noted that, if the platinum surface was fully oxidized prior to introduction of the phenol, dark red material covered much of the surface. Electrode rotation rates of 100 rad/s were used during film growth, although no dependence on this rate was found. Sufficient monomer is present in a $20\ \mu\text{m}$ electrolyte layer to meet the demands of the polymerization reaction.

The phenols (Aldrich) were used as received. Solutions were vigorously degassed with argon and the electrolytic cell was thermostated at 25°C . A B&L stereo-zoom microscope ($280\times$) with coaxial illumination was routinely employed for surface examinations. The apparatus for impedance measurements has been described previously (6).

Results

Aqueous solutions, $0.15N$ in NaOH and $0.02M$ in the phenol monomer, were used for the preparation of polymer films. Dubois *et al.* have used more concentrated phenol solutions in methanol (5). In the absence of phenol, substantial currents, presumably due to the oxidation of methanol to formaldehyde, are found at electropolymerization potentials with platinum electrodes. Stoichiometry between current and electrodeposited material is absent with alcoholic solutions because of oligomer solubility, and deposition efficiency is but a few percent. Films grown from aqueous solutions are soluble in methanol and are apparently of lower molecular weight material. On the basis of *in situ* impedance measurements, however, films grown from methanol solutions do not appear to be perceptibly thicker than their aqueous counterparts. While the former were not removed with methanol, their electrical response was altered, with a nearly exponential relaxation being replaced by a broader, nondescriptive dispersion. We interpret the latter as due to an inhomogeneous modification of the polymer layer.

When a freshly polished platinum electrode is immersed in the growth solution, the open-circuit potential is near $-0.1\ V_{\text{sc}}$. Based on cyclic voltammetric measurements for phenol-free solutions, this potential corresponds to the beginning of the oxidation plateau characteristic of platinum surfaces. The electrode was then scanned anodically from this potential (Fig. 1). Between 0.1 and $0.4\ V_{\text{sc}}$, depending on the phenol, the current begins to rise exponentially. Formation of an insulating layer passivates the surface and the current rapidly drops to a constant level characteristic of the oxidation of a bare platinum surface.

The shape of the oxidation wave does not change significantly with electrode rotation (100 - 0 rad/s) but, as seen in Fig. 1, the area beneath the wave is proportional to the scan rate. A constant faradaic charge is involved in formation of a surface film and integrations give 4.2×10^{-3} and $2.5 \times 10^{-3}\ \text{C/cm}^2$ for DMP and TBP films. Assuming $2e^-$ per monomer oxidized, 2.6 and $1.9\ \mu\text{g/cm}^2$ are deposited, respectively. The density of a bulk DMP polymer is 1.05 , leading to a nominal 250\AA thickness.

Growth kinetics can be examined through the current transients which follow jumps from open circuit to poten-

Fig. 2. a (top): Initial current transient for DMP film growth following a potential jump from -0.1 to $+0.15$ V_{sce} . b (bottom): Initial current transient for DMP film growth following a potential jump from -0.1 to $+0.35$ V_{sce} .

tials above the polymerization threshold (Fig. 2a and 2b). The initial current is less at the lower potential and passivation takes 10-20s. At a higher potential and higher initial current, passivation is largely completed with 0.5s. Integration of these transients yields the same coulombic values found from potential-sweep plots and supports the conclusion of a stoichiometry between current and deposited material. The transients can be followed to longer times until constant limiting currents less than $1 \mu A/cm^2$ are reached after 20 min (Fig. 3 and 4). For TBP films the decay varies approximately as $1/t$. For DMP films, there appears to be an exponential drop to an intermediate plateau, followed by a second drop to the limiting current.

Surfaces were examined microscopically before and after film growth. With normal (coaxial) illumination, no changes in surface features were evident, although there appeared to be a more yellow cast to the surface. With oblique illumination, only scattered light enters the microscope and features too small for direct resolution can be detected. No additional scattering was seen with TBP films, and micropolishing marks were equally apparent before and after film formation. The DMP films, however, were uniformly speckled blue. We attribute this

Fig. 3. Long-term current decay for DMP film growth at several potentials.

Fig. 4. Long-term current decay for TBP film growth at several potentials.

scattering to refractive index variations between crystalline and amorphous regions.

Most ac measurements were made with 100 Hz-200 kHz frequency scans, although occasionally lower frequency scans, 1-500 Hz, proved helpful. Even at 200 kHz, the film impedance was too high for a reliable evaluation of the electrolyte resistance. To determine this parameter, the film was removed, either by dissolution or repolishing, and the impedance of the bare electrode measured. With the electrolyte resistance in hand, corrections were made for the nonuniform current distribution at disk electrodes, the electrolyte resistance was subtracted from the corrected impedance, and results were plotted in the complex capacitance plane, *i.e.*, $i\omega C^* = (Z^* - R_{el})^{-1}$.

Figure 5 shows such a plot. It is representative of most measurements. The shape is approximately semicircular and well described over most of the frequency range by a circular arc centered 10° below the real axis. Straightforward extrapolations give 0.26 and $48 \mu\text{F}/\text{cm}^2$ for the high and low frequency intercepts. The relaxation time given by the frequency at the top of the arc is $180 \mu\text{s}$ ($1/2 \pi f$). The depressed center can formally be attributed to a relatively narrow distribution of relaxation times. There are no distortions to suggest the presence of more than one dispersion, except possibly at the lowest frequencies. A small dc conductance results in large deviations in C^* plots in this region.

Discussion

Interpretation of the complex capacitance function for the metal/polymer/electrolyte interface is best approached in terms of the behavior of an idealized blocking electrode (see Appendix). We suppose the polymer film contains positive and negative ions of arbitrary mobilities. Within the film, ionic fluxes are governed both by concentration gradients and an electric field. The gradient of this field is determined by the space charge resulting from unequal concentration profiles for anions and cations. The boundary conditions required to complete the description are rapid ion exchange at the polymer/electrolyte interface, pinning concentrations within the film at this boundary, and blocking conditions or null ionic fluxes at the metal/polymer boundary.

Macdonald has offered a formal solution for this problem couched in terms of a symmetric two-electrode cell (7). The half-cell response is, however, equivalent to the problem posed for concentration changes vanish through symmetry at the midplane. Macdonald's solution is rather complicated, in part because of the *ab initio* separation of ionic and dielectric displacement currents. Our Appendix offers an alternative expression somewhat more amenable to evaluation. The problem involves finding the time-dependent response of an equilibrium configuration to a perturbation. An analytic solution has so far been achieved only for the perturbation of a spatially uniform

configuration corresponding to the potential of zero charge (pzc). Gouy-Chapman theory describes equilibrium configurations at other potentials. Our result for the complex capacitance function can be written as

$$C^* = [(\epsilon + \sigma/i\omega)l][1 + \mathfrak{F}(i\omega)]$$

with

$$\sigma = (eF_c/kT)(D_p + D_n)$$

The numerator contains the leading high frequency terms and depends on bulk parameters, ϵ , the dielectric constant, and σ , the conductivity. Relaxation of the charge distribution to create a space-charge polarization is described by the function $\mathfrak{F}(i\omega)$. Five physical parameters are needed to describe the response: the thickness and dielectric constant of the film, the ionic concentration within the film, and the diffusion coefficients for both ions.

The nature of the solutions is best revealed by complex-plane plots for C^* (Fig. 6). Parameters were chosen for these computer-generated curves so that the low frequency capacitance intercept was much larger than the high frequency intercept. The shape of these plots then depends only upon the ratio of the diffusion coefficients. When these are equal, the calculated plot is a semicircle. Despite the complexity of $\mathfrak{F}(i\omega)$, the response is experimentally indistinguishable from a simple exponential relaxation. When the diffusion coefficients differ by orders of magnitude, the dispersion separates into a high frequency semicircle and a low frequency circular arc. The latter is characteristic of a diffusional relaxation process. The ratio of the dispersion amplitudes, $\sqrt{2}$, is set by the assumptions of a 1:1 electrolyte.

The potential perturbation initially creates a uniform perturbing field within the film. Under the guidance of this field, the more mobile ions drift towards or away from the metal/polymer interface, creating a space-charge region which quenches the field in the bulk of the film. This portion of the relaxation appears exponential in time. The slow ions can enhance the space-charge polarization by a factor $\sqrt{2}$, but, in the absence of a field within the film, their redistribution kinetics are diffusive.

If we accept this model, interpretations for parameters derived from experimental C^* plots are straightforward. For $D_p = D_n$ and $C_o \gg C_g$

$$C_g = \epsilon/l$$

$$C_o = \epsilon/\lambda$$

$$\omega_{\max} C_o = \sigma/l$$

$$1/\lambda^2 = 2eF_c/\epsilon kT$$

with C_g and C_o being the asymptotic high and low frequency intercepts, ω_{\max} the frequency at the C^* maximum, and λ a Debye length defined by the last equation which

Fig. 5. Complex-capacitance plot for a TBP film in 0.05N NaOH at $-0.1 V_{sce}$ (open-circuit potential).

Fig. 6. Theoretical complex-capacitance plots for the space-charge relaxation model. Values indicate the diffusion coefficient ratio D_p/D_n .

describes the width of the space-charge region. C_g is the geometric capacitance of the polymer film. Applying these results to the data plotted in Fig. 5 with $l = 250\text{\AA}$, we find $\epsilon = 7$, $\sigma = 7 \times 10^{-7}$ mho/cm, $c = 0.9M$, and $D = 10^{-10}$ cm²/s. However, $\lambda = 1.0\text{\AA}$, and the validity of macroscopic electrostatics used in the model appears questionable. The dielectric constant for analogous bulk polymers is 2.5. Were this the correct value for the film, the true thickness would be 85 \AA and inconsistent with growth coulometry.

Our suspicions regarding the small Debye length are confirmed by measurements at different potentials which show no changes in C_o . According to Gouy-Chapman theory, C_o should vary as $\cosh(e\eta/2kT)$. In fact, C_o is suspiciously similar in magnitude and potential dependence to the capacitance of a bare platinum electrode in the electrolyte. This capacitance has limiting high frequency values in the range 40-50 $\mu\text{F}/\text{cm}^2$. However, it also exhibits a very broad dispersion of unknown origin extending to very low frequencies. Examination of the width of classic cyclic voltammetric plots in the "double-layer" region gives values of several hundred microfarads per square centimeter. The correlation appears to be best between the low frequency film capacitance and the high frequency film-free capacitance.

When the electrolyte concentration was reduced to 10 mM, neither bare nor coated electrodes showed a capacitance dip indicative of the pzc. The absence of this dip points to specific ionic adsorptions. The magnitude of the capacitance requires a dielectric constant ca. 20 at the interface, which is rationalized in terms of a layer of water molecules (8). While the relation between interfacial structure and capacitance is ambiguous, it seems safe to conclude for polymer-coated surfaces that the equilibrium polarization is localized at the metal interface, the low frequency capacitance reflects the properties of this interface, and a water layer separates the metal and polymer. The low frequency capacitance cannot be relied on, however, for the evaluation of ionic concentration, and a diffusion coefficient cannot be extracted from the film conductivity.

The model analyzed assumes that ionic transport within the film limits polarization relaxation. Although experiments show but one dispersion, it is not immediately evident that the relaxation is not limited by interfacial rather than bulk kinetics. If the rate-limiting process were spatially localized at the outer and/or inner film boundaries, minimum capacitance values would be set by the geometric widths of these regions. Rapid transport within the bulk would eliminate a bulk electric field and hence the dielectric displacement polarization of the bulk. The magnitude of the high frequency capacitance rules out localized interpretations for the observed relaxation.

With some insight into the physical significance of the complex capacitance, the behavior of this function was examined during the period of film formation. Rapid initial changes precluded detailed measurements in the first few minutes. High-frequency measurements, however, showed the capacitance dropped from an initial value, $\sim 60 \mu\text{F}/\text{cm}^2$, to a limiting value within seconds. Thus the film thickness, given by C_g , is quickly established. Relaxation measurements at longer times were possible, and Fig. 7 plots the values for C_g , C_o , and the film conductivity, $G = \sigma/l$. No significant variations are seen for the capacitive parameters showing that the film thickness and the nature of the metal/polymer interface are not changing. The C_o values further indicate the absence of a steady-state electric field within the bulk of the film to assist phenolate anion transport.

The film conductivity shows a steady drop over this period. As the film thickness is invariant, the decrease must be attributed either to reduced ionic mobilities or solubilities. The steady-state current, representing phenolate oxidation, is independent of potential (Fig. 3, 4), and we may assume that it represents a diffusion limited current so that

Fig. 7. Variation of the relaxation parameters during TBP film growth at $+0.35 V_{sce}$.

$$I_m = 2FD_m K_m c_{m0}/l$$

with D_m the monomer diffusion coefficient, K_m the monomer partition coefficient, and c_{m0} the monomer concentration in the electrolyte. Film conductivity is primarily due to electrolyte ions and

$$G = 2eFD_e K_e c_e/kTl$$

The product of the diffusion and partition coefficients gives a permeability coefficient. Comparison of the steady-state current with the film conductivity indicates that the electrolyte permeability is $\sim 10^3$ times that of the monomer.

While the structure and ion transport mechanisms in these films are not known, the polymers are polyethers and have some features in common with polyethylene- and polypropylene-oxides. The latter form a variety of complexes with alkali metal salts and possess dielectric constants and room temperature conductivities similar to those measured here for polyphenylene oxide films (9). Armand has proposed that the stability of these complexes arises from cation solvation by a helical arrangement of the ether oxygens, and that the complexes are cationic conductors along these channels (10). Later measurements have indicated that cation and anion diffusion coefficients are nearly equal (11).

Figure 8 plots film conductivities obtained from relaxation measurements for TBP films in contact with various concentrations of three strong bases, NaOH, LiOH, and NPr_4OH . Measurements were made at open-circuit potentials, ca. $-0.1 V_{sce}$, just above the cathodic reduction peak for the platinum oxide region. For the latter two bases, this conductivity appears proportional to the electrolyte concentration. Conductivity is highest for NaOH solutions but appears to be less sensitive to concentration. Data were acquired using a single film and making successive 2:1 dilutions. The anomalous behavior of NaOH solutions is an artifact of an aging process which causes a conductivity increase with time.

Figure 9 shows aging results for separate TBP films in 0.5 and 0.05N NaOH and LiOH solutions. The electrodes had been stored in water prior to measurement. The conductivity of films in NaOH is seen to be proportional to concentration when aging is considered. There were some indications of systematic increases in C_g and C_o totaling no more than 10%, but this variation is commensurate with extrapolation uncertainties.

The large conductivity differences show that film permeability is strongly cation dependent, but we cannot separate solubility and diffusion effects. Electroneutrality requires the exchange of both cation and anions between polymer and electrolyte. The conductivity cannot be due to fixed ionic concentrations within the film, which

Fig. 8. Variation of film conductivity with electrolyte concentration or basic solutions.

would be the case if phenolate residues determined this value.

The time scale of the aging process is too long to be explained by diffusion of water or electrolyte into the film. Aging cannot be exclusively due to the incorporation of water or hydroxyl ions, for the effect is most marked with NaOH solutions. A configurational or structural relaxation of polymer molecules which opens up ionic transport paths seems most plausible. If polymer hydrolysis is involved, the effects are reversible. In a series of experiments, aging changes were measured during a 3h immersion period in 0.1N NaOH. The electrode was then rinsed in water for 15 min and dried under vacuum for 1h. The original parameters, including C_g , were found on remeasurement.

Fig. 9. Aging changes of TBP film conductivity in several basic electrolytes.

Fig. 10. Complex-capacitance plot for a "fast" TBP film in 0.2M H_2SO_4 at +0.6 V_{sc} . Frequencies are in kilohertz.

Polyphenylene oxide films are also stable in strong acids. For such solutions, however, two markedly different behaviors were observed. Figure 10 shows a fast relaxation in 0.2M H_2SO_4 , with $C_g = 0.28 \mu F/cm^2$, $C_o = 80 \mu F/cm^2$, and a relaxation time of 180 μs . These parameters are essentially identical to those obtained from Fig. 5 for a NaOH solution. The higher C_o value parallels the higher capacitance for a platinum oxide surface in sulfuric acid. In Fig. 11, we see a much slower relaxation for supposedly similar film. Even when the frequency scan was lowered to 1 Hz, the C^* maximum was not reached, and we can estimate a relaxation time $\geq 1s$. Moreover, the plot does not resemble the high frequency extension of a nearly semicircular arc. For three decades, the plot has a slope near unity, corresponding to $(i\omega)^{-1/2}$ dependence and suggesting a diffusion-controlled relaxation process.

As a rule, fast responses are found for films freshly formed and slow responses appear with films allowed to dry out, either under ambient or vacuum conditions. A given film can be reversibly cycled between fast and slow states. A vacuum treatment leads to a slow relaxation, while immersion in NaOH solutions restores fast behavior. The presence of water in the polymer seems implicated in the fast response films. The polymers are hydrophobic, and the facile removal of water is plausible (5). Immersion of a "slow" film for 2h in either water or acid gives no more than a threefold relaxation time decrease, whereas a similar treatment in base yields a 300-fold decrease.

A simple ion transport mechanism would not lead to diffusional relaxation. This behavior occurs while the capacitance is still close to its geometric value, and consequently an electric field must exist within the film as a driving force for ion migration (cf. Fig. 6). Diffusion of an electroneutral species appears to govern the relaxation.

Fig. 11. Complex-capacitance plot for a "slow" TBP film in 0.1M H_2SO_4 at +0.6 V_{sc} . Frequencies are in hertz.

Given the film thickness, a 1s relaxation time corresponds to a diffusion coefficient of order 10^{-11} cm²/s. This value seems too large to associate with water in a polymer matrix. Possibly polar or ionic groups at the ends of polymer chains are involved.

We have also observed that film conductivity in acid solutions can be altered by factors of 2-5 following potential changes. Suppose we measure the response of a "fast" film at +0.2 V_{sce} in the double-layer region of a platinum electrode. After the potential has been lowered to -0.2 V_{sce} and then returned to +0.2V_{sce}, thereby adsorbing and desorbing a monolayer of H atoms, the relaxation time is increased and the high frequency slope of C* plots is reduced. When the potential is then raised to +1.1 V_{sce}, oxidizing the metal surface, film conductivity is increased, and its higher value is maintained on return to +0.2 V_{sce}. Accompanying these potential changes are large pH transients as H⁺ and OH⁻ ions are taken up and released at the metal interface. We cannot draw an obvious connection between pH changes and the much larger effects of film dehydration. Alternative experiments more directly revealing the role of water in modifying the structure of the polymer films and their ionic permeability are necessary.

Our discussion so far has been restricted to results for TBP films. Corresponding measurements for DMP films gave similar results both qualitatively and quantitatively. Relaxation parameters, the influence of electrolytes, and aging effects were not distinctively different. Because of their thinness, film conductivities are readily measured. The slow response films in sulfuric acid have equivalent bulk conductivities of 10^{-10} mho/cm, making them respectable insulators. While lower values are normally cited for conventional insulating materials, they are not based on measurements with concentrated electrolytes as contacts. If the conductivity were ascribed to pinholes filled with electrolyte, the fraction of the surface covered by such holes would be 10^{-9} . Perhaps our most interesting observation is that the permeability of thin polymer layers can be reversibly altered by several orders of magnitude. These materials are not simply passive matrices. Effective utilization of this property will depend upon a clearer understanding of the structures and dynamics within thin films.

Our results also point out some difficulties inherent in thin film applications. The usefulness of ion-selective membranes depends on the relative ionic contributions to conductivity of the membrane through diffusion and partition coefficients (12). If one boundary of the membrane is a blocking contact, relaxation will lead to an equilibrium polarization at this contact which depends only on the properties of this interface and not the selective properties of the overlying matrix. In the case of a platinum contact, this interface turns into a pH sensor within a second for the films used in this work (13). Similar behavior can be anticipated with SiO₂ contacts.

Considerable interest exists in combining electrochemical polarizations with field-sensitive semiconductor surfaces (14). It is perhaps worth noting that the capacitance is closely related to the field at the surface, $C = \epsilon \Delta E(0)/\Delta V$. Capacitance relaxation measurements should permit an assessment of material performance for such applications without the additional complexities of microcircuit fabrication.

Manuscript submitted April 17, 1985; revised manuscript received Aug. 9, 1985.

APPENDIX

The purpose of this Appendix is to outline the derivation of an analytic expression for the complex capacitance of a blocking electrode more tractable than Eq. [44] of Ref. (7). The fundamental equations to be solved are

$$\begin{aligned} dp/dt &= -dJ_p/dx; J_p = -D_p [dp/dx - (ez/kT) p(x, t)E(x, t)] \\ dn/dt &= -dJ_n/dx; J_n = -D_n [dn/dx + (ez/kT) n(x, t)E(x, t)] \\ dE/dx &= (ez/\epsilon) [p(x, t) - n(x, t)] \end{aligned}$$

$$V(t) = - \int_0^l E(x, t) dx$$

with $p(x, t)$ and $n(x, t)$ cation and anion concentrations with diffusion coefficients D_p and D_n . $E(x, t)$ is an electric field, and $V(t)$ is the potential drop across the film with thickness l . Time-dependent parameters are considered to be harmonic perturbations of a uniform equilibrium distribution, i.e.

$$p(x, t) = c_0 + p^*(x) \exp(i\omega t)$$

$$n(x, t) = c_0 + n^*(x) \exp(i\omega t)$$

$$E(x, t) = E^*(x) \exp(i\omega t)$$

Substitution leads to a characteristic equation with roots

$$\begin{aligned} \gamma_{\pm}^2 &= 1 + (i\omega\lambda^2/2)(1/D_p + 1/D_n) \\ &\quad \pm \{1 + [(i\omega\lambda^2/2)(1/D_p - 1/D_n)]^2\}^{-1/2} \\ 1/\lambda^2 &= e^2 z^2 c_0 / \epsilon k T \end{aligned}$$

and

$$E^*(x) = E^*_0 + \sum_1^4 E^*_i \exp(\gamma_i x / \lambda)$$

with the coefficients E^*_i determined by boundary conditions. Similar expressions follow for $p^*(x)$ and $n^*(x)$.

At a blocking electrode, the perturbation current, $I^* = i\omega\epsilon E^*(0)$ and consequently the complex capacitance can be expressed in terms of the coefficients E^*_i

$$C^* = I^*/i\omega V^* = (\epsilon/l) \frac{E^*_0 + \sum E^*_i}{E^*_0 + \sum E^*_i [\exp(\gamma_i l/\lambda) - 1]/(\gamma_i l/\lambda)}$$

From the boundary conditions

$$p^*(l) = n^*(l) = J_p(0) = J_n(0) = 0$$

one readily finds

$$\sum E^*_i = E^*_0 (D_p + D_n) i\omega\lambda^2 = E^*_0 (\sigma/i\omega\epsilon) = E^*_0 / i\omega\tau$$

With considerably more effort, the denominator can be evaluated giving

$$C^* = \frac{(\epsilon + \sigma/i\omega)l}{1 + f_+ + f_-}$$

with

$$f_{\pm} = (\gamma_{\pm}^2 - \gamma_{\mp}^2)^{-1} [(\gamma_{\pm}^2 - 2)/i\omega\tau - 2] [\tanh(\gamma_{\pm} l/\lambda)/(\gamma_{\pm} l/\lambda)]$$

Photoelectrochemical Properties of Sputtered and Plasma-Oxidized Iron Oxide Films

Lynn C. Schumacher, Suzanne Mamiche-Afara, Michael F. Weber,^{*,1} and Michael J. Dignam*

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ontario, Canada M5S 1A1

ABSTRACT

The results for iron oxide, thin film ($\sim 500\text{\AA}$) electrodes, formed both by reactive sputtering from an iron target and by plasma oxidation of a sputter-deposited iron film, are reported. The reactively sputtered electrodes were formed by deposition onto sputter-deposited films of both iron and conducting indium tin oxide (ITO), while the plasma oxidized electrodes were formed with ITO only. The performance of the electrodes as photoanodes for O_2 evolution was found to be strongly dependent on a number of fabrication parameters, the best results being achieved for films formed on ITO and then vacuum annealed, both at 350°C . In this case, the performance matched or exceeded that reported in the literature for other methods of fabrication of polycrystalline iron oxide. Annealing these films in oxygen resulted in a decrease in photocurrent by a factor of three to four, as well as a 0.7V suppression of the photocurrent onset potential. The effect was reversed on reannealing *in vacuo*. Postfabrication treatment of electrodes in various aqueous solutions was found to effect their performance significantly. More specifically, a substantial enhancement of the photocurrent in the onset region was achieved by treatment in a boiling KSCN solution. Mott-Schottky plots and conductivity measurements are presented to illuminate these phenomena.

Iron oxide has two valuable properties as an oxygen photoanode in relation to the photoelectrochemical conversion and storage of solar energy: (i) it is stable against photodissolution; and (ii) its bandgap and flatband potential are close to the values required for achieving the maximum conversion efficiency in an unbiased, tandem, photoelectrochemical cell configuration. On the other hand, it suffers from poor transport properties, limiting quantum yields to $<27\%$ even for single crystals (1).

The stability of Fe_2O_3 against photodissociation is attributed to the fact that the optical transition, leading to the generation of electron-hole pairs, is a d-to-d transition (2) and hence not bond breaking. In contrast, most of the lower bandgap materials do undergo photodissociation.

Recently (3, 4), we determined the efficiency limits of a number of different unbiased configurations for the photoelectrochemical splitting of water using solar radiation. The calculations took account not only of the thermodynamics of the photophysical processes, but also of the transport properties of the semiconductor(s) and junctions. We concluded that a single bandgap device, under zero bias, is unlikely to achieve a conversion efficiency higher than $\sim 4.5\%$, this requiring a semiconductor of bandgap $\sim 2.6\text{ eV}$. However, for a tandem photoelectrochemical cell (tandem PEC), consisting, *e.g.*, of a photovoltaic of bandgap $\sim 1.4\text{ eV}$ in optical and electrical series with a photoanode of bandgap $\sim 2.0\text{ eV}$, a conversion efficiency $\sim 17\%$ in unbiased operation becomes a practical goal. Thus while Fe_2O_3 is unable to split water in a single-bandgap, unbiased PEC (its flatband potential is too anodic) it does possess close to the optimum bandgap and flatband potential for use in an unbiased tandem PEC, the former being $2.0 \pm 0.2\text{ eV}$ (5), the latter 0.3V with respect to the reversible hydrogen electrode (1).

The photoelectrochemical properties of both bulk Fe_2O_3 (1, 6-11) and thin film Fe_2O_3 (12-17) have been extensively studied. As already noted, the photostability of Fe_2O_3 has been attributed to the fact that the carrier generating transition is d-to-d. Unfortunately this same feature leads to low hole mobility and hence poor transport properties, since the d bands in which the holes are generated are narrow. It is, in fact, the small overlap of the d orbitals that leads to the narrowness of their band, so that this solution to photostability works directly against achieving good transport properties.

Sputtering is a convenient, inexpensive, readily automated method for producing thin film systems. Film properties can be varied by controlling the substrate temperature, sputtering gas composition and pressure, RF power, substrate bias, and magnetic field strength (in

magnetron sputtering). An important additional advantage of thin films over bulk specimens arises when dealing with relatively high impedance materials, since the film thickness can be tailored to achieve an optimum balance between photon absorption and impedance and recombination losses.

We report here the photoanodic and impedance properties of iron oxide films formed by (i) reactive sputtering of iron in an oxygen plasma onto a presputtered iron film, and (ii) sputtering iron onto a presputtered indium tin oxide (ITO) film, followed by oxidizing it in an oxygen plasma. We have also investigated oxide films formed onto ITO by reactive sputtering; Auger analysis indicates, however, considerable doping of the iron oxide film by the underlying ITO, thus complicating interpretation of the data. Properties of these doped films, while mentioned briefly here, will be treated in detail in a later publication.

Experimental

Sputtering.—Two different sputtering systems were used in the course of this investigation. For the films formed by reactive sputtering onto iron, a Varian, single-target, RF diode system was used. It was modified to include a 15 cm diam heated substrate table capable of achieving temperatures up to 400°C . The films on ITO were formed using a three-target Perkin Elmer Model 2400 RF system, also modified to include a heated, rotatable substrate table with an upper temperature limit of 420°C .

All films were deposited onto microscope slides which had been ultrasonically cleaned in 2-propanol, degreased via hot 2-propanol vapor, then held at $\sim 300^\circ\text{C}$ under vacuum (1×10^{-7} torr) for several hours in the sputtering chamber.

Sputter-deposited iron oxide on iron.—Following presputtering of the iron target in 8×10^{-3} torr argon, $\sim 5000\text{\AA}$ of iron metal was sputtered onto the glass slides at 1000V target bias and an argon pressure of 8×10^{-3} torr, the deposition rate being $\sim 100\text{ \AA}/\text{min}$. Immediately following the iron deposition, oxygen was bled into the plasma, and in most cases the argon flow stopped, leading to reactive sputtering in pure oxygen. The oxygen pressure and substrate temperature were varied from run to run. Following deposition of the desired thickness of iron oxide, the RF field was turned off, the substrate table cooled to room temperature, and the samples removed from the sputtering chamber.

Sputter-deposited iron oxide on ITO.—Deposition of the conducting ITO film proceeded by presputtering the target (Materials Research Corporation 99.97% pure In_2O_3 -9 mol percent SnO_2) in an argon, oxygen mixture, the total

* Electrochemical Society Active Member.

¹ Present address: 3M Center, St. Paul, Minnesota 55133.

pressure being 8×10^{-3} torr and the partial pressure of oxygen about 5×10^{-6} torr. Presputtering was continued until the oxygen partial pressure remained constant at 5×10^{-6} torr under fixed feed conditions. Precise control of the oxygen partial pressure was found to be essential for forming transparent ITO films of good conductivity. The best results were obtained at 1200V target bias, substrate temperature of 320°C, and oxygen partial pressure of 5×10^{-6} torr, the deposition rate being 130 Å/min. Films formed in this way to a thickness of 4000Å were a very pale green in color and had a specific conductivity $\sim 10^4$ mho-cm⁻¹.

Following ITO deposition, the iron target (Materials Research Corporation 99.995% purity) was presputtered at 1000V target bias in 8×10^{-3} torr argon for 30 min, at which time oxygen was introduced into the chamber and the argon flow stopped. The target was then presputtered at 900V target bias in 8×10^{-3} torr oxygen for 1h before deposition of the Fe₂O₃ at a rate of 17.5 Å/min. The long presputtering procedure was found to be necessary to eliminate CO₂ from the system. Mass spectrometric analysis of the chamber gases revealed that the CO₂ peak (mass 44) decreased by two to three orders of magnitude during the presputtering process. Failure to carry out this presputtering procedure led to irreproducible results.

Following deposition of the iron oxide, if no annealing was planned, the heater was allowed to cool to room temperature and the samples removed. If annealing was planned, the substrate table was adjusted to the desired temperature and the films annealed for 10-12h either *in vacuo* or in 2×10^{-2} torr oxygen.

Plasma-grown iron oxide on ITO.—Following deposition of 4000Å of ITO according to the procedure outlined above, the iron target was presputtered at 1000V bias in 8×10^{-3} torr argon for 30 min before depositing the iron film on top of the ITO, the deposition rate being 60 Å/min. When up to ~ 240 Å of iron are exposed to the same plasma conditions as were used to reactively sputter iron oxide (900V target bias, 8×10^{-3} torr oxygen), it is fully oxidized in less than 1.5 min. This thickness of metal (240Å), when fully oxidized, will yield ~ 510 Å of Fe₂O₃ assuming bulk densities. The final films were either annealed, or not, using the same procedure followed for the reactively sputtered films.

Thickness determination.—Deposition rates were determined by three different methods: using an Inficon XTM quartz crystal thickness monitor; by weighing the film deposited in a given time on a semimicrochemical balance; and using a Sloan, Dektac step profiler. The three methods agreed to about $\pm 20\%$ on assuming bulk density for the films.

Electrode preparation.—For photoelectrochemical and electrode impedance measurements, electrodes were fabricated by attaching tinned copper wire to one end of the coated glass slide using GC silver print. A 6 mm diam Pyrex tube was then fastened over the wire to the glass slide using 5 min epoxy glue. The entire assembly was coated with 734 RTV silicone sealant, except for the active oxide surface of area, typically, 0.06-0.10 cm².

Conductivity measurements.—The room temperature conductivity of the oxide films were determined by forming the oxide directly onto glass substrates. An indium-gallium paste was applied to the oxide at fixed intervals and the current-voltage behavior recorded using a PAR Model 170 electrochemistry system.

Photoelectrochemical and impedance measurements.—Photoelectrochemical response curves were made using a PAR Model 170 electrochemical system in conjunction with a focused xenon lamp source, giving a total incident power density at the electrode surface of ~ 0.7 W/cm². Impedance measurements were made using a PAR dual-phase, phase-sensitive amplifier, Model 129A. The 1 kHz ac signal (3 mV peak to peak) was provided by a Wavetek Model 182A function generator. The phase of the lock-in

amplifier was referenced against the ac voltage across the cell and the in- and out-of-phase components of the cell current were measured via a standard $10\Omega \pm 0.005\%$ resistor in series with the cell. Further experimental details can be found elsewhere (18). All measurements were performed at room temperature, $24^\circ \pm 2^\circ\text{C}$, and in N₂-purged 0.10M NaOH, using triply distilled water and analytical reagent-grade sodium hydroxide.

Spectral measurements.—The absorbance of thin oxide films formed directly on vitreous quartz slides were obtained in the range 190-820 nm using a Hewlett-Packard diode array spectrometer, Model 8451A, with the bare quartz slide as reference.

Action spectra were obtained using a Spex Minimate monochromator and a 150W xenon light source. Quantum efficiencies, ϕ , were calculated using the expression $\phi = 1.2408J/I_0\lambda$, where J is the photocurrent density in microamperes per square centimeter, 1.2408 is a conversion factor relating photon flux density to power flux density, and I_0 is the incident power flux density in milliwatts per square centimeters at wavelength λ (expressed in nanometers). While no corrections were made either for transmission losses or for reflection losses at the oxide-electrolyte interface, the procedure followed took account of losses at the electrochemical cell window, since they are matched by losses at the window of the actinometer cell [aqueous iron oxalate (19)] used to calibrate the radiometer (Moletron Model PR 200). The calibration was performed at six different wavelengths with the radiometer used henceforth over the entire wavelength range of interest, 250-750 nm. The electrochemical cell was positioned so that the monochromator slits were imaged at the photoelectrode surface. Thus, I_0 was set equal to the total power flux divided by the area of the slit image, 0.80 cm². Using a diode detector, it was determined that the slit image was uniform in power flux density to within a few percent.

Results and Discussion

Sputter-deposited iron oxide on iron.—Films formed in this way on substrates held at 100°C or less lead to very small photoanodic currents, in agreement with the result reported by Benko *et al.* (17). Performance improved substantially with increasing substrate temperature, however. Figure 1 and 2 show the dc photoanodic response and action spectrum, respectively, for a film about 500Å thick deposited in a pure oxygen plasma onto the iron substrate held at 350°C then cooled immediately to room temperature. Increasing the substrate temperature to 400°C led to no further improvement. While changing the oxygen pressure had no effect on the measured photocurrents, the inclusion of argon in the sputtering gas resulted in substantially lower photocurrents, as was found previously for sputtered TiO₂ films (18).

The data from the action spectrum are plotted in Fig. 3 in a form appropriate for an indirect bandgap semiconductor [$(\phi h\nu)^{1/2}$ vs. $h\nu$, Ref. (20)]. The data for $h\nu < 2.70$ eV

Fig. 1. Photoanodic response curve for 1000Å Fe₂O₃/Fe sputter deposited at 350°C and cooled immediately.

Fig. 2. Action spectrum for electrode of Fig. 1 taken at 0.50V (SCE)

Fig. 3. Indirect bandgap plot for the electrode of Fig. 1, showing a low energy linear region extrapolating to $E_g = 2.05$ eV.

are linear and extrapolate to a bandgap of 2.05 eV, in agreement with the result reported for α - Fe_2O_3 by Morin (5), namely, 2.2 ± 0.2 eV. A Mott-Schottky plot of the impedance data is presented in Fig. 4. The data are similar to results reported for bulk polycrystalline (7) and thermally grown (16) thin α - Fe_2O_3 films. The break occurring at ~ -0.4 V (SCE) has been attributed to deep donor (5, 7, 21) levels which act as electron-hole recombination centers, thereby suppressing the photocurrent onset potential, V_{pc0} to a value ~ 0.3 V anodic of the flatband potential, V_{FB} . Note, however, that V_{pc0} for the film of Fig. 1 is ~ 0.9 V anodic of V_{FB} , representing a further 0.6V anodic suppression of the photocurrent onset compared to that reported for polycrystalline (6) and single-crystal (1) Fe_2O_3 . This could be due to high recombination losses in the bulk and/or at the interface(s), to a kinetic block at the

Fig. 4. Mott-Schottky plot (1 kHz) for the electrode of Fig. 1. Since the dielectric constant, K , was not determined, the slopes are reported in terms of the product of K and N_d , the donor density.

oxide-electrolyte interface, or to nonohmic contact of the oxide to the underlying iron metal. This same very large suppression of V_{pc0} is reported by Benko *et al.* for sputtered films of Fe_2O_3 (17). Transient photocurrent studies obtained by chopping the white light at 40 Hz showed photo-onset around -0.70 V (SCE), which is close to the extrapolated flatband from Fig. 4. This indicates that the large suppression of V_{pc0} is not arising due to an anodic flatband shift.

In an attempt to check the ohmic conduction behavior of the oxide-metal contact, an indium-gallium paste was applied to the front surface of the oxide film and the conduction properties of the iron/ Fe_2O_3 /indium-gallium system measured. Highly nonlinear current-voltage curves were obtained in contrast to the behavior of annealed films of Fe_2O_3 on ITO, where ohmic behavior, was obtained. When indium-gallium contacts were made to films of iron oxide reactively sputtered directly onto glass at 350°C and cooled immediately to room temperature, nonlinear i - V behavior was again obtained. However, films which were vacuum annealed (350°C , 10h) showed linear i - V behavior and conductivities of the order of 2.0×10^{-4} mho-cm $^{-1}$. From these results, we cannot conclude that the $\text{Fe}_2\text{O}_3/\text{Fe}$ back contact is ohmic, but the fact that the Mott-Schottky plot extrapolates to the accepted flatband potential and the transient onset potential also occurs near flatband suggests that it is ohmic.

Annealing of the iron/ Fe_2O_3 thin film elements at 350°C *in vacuo* (10^{-7} torr) for 10h led to highly reduced films and no photocurrent.

Sputter-deposited iron oxide on ITO.—As for the iron-supported films, films deposited on ITO at or below 100°C showed only a very small photocurrent. Films deposited onto ITO at 350°C in a pure oxygen plasma and cooled immediately gave results very similar to those deposited onto an iron substrate. Vacuum annealing for 10h at 350°C , however, led to a dramatic improvement in their photoanodic response, as illustrated in Fig. 5, for a film 500Å thick.

While these results showed clearly the pronounced benefit of vacuum annealing, further studies were restricted to plasma-grown films, since Auger depth profile analysis of a 250Å film formed by reactive sputtering onto ITO showed indium doping to the extent of 10-15% at the outer surface, decreasing to 7-8% in the bulk of the film, before increasing again near the $\text{Fe}_2\text{O}_3/\text{ITO}$ back contact.

Plasma-grown iron oxide on ITO.—Auger depth profile analysis of iron oxide films grown in this way showed no detectable indium (<2%) at either the front surface or in the bulk of the film.

Figures 6-8 show the action spectrum, indirect bandgap plot, and Mott-Schottky plot for a 500Å film formed by plasma oxidation at 350°C followed by vacuum annealing for 10h at 350°C . The results are close to those

Fig. 5. Photoanodic response curve for 500Å $\text{Fe}_2\text{O}_3/\text{ITO}$ sputter deposited at 350°C then cooled over 3h *in vacuo* (curve 1) or vacuum annealed for 10h at 350°C (curve 2).

for the reactively sputtered and vacuum-annealed films. However, comparison of the Mott-Schottky plots indicates both a higher doping density and a cathodic shift of 0.1V in V_{FB} for the plasma-grown oxide relative to the reactively sputtered oxide.

To ascertain the role of vacuum annealing, some films were annealed for 10h in 2×10^{-2} torr oxygen following film formation. The photoanodic response curve and Mott-Schottky plot for one of these samples are shown in Fig. 9 and 10, respectively, along with those for a sample from the same batch that was returned to the

Fig. 9. Photoanodic response curves for 500Å $\text{Fe}_2\text{O}_3/\text{ITO}$ formed by plasma oxidation at 350°C. Both film systems were initially annealed 10h in oxygen at 350°C, but the effect of reannealing at 350°C in vacuum for 10h can be seen.

Fig. 10. Mott-Schottky plots (1 kHz) for electrodes of Fig. 9

vacuum chamber and vacuum annealed for 10h at 350°C. The pronounced improvement in both V_{poc} and the photocurrent produced by annealing *in vacuo* rather than in an oxygen atmosphere is clearly illustrated in the results. The reversibility of the changes brought about by annealing alternately *in vacuo* and in oxygen suggests a compositional, rather than structural, basis for the changes. Samples annealed in vacuum initially then reannealed in oxygen also showed the same degraded photocurrent behavior as the films annealed in O_2 initially.

The absorption spectra for 500Å, plasma-formed iron oxide films on vitreous quartz (no ITO present) are presented in Fig. 11. There is a significant difference in the spectra, depending on whether the film is annealed at 350°C for 10h in oxygen or *in vacuo*. Both spectra, however, are similar to that reported by Gardner *et al.* (21) for a 440Å thick iron oxide film formed on alumina by an unspecified procedure. The absorption shoulder at 560 nm (2.2 eV) is consistent with the indirect bandgap determined here (2.05 eV). Also apparent is an absorption peak beginning at about 460 nm (2.7 eV) and reaching a maximum of 385 nm (3.22 eV). This absorption peak has been attributed by Gardner *et al.* (19) to direct charge transfer from oxygen to iron. A direct bandgap plot of the quantum efficiency data (Fig. 12) does indeed produce a linear region from 2.85 to 3.2 eV, which extrapolates to a bandgap of 2.8 eV. This direct

Fig. 11. Absorbance plots for 500Å plasma-formed Fe_2O_3 films on vitreous quartz. Curve 1: annealed 10h in oxygen. Curve 2: annealed 10h *in vacuo*. Note suppression of onset at 2.2 eV of oxygen-onnealed film is reflected in poor photoanodic behavior, Fig. 9.

Fig. 12. Direct bandgap plot for electrode of Fig. 6

transition, which is superimposed on the indirect transition, is clearly responsible for the break in the indirect bandgap plots of Fig. 3 and 7.

Conductivity measurements made on films deposited directly onto glass slides, using indium-gallium contacts, yielded values in the range 5×10^{-6} – 10^{-5} mho-cm $^{-1}$ for unannealed samples, and in the range 2×10^{-4} – 2×10^{-3} mho-cm $^{-1}$ for vacuum-annealed samples. This change in conductivity is by a factor substantially larger than one would infer from the slopes of the Mott-Schottky plots (Fig. 10). This result, as well as the spectra of Fig. 11, suggests that vacuum annealing brings about more than simply an increase in the electron donor concentration. We are currently in the process of studying systematically the solid-state properties of plasma-formed iron oxide and the role of vacuum annealing, with this paper concentrating on their photoelectrochemical properties.

Postformation modification of vacuum-annealed, plasma-formed films.—In order to improve the photocurrent onset behavior of the vacuum-annealed films formed by plasma oxidation, postformation treatment with a number of aqueous solutions was tried, with

those producing a significant change, for better or for worse, being reported here.

Figure 13 shows the effect of including different concentrations of sodium vanadate in the 0.10M NaOH electrolyte on the photoanodic response curve. The effect is entirely reversible in that upon rinsing the electrode and returning it to fresh 0.10M NaOH (no vanadate) the original response curve is recovered.

Kyriacou (22) has shown that vanadate ions adsorb and polymerize on the surface of hematite at and above pH 10. The mechanism is assumed to involve the displacement of surface OH^- , which would explain the suppression of the photocurrent observed here in the presence of vanadate ions, as the surface OH^- are presumably the sites for water oxidation.

A number of electron donor complexing agents were tested for their efficacy in increasing the photocurrent, the most active of which was the thiocyanate ion, SCN^- . While treatment of an electrode in 0.50M KSCN for 5 min at room temperature produced no significant change in photocurrent, the same treatment in a boiling solution brought about a marked improvement in the photoanodic response. As can be seen from Fig. 14, the improvement is in the rate of current rise from V_{pco} to saturation (*i.e.*, in the fill factor) rather than in V_{pco} or the saturation current. The improvement, however, is substantial, representing a factor of two to three increase in photocurrent over much of the rising portion of the photoanodic response curve. Mott-Schottky plots for a plasma-oxidized film, both before and immediately after treatment with KSCN, are illustrated in Fig. 8. While the results appear to indicate that the treatment leads to a significant increase in carrier concentration, an additional, specific surface effect is not precluded. An improvement in photoanodic behavior has been reported by Kennedy *et al.* (8) resulting from immersing polycrystalline Fe_2O_3 in 1M KI for 3 weeks. They also observed the onset of a small photocurrent at the flatband potential associated with photo-oxidation of I^- (9). While they attribute these results to surface modification, the possibility of a concurrent change in the bulk properties through incorporation of I^- cannot be ruled out.

Results for treatment with cyanate (OCN^-) and pyrazine are shown in Fig. 14. As for thiocyanate, no effect was observed for treatment at room temperature. All of the nitrogen containing ligands tested led to some improvement in the fill factor for the photoanode when the treatment was carried out in boiling solution. Simply treating an electrode in boiling 0.10M NaOH, however, had no effect on the photocurrent, but such treatment,

Fig. 13. Photoanodic response curves for 500Å $\text{Fe}_2\text{O}_3/\text{ITO}$ plasma formed and annealed 10h *in vacuo*, both at 350°C, showing the influence of vanadate ion in the electrolyte. Curves 1-3 are for, respectively, 0, 0.0010, and 0.010M NaVO_3 in 0.10M NaOH. The response returns to that of curve 1 when the electrode is rinsed and returned to fresh 0.10M NaOH.

Fig. 14. Photoanodic response curves for electrodes formed as per Fig. 13, then treated in boiling aqueous solutions of different complexing Lewis bases for 5-10 min, the concentration being in the range 0.10-0.50M.

following *e.g.*, the KSCN treatment, restored the photocurrent response to that of an untreated electrode. The change brought about by the complexing agent is evidently fairly easily reversed. Thus, while the photocurrent enhancement was stable for up to 3h, sitting in 0.10M NaOH for 24h at room temperature restored pretreatment behavior.

The results of Lin *et al.* (23) indicate that the active sites for H₂O oxidation are associated with Fe₂⁺ ions on the surface of α -Fe₂O₃. Perhaps the complexing agents stabilize this oxidation state, thereby enhancing the charge transfer step at the oxide-electrolyte interface. Such a proposition is consistent with the fact that the strongest Lewis base, SCN⁻, produced that greatest improvement in the fill factor. Whatever the explanation, however, the improvement achieved is considerable, and suggests the possibility of achieving further improvement in this way. Note, however, that these complexing agents have little or no effect on V_{pc0} , which is $\sim 0.3V$ anodic of V_{FB} . If the source of this anodic shift in V_{pc0} is indeed the presence of deep donor levels, 0.3V below the Fermi level (5, 7, 19), then one could not expect to alter V_{pc0} through surface treatment alone. Likewise, surface treatment is not expected to alter the saturation photocurrent. Thus, while we have shown that treatment with certain complexing agents can result in a substantial improvement in the fill factor, the problems of late photocurrent onset and low quantum yield remain.

Summary and Conclusions

Thin film (500Å) Fe₂O₃ photoanodes, with characteristics closely matching those for polycrystalline iron oxide formed by other methods (8, 15) have been fabricated using atomic sputtering techniques. Achievement of such behavior requires annealing the films at $\sim 350^\circ C$ *in vacuo*. In turn, this treatment dictates a back contact material that does not lead to reduction of the Fe₂O₃ film during the annealing process, eliminating iron for this purpose. Procedures for depositing high conductivity, high transparency ITO films were developed and such films found to form excellent, ohmic back contacts for the Fe₂O₃ films produced either by reactive sputtering or plasma oxidation of iron films. While reactive sputtering produced Fe₂O₃ films containing 7-15% In, no In could be detected in the films formed by plasma oxidation.

The very large improvement in the photoanodic response characteristics brought about by vacuum annealing at 350°C are reversed on annealing in oxygen at 350°C.

Mott-Schottky, spectral, and conductivity measurements were performed on both the vacuum- and oxygen-annealed samples to illuminate the mechanism involved in this process; the problem, however, awaits a thorough investigation.

Treatment of the electrodes in boiling aqueous solution containing electron donor complexing agents resulted in larger fill factors, the most substantial increase resulting from treatment in KSCN. Boiling in 0.10M NaOH apparently removed the complexing agent as the fill factor returned to its original value. The magnitude of the effect appears to be related to the Lewis base strength of the complexing agent, and we have suggested that the complexing agent may facilitate electron transfer at the oxide-electrolyte interface by stabilizing surface Fe²⁺ ions, believed to be connected with the sites for water oxidation (23). Other possibilities exist, however. Inclusion of vanadate ion in the electrolyte suppresses the photocurrent, the mechanism being perhaps the chemisorption of vanadate ion through substitution for the surface OH⁻ ions (22), such OH⁻ presumably being the site for water oxidation.

Electrochemical Oxidation of Methane in Nonaqueous Electrolytes at Room Temperature

Application to Gas Sensors

Takaaki Otagawa,*¹ Solomon Zaromb,* and Joseph R. Stetter

Argonne National Laboratory, Energy and Environmental Systems Division, Argonne, Illinois 60439

ABSTRACT

The electrochemical oxidation of methane at room temperature was studied using several nonaqueous solvents and electrocatalysts. The best sensitivity and reaction stability were obtained with an electrode composed of platinum black mixed with a 35 weight percent Teflon® dispersion and deposited on a porous Teflon membrane in contact with an electrolyte of 2M NaClO₄ in γ -butyrolactone. A working electrode potential of 800 mV *vs.* Ag/AgCl gave the least current variation with changing relative humidity. However, a potential of 600 mV *vs.* Ag/AgCl gave the highest signal-to-background current ratio. The sensitivity (net current) measured for the electro-oxidation of methane in γ -butyrolactone increased significantly with increasing temperature. The reaction has an activation energy of approximately 12 kcal/mol. An electrochemical methane monitor was constructed exhibiting a sensitivity of 1 μ A/% CH₄ and negligible sensitivity to parts-per-million levels of CO or NO₂. However, it gave responses to > 0.3% H₂, 49 ppm NO, and 50% C₂H₆ that could be mistaken for methane signals.

The potential advantages of amperometric methane sensors have been recognized for detecting natural gas (1) and for meeting the requirements of the U.S. Bureau of Mines' Intrinsic Safe Mine Monitoring System (2, 3).

Although electro-oxidation of methane on a platinum electrocatalyst occurs at an appreciable rate in aqueous phosphoric, sulfuric, and perchloric acids in the 60°-150°C range (4-8), methane's poor electrochemical reactivity at lower temperatures has frustrated attempts to develop room temperature reactors and sensors (1, 9). A high overpotential is required to oxidize methane at room temperature (4, 9), although the electro-oxidation of methane is thermodynamically favored at modest potentials, *i.e.*, the reaction CH₄ (g) + H₂O (l) → CH₃OH (aq) + 2H⁺ + 2e⁻ has $E^\circ = 0.586$ V *vs.* the reversible hydrogen electrode (RHE) (10). At high overpotentials (≥ 0.8 V), the water oxidation reaction proceeds at a high rate and results in intolerable high background currents in sensors containing aqueous electrolytes.

Problems of this type have been encountered and solved in practical sensors by varying the sensing electrode catalyst, the method of catalyst preparation, the electrolyte composition, or the cell geometry (11). The use of nonaqueous electrolytes (*e.g.*, propylene carbonate, glycols, and solid polymers) has been reported as a particularly promising approach for methane oxidation (12).

Several novel amperometric sensors that respond to methane at room temperature, each using a Teflon®-bonded platinum black working electrode and a nonaqueous electrolyte in a three-electrode cell, have been developed recently at Argonne National Laboratory (13-15). The electrochemical studies that led to development of these sensors are described in this paper.

Experimental

Cell construction.—The Teflon-bonded platinum black electrodes were prepared by mixing the desired proportions of commercial platinum black (Engelhard Industries, East Newark, New Jersey), with Teflon 30 dispersion (E.I. du Pont de Nemours and Company, Incorporated, Wilmington, Delaware), and bonding the mixture to a porous Teflon membrane (Zitex™, Chemplast, Incorporated, Wayne, New Jersey), in a way similar to previously reported procedures (16). The platinum black catalyst loading was 14 mg/cm², and the Teflon content of the dehydrated mix was varied between 20 and 45% of weight. Other noble metal black (Engelhard Industries) or oxide electrodes [prepared by coprecipitation of nitrates (17) obtained as reagent-grade chemicals

from Aldrich Chemical Company, Incorporated, Milwaukee, Wisconsin], were made in a similar way.

Each electrode was heat pressed at 100°C and 0.81 kg/cm² for 5 min, with the catalyst pressed against a 40 mesh platinum screen that served both as a support and as an efficient current collector. The electrodes were then sealed onto a polypropylene sensor body, in which the vertically positioned working and counter-reference electrodes were located at opposite ends of the electrolyte chamber (see Fig. 1). The geometric areas of the working, reference, and counterelectrodes were 1.27, 0.42, and 0.84, respectively.

Electrochemical measurements.—The impedance between each pair of electrodes was determined using a conductivity bridge (Model 31, Yellow Springs Instrument Company, Incorporated, Yellow Springs, Ohio), at 1 kHz, after allowing the electrodes to stay in contact with an electrolyte solution overnight. The potential of the platinum/air reference electrode was measured using a microflexible Ag/AgCl reference electrode (Model MI-402, Microelectrodes, Incorporated, Londonderry, New Hampshire). The potential of the working electrode was maintained constant *vs.* the platinum/air reference electrode, which was built into each sensor, using a potentiostat designed and constructed in house. The signal output from the current/voltage converter of the potentiostat was recorded on a three-channel strip-chart

recorder (Model 1243, Soltec Corporation, Sun Valley, California).

Current/potential curves for methane oxidation at each potential were determined only after allowing the working electrode to equilibrate at the desired potential for at least 12h. The current was initially recorded in a background of "zero" air (*i.e.*, air containing no methane or other known impurities) of a constant relative humidity for at least one hour, until it reached a steady-state value. Subsequently, the steady-state currents were measured for methane samples of the same relative humidity.

Various nonaqueous solvents (99.99% purity, Aldrich Chemical Company, Incorporated), containing 1-3M NaClO₄ or LiClO₄ (99.99% purity, Aldrich Chemical Company, Incorporated), as the electrolytes were prepared and placed in the solution reservoir of the sensor (see Fig. 1). All chemicals were used without further purification.

Gas sample preparation.—High purity methane (99.99%, Scott Environmental Technology, Incorporated, Troy, Michigan) was used for all experiments. The purity of the methane samples was further verified using a sensor array in a portable device for detecting and identifying hazardous vapors developed at Argonne (18, 19). No traces (≥ 1 ppm) of CO, NO, NO₂, or H₂ were detected. Various concentrations of methane in air were prepared by dynamically mixing 99.99% methane and hydrocarbon-free air (Scott Environmental Technology, Incorporated) at proper ratios using two flow meters. All other gas mixtures used in this work (200 ppm CO in air, 49 ppm NO in N₂, 48 ppm NO₂ in air, 200 ppm and 0.5% H₂ in air, and 99.9% C₂H₆) were obtained from Scott Environmental Technology, Incorporated, in premixed cylinders. About 2 liters of each pure gas or gas mixture was first collected into a Teflon gas sampling bag (30 × 30 cm, Pollution Measurement Corporation, Chicago, Illinois) before use.

Humidified methane samples were prepared by passing dry gas samples through a 2.5-5 cm Gore-Tex® (porous Teflon) tube (Gore-Tex TA001, W. L. Gore & Associates, Incorporated, Elkton, Maryland) immersed in water. The relative humidity of the gas mixture was determined by placing a humidity sensor (Model 455, General Eastern Instruments Corporation, Watertown, Massachusetts) in the gas flow path.

In all experiments, the methane samples were pumped with a portable air pump (Model AS-100-1, Spectrex Corporation, Redwood City, California) through a "zero" filter (10 cm length by 2 cm diam) that contained sequential beds of activated carbon, Purafil (KMnO₄/Al₂O₃) and 1% platinum coated on alumina. This purification system was designed to remove CO, H₂, and other trace impurities from the methane gas before it entered the sensor's gas exposure chamber. Unless otherwise stated, all measurements were performed at 23°C. The flow rate for the gas samples through the sensor was typically 100 cm³/min.

An environmental chamber (Model 816, GCA/Precision Scientific, Chicago, Illinois) was used to control the temperature of the experiments. The entire experimental setup, including gas sampling bags for methane and pure air, was placed inside the environmental chamber. The system was allowed to thermally equilibrate at the temperature of interest for at least 3h before any data were taken.

Results and Discussion

Selection of solvent.—The response to dry methane of sensors using a platinum black working electrode (20 weight percent [w/o] Teflon) on a porous Teflon membrane (Zitex H606-122) was recorded for sensors containing 11 solvent and solvent-gel combinations. Table I summarizes the results obtained. Two nonaqueous solvents not listed in the table, benzonitrile and dimethylformamide, did not dissolve enough electrolyte (NaClO₄) to yield a conductivity sufficiently high for use in an amperometric sensor (low conductivities result in small signals and slow responses). Also, solvents with low

boiling points (*e.g.*, acetonitrile) gave small or insignificant signals for methane. These solvents may have been too volatile for the electrodes to be properly wetted. Solvents can also influence the methane signal by inhibiting the reaction at the electrode surface or by inhibiting efficient transport of the methane to the electrode.

Propylene carbonate and γ -butyrolactone gave the best responses to methane under the test conditions. Although the propylene carbonate electrolyte yielded a response of about 10 μ A to 100% methane, it exhibited a continuously changing background current. This current may have been associated with the electrochemical decomposition of propylene carbonate into propylene and carbonate at the potential used in these experiments (20). The low sensitivity and rather slow response of this sensor could be due to partial or complete flooding of the pores in the Teflon-bonded electrode by the electrolyte. To eliminate or reduce pore flooding, the propylene carbonate electrolyte was gelled by adding approximately 10 w/o polymethylmethacrylate. A rapid response but a weak signal was observed for 100% methane. Because polymethylmethacrylate cannot withstand the highly anodic electrode potentials required for methane oxidation, sensors containing this gel were characterized by high background currents and unstable sensor response over short time periods.

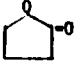

The smallest background current drift was obtained with γ -butyrolactone or sulfolane. Because sulfolane does not dissolve salt readily, the electrolytes obtained had low conductivity, which results in weak sensor signals. On the other hand, the sensitivity achieved with γ -butyrolactone was as high as that achieved with propylene carbonate. The γ -butyrolactone system also exhibited lower cell resistance ($\sim 60\Omega$) than the propylene carbonate system ($\sim 150\Omega$). This result suggested the possibility of achieving more efficient methane oxidation with γ -butyrolactone and a working electrode designed to control pore flooding. Therefore, small quantities (~ 4 w/o) of polymethylmethacrylate were added to γ -butyrolactone, which rendered the electrolyte more viscous. Such additions resulted in methane signals as large as 70 μ A, a result that can be attributed to reduced pore flooding. However, such methane signals are not easily reproduced because of the electrochemical instability of polymethylmethacrylate and the formation of an insulating white polymer film in the electrode pores when the electrode is exposed to moisture.

In summary, the most reproducible methane oxidation currents were achieved with pure γ -butyrolactone electrolyte, which was used as the solvent in the remainder of the experiments.

Optimization of porous electrodes.—A catalyst bed of platinum black with a 20 w/o Teflon content was deposited on different Zitex (porous Teflon) membranes to study the effect of pore size and pore thickness on the electrochemical signal resulting from methane oxidation. Zitex membranes having pores of from 2.5 to 20-30 μ m were used. Only those with pores between 5 and 20 μ m gave large, stable, and repeatable currents. It was apparent from these measurements that mass transport of the reactant to the electrode was important. Satisfactory results were obtained with either Zitex H662-123 (10-20 μ m pores) or Zitex E606-122 (5-10 μ m pores). The Zitex H662-123 membrane performed better because of its open structure, which permitted it to supply gas quickly to the electrode-electrolyte interface. This membrane was used in the following experiments.

As in fuel cell operation, electrochemical gas sensing requires establishing a stable triple-phase (gas-electrode-electrolyte) interface at the working electrode. The Teflon content of the electrode significantly affects the nature of this interface, which has a profound effect on sensor performance, especially sensitivity and response time. Of the three Teflon concentrations tested, the sensitivity to methane was highest at a concentration of 35 w/o Teflon (see Fig. 2). This behavior is similar to that ob-

served for porous gas diffusion electrodes used in fuel cell technology (16, 21). At low Teflon concentrations, the active electrocatalyst layer was filled with electrolyte, resulting in internal diffusion control; hence, observed oxidation currents were small. Indeed, in the case of 20 w/o Teflon, an increase in the potential of the working elec-

trode did not enhance oxidation currents for methane, which clearly indicated a diffusion-controlled condition rather than one limited by electrocatalyst activity. As the Teflon concentration was increased to 35 w/o, the degree of pore flooding in the electrode decreased, and the control of the reaction rate changed from diffusion to electrochemical activation. An increase in the Teflon concentration beyond 35 w/o resulted in lowered electrochemical activity caused by a decrease in the catalyst's effective conductivity and surface area.

In the case of 35 w/o Teflon, the addition of polymethylmethacrylate gave oxidation currents of the same magnitude as those obtained with pure γ-butyrolactone. This observation supports our conclusion that the maximum degree of utilization of the catalyst may have been achieved with a Teflon concentration of 35 w/o.

Electrode performance characteristics.—Effect of the electrolyte.—The electrolyte used with the γ-butyrolactone solvent was NaClO₄. No substantial differences were observed in methane oxidation currents when LiClO₄ was substituted for NaClO₄. The solubility of NaPF₆, which is reported to be electrochemically more stable than perchlorates (22), is too low in γ-butyrolactone to produce a usable electrolyte.

There have been reports of explosion incidents involving LiClO₄ in dioxolane (23) or nitromethane (24, 25). In both cases, the electrolyte was in direct contact with metallic Li. Our literature search has not uncovered any reports of explosion incidents involving NaClO₄ in γ-butyrolactone, and we believe that our operating conditions (10°-42°C ambient temperature, low operating current densities) are sufficiently different from those in the reported incidents to render the probability of an explosion hazard with this system extremely remote.

The variation in the magnitude of the methane oxidation current with the concentration of NaClO₄ in γ-butyrolactone is shown in Fig. 3. The highest current is

Fig. 2. Net response to various concentrations of methane in air as a function of Teflon concentration. Pt block: 14 mg/cm². Zitetex: H662-123. Electrolyte: 2M NaClO₄ in γ-butyrolactone. Electrode potential: 0.85V vs. Ag/AgCl. Flow rate: 100 cm³/min with a zero filter.

Fig. 3. Net response to various concentrations of dry methane in air and cell impedance as functions of the concentration of NaClO_4 in γ -butyrolactone. Pt black: 14 mg/cm^2 . Teflon: 35 w/o. Zitex: H662-123. Electrode potential: $0.75 \text{ V vs. Ag/AgCl}$. Flow rate: $100 \text{ cm}^3/\text{min}$ with a zero filter. Data were taken on cells freshly filled and equilibrated with each electrolyte for at least 12h.

observed for 2 M NaClO_4 , and the smallest impedance between the working and counterelectrodes is also observed at this concentration. The remaining experiments were therefore carried out with 2 M NaClO_4 in γ -butyrolactone.

Effect of the working-electrode potential.—The effect of the electrode potential on methane oxidation was studied at two relative humidities (75% and 30% RH). The typical response (net current due to electro-oxidation of methane) vs. potential at 75% RH is plotted in Fig. 4. The background current increases sharply with increasing potential, presumably due to oxidation of water, and the observed net oxidation currents for methane go through maxima at a potential of $800 \text{ mV vs. Ag/AgCl}$. A decrease in sensitivity at a potential of 900 mV is attributed to the large background current ($\sim 90 \mu\text{A}$) at this potential. At 75% RH, the current is substantially proportional to methane concentration over a wide range of concentration (0-90%) and potential (500-900 mV vs. Ag/AgCl).

Fig. 4. Net response to various concentrations of methane in pure air vs. working electrode potential at 75% relative humidity.

At 30% RH, the methane currents gradually increase as the potential becomes more anodic. These currents display a diffusion-limited region at potentials above $800 \text{ mV vs. Ag/AgCl}$ for concentrations of methane below 50%. The background current remained below $20 \mu\text{A}$ at the potentials used. However, at 30% RH, the response becomes nonlinear for methane concentrations greater than 50% at potentials greater than $700 \text{ mV vs. Ag/AgCl}$.

The variation of sensitivity with potential for the two relative humidities studied is illustrated in Fig. 5. The sensitivity values were calculated by applying the least squares method to plots of the steady-state current vs. concentration. At potentials lower than $800 \text{ mV vs. Ag/AgCl}$, increased availability of water vapor increases the methane current, which suggests that water is important in the mechanism of the anodic oxidation of methane. At these potentials, a probable reaction is (26)

However, at $800 \text{ mV vs. Ag/AgCl}$, the effect of humidity becomes negligible, indicating a change in the dominant mechanism for the electro-oxidation of methane. The predominant reaction at this potential could be (8)

Thus, a working electrode potential of $800 \text{ mV vs. Ag/AgCl}$ gives the highest response to methane and the least variation in response at various relative humidities. However, the use of this potential in a practical sensor might be limited by the excessive background current ($60 \mu\text{A}$, cf. Fig. 4), even though this current could be compensated by using a nearly identical sensor or working electrode that is not exposed to methane (15).

The ratio of sensitivity to background current at 75% RH is plotted against the potential in Fig. 5. In this case, the optimum potential for observing the oxidation current due to methane is $600 \text{ mV vs. Ag/AgCl}$. The effect of relative humidity at this potential could be minimized by preconditioning the gas samples to an approximately constant humidity before introducing them to the working electrode. This approach could lead to a practical instrument configuration for certain field applications.

Effect of temperature on methane oxidation.—The effect of temperature on methane oxidation is summarized in Table II. The currents due to methane oxidation are substantially proportional to methane concentration from 0 to 100% methane at each temperature. However, the

Fig. 5. Sensitivity at 30% and 75% RH and ratio of sensitivity to background current at 75% RH vs. working electrode potential.

Table II. Summary of temperature effect on sensor response

Temperature (°C)	Pt/air reference electrode potential (V vs. Ag/AgCl at 25°C) ^b	Background current (μA)	Response to percentage of methane in pure air (μA, net signal) ^a					Sensitivity (μA/% CH ₄)
			100	75	50	25	12	
10	0.346	19	19	14	7	2.5	1.4	0.209
25	0.329	51	50	38	23	10	5	0.524
35	0.317	60	82	60	40	17	8	0.847
42	0.308	150	165	120	80	40	20	1.64

^a The working electrode potential was adjusted to 800 mV vs. Ag/AgCl at 25°C and maintained at the indicated temperature and at the same flow rate (100 cm³/min). The relative humidity at 25°C was 76%.

^b The Ag/AgCl reference electrode was maintained at 25°C and inserted into the sensor (kept at the indicated temperature) during the brief duration (~10s) of relative potential measurement. No attempts were made to correct for possible changes in the temperature of the Ag/AgCl electrode during this brief measurement period or for any temperature gradients at the liquid junction that could have affected the liquid junction potential.

sensitivity and the background current are dependent on temperature. The sensitivity increases by a factor of eight as the ambient temperature is raised from 10° to 42°C, although the potential of the platinum/air reference electrode decreases slightly (< 0.04V), as measured by the Ag/AgCl electrode.

The Arrhenius plots of the temperature/current data are shown in Fig. 6. In these measurements, the working electrode potential at each temperature was adjusted to 800 mV vs. Ag/AgCl at 25°C in accordance with the readings of the Pt/air reference-electrode potential of Table II. No substantial differences in the magnitude of the signals were observed with or without the adjustment of the potential.

The apparent activation energies for the observed methane oxidation at constant potential, ΔE^\ddagger , calculated using the equation $\Delta E^\ddagger = -2.3R [\partial \log(i) / \partial (1/T)]_v$, average 12 kcal/mol. The values of the activation energy are lower than those measured in inorganic acids. For instance, in 1N H₂SO₄, a value of approximately 30 kcal/mol has been reported (8). The electro-oxidation of methane in γ -butyrolactone containing 2M NaClO₂ may proceed by a different mechanistic path than in sulfuric acid. An activation energy of 8.9 kcal/mol has been reported for the electro-oxidation of methane in trifluoromethanesulfonic acid monohydrate (27). These studies demonstrate the profound influence of the electrolyte on the ability to oxidize hydrocarbons electrocatalytically and ultimately on the design of electrochemical sensors.

Reactivity of other gases.—To design a practical methane monitor, the electrochemical sensors must be specific to methane and give a minimum signal in response to other pollutants that may be present. Figure 7 illustrates the response vs. time behavior of the experimental sensor upon exposure to several gas mixtures in air or N₂ at 78% RH. The interference gases were either passed directly into the sensor or first through a zero filter. No oxidation currents were observed for 200 ppm CO, 200 ppm H₂, or 48 ppm NO₂. Without a zero filter,

strong responses were observed for 25% CH₄, 0.5% H₂, and 49 ppm NO. Upon insertion of the zero filter, the signal for 0.5% H₂ decreased by about one-third, whereas the signals from 25% CH₄ and 49 ppm NO remained substantially unchanged. The response to 50% C₂H₆ was comparable to that of 50% methane.

Therefore, H₂, NO, and C₂H₆ yielded responses that might be mistaken for methane signals, even after some chemical filtration. Although the zero filter is designed to remove CO, some H₂, and other trace impurities, the effectiveness of this kind of filter is variable. An improved filter with an appropriate selection of heterogeneous catalysts might enhance the selectivity of the electrochemical approach to methane detection. Alternatively, the methane sensor could be used in conjunction with either a gas chromatograph or with sensors responding to H₂, NO, and C₂H₆, but not to methane (so that the methane concentration could be computed from the responses of all four sensors).

Methane electro-oxidation catalysts.—Preliminary investigations were conducted on various electrocatalysts, including platinum mesh, platinum black, platinum black/carbon, iridium black, palladium black, carbon, Co₃O₄, and Co₃O₄/carbon. Of the noble metals tested, only platinum black yielded a significant activity for methane oxidation, but it exhibited a relatively slow response time of approximately 4 min. The platinumized platinum mesh alone produced no signal, but when used as a current collector in conjunction with platinum black, it reduced the response time (to 90% of final signal) from about 4 to about 1 min. The Co₃O₄ catalyst produced weak signals and a slow response, presumably due to the excessive resistivity of this catalyst, which yielded an electrode resistance of about 1 k Ω , even with a current collector. To reduce the high resistance of the Co₃O₄ catalyst, the oxide was mixed with fine carbon black powders (Cabot Corporation, Boston, Massachusetts, or Gulf Oil Products Company, Baytown, Texas). However, the carbon black did not significantly improve the conductivity of the oxide.

Fig. 6. Plots of current (log scale) vs. $1/T$ at various concentrations of methane in pure air. Electrode potential: 0.8V vs. Ag/AgCl.

Fig. 7. Response to selected interfering gases in air passed through a zero filter or no filter. Unless specified, signals are taken in pure air. Electrode potential: 0.7V vs. Ag/AgCl.

Efficiency of the electro-oxidation of methane.—It is possible to estimate a dynamic steady-state efficiency for the electro-oxidation of methane at a porous platinum black electrode in the γ -butyrolactone/ NaClO_4 system. An elementary argument shows that the number of moles per second being supplied to the sensing electrode gas chamber for a 50% methane sample at $100 \text{ cm}^3/\text{min}$ is $3.41 \times 10^{-5} \text{ mol/s}$. If the overall reaction [1] is assumed to occur, then the maximum obtainable current at 100% efficiency would be $i = 8F \text{ dn}/\text{dt} = 26.3 \text{ A}$. A typical signal of $50 \mu\text{A}$ was obtained for 50% methane at $800 \text{ mV vs. Ag/AgCl}$, which yields an estimated efficiency of 1.9×10^{-6} . Although the dynamic steady-state efficiency for methane oxidation is quite low under these conditions, this current suffices to detect relatively low methane levels.

In contrast, the estimated efficiency for the oxidation of NO on the same platinum black electrode in the γ -butyrolactone/ NaClO_4 system is 6.6×10^{-2} . This efficiency yields a response ratio about 35,000 times greater per molecule of NO relative to that of methane. Since the size and weight of methane molecules are comparable to or smaller than those of NO molecules, the low efficiency for methane oxidation cannot be due to a diffusion-limited process. Therefore, the far smaller efficiency of methane oxidation must be due to the kinetics of the reaction on the platinum black electrode. The catalytic activity of platinum for methane oxidation at room temperature in the γ -butyrolactone/ NaClO_4 system is very poor when compared with that of other gaseous species. Further, the rate of CO oxidation is approximately 100 times faster on platinum electrodes than on gold electrodes (28). Thus, widely varying sensor responses can be produced by variations in the electrode catalyst. A search for new electrocatalysts to increase the efficiency of methane oxidation could result in significant improvements in the ultimate detection limit of an amperometric sensor.

Application to Gas Sensors

Significant electrochemical oxidation of methane at room temperature was observed using a Teflon-bonded platinum black ($14 \text{ mg}/\text{cm}^2$) electrode. The electrode, which contained a 35 w/o Teflon dispersion, was deposited on a porous Teflon (Zitex) membrane with $10\text{--}20 \mu\text{m}$ diam pores. The electrolyte was $2M \text{ NaClO}_4$ dissolved in γ -butyrolactone solvent. This system can be used to construct a room temperature electrochemical methane monitor (14, 15). As an example, Fig. 8 illustrates the typical response characteristics of a sensor for seven different concentrations of methane ranging from 1.3 to 50%. The response is substantially linear with the methane concentration, and the response and recovery times are about 1 min. Concentrations as low as 0.3% methane in air can be distinguished from the background current and noise, and the response and recovery times are substantially independent of methane concentration.

Fig. 8. Typical chart recordings of amperometric sensor responses to various concentrations of methane in dry air. Electrode potential: $0.75V$ vs. Ag/AgCl . Source: Ref. (14).

To develop a monitor for lower methane concentrations (i.e., 0.5%) that has a detection alarm level of say 0.1% (1000 ppm) methane in air, further enhancement of the sensor signal-to-noise ratio is needed, as are increases in the efficiency of the electro-oxidation reaction. Also required are improvements in the selectivity of the sensor, as well as compensation for, or a reduction in, the temperature dependence of the methane oxidation currents and background currents.

Oxygen Evolution on Nickel Oxide Electrodes

J. C. Botejue Nadesan and A. C. C. Tseung*

Chemical Energy Research Centre, Department of Chemistry, The City University, London, England EC1V 0HB

ABSTRACT

The anodic oxygen evolution reaction on Teflon-bonded NiO and Li-doped NiO in KOH solution was studied by potentiostatic and galvanostatic techniques as a function of hydroxyl ion concentration, and the kinetic equations were derived. It was shown that the rate-determining step (rds) for NiO at current densities of 100-1000 mA-cm⁻² is S + OH⁻ → SOH + e, and the Tafel slope is approximately 118 mV/decade at 25°C. The rds for Li-doped NiO at current densities of 10-1000 mA-cm⁻² is SOH + OH⁻ → SO⁻ + H₂O, and the Tafel slope is approximately 60 mV/decade. The likely reason for this difference in rds is related to the concentration of Ni²⁺ and Ni³⁺ ions in NiO and Li-doped NiO electrodes.

Nickel metal has long been known as the most suitable material for anodes in alkaline water electrolyzers (1-3). However, a major drawback in the use of this metal is that the potential drifts unavoidably toward more positive values with time.

Work at the City University has indicated that there is a correlation between the minimum voltage for oxygen evolution on semiconducting oxides and the potential of the lower oxide/higher oxide couple (4-7). In the case of nickel cobalt oxide and Li-doped cobalt oxide, the minimum voltage for oxygen evolution is approximately 1.45V *vs.* RHE, comparable to the published values of the lower oxide/higher oxide couple for nickel and cobalt oxide. The purpose of the present work is to study the mechanism of oxygen evolution on NiO as well as Li-doped NiO.

Experimental

Stoichiometric quantities of Ni(NO₃)₂ · 6H₂O and LiNO₃ · 6H₂O required to prepare 10g of 10, 5, and 0 atom percent (a/o) Li-doped NiO was dissolved in 100 cm³ of distilled water and freeze dried (8). The decomposed powder was sintered at 600°C for 5h. The catalyst structures were confirmed by x-ray diffraction analysis.

The catalyst powders were then fabricated into fluorinated ethylene propylene (FEP)-bonded electrodes (9), supported on 60 mesh nickel screens of geometric area 1 cm². Catalyst loadings were approximately 23 mg-cm⁻², and the FEP solid content approximately 25%.

The oxygen evolution performance of the preanodized electrodes were tested at 25°C in a thermostated three-compartment Pyrex cell. The electrodes were mounted in the submerged mode in 5 mol-dm⁻³ KOH electrolyte, prepared by dissolving KOH pellets in doubly distilled deionized water. A piece of platinum was used as the secondary electrode, and the potentials were measured against the reversible hydrogen electrode (RHE). A chemical electronics potentiostat (H. B. Thompson, Model 251) was used in the galvanostatic and potentiostatic modes. The interrupter technique (10) was used to measure the ohmic drop between the Luggin capillary and working electrode.

Experimental reaction order parameters were obtained by simple analysis of the polarization data in KOH concentrations of 0.6, 0.8, 1.0, and 1.2 mol-dm⁻³ KOH at 25°C. Anodic charging of the electrodes was studied by applying a current of 10⁻⁴ A-cm⁻² to the electrodes, held at 1V *vs.* RHE and recording the potential time response on a Y-T recorder.

*Electrochemical Society Active Member.

Results and Discussion

Table I lists the specific surface area (ssa) and resistivities of the NiO and Li-doped NiO. It is interesting to note that there is a significant difference in the resistivity of the Li-doped NiO and the pure NiO, confirming that Li⁺ ions have indeed diffused into the NiO lattice, thereby creating trivalent nickel ions. The existence of divalent and trivalent nickel cations are responsible for the greatly enhanced conductivity of the doped oxides, and this should also have a significant effect on their electrochemical activity.

Figure 1 gives a comparison of catalytic activity for oxygen evolution on NiO and Li-doped NiO electrodes. It is evident from the figure that the oxygen evolution potential of NiO decreases with increase in lithium content. Two reasons could be put forward to explain this trend: (i) an increase in electrical conductivity with increase in lithium doping (*cf.* Table I), (ii) an increase in the Ni³⁺ ion concentration with lithium doping.

A consideration based solely on increased electrical conductivity will not explain the trend observed, especially the difference in performance of the 5 and 10 a/o Li-doped NiO, both having an electrical resistivity of approximately 1 Ω-cm. However, if the Li⁺ ions enter the NiO lattice, this would oxidize corresponding amounts of Ni²⁺ ions to Ni³⁺ ions; thus, 10 a/o Li-doped NiO will have a higher percent of Ni³⁺ ions than 5 a/o Li-doped NiO; Ni³⁺ ions could be the active sites for the oxygen evolution reaction, and hence, greater the Ni³⁺ ion concentration better the performance. This trend is more in accordance with the oxygen evolution trend.

An interesting point to note is that the Tafel plots for the two compounds are different. NiO has three slopes. At high current densities (100-1000 mA-cm⁻²), the slope was ~ 132 mV/decade. At current densities between 5 and 100 mA-cm⁻², the slope was ~ 85 mV/decade, and at current densities lower than 5 mA-cm⁻² the Tafel slope was ~ 43 mV/decade. On Li-doped NiO, two slopes were observed, *i.e.*, at high current densities (~ 10-1000 mA-cm⁻²) the

Table I. Characterization of NiO and Li-doped NiO catalysts

Nominal Li content (a/o)	10	5	0

slope was ~ 73 mV/decade, and at current densities than 5 mA-cm⁻² the slope had a value of ~ 44 mV/decade.

The experimental reaction order parameters for oxygen evolution on NiO and 5 a/o Li-doped NiO are as shown in Fig. 2.

Figure 3 shows the potential response of a NiO electrode (catalyst loading 20.45 mg-cm⁻²) held at 1V vs. RHE on applying an anodic current of 10⁻⁴ A-cm⁻². The response curve for NiO has two potential arrest regions before oxygen evolution. The first potential arrest occurs at approximately 1.31V, and the second at a potential of approximately 1.45V vs. RHE. The potential response of a 5 a/o Li-doped NiO electrode (catalyst loading 21.4 mg-cm⁻²) under similar experimental conditions is given in Fig. 4. The trace, unlike that of NiO, shows only one potential arrest region before oxygen evolution, i.e., at ~ 1.42 V vs. RHE. The thermodynamic potential of Ni³⁺ \rightarrow Ni²⁺ is 1.304V vs. RHE, and that of Ni³⁺ \rightarrow Ni⁴⁺ is 1.434V vs. RHE (11). Therefore, the potential arrest observed at 1.31V on the NiO charging curve is due to the formation of Ni³⁺ ions, and the potential arrest at 1.45V on both com-

Fig. 2. KOH concentration dependence of oxygen evolution on NiO (solid circles) and on 5 a/o Li-doped NiO (solid squares) at a constant current density of 5×10^{-3} A-cm⁻² at 25°C. The figure also shows the KOH concentration dependence of oxygen evolution on NiO (open circles) and on 5 a/o Li-doped NiO (open squares) at a constant potential of 0.72V vs. SHE at 25°C.

Fig. 3. Anodic charging curve on a FEP-bonded NiO electrode of catalyst loading 21.2 mg-cm⁻².

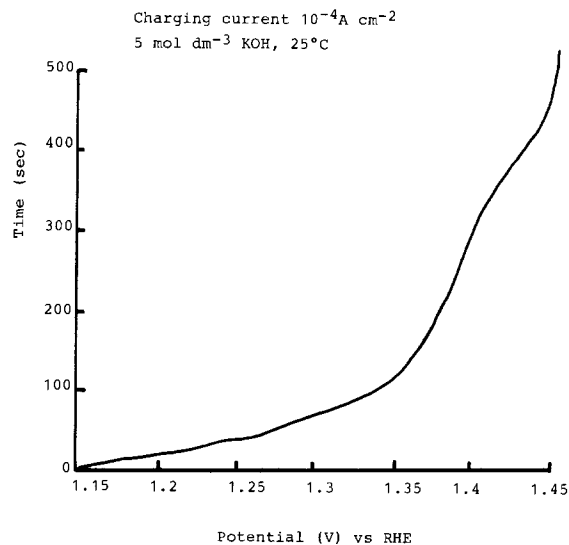

Fig. 4. Anodic charging curve on a FEP-bonded 5 a/o Li-doped NiO electrode of catalyst loading 20.67 mg-cm⁻².

pounds corresponds to the formation of Ni⁴⁺ ions. Another difference between the two curves was the time taken to reach oxygen evolution potential. The time is longer on NiO than on 5 a/o Li-doped NiO. This is most probably due to the lower conductivity of the NiO, and therefore a slower rate of oxidation.

From the charging curves, it is inferred that the majority of ions on 5 a/o Li-doped NiO are Ni³⁺; this is as expected due to lithium doping. Before oxygen evolution these ions form Ni⁴⁺ ions. Therefore, the Ni³⁺ ions can be considered to be the active sites for oxygen evolution on Li-doped NiO. NiO is a nonstoichiometric oxide; hence, it will have a certain percentage of Ni³⁺ ions, but the majority of ions will have a valency of 2+. The experimental results where the oxygen evolution performance increases with increase in the Li doping of the oxides (Fig. 1) also supports this hypothesis. It should be noted that the postulations of the charge transfers were based on the potential values and no analysis of the Ni²⁺ and Ni³⁺ ions or the structure of the species containing these ions was carried out.

A survey of likely reaction paths (12) for the oxygen evolution on NiO and Li-doped NiO shows a consistency with the path previously proposed by Rasiyah and Tseung (6). It is shown that the rate-determining step (rds) for NiO at current densities of 100-1000 mA-cm⁻² is S + OH⁻ \rightarrow SOH + e, and the Tafel slope is approximately 118 mV/decade at 25°C. The rds for Li-doped NiO at current densities of 10-1000 mA-cm⁻² is SOH + OH⁻ \rightarrow SO + H₂O, and the Tafel slope is approximately 60 mV/decade. The likely reason for this difference in rds is related to the concentration of Ni²⁺ and Ni³⁺ ions in NiO and Li-doped NiO electrodes.

The rate equations derived for the two catalysts are as follows.

Table II. Comparison of kinetic data for the oxygen evolution reaction on NiO and 5 a/o Li-doped NiO

Kinetic parameter	Theoretical	Experimental
<u>NiO</u>		
$(E/\log i)_{\text{OH}^-, \tau}$	$2.303 \times 2 \times RT/F$ = 118 mV/decade	128 mV/decade

$(\log i/\log C_{\text{OH}^-})_{\text{e}, \tau}$	1	1.14 ~ 1
<u>5 a/o Li-doped NiO</u>		
$(E/\log C_{\text{OH}^-})_{\text{OH}^-, \tau}$	$2.303RT/F$ = 59 mV/decade	73 mV/decade
$(E/\log C_{\text{OH}^-})_{\text{l}, \tau}$	$-2 \times 2.303RT/F$ = -118 mV/decade	-123 mV/decade
$(\log i/\log C_{\text{OH}^-})_{\text{e}, \tau}$	2	1.86 ~ 2

At high current densities and at limitingly low coverage of SOH, the rate equation for NiO is

$$i = FK_1C_{\text{OH}^-} \exp(EF/2RT) \quad [1]$$

The Tafel slope on NiO changes to ~ 85 mV/decade at lower current densities. As mentioned earlier, the change may be as a result of the change in the rate-determining step, i.e., due to oxygen being evolved on Ni^{3+} ions. The concentration of Ni^{3+} ions on NiO are limited, and hence, with increase in current density the Ni^{2+} ions become the active sites. Unfortunately, it was not possible to carry out reaction order studies at the intermediate current density region as the demarcation when the active sites for oxygen evolution changes from Ni^{3+} to Ni^{2+} is not very clear, specially at low KOH concentrations.

The rate equation for oxygen evolution on Li-doped NiO is

$$i = (FK_1K_2/K_{-2}) C_{\text{OH}^-}^2 \exp(EF/RT) \quad [2]$$

Table II compares the experimentally obtained and the theoretically predicted values of the kinetic parameters for oxygen evolution on NiO and 5 a/o Li-doped NiO. The experimentally obtained values agree well with the theoretically predicted values.

On all the Tafel plots (i.e., NiO and Li-doped NiO), a slope of ~ 40 mV/decade was observed at current densities less than 1 mA-cm⁻². The potentials at these currents correspond to higher oxide formation, and, therefore, the

Tafel slope of ~ 40 mV was not considered to be related to oxygen evolution but to oxide formation reactions.

Conclusions

The difference in the rate-determining step for the evolution of oxygen on NiO and Li-doped NiO at high current densities is related to the difference in the $\text{Ni}^{3+}/\text{Ni}^{2+}$ ion concentration. In the case of NiO, the evolution of oxygen at high current densities is postulated to be on Ni^{2+} sites and at low current densities from the Ni^{3+} sites, which are the minority ions. By doping the NiO lattice with Li^+ ions, the concentration of Ni^{3+} ions is increased proportionately, and, hence, sufficient Ni^{3+} ions are available for the evolution of oxygen even at high current densities.

ABSTRACT

The boundary element method coupled with a Newton-Raphson iteration technique is used to determine current distributions in electrochemical systems, particularly for applications involving electrode shape change such as electroplating and electrochemical machining (ECM). The derivation of the system of equations with the appropriate boundary conditions is presented. Primary and secondary current distributions are calculated for applications including simultaneous deposition and dissolution on opposing electrodes. In the case of copper electrorefining, a comparison between theory and experiment is made. An example of surface leveling in ECM is also given.

The quantitative determination of current distribution and the simulation of changing electrode shape in applications such as electroplating and electrochemical machining are of industrial interest.

It is well known that only the current distribution of rather simple geometries with linear boundary conditions can be solved with analytical techniques. In all other cases, numerical methods must be used. Prentice (1) gives a good survey of literature.

In this paper, it is shown that the boundary element method, in combination with a Newton-Raphson iteration method (to treat the nonlinearity introduced by the boundary conditions), is very well suited to calculations of current distribution and electrode shape change.

Equations

When the solution is sufficiently stirred, the general problem of electrochemical transport can be divided into two regions: a homogeneous bulk solution where potential theory applies, and a boundary layer at the electrodes where all mass-transport effects must be considered. In many practical cases, this diffusion boundary layer is very thin, so that the effects of these phenomena can be encompassed in the boundary condition. This introduces the concept of concentration overpotential, which must be added to the activation overpotential characterizing electrode kinetics.

The distribution of potential in an electrochemical system can then be described by the following equation and boundary conditions (Fig. 1)

$$\nabla \cdot (-\sigma \nabla U) = 0 \quad [1]$$

in the electrolyte Ω bounded by $\Gamma = \Gamma_1 \cup \Gamma_2 \cup \Gamma_3$

$$U = V - \eta_1(U') \quad [2]$$

on the anode Γ_1

$$U = -\eta_2(U') \quad [3]$$

on the cathode Γ_2

$$U' = \frac{\partial U}{\partial n} = 0 \quad [4]$$

on the boundary Γ_3 (insulator, axis of symmetry), with U being the potential field, U' the electric field normal to the boundary, V the potential difference between anode and cathode minus the Nernst-potential difference, η , the total overpotential (activation and concentration) on the anode ($\eta_1 \geq 0$), η_2 the total overpotential on the cathode ($\eta_2 \leq 0$), and σ the electric conductivity of the solution. Often, σ is assumed to be constant.

*Electrochemical Society Active Member.

In order to describe the electrode shape change, Faraday's law in differential form must be solved

$$\frac{d\bar{h}(\bar{x}_i, t)}{dt} = -\theta \frac{m}{zF\rho_m} \sigma U'(\bar{x}_i, t) \bar{I}_n + \bar{u}(\bar{x}_i, t) \quad [5]$$

with $\bar{h}(\bar{x}_i, t = 0) = 0$. \bar{h} is a vector describing the displacement of each point \bar{x}_i of the boundary with respect to the boundary Γ at $t = 0$. At each moment, the electric field U' satisfies Eq. [1]-[4] with the electrolyte Ω and its boundaries Γ changing in time. \bar{u} is the vector describing the rate and the direction of the displacement of each point \bar{x}_i of the boundary. Usually, \bar{u} is taken as time independent.

Note that, from the mathematical point of view, Eq. [5] is also applicable to boundaries where U' is zero.

For the purpose of determining potential and current distribution along electrodes, membranes, and boundaries, it is advantageous to transform Eq. [1] into an equivalent relation involving only the boundaries.

The Boundary Element Method

Several approximation methods are available to reduce the continuum problem to a discrete system of algebraic equations. Using the method of weighted residuals, one can classify (2) all such methods including the finite difference method (FDM) and the finite element method (FEM).

Although it is more general to derive the boundary element method (BEM) using the weighted residual method (3) or a variational principle (4), it is much more straightforward, in the case of the Laplace equation, to use Green's identity

$$\int_{\Omega} (-w \nabla^2 U + U \nabla^2 w) d\Omega = \int_{\Gamma} w \frac{\partial U}{\partial n} d\Gamma - \int_{\Gamma} U \frac{\partial w}{\partial n} d\Gamma \quad [6]$$

Fig. 1. General representation of an electrochemical system

where w and U are arbitrary, sufficiently continuous functions. We can choose U equal to the unknown potential field and define w in such a way that the following equation is satisfied

$$\nabla^2 w = \delta_i \tag{7}$$

where δ_i is the Dirac delta function at point i . The function w is called the fundamental solution and represents the solution for the Laplace equation in an infinite isotropic space with a unit potential source at a given point i .

In a two-dimensional system, the fundamental solution is

$$w = \frac{1}{2\pi} \ln\left(\frac{1}{r}\right)$$

and, in three dimensions, one has

$$w = \frac{1}{4\pi r}$$

Using Eq. [1] and the appropriate choice of w , Eq. [6] can be reduced to

$$c_i u_i + \int_{\Gamma} U \frac{\partial w}{\partial n} d\Gamma = \int_{\Gamma} w \frac{\partial U}{\partial n} d\Gamma \tag{8}$$

where c_i is equal to 1 at a point i inside the domain Ω , equal to 1/2 at a point on the boundary Γ , and equal to zero at any point outside Ω (Fig. 1). Equation [8] enables us to calculate the value of the potential at any point on the domain if U and U' are known on the boundary Γ . Furthermore, when the point i lies on Γ , Eq. [8] is a functional relation between U and U' ensuring their compatibility as boundary functions for the Laplace equation.

In order to evaluate the integrals in Eq. [8], the boundary is subdivided into a number (M) of segments or "boundary elements" Γ_j (Fig. 2). On each element, it will be supposed that the functions U and U' can be approximated by a combination of linearly independent trial functions ϕ_k . An example is

$$U = \sum_{k=1}^l \phi_k U_k \text{ and } U' = \sum_{k=1}^l \phi_k U'_k \tag{9}$$

where U_k and U'_k are the values of the potential and its normal derivative at l well-defined points of the element Γ_j , namely, the nodal points.

Substitution of Eq. [9] into Eq. [8] and the evaluation of the integrals over each element Γ_j yields the following equation for a nodal point i on the boundary

$$\sum_{j=1}^N H^*_{ij} U_j = \sum_{j=1}^N G^*_{ij} U'_j \tag{10}$$

Such an equation can be written for each node i , producing an $N \times N$ system of equations having the following matrix form

Fig. 2. Discretization of the boundary in M elements and a total of N nodal points.

$$[H]^* \{U\} = [G]^* \{U'\} \tag{11}$$

Introducing the boundary conditions and passing all unknowns into the right-hand term yields

$$[G] \begin{Bmatrix} U'_1 \\ U'_2 \\ U_1 \end{Bmatrix} = [H] \begin{Bmatrix} V - \eta_1(U'_1) \\ -\eta_2(U'_2) \\ 0 \end{Bmatrix} \tag{12}$$

This is a system of nonlinear equations with the unknowns U'_1 and U'_2 being the normal electric field at the nodal points on the anode and cathode, respectively, with U_1 being the potential at the nodal points on the insulating boundaries.

Effectively, by the particular choice of w , the field Eq. [1] is automatically satisfied, and a point collocation is used to match the boundary conditions.

It should be noted that the normal electric field at each node is found directly. It is not necessary to differentiate the potential with respect to the surface normal (as it is in FDM or FEM).

Another important advantage is that only the boundaries need to be discretized. This results in a smaller system of equations to be solved and a considerable reduction of effort in terms of defining the nodal structure. Moreover, with straight-line elements used to discretize the boundary with polynomial trial functions, the integrals can be calculated analytically, giving very accurate results.

Solution of the Nonlinear System of Equations

When the overpotential functions η_1 and η_2 are linearized, as is frequently done, the system of Eq. [12] can be solved directly. Otherwise, one needs an iterative process to obtain the solution. Often, a successive approximation method or a Newton-Raphson iteration technique is used.

Since the matrices $[G]$ and $[H]$ depend only on geometry, the Newton-Raphson process is easily implemented (5, 6).

Defining a function

$$\psi \begin{Bmatrix} U'_1 \\ U'_2 \\ U_1 \end{Bmatrix} = [G] \begin{Bmatrix} U'_1 \\ U'_2 \\ U_1 \end{Bmatrix} - [H] \begin{Bmatrix} V - \eta_1(U'_1) \\ -\eta_2(U'_2) \\ 0 \end{Bmatrix} \tag{13}$$

it is found, after some calculation, that the values of the unknowns at iteration step $(n + 1)$ are related to those at step n as follows

$$\begin{Bmatrix} U'^{n+1}_1 \\ U'^{n+1}_2 \\ U_1^{n+1} \end{Bmatrix} = \begin{Bmatrix} U'^n_1 \\ U'^n_2 \\ U_1^n \end{Bmatrix} - [K_T^n]^{-1} \cdot \psi \begin{Bmatrix} U'^n_1 \\ U'^n_2 \\ U_1^n \end{Bmatrix} \tag{14}$$

where the tangential matrix $[K_T^n]$ is

$$\begin{aligned} K_{Tij}^n &= G_{ij} - \eta'_1(U_1^n) \cdot H_{ij} \text{ for } \forall j \in \Gamma_1 \\ &= G_{ij} - \eta'_2(U_2^n) \cdot H_{ij} \text{ for } \forall j \in \Gamma_2 \\ &= G_{ij} \text{ for } \forall j \in \Gamma_1 \end{aligned}$$

η'_1 and η'_2 are the derivatives of the functions η_1 and η_2 with respect to U' .

Both solution techniques were tested for several example problems. Using a Newton-Raphson technique, convergence was obtained after three to six iterations, whereas the successive approximation method always required more than 100 iterations. Using finite elements in combination with a Newton-Raphson iteration process, Alkire *et al.* (7) also obtained convergence after three to four iterations. The authors' previous experience with finite elements (8) as well as the results of Prentice (9) confirm that, in the case of successive approximations, many iterations are necessary for convergence.

Therefore, it is clear that whichever numerical method is used to discretize the field Eq. [1], a Newton-Raphson

iteration process is highly advantageous for treating the nonlinear boundary conditions.

Determination of Electrode Shape Change

After resolution of Eq. [1]-[4], Eq. [5] can be solved with a forward-difference approximation (Euler).

As already mentioned, all calculations are restricted to the boundaries of the system ($U, U', \bar{I}_n, \Delta \bar{h}_n$). This implies that the method is well adapted to simulate electrode shape change or ECM since no internal nodes are to be re-ordered after each time step.

This method was implemented on a H-P 1000 21 MX/E (196K) minicomputer. With this configuration, a two-dimensional or axisymmetric current-distribution problem with 75 unknowns takes no longer than a few minutes.

Examples

Copper electrorefining.—Copper electrorefining from a 0.8M CuSO_4 , 0.8M H_2SO_4 solution ($\rho = 4.67 \Omega\text{-cm}$) was studied in a cell with a singularity (Fig. 3).

To model the overpotentials on anode and cathode in the program, an interpolation by cubic natural splines between measured points, obtained with a standard three-electrode configuration, was used. The advantages are that no Tafel relation is to be fitted, and that the derivatives of the functions $\eta'_1(U')$ and $\eta'_2(U')$ (used in the Newton-Raphson process) are easily obtained.

In order to evaluate the computed current distribution, a cell with removable segmented cathode was built. This cathode was an electronic printboard etched to obtain fine parallel strips of 4.2 mm, 0.8 mm from each other. To avoid disturbing the system with the measurements (no supplementary voltage drop should be created), we used

a dc current probe to measure the current through each strip.

In Fig. 4, comparison between calculation and experiment is summarized (applied voltage: 0.5V). The agreement is within 5%.

Since reactions on anode and cathode take place, we introduced two Wagner numbers

$$W_a = \frac{\partial \eta_1}{\partial J} \Big|_{J_{av}} \frac{J_{av}}{\rho L}$$

on anode and

$$W_c = \frac{\partial \eta_2}{\partial J} \Big|_{J_{av}} \frac{J_{av}}{\rho L}$$

on cathode. As a general, the characteristic length L is taken equal to the shortest distance between anode and cathode.

Using the cell geometry of Fig. 3 in the same circumstances, the simultaneous dissolution and deposition of copper was simulated. Figure 5 gives the obtained calculated profile after 110h electrolysis.

Two remarkable features are the overgrowth over the insulating boundary and the orthogonal incidence between the electrode and the boundary. The latter can be rationalized as follows. If we replace the insulating boundary in line with the cathode by an equivalent symmetry plane, we see that there is no reason to expect the deposit profile to not be perpendicular to this plane. The overgrowth phenomenon is due to the fact that once metal is deposited on the cathode, deposition continues in all directions perpendicular to the new cathode surface.

In order to verify these results an experiment was performed. After electrolysis, the cathodes were embedded in a resin, cut over the length, and polished before measurement. The mean of six profiles was taken.

Figure 6 gives a comparison between the numerical result after 68h and an experiment that ran for the same length of time under the aforementioned conditions. In practice, one common strategy for reducing the edge effect is to interpose a screen or "shield" masking the edge. The influence of such a screen is represented in Fig. 7

Fig. 6. Copper electrorefining in a rectangular cell with edge effect. Comparison between numerical result and experiment (68h electrolysis).

Fig. 7. Copper electrorefining in a rectangular cell with partial masking of the edge effect. Simulation of dissolution and deposition.

Fig. 8. Copper electrorefining in a rectangular cell with partial masking of the edge effect. Primary and secondary current density distribution along the cathode at $t = 0_+$ (63 nodal points).

Fig. 9. Diaphragm cell for the production of chlorine. Element distribution (74 nodal points). Resistivities: anolyte = $1.0 \Omega\text{-cm}$; catholyte = $3.0 \Omega\text{-cm}$; diaphragm = $10.0 \Omega\text{-cm}$.

Fig. 10. Diaphragm cell for the production of chlorine. Primary and secondary distribution along the anode: $W_a = 0.09$, $W_c = 0.18$. Applied voltage: 5.0V.

and 8 (the optimal position of the screen was not investigated).

Production of chlorine in a diaphragm cell.—This example shows that it is possible to deal with systems having uniform subregions of differing conductivity. Let us consider the repetitive part of a diaphragm cell for the production of chlorine shown in Fig. 9.

The overpotential functions on anode and cathode were natural cubic spline interpolations of measured values from the literature (10).

The resulting primary and secondary distributions along the anode are given in Fig. 10.

Influence of the Wagner number on the shape change.—The influence of overpotentials on simultaneous deposition and dissolution of a sinusoidal profile is illustrated. Figures 11, 12, and 13 represent the electrode shape changes for three Wagner numbers; the applied voltage is 0.5V and total charges (C) are almost the same.

Fig. 11. Sinusoidal profile. Simulation of deposition and dissolution. Resistivity: $4.67 \Omega\text{-cm}$. $W_c = 0.001$ with overpotential relation $\eta_2 = 0.001J$. $W_a = 0$. $Q = 9787C$.

The boundary was divided into only 41 elements with a total of 45 nodal points. Twenty time steps were used. On the cathode, the shapes obtained by Prentice (9) are confirmed, and it is seen that, even for a small Wagner number, the dissolution rate of the anode is uniform for the interelectrode distance in question.

Fig. 12. Sinusoidal profile. Simulation of deposition and dissolution. Resistivity: $4.67 \Omega\text{-cm}$. $W_c = 1.07$ with overpotential relation $\eta_2 = 10J$. $W_a = 0$. $Q = 9963C$.

Fig. 13. Sinusoidal profile. Simulation of deposition and dissolution. Resistivity: $4.67 \Omega\text{-cm}$. $W_c = 107$ with overpotential relation $\eta_2 = 1000J$. $W_a = 0$. $Q = 9719C$.

Electrochemical machining.—An iron anode of irregular shape stands in front of a flat cathode (Fig. 15). The electrolyte has a resistivity of $5 \Omega\text{-cm}$, the applied voltage is $10V$, and the cathode moves at the rate of 1.2 mm/min . No overvoltages were considered.

Figure 14 gives the primary current distribution along the anode, and Fig. 15 gives the obtained profile after each time step (0.15 min). The results confirm the notion that small irregularities take longer to vanish.

Fig. 14. Surface leveling in ECM. Primary current distribution ($W_a = W_c = 0$) along the anode at $t = 0_+$ (geometry of Fig. 15).

Fig. 15. Surface leveling in ECM. Evolution of the anode profile. The steady-state gap is about 0.46 mm .

Conclusions

A new method, the BEM in combination with a Newton-Raphson iteration, is presented to determine current distribution and electrode shape change.

The main advantages are that: discretization and calculations are restricted to the boundary; data input is easy; accuracy is great; a reduced number of unknowns is needed; the normal derivative is obtained directly and accurately; convergence on the nonlinear boundary conditions is fast (Newton-Raphson); singularities are well described because the element distribution can be refined in their vicinity; and problems with infinite domain can be solved.

The method has also its disadvantages. They are as follows:

(i) The method is less general. For example, to transform the Laplace equation into an integral equation we need an isotropic medium; otherwise, the function w is hard to find. The "domain methods" (FDM and FEM) are local discretizations and permit a variation of conductivity. In the BEM, the conductivity must be piecewise uniform (cf. Fig. 9).

(ii) The underlying mathematics are somewhat more difficult. In particular, the integrals necessary to compose the matrices G and H can be troublesome since they are singular when the distance r in the function w becomes zero.

(iii) The matrices G and H are fully populated, whereas the FDM and FEM generate sparse matrices.

(iv) To simulate electrode shape change, at each time step the matrices G and H are to be recalculated since each nodal point of the boundary is related to all others.

LIST OF SYMBOLS

F	Faraday constant
G, G^*	influence matrices depending only on geometry
G_{ij}, G^*_{ij}	influence coefficients defining the interaction between the nodal points i and j
H, H^*	influence matrices depending only on geometry
H_{ij}, H^*_{ij}	influence coefficients defining the interaction between the nodal points i and j
\bar{h}	displacement of the boundary
J, J_{av}	(average) current density normal to an electrode
K_T	tangential matrix
K_{Tij}^n	coefficient of the tangential matrix at time step n
L	characteristic length
m	molecular weight
M	total number of elements
N	total number of nodal points
Q	total charge
r	distance between a field point and an observation point
t	time parameter
U	potential field
U_i	value of the potential at a point i
U_1	values of U at nodal points on the insulating boundary Γ_1
U'	electric field normal to the boundary
U'_i	value of the electric field normal to the boundary at a point i
U'_1, U'_2	values of the electric field at nodal points on anode and cathode, respectively
\bar{u}	displacement rate of a point on the boundary
V	potential difference between anode and cathode minus the Nernst-potential difference
w	fundamental solution
W_a, W_c	Wagner number on anode and cathode, respectively
\bar{x}_i	point on the boundary
z	charge number
\bar{z}	direction normal to the boundary (outward pointing)
$\Delta\bar{h}_n$	increment of \bar{h} at time step n
Γ	boundary
Γ_j	boundary element

Γ_1, Γ_2	anode and cathode, respectively, part of the boundary
Γ_1	insulating part of the boundary
δ_i	dirac delta function
η_1, η_2	overpotential on anode and cathode
η'_1, η'_2	derivative of η_1 and η_2 with respect to U'
θ	current efficiency
ρ	electrolyte resistivity
ρ_m	metal density
σ	electrolyte conductivity
ϕ_k	shape function
ψ	function defined to be zero after convergence
Ω	computational domain

Technical Notes

Electrochemical Determination of Hydrogen Transport Through Copper

David W. DeWulf and Allen J. Bard*

Department of Chemistry, The University of Texas, Austin, Texas 78712

The diffusion of hydrogen into metals and other materials has been widely studied because of its importance in embrittlement, permeation through vessels and pipelines, and hydrogen storage in metal alloys (1). The diffusion of hydrogen in many metals is rapid, and there are many cases, *e.g.*, in a hydrogen pipeline, where a practical impermeable material is desired. We became interested in this problem in connection with submarine fiber optic cable systems, where a transmission loss increase caused by hydrogen permeation occurs at wavelengths important in communications (2-5). The question of finding a suitable material to block this permeation led to consideration of copper. We report here studies of hydrogen permeation in copper by the electrochemical method of Devanathan and Stachurski (6, 7). This method has been applied to hydrogen and oxygen diffusion studies in a number of materials (8-15).

Experimental

The basic experiment followed previous studies (6-8). A thin (15 and 25 μm) copper foil was clamped as a separator (bielelectrode) between two half-cells; the clamping arrangement consisted of O-ring seal joints and utilized Teflon spacers. The area of Cu exposed to each half-cell was 0.78 cm^2 . The counterelectrodes in each half-cell compartment were Pt foil. A saturated calomel electrode (SCE) served as a reference electrode in the detection half-cell. The Cu foil bielelectrode acted as an anode. This compartment was filled with 0.2M KOH, and this side of the Cu foil was coated with Pt to improve the kinetics of hydrogen oxidation. The potential of the Cu bielelectrode anode was held at a potential of -0.30V vs. SCE with a Princeton Applied Research Model 173 potentiostat. A constant current (19.5 mA) was applied between the cath-

ode side of the Cu foil and the Pt counterelectrode; the catholyte was 0.2M H_2SO_4 containing 10 $\text{mg}\cdot\text{liter}^{-1}$ As_2O_3 . Copper foils (99.999%, 25.0 μm and 99.8%, 15.0 μm) were purchased from Aesar, Incorporated, Seabrook, New Hampshire. A Pt film, 0.1 μm thick, was formed on one side by Ar ion sputtering from a Pt target (Material Research Corporation Model 8620 sputtering system). Other thicknesses of Cu were obtained by electrodeposition of Cu from a copper pyrophosphate bath (16). The additional thickness of Cu plated was calculated from the number of coulombs passed, the exposed area of the foil, and the bulk density of Cu. In experiments involving deposition of Pd on the Cu, a thin film (0.050 μm) was formed by

Foil type	L(μm)	Number of trials	D _{23°C} (cm ² /s)
Puratonic (99.999%)	25.0	3	2.6 × 10 ⁻⁹
	27.5	3	2.3 × 10 ⁻⁹
	30.0	3	2.1 × 10 ⁻⁹
Total 99.8%	15.5	9	2.3 (± 0.3) × 10 ⁻⁹
		5	5.2 (± 0.5) × 10 ⁻⁹

^a *i*_{appl} (cathode side) = 19.5 mA; *E* (anode side) = -0.3V vs. SCE; anolyte, 0.2M KOH; catholyte, 0.2M H₂SO₄ + 10 mg-liter⁻¹ As₂O₃.

vacuum evaporation. All solutions were prepared with reagent-grade chemicals and milli-Q (Millipore Corporation) water.

Results and Discussion

The nature of the anodic current (*i*) (for the oxidation of hydrogen) with time (*t*) for the platinum side of the Cu held at -0.30V vs. SCE and with a constant current of 19.5 mA applied to the cathode side was used to determine the diffusion coefficient, *D*. The basic experiment and treatment followed previous practice (12). The anode side was pre-electrolyzed at -0.30V for 4-8h before the constant current was applied to oxidize any residual hydrogen or impurities. Background currents less than 1 μA were obtained. A typical *i*-*t* curve is shown in Fig. 1. This transient can be fit to the equation (12)

$$\frac{i_t}{i_\infty} = 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \exp \frac{-(2n+1)^2 \pi^2 \tau}{4} \quad [1]$$

where *i*_{*t*} is the permeation current at time *t*, *i*_∞ is the steady-state permeation current, and $\tau = Dt/L^2$ (where *L* is the foil thickness). The τ values were obtained by a computer fit of Eq. [1] to the experimental results. An initial guess for τ could be obtained by noting that at *i*_{*t*}/*i*_∞ = 0.5, $\tau \approx 0.630$. Values of *D* determined in this way at 23°C for two different Cu samples and several thicknesses are given in Table I. The agreement of *D* values for the 99.999% sample for the three thicknesses demonstrates that hydrogen permeation occurs by diffusion. An alternative way of showing this is a plot of *t* vs. *L*² for several values of τ (Fig. 2). As predicted by the equation defining τ , straight lines that intersect the original with a slope of *D*/ τ result.

The diffusion coefficient was significantly higher for the 99.8% sample than for the 99.999% one, suggesting that impurities have an important effect on the rate of hydrogen permeation in Cu. A comparison of the *D* value reported here at 23°C to earlier studies is given in Table II; most involved determinations at much higher temperatures and thus long extrapolations based on the reported heats of activation. The value we report is considerably higher than that previously measured at ambient temperatures (13, 14).

The diffusion coefficient measurement on Cu required that As₂O₃ as a "poison" be added to the catholyte. If As

Fig. 2. *t* vs. *L*² at given values of τ (constant *i*_{*t*}/*i*_∞) slopes of all lines = τ/D : (a) $\tau = 0.24$, slope = 1.29×10^8 , intercept = -28; (b) $\tau = 0.38$, slope = 1.73×10^8 (s-cm⁻²), intercept = -28; (c) $\tau = 0.54$, slope = 2.20×10^8 , intercept = -28. *D* calculated from these values is $2.2 (\pm 0.3) \times 10^{-9}$ cm²/s.

(III) was not added to the catholyte, no detectable hydrogen permeation current through the Cu foil was found, even after 6h of electrolysis. This effect is similar to that observed for hydrogen diffusion through Pt (8, 20), where hydrogen permeation is found only when the cathodic side of the metal membrane is poisoned. For other materials, e.g., Pd (20) and pyrite (12), such poisoning is unnecessary. This effect of As (III) has been ascribed to blockage of sites on the electrode surface for recombination of atomic hydrogen to molecular hydrogen, thus increasing the concentration of atomic hydrogen at the surface. Presumably, it is atomic hydrogen that diffuses through the Cu lattice (1, 14, 18, 21). Evidence for the lack of penetration of H₂ through the copper film was obtained by the following experiment. When the catholyte was replaced by moist hydrogen gas, with exactly the same anode and anolyte configuration as before, no detectable permeation current was observed after 30h. Even when a 0.05 μm Pd covering was deposited on the cathodic side and gaseous hydrogen introduced, no permeation current was observed. Since Pd is known to dissociate H₂ and allow permeation measurements in the absence of a poison (20),

This work	99.8%	296			2.33 × 10 ⁻⁹
					5.2 × 10 ⁻⁹

^a *D*_T (K) = *D*₀ exp [-Δ*H*_D/*kT*].

^b The value reported by the authors at 292 K is based on application of a constant current to generate hydrogen, but the application of a constant potential boundary condition for the theoretical treatment. This value is a recalculation based on a constant current treatment.

the lack of permeation for the Pd-coated Cu configuration suggests rapid H atom recombination at the Pd/Cu interface. A number of studies have been concerned with the mechanism of "poisoning" by arsenic species (22-26). It is interesting that As acts in a similar way for such different metals as Pt and Cu. From the point of view of blockage of H₂ permeation, the slow step in penetration of hydrogen through a Cu film would be the dissociation of H₂ to hydrogen atoms (or in a membrane sense, the rate of equilibration of hydrogen at the H₂/Cu interface) rather than the rate of diffusion through the film.

Conclusions

The diffusion coefficient (*D*) of hydrogen through a 99.999% Cu foil at 23°C is $2.3 (\pm 0.3) \times 10^{-9}$ cm²-s⁻¹. *D* is affected by the purity of the Cu. With regard to Cu as a barrier to H₂ permeation, the surface properties of the Cu are important, and the rate of H₂ crossing the Cu/gas interface is the rate-determining step.

Electrochemical Observations as Related to Marine Atmospheric Corrosion of Chrome-Flashed Stainless Steels

Gardner Haynes and Robert Baboian*

Texas Instruments, Incorporated, Attleboro, Massachusetts 02703

Generally, stainless steels are susceptible to localized corrosion (such as pitting) in chloride containing environments. This occurs in environments where the alloys are totally immersed as well as in those where intermittent wetting occurs, such as marine atmospheres and splash and spray zones. Often the concentration of alloying elements such as molybdenum is increased to provide improved resistance to localized corrosion.

Stainless steels have been plated with a thin layer of chromium (chrome flashed) for decorative purposes for automotive applications (1-3). The chromium electrodeposit is usually about 0.01 mil thick and does not completely cover the stainless steel. It provides a better color match with other trim components, improves appearance, and adds abrasion resistance. It has been established that chrome-flashed stainless steels have better resistance to localized corrosion than their base counterparts in marine atmospheres and chloride environments such as the salt-belt region for automobiles (1-3). Little is known, however, about the performance of chrome-flashed stainless steels under total immersion conditions. The purpose of this work was to elucidate the mechanisms of corrosion resistance of chrome-flashed stainless steels in chloride containing atmospheres and compare its performance in

these atmospheres to its performance when totally immersed.

Experimental

The comparative performance of bare and chrome-flashed stainless steels was evaluated in laboratory accelerated tests and environmental exposure tests. A cyclic immersion testing procedure was used in the laboratory to simulate marine atmospheric exposure. This test for pitting resistance of stainless steels for automotive service consisted of a 10s immersion period in a 5% sodium chloride solution followed by a 90s drying period at 105°F. A multiple crevice washer (ASTM G78-83) was tightened to a torque of 75 in.-lb in the center of 4 × 6 in. sections of 434 stainless steel-clad aluminum and chrome-flashed 434 stainless steel-clad aluminum. These specimens were then run for 100 cycles in the cyclic immersion test.

Bare and chrome-flashed 301 stainless steel-clad aluminum bumpers were exposed in the splash and spray zone at the LCCT test facility in Wrightsville Beach, North Carolina, to determine their performance in an alternate immersion environment. These same materials were totally immersed in seawater at the Texas Instruments test facility in Buzzards Bay, Massachusetts. The aluminum was masked in the total immersion tests so that it could not provide galvanic protection to the stainless steel.

*Electrochemical Society Active Member.

Fig. 1. Appearance of bare and chrome flashed type 304 stainless steel after 100 cycles in the cyclic immersion test.

Electrochemical techniques were used to investigate the mechanisms of corrosion. Cyclic potentiodynamic polarization measurements were made for 301 stainless steel and 434 stainless steel in 5% sodium chloride solution and fresh seawater according to ASTM Designation G61-78. Potential measurements for bare and chrome-flashed stainless steels were made in 5% sodium chloride solution and fresh seawater under conditions of total and alternate immersion.

Results and Discussion

The appearance of the bare 434 stainless steel surface and the chrome-flashed 434 stainless steel surface after 100 cycles in the cyclic immersion test is shown in Fig. 1. Crevice corrosion of the 434 stainless steel occurred at four sites, while no crevice corrosion of the chrome-flashed 434 stainless steel occurred. Similar results were found for 301 stainless steel in the splash and spray zone after 1 yr of exposure. In this case, the bare 301 stainless steel surface had numerous pits, while the chrome-flashed stainless steel did not pit. These results confirm the beneficial behavior of chrome flashing that has been observed in automotive applications.

These results for intermittent wetting can be contrasted with the results of total immersion tests. After six months exposure in seawater, both bare 301 stainless steel and chrome-flashed 301 stainless steel had crevice corroded. The chrome flashing did not provide the improved resistance to pitting or crevice corrosion of the stainless steel that was observed in the marine atmospheres.

Results from cyclic potentiodynamic polarization and the "mixed potential" theory have been used previously to describe the behavior of stainless steels in galvanic

Fig. 2. Schematic potentiodynamic polarization curve for stainless steel in chloride solution showing three corrosion potential regions.

couples (4-8). This same treatment can be used to provide insight into the mechanisms of corrosion in these tests. Referring to the schematic polarization curve in Fig. 2, the corrosion behavior of a stainless steel can be separated into three potential regions: Region I, below E_p , where protection from pitting and crevice corrosion are observed; Region II, between E_p and E_c , where propagation of existing pits and crevices occurs; and Region III, above E_c , where initiation of pitting and crevice corrosion occurs. Galvanic coupling of the stainless steel with another alloy regulates the potential of the stainless steel into one of these regions where the appropriate corrosion behavior for the stainless steel in that region occurs. This behavior has been described for galvanic couples between 321 stainless steel and copper and between 304 stainless steel and carbon steel.

The potentiodynamic polarization curves for 434 stainless steel and 301 stainless steel in 5% sodium chloride solution are shown in Fig. 3. The breakdown potential, E_c , for 301 stainless steel was more noble than the breakdown potential for 434 SS, while the protection potential, E_p , for both alloys was similar. The open-circuit potentials as a function of immersion time in 5% sodium chloride solution are shown in Fig. 4 for 301 stainless steel and chromium. Also shown is the mixed potential for 301 stainless steel galvanically coupled to chromium (1:1 surface area ratio). During this test, the potential of the 301 stainless steel remained in Region II of its polarization curve (Fig. 3), indicating that propagation of existing pits and crevices could occur. The potential of the chromium was much more active than 301 stainless steel, and the mixed potential, as expected, was intermediate. The mixed potential data showed that the galvanic couple between the 301 stainless steel and the chromium regulated the potential of the 301 stainless steel below its protection potential (Region I in Fig. 2), thereby preventing propagation of existing pits and crevices on the 301 stainless steel.

Fig. 3. Potentiodynamic polarization curves for Type 301 SS and Type 434 SS in 5% sodium chloride solution at 30°C (0.6 V/h scan rate).

Fig. 4. Corrosion potentials for Type 301 stainless steel and chromium in 5% sodium chloride solution at 30°C.

Fig. 5. Corrosion potentials of constantly and alternately immersed chrome flashed 301 stainless steel in 5% sodium chloride solution at 30°C.

Thus, for the 5h immersion period, 301 stainless steel was protected from localized corrosion when coupled to chromium but was susceptible to localized corrosion when isolated.

Since the data in Fig. 4 indicated that the potential of chromium drifted toward more noble values with increased immersion time, additional tests were conducted to determine potentials for longer immersion periods as well as potentials for repeated short immersion periods. These data are shown in Fig. 5 for 301 stainless steel and chrome-flashed 301 stainless steel. Two significant trends are shown. The potential for chrome-flashed 301 stainless steel continuously drifted toward more noble values with longer exposure time. After an extended pe-

Fig. 6. Potentiodynamic polarization curve for Type 434 stainless steel in seawater at 30°C (0.6 V/h scan rate).

Fig. 7. Corrosion potentials of constantly and alternately immersed chrome flashed Type 434 stainless steel in seawater at 30°C.

riod of time the potential eventually drifted into Region II of the polarization curve for 301 stainless steel (Fig. 3) and, thus, localized corrosion of the 301 stainless steel became possible. Each time the chrome-flashed 301 stainless steel was removed from the solution and reimmersed after 22h, its potential shifted back to the active value initially measured which lies in Region I of the polarization curve for 301 stainless steel (Fig. 3). This behavior continued irrespective of the number of cycles, as shown in Fig. 5. Thus, provided that the chrome-flashed 301 stainless steel is removed from the solution at periodic intervals, the chrome flashing regulates the potential of the 301 stainless steel in Region I (Fig. 3) of its polarization curve and localized corrosion does not occur. This behavior can be attributed to a change in the morphology of the oxide film on chromium with continued exposure or absorption-desorption kinetics for the chloride ion.

Similar results were found for the behavior of 434 stainless steel and chrome-flashed 434 stainless steel in seawater. The cyclic potentiodynamic polarization curve for 434 stainless steel in seawater is shown in Fig. 6, while the results of potential measurements for bare 434 stainless steel and chrome-flashed 434 stainless steel under conditions of constant immersion and intermittent immersion in seawater are shown in Fig. 7. The potential of the chrome-flashed 434 stainless steel gradually became more noble with increased immersion time until the mixed potential resided in Region II of the polarization curve for 434 stainless steel (Fig. 6), thus making localized corrosion of the 434 stainless steel possible. When alternately immersed, the mixed potential of the chrome-flashed 434 stainless steel remained more active (Fig. 7). Thus, under conditions of intermittent wetting, the chrome flashing regulates the potential of the 434 stainless steel in Region I of its polarization curve and prevents localized corrosion of the 434 stainless steel.

Conclusions

Chrome-flashed 301 stainless steel and chrome-flashed 434 stainless steel undergo localized corrosion when constantly immersed in chloride containing environments for extended periods of time. Chrome flashing, however, provides improved resistance to localized corrosion for both alloys in marine atmospheric (and automotive) environments where intermittent wetting occurs.

Cyclic potentiodynamic polarization data and the mixed potential theory can be used to determine the mechanisms of corrosion and explain this behavior. Initially, the more active potential of the chromium polarizes the stainless steel into a region where localized corrosion does not occur. With continued exposure, changes in the nature of the oxide on chromium and/or chloride absorption cause the mixed potential to rise to a value where localized corrosion of the stainless steel occurs. Periodic removal of the chrome-flashed stainless steel from the electrolyte reverses or inhibits these changes so that the mixed potential remains in a region where localized corrosion does not occur.

The Production of High Purity Oxygen

Kurt Buehler¹ and Jack Winnick*

Georgia Institute of Technology, Atlanta, Georgia 30332

High purity oxygen (HPO) (99.99%) is used as a feed for the Space Shuttle fuel cells. NASA stores the HPO on base. The boiloff from the storage tank must be reliquefied instead of vented to maintain the hydrocarbon contamination below 20 ppm. A traditional turnkey distillation process will not allow methane-free HPO to be obtained economically, and electrolysis with an energy-intensive operation becomes uneconomical. We examined use of an oxygen concentration cell as a means of economic, on-site production.

Electrochemical production of oxygen has been reported by Langer (1), Tomter (2), Wynveen (3), and Tseung (4). Langer achieved > 97% oxygen with acidic and basic electrolytes with catalyst-polytetrafluoroethylene gas-permeable electrodes. The over-all four-electron mechanism was found to be operative in both acid and base. Tomter used two porous oxygen electrodes separated by an asbestos matrix saturated with potassium hydroxide. At 0.7V and 71.4°C, Tomter achieved 215.3 mA/cm². He recirculated the electrolyte past the anode to reduce the concentration overvoltage due to oxygen evolution. He did not report product purity. Wynveen used a KOH electrolyte with Pt black electrodes. No oxygen purity was stated, but a four-electron mechanism was found. He achieved current densities of 129 mA/cm² at 40°C. Tseung did not state the oxygen purity achieved; however, a two-electron mechanism reduced the power consumption with H₂O₂ chemically decomposed and collected in the anode compartment.

The concentrator cell operates by reducing oxygen in the feed gas flowing past the cathode

The hydroxyl ions migrate through the asbestos matrix, soaked with saturated potassium hydroxide electrolyte, toward the anode where the reverse reaction occurs releasing pure oxygen off the anode. A dc power supply is necessary to bias the cell. To prevent anodic degradation, the designated cell operating voltage did not exceed 1.2V (5). The feed gas was scrubbed with alkaline solution before entering the cell to prevent loss of electrolyte (3) and carbonate poisoning of the electrodes. The oxygen concentration cell has a hydrophobic cathode and a hydrophilic anode. The hydrophobic electrode permits three-phase reaction sites while the hydrophilic allows two-phase reaction sites. The theoretical voltage needed to bias the cell at open circuit voltage (OCV) can be calculated from the Nernst equation (6)

$$E = (RT/nF) \ln (\text{PO}_2 \text{ anode}/\text{PO}_2 \text{ cathode}) \quad [2]$$

For the four-electron reaction mechanism presented in Eq. [1], the calculated theoretical OCV is 0.01V with air as the feed gas and approximately zero with a propellant-grade oxygen (99.6%) feed gas.

Experimental

The anodes and cathodes were donated by United Technologies (Power Systems Division). The anode, 26 cm² apparent area, consisted of nickel cobalt oxide (NiCo₂O₄) 20 mg/cm², TFE-bonded, on gold-plated 100 mesh nickel screen. The intrinsic surface area of the anode was estimated between (15-20) m²/g (NiCo₂O₄) (5). The cathode, 26 cm² apparent area, consisted of platinum black 10 mg/cm², TFE bonded, on gold-plated 100 mesh, nickel screen. The intrinsic surface area of the cathode was estimated between (20-25) m²/g (platinum black) (5).

*Electrochemical Society Active Member.

¹Present address: NASA/KSC, Kennedy Space Center, Florida 32899.

The actual area of the anode and cathode was approximated at 104,000 and 65,000 cm², respectively. A saturated calomel electrode (SCE) with a porous-plug-type 5 in. body and 1/2 in. diam was used as reference. An asbestos matrix 20 mil thick separated the electrodes and supported twice-distilled water saturated with certified ACS potassium hydroxide.

The current collectors, donated by Exmet, Incorporated, were a perforated expanded-metal material (EXMET), with a sheet thickness of 10 mil, and a strand width of 58 mil. The anodic current collectors were gold plated, which prevented oxidation for the relatively short experiments performed. Ten-gauge silver wires attached to the EXMET provided the electrical leads out of the acrylic cell housing. The cell housing consists of two pieces of acrylic each 5 × 5 × 1 in. Ports were drilled in the acrylic for feed gas inlet and outlet, electrical leads, product gas outlet, and the SCE. The cell housing was sealed with a two-part epoxy resin made by Emerson and Cumings, Incorporated (stycast 2741 and catalyst 15). A Perkin-Elmer Model Sigma 3 gas chromatograph equipped with a thermal conductivity detector analyzed the purity of the oxygen evolving off the anode. A molecular sieve packing removed the water and KOH from the product stream before the gas entered the gas chromatograph.

The current-interruption technique was used to determine ohmic loss, using a Tektronix 5111 single-beam stor-

age oscilloscope with no. 5BION time base and 5A19N differential amplifier along with a Princeton Applied Research Potentiostat/Galvanostat (Model 371) in the galvanostatic mode.

Electrodes, current collectors, and leads were cleaned before assembling the concentrator cell. The cell was filled with electrolyte through the HPO collector port; experiments were conducted immediately after filling to prevent the conversion of the electrolyte to carbonate by reaction with CO₂. Polarization measurements were taken starting at the lowest current reading and incrementally increasing the bias of the cell up to 1.2V. Cathodic measurements were taken immediately after anodic, and as soon as a reasonable steady state was reached. In this way, a possible change in the electrode surface during cathodic polarization is minimized. Polarization measurements were repeatable and taken in 5h runs. The purity measurements were taken four times in 12h runs.

Results and Discussion

The purity of the oxygen evolving off the anode was found to be 99.996% after the water and KOH were removed with either air or propellant-grade oxygen as cathode feed. The impurities were N₂, Ar, and Kr. The four-electron path was verified through volumetric measurement of the oxygen evolving off the anode; the current

efficiency was 100% ± 5%.² The polarization data are plotted in Fig. 1 and 2. The actual cell bias needed is two orders of magnitude larger than the calculated theoretical OCV because of activation, diffusion, and ohmic losses. The ohmic cell losses ranged from 0.0908 to 0.0978Ω; the diffusion losses for the air cathode were negligible compared to the ohmic cell losses.

The Butler-Volmer equation (6), reduced to the Tafel form, was employed to describe the anodic data and the propellant-grade oxygen cathodic data in which diffusion effects can be neglected. Diffusion effects cannot be neglected with the air cathodic data. The mass-transfer limitation is incorporated into the Tafel form of the Butler-Volmer equation in the following manner. The Nernst effect (Eq. [2]) of 0.01V was subtracted from the polarization measurements

$$\ln [I/(1 - I/I_0)] = \ln(I_0) - \frac{F\alpha\eta}{RT} \quad [3]$$

The exchange current densities and Tafel slopes will not be equal at the anode and cathode because of different electrode material and different reaction mechanisms. However, identical values for the cathodic Tafel slope and exchange current are found for the two different feed gases when the data are fit in this manner (Tables I and II).

Our polarizations are somewhat lower than Wynveen's (3) anodic and cathodic data and Tomter's (2) cathodic data (Fig. 1 and 2). However, they are higher than Tomter's anodic data because he recirculated the electrolyte past the anode, eliminating much of the concentration polarization. The break point in the anodic data could not be verified conclusively due to experimental uncertainties [e.g., Ref. (7)]. However, the data obtained compared well with those of Srinivasan (8), who does show a break. Figure 3 presents an expanded-scale view of our anodic data with two lines with Tafel slopes of 60 and 120 mV at low and high overpotentials, respectively. The anodic Tafel parameters found in the present study are compared to the Tafel parameters found in other studies (8-11) in Table I. All these authors show a break point with two Tafel slopes. The Tafel parameters were unaf-

²Water content of the evolved oxygen was not considered, contributing to the uncertainty.

ected by a change in electrolyte, anode, or electrolyte concentration.

The cathodic Tafel parameters found in the present study are compared to the parameters found in other studies (9, 12), in Table II. Platinum was the common electrode, but the electrolyte and electrolyte concentration differ from the present study. No limiting current density was found by the other studies nor was a break point proposed. Our data were corrected for diffusion polarization using the limiting current obtained.

With an expected cell resistance of $0.34 \Omega\text{-cm}^2$ (5), the Tafel parameters incorporated into the Butler-Volmer equation predict current densities of 500 mA/cm^2 with a total cell bias of 1.1V. To produce 5606 kg/week of HPO, a total apparent electrode area of 27.9 m^2 would be required. The power consumption of $4.05 \times 10^{-3} \text{ kWh/liter}$ of O_2 at 500 mA/cm^2 is slightly lower than conventional electrochemical oxygen extractors but higher than Tseung's (4) two-electron mechanism $2.69 \times 10^{-3} \text{ kWh/liter}$ of O_2 .³ The feasibility of implementing Tseung's process to produce 5606 kg of HPO per week seems remote because of the difficulty in scaling up the apparatus,⁴ although the two-electron mechanism is attractive when considering operating costs.

Complete information is now available to design a full-scale system. The economics appear attractive; the operating costs are quite low, but total equivalent cost depends strongly on the purchased cost for the full-scale concentrator cells.

³Apparently incorrectly calculated by Tseung (4).

ABSTRACT

Wet etching of Al/Si (2%) films for fine pattern engraving has been studied using an evacuated wet etching system. The results indicate that isotropic etching by conventional atmospheric wet etching changes to quasi-anisotropic etching with decreasing pressure. The amount of lateral etching beneath the photoresist pattern, which is around $0.8 \mu\text{m}$ in conventional atmospheric wet etching, decreases with decreasing pressure and reaches $0.42 \mu\text{m}$ at a pressure of 9 torr. Uniformity of lateral etching is much better than that by conventional wet and dry etching. This technique is useful in the manufacture of fine-pattern aluminum electrodes, for instance, with $1.0\text{--}1.2 \mu\text{m}$ linewidths.

Wet etching is a well-established technique and has been extensively used for IC production. However, this is typical isotropic etching, and the amount of lateral etching beneath photoresist pattern is much greater than can be achieved by anisotropic etching, such as reactive ion etching (RIE). Therefore, fine-pattern engraving of aluminum electrodes less than $2.5\text{--}3.0 \mu\text{m}$ in linewidth is difficult because linewidth narrowing is evident and etching uniformity is insufficient.

In RIE, however, surface damage induced during the etching is a serious problem (1). The etching selectivity of aluminum to SiO_2 is not so high, for instance, 15/1. Etching uniformity, however, was not acceptable. For instance, uniformity normal to the wafer surface within wafer was about 10% (2).

Thus, the wet etching technique is still useful in the fabrication of conventional bipolar and MOS IC's, owing to its damage-free surface and infinite etching selectivity. If anisotropic etching can be realized by wet etching, it becomes useful for VLSI fabrication. Etching uniformity within a wafer is important in fine-pattern engraving to avoid overetching. Lateral etching uniformity is also important in the fabrication of fine pattern aluminum electrodes. The removal of hydrogen bubbles formed on the aluminum surface should be controlled to attain uniform and reproducible etching.

This paper describes a newly developed aluminum electrode etching technique called evacuated wet etching. The reduction of lateral etching and improvement of etching uniformity within a wafer are also mentioned.

Experimental Procedure

Thin aluminum films, Al/Si (2%), were deposited on 6000\AA thick CVD SiO_2 layer. Negative photoresist patterns with linewidths and spacings of $2/2 \mu\text{m}$ and $3/3 \mu\text{m}$ were defined on the aluminum film.

The etching of the film was performed in hot phosphoric acid without dilution maintained at 55°C , where the etching bath was evacuated to pressures ranging from 9 to 80 torr using a newly developed etching apparatus.¹

The etching end point was monitored from the time variation of current flowing by the electrochemical potential generated between the aluminum electrode under etching and a platinum electrode dipped in the phosphoric acid. A schematic model of the end point detection procedure is shown in Fig. 1. Variation of current flowing from these electrodes with etching time is shown together with the cross-sectional view of the electrode. At A, etching is proceeding, as seen in the cross-sectional view, A. Current remained constant at i_2 . The etching of the aluminum film normal to the SiO_2 surface was finished at time t_2 , as seen in the cross section B. The current decreased rapidly from i_2 to i_1 at point B. If etching was continued, moreover, lateral etching proceeded as shown in cross section C, where the current remained nearly constant at i_1 , as shown by point C. From observation of the cross-sectional view of aluminum electrode by SEM at different etching times, we have obtained the relation between current and cross-sectional view of the etching (2). From this, the exact end point of the etching can be established.

Fig. 1. Schematic model of end point detection using electrochemical potential generated between aluminum electrode and platinum electrode dipped in phosphoric acid. Variation of current flowing from these electrodes and of cross sectional view of the electrode observed by an SEM are shown. Points A, B, and C show etch point of the etching procedure. A: During the etching. B: End point for the etching normal to wafer surface. C: Overetching, lateral etching is proceeding.

Fig. 2. Top view of SEM micrographs for Al/Si (2%) electrodes etched by evacuated wet system at different pressures. Rectangular test patterns with line/space = $2/2 \mu\text{m}$ were etched in hot phosphoric acid at 55°C at various pressures in the range 9-80 torr. Photoresist patterns were stripped before measurement. Cross-sectional view of each electrode is shown schematically, where the width of electrode at top and bottom is given in micrometers.

Results and Discussion

Etching of the film was performed in phosphoric acid at 55°C with evacuated pressure of 80, 30, and 9 torr. Etching times, determined by end point detection at point B shown in Fig. 1, were around 6 min. Etch rates of the aluminum film normal to the silicon surface were 0.18, 0.17, 0.18, and $0.18 \mu\text{m}/\text{min}$ at pressures of 760, 80, 30 and 9 torr, respectively. This shows that etching rate in this direction is unchanged with evacuated pressure, although bubble sizes removed from aluminum surface decreased rapidly with decreasing pressure. The etching rate uniformity over a 3 in. wafer was better than 5%, which is much better than 10% of conventional wet and dry etching technology (2).

Fig. 3. The amount of lateral etching, L_1 and L_2 , of Al/Si (2%) electrode as a function of pressure in evacuated wet etching system, where L_1 and L_2 are defined in this figure. Rectangular test patterns with line/space of $3/3 \mu\text{m}$ were examined. Mean value of L_1 and L_2 , observed from cross-sectional view of SEM micrographs at 50 points over whole region of wafer, is shown. The electrode was etched in hot phosphoric acid at 55°C .

In the study of lateral etching, etching was stopped at etching point B defined by t_2 in Fig. 1. After photoresist patterns were removed, and the top view of each electrode was observed using a scanning electron microscope (SEM). Figure 2 shows the SEM micrographs for $2/2 \mu\text{m}$ in line/space pattern electrode at etching pressures of 80, 30, and 9 torr, respectively. A cross-sectional view of each electrode is also shown schematically, where aluminum linewidth at top and bottom of each electrode at different pressures are shown numerically in micrometers. Photoresist pattern with $2 \mu\text{m}$ linewidth used in the etching is shown by broken line. As seen in these micrographs, the top linewidth of the aluminum line, which was $0.1\text{-}0.2 \mu\text{m}$ in atmospheric pressure wet etching, increased drastically with decreasing pressure. That is, a linewidth of $0.8 \mu\text{m}$ at 80 torr increased to $1.3 \mu\text{m}$ at 9 torr by the reduction of lateral etching. Bottom width also increased to $1.6 \mu\text{m}$. Typical isotropic etching in atmospheric wet etching changes to quasi-anisotropic etching. This leads to increased linewidth.

The amount of lateral etching for each electrode beneath the photoresist pattern, L_1 and L_2 defined in Fig. 3, was measured from cross-sectional view of SEM micrographs. Mean values of L_1 and L_2 , obtained at 50 points over whole region of the wafer, are shown in Fig. 3 as function of pressure. The value of L_1 was $0.8 \mu\text{m}$ at atmospheric pressure. The values of L_1 and L_2 decrease with decreasing pressure and approach 0.42 and $0.24 \mu\text{m}$, respectively, at a pressure of 9 torr. This shows that isotropic wet etching at atmospheric pressure becomes increasingly anisotropic with decreasing pressure. Therefore, fine pattern electrodes can be manufactured using the reduced pressure wet etching only if uniformity of lateral etching is within acceptable limits.

Uniformity of lateral etching within a wafer was also studied from these data. The standard deviation of L_1 is

Fig. 4. Uniformity of lateral etching L_1 of Al/Si (2%) electrode shown as a function of pressure in evacuated wet etching system. Test patterns with line/space of $3/3 \mu\text{m}$ were examined. The standard deviation of L_1 , observed at 50 points over whole region of a wafer, is shown. The electrode was etched in hot phosphoric acid at 55°C .

Fig. 5. Model of anisotropic etching in evacuated wet system. Effective diffusion barrier was formed by small hydrogen bubbles on aluminum side wall surface. Here, open and filled circles indicated hydrogen and phosphoric acid, respectively, and arrows show the flux of each molecule.

shown in Fig. 4 as a function of pressure. This shows that lateral etching uniformity was improved remarkably with decreasing pressure. That is, the deviation of $0.2 \mu\text{m}$ at atmospheric pressure decreased to $0.03 \mu\text{m}$ (5%) at 30-100 torr and increased again at still lower pressures. This indicates clearly that evacuated wet etching system offers excellent lateral etching uniformity. Thus, one is able to achieve fine pattern electrode etching with $1.0\text{-}1.2 \mu\text{m}$ linewidth, by the evacuated etching, if the end point detection technique employing electrochemical potential is used.

In wet aluminum etching, hydrogen bubbles are generated on the aluminum film by the chemical reaction with phosphoric acid. Therefore, control of hydrogen bubble removal is important to the improvement of etching uniformity and reproducibility. The fact that the etch rate of aluminum films normal to the wafer surface was constant with time while the lateral (undercutting) etching rate decreased with decreasing pressure suggests the model shown in Fig. 5, which shows the flux of hydrogen bubbles (open circles) and ions of phosphoric acid (filled

circles) during the etching. It is clear from pressure and time variations of the etch rate that the removal rate of hydrogen bubbles through the very narrow channel region ($1 \mu\text{m}$ thick) beneath the photoresist can apparently be restrained with decreasing pressure. Detailed features of this model are reported elsewhere (3).

Conclusions

The consideration of the evacuated wet etching of Al/Si (2%) electrodes resulted in the following conclusions.

1. The etch rate of aluminum films normal to the wafer surface was nearly constant at a value of approximately $0.18 \mu\text{m}/\text{min}$ over the pressure range studied.
2. The amount of lateral etching in the grooves decreased with decreasing pressure, resulting in increased linewidth. Typical undercutting of the conventional (isotropic) wet etching was $0.8 \mu\text{m}$. This was reduced to $0.42 \mu\text{m}$ at 9 torr. Thus, the etching has changed from isotropic to quasi-anisotropic.
3. Uniformity of lateral etching within a wafer was also improved with decreasing pressure. The standard deviation for side etching within a wafer reaches a minimum value of $0.03 \mu\text{m}$ (5%) at 30-100 torr. This is greater uniformity than conventional wet and dry etchings.
4. Overetching for fine pattern aluminum electrodes can be reduced markedly by precisely monitoring the end point. This leads to $1.0\text{-}1.2 \mu\text{m}$ linewidth etching including the deviation.

Characterization of Oxide Growth at High Temperatures and Low Pressures from Silane/Nitrous Oxide Reaction

Arthur J. Learn* and R. B. Jackson

Anicon, Incorporated, San Jose, California 95131

ABSTRACT

The reaction of silane and nitrous oxide at high temperatures and low pressures was investigated for a large range of mole ratio of the reactants. For a nitrous oxide/silane mole ratio of approximately 100, silicon dioxide having the stoichiometric refractive index of 1.45 is obtained for growth at $800^{\circ}\text{-}850^{\circ}\text{C}$. For a mole ratio of 2.2 and growth at $700^{\circ}\text{-}750^{\circ}\text{C}$, silicon-rich oxide results with the refractive index increasing linearly from 1.75 to 1.94 with increasing temperature. The growth rate exhibits an Arrhenius-type temperature dependency in the above ranges with activation energies of 1.43 and 0.89 eV for stoichiometric and silicon-rich oxide, respectively. The increase in growth rate for both oxides with increased wafer spacing is quantitatively interpreted, for small wafer spacings, in terms of a modified model developed for semi-insulating polysilicon growth from the same reactants. The refractive index of silicon-rich oxide also increases with increased spacing, which correlates with greater silicon incorporation at higher growth rates. The functional form of the within-wafer thickness profile for both oxides is also consistent with the model referred to, as is the linear dependence of stoichiometric-oxide growth rate on silane partial pressure.

The use of silane and nitrous oxide reactants in the low pressure chemical vapor deposition (LPCVD) of semi-insulating polysilicon (SIPOS) is well documented (1). Nitrous oxide/silane mole ratios, γ , of less than one are employed for this application. Silicon-rich oxides with an excess silicon content on the order of 10% are attractive for use as electron injectors in electrically alterable-memory devices (2) or as an aid to yield improvement on MOS structures with very thin oxides (3). The value of γ used for formation of such films is greater than one and

typically 2-3. Silicon-rich oxides have been prepared by atmospheric-pressure CVD (4) and plasma-enhanced CVD (5). Stoichiometric oxide grown by CVD at high temperatures promises significantly improved conformality (6) and reduced etch rate arising from denser deposits. In particular, a similar wet-chemical etch rate for deposits on horizontal and vertical surfaces could be expected. Such material has been grown by LPCVD (7) with a γ of 50, but little characterization was performed. A preferred silicon bearing reactant is dichlorosilane (8), in some measure due to the more-ready achievement of acceptable thickness uniformity in this case (7).

* Electrochemical Society Active Member.

In the present paper, the growth of silicon-rich and stoichiometric oxide from silane and nitrous oxide by LPCVD in a vertical-flow reactor is characterized. The growth parameters considered are temperature, γ , silane partial pressure and flow rate, and wafer spacing. The effect of these parameters on growth rate, refractive index, and uniformity is considered in most detail.

Experimental

Experiments were performed in a vertical system (9) configured to provide gas flow parallel to the wafer surface. The wafers are held upright in the wafer carrier (boat). A cage is placed around the wafers in order to enhance uniformity of the deposit (9). A caged boat is placed on either side of elongated injectors positioned at the center of the system. An exhaust slot lies opposite the injectors for each boat. Provision is made in the boat for varying wafer spacing in increments of 4.76 mm. The reactant gases, silane and nitrous oxide, are metered through mass flow controllers. Heaters are arranged in such a way as to provide an isothermal chamber for the reaction.

Bare silicon wafers of 100 mm diam were used as substrates. For the high temperature oxide, the ranges investigated for growth parameters were: temperature, 800°-850°C; γ , 36-125; silane partial pressure, 4.0-13.8 mtorr; and silane flow rate, 8-40 $\text{cm}^3\text{-min}^{-1}$. For the silicon-rich oxide, the primary variable considered was temperature, which ranged from 650° to 750°C. Typically, the growth times were in the 30-60 min range. The refractive index and thickness of the resultant films were measured by ellipsometry. As was pointed out (4), for optically absorbing materials such as the silicon-rich oxide, multiple ellipsometric measurements should be made in order to precisely determine thickness. In the present study, the direct ellipsometric readings were considered to be sufficient to reveal significant trends in the data. The growth rate in all cases was calculated on the basis of the thickness at wafer centers. For extensive within-wafer-thickness-uniformity measurements, an interferometric technique was used after determination of the refractive index as above. A significant measure (9) of such uniformity is the ratio of thickness at the wafer center to the average thickness near the wafer edge. Edge measurements were taken at the top, major flat, left and right positions, excluding the outer 6 mm of the wafer.

Some characterization of the films was done by Auger electron spectroscopy. In particular, the silicon content was determined for selected samples. In order to quantify such measurements, a stoichiometric silicon dioxide sample grown thermally was used for calibration. The AES technique was also utilized to test for impurities in the interior of the films.

Results and Discussion

Results were obtained for both high temperature oxide (HTO) and silicon-rich oxide (SIROX). The dependencies for HTO will be discussed first and for SIROX subsequently.

Nitrous oxide/silane mole ratio, γ .—The growth rate and the refractive index of HTO as a function of γ are shown in Fig. 1. Other conditions were held constant at a temperature of 825°C, and silane flow rate and partial pressure of 20 $\text{cm}^3\text{-min}^{-1}$ and 10.8 mtorr, respectively. In general, the data points in Fig. 1 are the result of a single experiment. For a γ of 100, however, several runs were made under ostensibly identical conditions. The ranges of growth rate and refractive index observed are shown in Fig. 1. The leveling off of the refractive index indicates the attainment of stoichiometric HTO for γ near 100. Analysis of such films by AES verified their stoichiometry within the accuracy of this technique (± 2 a/o). The growth rate reaches a maximum at about the same value of γ . This also suggests that the reaction is deficient in oxygen for smaller values of γ . For values of $\gamma > 112$, excess nitrous oxide adsorbed on the substrate surface may inhibit the reaction resulting in reduced growth rate. Somewhat similar behavior, as regards growth rate, is observed (9) for

Fig. 1. Oxide growth rate and refractive index as a function of nitrous oxide/silane mole ratio for growth at 825°C with a silane partial pressure of 10.8 mtorr and a silane flow rate of 20 $\text{cm}^3\text{-min}^{-1}$.

the low temperature LPCVD silane/ O_2 reaction. In that case, the growth rate also passes through a maximum, though for $\gamma \approx 1$. The much lower reactivity of nitrous oxide than O_2 , therefore, is apparent.

Fig. 2. Oxide growth rate as a function of silane partial pressure for growth at 825°C with a silane flow rate of 20 $\text{cm}^3\text{-min}^{-1}$ and a nitrous oxide/silane mole ratio of 100.

Silane partial pressure.—The growth rate of HTO as a function of silane partial pressure is shown in Fig. 2. In this case, the growth temperature is 825°C, the silane flow is 20 cm³·min⁻¹, and γ is 100. Clearly, a linear dependence of growth rate on silane partial pressure is exhibited. The refractive index for the films of Fig. 2 is not distinguishably different from that for the stoichiometric HTO in Fig. 1.

Silane flow rate.—The growth rate of HTO as a function of silane flow rate is presented in Fig. 3. The temperature and γ are as above, i.e., 825°C and 100, respectively, while the silane partial pressure is 10.8 mtorr. As for the silane/ammonia reaction (10), an increase in growth rate from zero with increased flow is anticipated. This dependency is apparently present for the lower flow rates. The decreased growth rate for the larger flow rates may be a consequence of the reduced residence time for reactants becoming dominant at high flow rates. The refractive index does not exhibit any dependency on flow rate.

Growth temperature.—The logarithm of growth rate as a function of the reciprocal of absolute growth temperature is shown in Fig. 4. The silane flow rate is 20 cm³·min⁻¹, the silane partial pressure is 10.8 mtorr, and γ is 73 for these data. There is a tendency for growth-rate saturation at the highest temperature for this set of growth con-

Fig. 3. Oxide growth rate as a function of silane flow rate for growth at 825°C with a silane partial pressure of 10.8 mtorr and a nitrous oxide/silane mole ratio of 100.

Fig. 4. The logarithm of oxide growth rate as a function of reciprocal absolute temperature for a silane partial pressure of 10.8 mtorr, a silane flow rate of 20 cm³·min⁻¹, and a nitrous oxide/silane mole ratio of 73.

ditions. The lower temperature data points yield an activation energy of 1.43 eV. This activation energy is much larger than the value of 0.52 eV observed (11) for the O₂/silane reaction at temperatures near 400°C. It is, however, lower than the activation energy for the dichloro-silane/nitrous oxide reaction of about 2 eV (8). The refractive index for the highest temperature (850°C) film is approximately 0.02 higher than for the other films.

Wafer spacing.—All of the data listed above were gathered for a wafer spacing of 9.5 mm. The growth rate of HTO at the wafer center as a function of wafer spacing is shown in Fig. 5. The associated growth conditions are a temperature of 825°C, a silane partial pressure of 10.8 mtorr, a silane flow rate of 22 cm³·min⁻¹, and a γ of 90. The growth rate has a sublinear dependency on wafer spacing. A similar dependency is noted for low temperature LPCVD oxide (9). In that case, a proportionality for growth rate, GR , is derived as follows

$$GR \propto d \frac{r_c^2 - r^2}{r_c d + r_w^2 - r^2} \quad [1]$$

where d is wafer spacing, r_c is the inner radius of the cage surrounding wafers, r_w is the wafer radius, and r is the radial position on a wafer. This relationship for GR essentially involves (9) the volume to area ratio of a reaction cell comprised of two adjacent wafers and the portion of the cage between the two wafers. For boats utilized in the vertical-flow reactor, openings in the cage are required in order to allow introduction of reactants to the wafers. The openings are configured as rings of circular holes spaced along the length of the boat. Taking into account these holes, the expression for GR becomes

$$GR \propto d \frac{r_c^2 - r^2 + \frac{d_h^2}{2d}(s+w)n}{r_c d + r_w^2 - r^2 + d_h w n} \quad [2]$$

where d_h is the hole diameter, s is the effective spacing between the cage and the reaction-chamber wall, w is the thickness of the cage wall, and n is the number of holes per reaction cell. The additional volume term is that for cylinders extending from the inner surface of the cage to the chamber wall. The additional area term is that for the peripheries of the holes. For optimum within-wafer thickness uniformity, there is no radial variation of GR , i.e., $d(GR)/dr = 0$. This condition leads to the following equality

$$r_c^2 - r_c d - r_w^2 = n d_h \left\{ w - \frac{d_h}{2d}(s+w) \right\} \quad [3]$$

Fig. 5. Oxide growth rate as a function of wafer spacing for growth at 825°C with a partial pressure of 10.8 mtorr, a silane flow rate of 22 cm³·min⁻¹, and a nitrous oxide/silane mole ratio of 90. The curve is a fit of Eq. [2] to the experimental results.

The boat dimensions resulting in this optimum condition for a d of 9.5 mm and a r_w of 50 mm are r_c , n , d_h , and w equal to 52.5, 12, 2.36, and 2.5 mm, respectively. Calculation of s from Eq. [3] yields a value of 87 mm. A boat essentially resides in a reaction chamber of square cross section with a side dimension of 204 mm. Accordingly, the range of s expected is 47-89 mm. The calculated value of s falls within this range, albeit at the high end.

The growth rate at the wafer center as a function of d is given by setting r equal to zero in expression [2]. Using the values for other parameters listed above, the curve in Fig. 5 is obtained. The constant of proportionality was obtained by fitting Eq. [2] to the data point at a d of 9.5 mm. It may be noted that the experimental results fall significantly below this curve for large d .

The uniformity parameter mentioned in the Experimental section, *i.e.*, the ratio of thickness at the wafer center to the average near the edge, is shown in Fig. 6 as a function of d . Relationship [2] can be used to predict this ratio. Comparison is made for r equal to zero and r equal to the wafer radius minus 6 mm. The resultant curve is presented in Fig. 6. Again, as for the GR of Fig. 5, the experimental points fall below this curve for large d . Shifting the GR at wafer center for the two large d up to the level of the curve in Fig. 5 results in the shift in uniformity indicated by the arrows in Fig. 6. A good fit to the theoretical uniformity curve is thereby obtained. The implication is, therefore, that the GR near the edge of wafers varies with d as predicted by Eq. [2]. The different behavior for the edge and center GR may be explained by a diffusion effect. For example, for a d of 19 mm two rings of holes lie between adjacent wafers. Less reactant may diffuse to the wafer center from the more remotely located holes. Such an effect would be less pronounced at the wafer edges, since they are nearer the holes, or for smaller d , for the same reason.

The remainder of the results presented are for SIROX.

Growth temperature.—The logarithm of SIROX growth rate as a function of the reciprocal of absolute growth temperature is shown in Fig. 7. The results were obtained with a nitrous oxide/silane mole ratio of 2.2, a total flow rate of 800 $\text{cm}^3\text{-min}^{-1}$, and a silane partial pressure of approximately 60 mtorr. The straight-line portion of the curve at higher temperatures yields an activation energy of 0.89 eV. This activation energy is comparable to the 0.78 eV value observed (1) for SIPOS for a γ of 0.4. The reaction rate appears to decrease disproportionately at the lowest temperature (650°C). As discussed below, however, the thickness was determined in this case by assuming a value of refractive index and may therefore be somewhat in error.

Fig. 6. Oxide-thickness uniformity parameter as a function of wafer spacing. The growth conditions are as listed for Fig. 5. The curve is uniformity as predicted from Eq. [2]. As discussed in the text, the arrows represent corrections for wafer-center growth rates.

Fig. 7. The logarithm of oxide growth rate as a function of reciprocal absolute temperature for a silane partial pressure of 60 mtorr, a silane flow rate of 250 $\text{cm}^3\text{-min}^{-1}$, and a nitrous oxide/silane mole ratio of 2.2.

The refractive index, n , as a function of growth temperature is presented in Fig. 8. A linear variation of n with growth temperature is indicated. The bars encompass the range of n observed at the different temperatures. There is less variation in n as the growth temperature is reduced. At 650°C, the films were sufficiently thin such that n and thickness could not both be determined. An extrapolated value of 1.56 for n was utilized in measuring thickness. Although perhaps not entirely meaningful, extrapolation of the curve to 1.45 for n indicates growth of stoichiometric oxide at approximately 625°C for γ equal to 2.2.

Wafer spacing.—Growth rate and n are shown as a function of wafer spacing in Fig. 9. Growth was at 725°C, with a nitrous oxide/silane mole ratio of 2.2, a total flow rate of 400 $\text{cm}^3\text{-min}^{-1}$, and a silane partial pressure of 47 mtorr. The curve presented for GR was obtained from Eq. [2] by fitting to the data point for a d of 9.5 mm. The variation of GR with d is virtually identical to that for HTO in Fig. 5. In particular, the experimental GR values fall below the theoretical curve for large d . The data of Fig. 7 were obtained for a d of 9.5 mm, where a growth rate of 2.4 $\text{nm}\text{-min}^{-1}$ is noted at 725°C. For the same d , from Fig. 9, the growth rate is 0.8 $\text{nm}\text{-min}^{-1}$. This change in growth rate corresponds roughly to the combined effects of a twofold reduction in silane flow rate and a 20-25% reduction in silane partial pressure, if a linear dependence of growth rate on these parameters applies.

The refractive index exhibits a monotonic increase with increasing d . Films grown at the extreme wafer spacings

Fig. 8. Refractive index for silicon-rich oxide as a function of growth temperature. The growth conditions are as listed for Fig. 7.

Fig. 9. Silicon-rich oxide growth rate and refractive index as a function of wafer spacing for growth at 725°C with a silane partial pressure of 47 mtorr, a silane flow rate of 125 cm³-min⁻¹, and a nitrous oxide/silane mole ratio of 2.2. The curve is a fit of Eq. [2] to the experimental results.

of 4.76 and 19 mm were tested by AES and found to contain 41 ± 2 and 47 ± 2 a/o silicon, respectively. The higher values of n clearly correspond, therefore, to more silicon-rich composition. In fact, combining the above silicon contents, and their associated values of n from Fig. 9, with the silicon content (33 a/o) and n (1.45) for stoichiometric oxide reveals that a change in n of 0.024 per atom percent of excess silicon applies. In any case, increased silicon incorporation is promoted at the higher growth rates. Such an effect may also account, in part, for the lower n of Fig. 9 than that of Fig. 8 at 725°C. Similarly, the increased n at higher temperatures (Fig. 8) may be partially attributable to the increased growth rates (Fig. 7).

The silicon contents listed above are comparable to those (4) for atmospheric growth at 700°C with the same γ . Also, as is found for the atmospheric films, the AES analysis suggests that the excess silicon exists as a separate phase in the silicon dioxide matrix. For a γ of 2.2 with the atmospheric process, carbon at the several atom percent level and nitrogen in a lesser amount are observed (4) in deposits. Neither of these elements was detected in films of the present study by AES, which has sensitivity down to about 1 a/o.

Center-to-edge uniformities for thickness and n as a function of d are shown in Fig. 10. The thickness-uniformity variation is similar to that for HTO in Fig. 6. As was noted above, the same is true of the GR variation with d . Consequently, the discussion in connection with the HTO data is equally applicable to SIROX. The variation with d of refractive-index uniformity illustrated in Fig. 10 is generally consistent with the dependency of n on growth rate. An exception is the result for the lowest value of d in Fig. 10. Since the center growth rate is less than the edge growth rate in this case, a lower n at the wafer center would be anticipated.

Conclusions

The silane/nitrous oxide reaction was utilized at high temperatures for the low pressure CVD formation of high temperature oxide (HTO) and silicon-rich oxide (SIROX). The nitrous oxide/silane mole ratio was varied from 35 to

Fig. 10. Thickness and refractive index uniformity parameters for silicon-rich oxide as a function of wafer spacing. The growth conditions are as listed for Fig. 9.

125 for HTO and fixed at 2.2 for SIROX. For low values of this ratio, the HTO growth rate increases, and refractive index decreases as the ratio is increased. The growth rate and refractive index level off for a mole ratio of approximately 100, indicating the attainment of stoichiometric HTO. The growth-rate activation energies for stoichiometric HTO in the 800°-840°C temperature range and for SIROX in the 700°-750°C range are 1.43 and 0.89 eV, respectively. The SIROX refractive index is a strong, linear function of temperature and increases by 0.19 over the 50°C range above. The growth rate of HTO depends linearly on silane partial pressure and passes through a maximum with respect to silane flow rate at high total flow rates. The refractive index and silicon content for SIROX increase with increased wafer spacing. This is a consequence of the monotonic increase in growth rate with increased wafer spacing. Quantitatively, at small wafer spacings, the variation of growth rate at wafer centers for both HTO and SIROX as a function of wafer spacing is in accordance with a modified version of the model developed by Hitchman *et al.* (1) for SIPOS. The within-wafer uniformity variation with wafer spacing in the same range is also consistent with this model. In particular, a reversal in the slope of the center-to-edge thickness profile at a certain wafer spacing is predicted. For large wafer spacings, a diffusion-length effect may cause deviation of the wafer-center growth rate and uniformity from the modeled values. The commonality for all processes to which the model applies appears to be the use of silane as a silicon bearing reactant. This list now includes, SIPOS (1), HTO, SIROX, low temperature LPCVD oxide (9), and silicon nitride (12).

ABSTRACT

A correlation between reactive ion etching (RIE) characteristics of W films and their microstructural features has been investigated, and it was found that the α -phase W can be controllably etched compared with the $\alpha + \beta$ mixed modification. The etch rate for the stable, α -phase W films with CF_4 and SF_6 plasmas has been shown to depend strongly on the discharge parameters—RF power and reactor pressure. Effects of the Ar, O_2 , and N_2 additions and the etching selectivity between the W film and photoresist (Shipley AZ-1350) have also been studied in detail. These observations have led to the conclusion that the CF_4/N_2 (SF_6/N_2) mixed system is mostly attractive for a variety of device processing applications. The chemical nature of the RIE-processed W surface has been examined by secondary ion mass spectrometry, and an apparent presence of C, O, F, and S species on the surface has been confirmed. By I-V and C-V measurements of Schottky contacts fabricated on RIE-processed GaAs surface, no indication of damage layers has been detected.

Reactive ion etching (RIE) is of current interest because of its importance for use in the fabrication of VLSI (VLSI) circuits. The processing of refractory metals is also become of great importance for the fabrication of low resistive interconnects and contacts for such semiconductor devices. W film deposition has, therefore, been investigated extensively, and sputtering, electron-beam evaporation, and chemical vapor deposition as well as laser photolysis have been developed as deposition techniques (1). W plasma etching has also been performed widely in both barrel and parallel-plate reactors.

Maeda and Fujino (2) have demonstrated that the refractory metals, such as W and Mo, can be attacked and etched considerably by activated F atoms produced in a barrel-type reactor with a CF_4 discharge. The effects of O_2 additions to SF_6 on W etch rate in a reactor have been studied by Randall and Wolfe (3). They have found that the maximum etch rate occurs with a pure SF_6 discharge and decreases gradually with increasing O_2 additions. Tang and Hess (4) have also carried out a systematic investigation on plasma etching characteristics of W films in CF_4 and SF_6 discharges. They have measured relative F atom concentrations by means of optical emission spectroscopy, and concluded that the W etching is primarily controlled by F atoms in the CF_4 plasmas, but the mechanism is not so simple in the case of the SF_6 plasmas. Recently, Tsujimoto *et al.* (5) have reported fundamental properties of W dry etching, such as etching selectivity between the W and dielectric films and etching profiles of the W films, from the viewpoint of the VLSI applications.

It is the purpose of this paper to clarify a correlation between the RIE characteristics of the W films and their microstructural features and, moreover, to present accurate experimental data on the etch rate of W films (hereafter referred to as R_w) as a function of the discharge parameters, such as RF power and reactor pressure, in a parallel-plate reactor with CF_4 and SF_6 plasmas. Effects of

the Ar, O_2 , and N_2 additions to CF_4 and SF_6 on R_w are also studied in detail. The etching reactions in such plasmas are discussed. Considering the growing importance of submicrometer-design device rule fabrication, it is somewhat surprising that relatively little or, to our knowledge, no attention has been given in the literature to the etching selectivity between the W films and photoresists. Because of this, we simultaneously carried out RIE studies on photoresists. Shipley AZ-1350 was chosen as the photoresist for this study. This resist is positive type and is frequently used in the VLSI processes. The chemical nature of the RIE-processed W surface is examined by secondary ion mass spectrometry (SIMS). The feasibility of the RIE process in the VLSI technology strongly depends on its capability of producing damage free surface. A group of researchers (6, 7) have proposed a new type of the transistor, namely, permeable base transistor (PBT). The unique feature of this transistor is the use of W-metal grating embedded in the single-crystal semiconductor. Because of this importance, Schottky contacts were formed on RIE-processed GaAs surface, and the surface quality was characterized by I-V and C-V measurements.

Experimental

Tungsten deposition.—W films were deposited by conventional RF diode sputtering system on (001) GaAs substrates. The W target used was a commercially available one (99.9% pure). After the system had been pumped down to $\sim 5 \times 10^{-7}$ torr, the target was cleaned by pre-sputtering for about 30 min while the GaAs substrates were isolated from the plasma by a stainless steel shutter. The working gas was argon, 99.999% pure. Sputtering pressures tried were in the range of 1×10^{-2} to 3×10^{-1} torr. Unless otherwise noted, the W films used were deposited at working pressure of 4×10^{-2} torr. The deposition runs were carried out at an RF power of 100W. The substrate temperature was not measured during deposition. A separate series of sputtering experiments, how-

ever, indicated an increase of the substrate temperature to a saturation value ($\sim 200^\circ\text{C}$) as the film deposition was taking place for about 20 min.

RIE apparatus.—The RIE apparatus used in this work was a commercial parallel-plate reactor. It consists of a stainless steel chamber and 28 cm diam SiO_2 electrodes. The etch gases used in this study were CF_4 (99.9999% pure) and SF_6 (99.99% pure) purchased from Asahi Glass Company. High purity argon, oxygen, and nitrogen gases were also added and mixed prior to entering the reactor chamber. The flow rates of individual gases were controlled by thermal mass flow meters. They were corrected with the following gas calibration factors: CF_4 (0.44), SF_6 (0.28), Ar(1.43), O_2 (0.99), and N_2 (1.00). The etching samples, about $5 \text{ mm} \times 5 \text{ mm} \times 320 \mu\text{m}$ size, were loaded at the center of the electrode. In conducting our experiments, we evaluated separately the effects of various plasma parameters on the etch rate with a set of standard etch conditions. They are; 50W (RF power), 10 Pa (reactor pressure), and 35 sccm (gas flow rate).

Etch rates.—Etching studies were performed for the etching selected regions of W films sputter-deposited on (001) GaAs substrates through windows in AZ-1350 photoresist mask. The open windows, $100 \mu\text{m}$ wide and $200 \mu\text{m}$ long, were defined by standard photolithography technique. After etching, removing the AZ-1350 mask, and rinsing in deionized water, the etched depths of the W films were measured from a step height between the etched and unetched surfaces using a Talystep meter. The etch rate of photoresists AZ-1350 was also examined similarly. Hereafter, we refer to this value as $R_{\text{AZ-1350}}$. The etching profile was also examined by cleaving the samples in a direction along the GaAs (110) cleavage plane.

Etched-surface quality.—After RIE processing, the W films were removed from the RIE chamber and characterized by means of the SIMS analysis. Au-evaporated Schottky diodes were fabricated on a RIE-processed GaAs surface, and the surface quality was tested by I-V and C-V measurements.

Microstructure-Related Data on Sputtered-W Films

The purpose of this section is to present a study of the dependence of the properties of Ar-ion-sputtered W films upon deposition condition (working pressure). A series of refractory-metal elements, like W, Mo, and Ta, form stable or, sometimes, metastable crystal structure. In the case of W, its stable structure is the so-called α -W modification with lattice constant $a = 3.156\text{\AA}$ and density $\rho = 19.6 \text{ g/cm}^3$, and its metastable one is the β -W modification of the A-15 cubic crystal structure with $a = 5.038\text{\AA}$ and $\rho = 19.0 \text{ g/cm}^3$.

In the W metallization process used for the fabrication of electron devices, a number of requirements, such as low stress, low interface-state density, and low electrical resistivity, have to be satisfied. Especially, the film resistivity is one of the most important factors for applications to W-gate FET's and circuit interconnects. The room temperature electrical resistivities of the W films sputtered at various pressures were measured by the standard four-point probe method. The results of this experiment are shown in Fig. 1 by the crosses (curve 1). The corresponding sputter deposition rates are also shown in the figure by the open circles (curve 2). It can be seen that the electrical resistivity decreases slightly with increasing working pressure, showing a minimum at about 4×10^{-2} torr, and then increasing sharply. This result is identical to that reported by Hoffman and Thornton (8). The deposition rate also increases gradually with increasing working pressure. It is interesting and important to make clear some correlations between the electrical resistivities and microstructural features of the W films. From this point of view, the crystal structure of the films was examined by an x-ray diffractometer analysis. When the films were deposited at low pressures ($p \leq 4.5 \times 10^{-2}$ torr), they were in a single α -phase because only two peaks of (110) and

(211) of the α -W were detected. When the films were deposited at pressures greater than 4.5×10^{-2} torr, they became α -W/ β -W mixture containing a new phase modification, WO_3 , and the fraction of the β -W modification increased with increasing working pressure. As is shown in Fig. 1, the pure α -W films have a low resistivity. An increase in the film resistivity at higher sputtering pressures corresponds to the appearance of the β -W and WO_3 modifications. It can, therefore, be recognized that relatively large resistivity of the W films deposited at higher pressures is controlled by the amounts of β -W and WO_3 present in the film. Similarly, Petroff *et al.* (9) have found from studies on RF-sputtered films that α -W films consist of large grains (1500 - 2000\AA) free of defects, while β -W films consist of small grains (50 - 100\AA) with a high density of stacking faults and twins. They reported that the high resistivity of the β -W films was attributed to diffuse scattering of electrons by grain boundaries.

The plots of the etch rate against working pressure for the sputter-deposited W film are shown in Fig. 1 by the filled circles. The data were taken in CF_4 plasma with the flow rate of 35 sccm at 10 Pa pressure and 50W RF power. In the figure, the solid line corresponds to that of the as-deposited and without intentional room ambient exposure W films (curve 3a), and the dashed line corresponds to films exposed to room ambient for about two months (curve 3b). It should be noted that the etched depth of the W films in the α -W/ β -W mixture region ($p > 4.5 \times 10^{-2}$ torr) does not increase linearly with etching time (see Fig. 2). When the linear relationship is extrapolated, the line does not pass through the origin, indicating that a lag time exists at the start of the W-film etching in this region. A considerable change in the etch rates of samples with and without room ambient exposure in the α -W/ β -W mixture region, moreover, suggests instability of the ($\alpha + \beta$) W films with room ambient exposure. It is apparent from the figure that the etch rate increases dramatically as the Ar working pressure falls in the ($\alpha + \beta$) W mixture region. This feature is quite similar to that found in the resistivity variation. An identical trend was also seen for the W etching in SF_6 plasma.

Etch Rates

Pure CF_4 and SF_6 plasmas.—The etched depths as a function of etching time for W film and photoresist

Fig. 1. Plots of electrical resistivity (curve 1), deposition rate (curve 2), and etch rate (curve 3) against working pressure for W films sputter-deposited in Ar using an RF diode sputtering system. Curve 3a corresponds to that of the as-deposited, without intentional room ambient exposure W films, and curve 3b corresponds to that of about two months room ambient exposed ones.

Fig. 2. Relation between etched depth and etching time for α -W (deposited at 4×10^{-2} torr), $(\alpha + \beta)$ W (deposited at 1.5×10^{-2} torr), and AZ-1350 in pure CF_4 plasma.

(AZ-1350) in pure CF_4 plasma are shown in Fig. 2. Similar results were also obtained for SF_6 plasma, except that the α -W film was etched faster than the AZ-1350 photoresist. The etched depth vs. etching time for GaAs in pure CF_4 plasma is also shown in the figure. As clearly seen in the figure, the depth of the α -W film (sputtered at 4×10^{-2} torr) and AZ-1350 photoresist increases linearly with etching time. When this relationship is extrapolated, the line

passes through the origin, indicating that no lag time exists at the start of the α -W and AZ-1350 etching. This etching property of W film is consistent with that reported by Tang and Hess (4). However, the result of $(\alpha + \beta)$ W film is in sharp contrast to that of the α -W films. It is worth noting that the $(\alpha + \beta)$ W film (sputtered at 1.5×10^{-1} torr) shows a clear lag-time effect. This feature of the $(\alpha + \beta)$ W film etching is similar to that observed during Al etching (10). Thin native oxide film always presents an Al surface, and it causes a lag-time effect on the Al etching. An absence of the β -phase in the W films deposited at $p \approx 4.5 \times 10^{-2}$ torr is attributed to their lower oxygen content, resulting in lower resistivity of the films (9). The $(\alpha + \beta)$ W films cannot be etched with good reproducibility and stable etch rates, especially when they are room ambient exposed for a long time, whereas the α -W films can be. Beyond the lag time, the $(\alpha + \beta)$ W films can be etched with relatively high speed compared with the α -W films (see also Fig. 1). Such etching characteristics of the $(\alpha + \beta)$ W films would be caused by surface oxidation (and/or WO_3 transformation) but not by $\alpha \rightarrow \beta$ phase transformation (11). Unless otherwise noted, the stable α -W films (sputtered at 4×10^{-2} torr) were used for RIE studies in the following. It has also been found that both the CF_4 and SF_6 plasmas etch GaAs very slowly. In order for a plasma etching system to be successful, a volatile derivative of the substance to be etched must be produced. Relatively low etch rate of GaAs found here is most likely due to the lower volatility of gallium products (GaF_3 , b.p. $> 950^\circ\text{C}$) (12).

It is known (4) that by increasing RF power the electron density and average electron energy increase and, as a result, the rate of ionization, excitation, and decomposition of gas phase molecules increase. Figure 3 shows the etch rate as a function of RF power for the W films (R_W) and AZ-1350 ($R_{\text{AZ-1350}}$) in pure CF_4 and SF_6 plasmas. The etch rate of GaAs in the CF_4 plasma is also shown in the figure. R_W , $R_{\text{AZ-1350}}$, and also the etch rate of GaAs in the CF_4 plasmas increase with RF power superlinearly within our experimental range; a relation between the etch rates R and RF power P for these substances can be expressed exactly by $R \propto P^{2.0}$. The etch rates in the SF_6 plasma, on the other hand, increase linearly up to $P = 50\text{W}$, and then

Fig. 3. Etch rate as a function of RF power for α -W, AZ-1350, and GaAs in pure CF_4 plasma (a) and that for α -W and AZ-1350 in pure SF_6 plasma (b).

Fig. 4. Etch rate as a function of reactor pressure for α -W and AZ-1350 in pure CF_4 (a) and SF_6 plasma (b)

increase superlinearly for both the W film and AZ-1350 photoresist.

The dependence of R_W and $R_{\text{AZ-1350}}$ on the reactor pressure is shown in Fig. 4. Both R_W and $R_{\text{AZ-1350}}$ in the CF_4 plasmas decrease linearly as the reactor pressure increases, showing a minimum at about 40 Pa, and then increase with further increase of the pressure. The functional pressure dependence of R_W and $R_{\text{AZ-1350}}$ in the SF_6 plasmas is quite different. R_W is nearly constant up to 10 Pa, and decreases drastically with increasing pressure. $R_{\text{AZ-1350}}$, on the other hand, does not depend strongly on pressure within our experimental range.

Effects of Ar, O₂, and N₂ additions.—Inert gas additions can stabilize and homogenize plasmas through the effects of their addition on the thermal properties of the discharge gas or on the electron density and average electron energy resulting from altered electron balance processes. It is also known that radical or unsaturated scavenger effect is expected with the addition of some gases to reactive gas plasmas, e.g., O₂ gas to CF_4 plasmas, where the removal of CF_x radicals prevents their recombination with F atoms and contributes to the ensuing increase in atom density. In the following, the etch-rate data of the W films and AZ-1350 photoresists will be presented as a function of the Ar, O₂, and N₂ additions in the CF_4 and SF_6 plasmas.

The effects of varying Ar partial pressure on R_W and $R_{\text{AZ-1350}}$ in mixed CF_4/Ar and SF_6/Ar systems are shown in Fig. 5. In both mixtures, R_W increases gradually with increasing percent Ar from 0 to 85 (CF_4/Ar) and to 95 (SF_6/Ar). Further increases of percent Ar result in a drastic decrease in R_W . No measurable etched depth on the W film was observed with pure Ar plasma. $R_{\text{AZ-1350}}$ also increases gradually with increasing percent Ar, exhibiting a maximum near 95% Ar in both the CF_4/Ar and SF_6/Ar mixtures. Pure Ar plasma results in considerable etching of the AZ-1350 photoresist ($R_{\text{AZ-1350}} \approx 200 \text{ \AA}/\text{min}$).

Figure 6 shows the effects of varying O₂ partial pressure on R_W and $R_{\text{AZ-1350}}$ in mixed CF_4/O_2 systems. It is known (13, 14) that in the case of Si etching, O₂ additions to CF_4 enhance the products of F atoms and reduce carbon-related residues, thereby increasing the etch rate of Si. R_W in the CF_4/O_2 system goes through a maximum at about 40% O₂. When the percentage of O₂ exceeds 90, R_W de-

creases rapidly and approaches zero as a pure O₂ plasma is approached. Such a trend is very similar to that found for Si etching in CF_4/O_2 plasmas (13, 14). A qualitative feature of W etching in the SF_6/O_2 plasmas is quite different from that in the CF_4/O_2 plasmas. As clearly seen in Fig. 6, R_W in the SF_6/O_2 plasma decreases monotonically with increasing O₂ percentage. $R_{\text{AZ-1350}}$, contrarily, increases gradually and exhibits a maximum at 90% O₂ addition. This trend of $R_{\text{AZ-1350}}$ is nearly identical to that observed in the CF_4/O_2 plasmas.

To our knowledge, there has been no report on the plasma etching of any kind of metals in CF_4/N_2 or SF_6/N_2 mixtures. The effect of varying N₂ partial pressure on R_W and $R_{\text{AZ-1350}}$ in mixed CF_4/N_2 and SF_6/N_2 systems is shown in Fig. 7. In these mixtures, R_W increases dramatically as the addition of N₂ to CF_4 or SF_6 from zero to few percent. Further increases of the N₂ additions result in a slight increase in R_W . The etch rate then decreases as the percent N₂ approaches 100 (pure N₂). The W films were not etched with pure N₂ plasma. $R_{\text{AZ-1350}}$, on the other hand, does not depend so strongly on the N₂ additions, except at the region near pure SF_6 . It is noted that from an aspect of the etching selectivity $S (= R_W/R_{\text{AZ-1350}})$ the CF_4/N_2 (SF_6/N_2) mixture is more suitable than the CF_4/Ar (SF_6/Ar) and CF_4/O_2 (SF_6/O_2) mixtures. In the following, we present the data on R_W and $R_{\text{AZ-1350}}$ as a function of the plasma parameters in the CF_4/N_2 and SF_6/N_2 mixtures.

Figure 8 shows the variation of R_W and $R_{\text{AZ-1350}}$ as a function of the applied RF power in 90% $\text{CF}_4 + 10\% \text{ N}_2$ and 80% $\text{SF}_6 + 20\% \text{ N}_2$ mixtures. The dependence of R_W and $R_{\text{AZ-1350}}$ on RF power in the CF_4/N_2 plasmas can be given by $R_W \propto P^{1.5}$ and $R_{\text{AZ-1350}} \propto P^{2.0}$. The power dependence of the etch rate in the SF_6/N_2 plasmas, on the other hand, can be classified into two regions; $R_W \propto P^{0.5}$ and $R_{\text{AZ-1350}} \propto P^{1.0}$ at RF powers up to 100W, and $R_W \propto P^{1.0}$ and $R_{\text{AZ-1350}} \propto P^{3.0}$ at above 100W.

The etch rates of the W films and AZ-1350 photoresists as a function of the reactor pressure in the CF_4/N_2 and SF_6/N_2 plasmas are shown in Fig. 9. R_W in the CF_4/N_2 mixture increases with increasing pressure, peaking at 20 Pa, and then decreases with increasing pressure. R_W in the SF_6/N_2 mixture also increases with increasing pressure, peaking at 20 Pa, and then decreases abruptly with increasing pressure. $R_{\text{AZ-1350}}$ in the CF_4/N_2 mixture de-

Fig. 5. Effect of varying Ar partial pressure on etch rate of α -W and AZ-1350 in mixed CF_4/Ar and SF_6/Ar plasmas

creases as the pressure increases, showing a minimum at 20 Pa, and then increases very slowly with increasing pressure. $R_{\text{AZ-1350}}$ in the SF_6/N_2 mixture, on the other hand, does not depend on pressure within our experimental range. Such pressure dependence of R_{W} and $R_{\text{AZ-1350}}$ is similar to that found in pure CF_4 and SF_6 plasmas (Fig. 4).

Etching Reaction in Plasma

The chemistry which takes place in a plasma is usually quite complex and involves a large number of elementary reactions (15). There exists a large number of radicals in

fluorinated gases and gas mixtures. The chemical reactions may occur between such radicals and solid materials. If the products which result from the chemical reactions have relatively high volatility, just as in the case of tungsten hexafluoride (WF_6 , b.p. = 17.5°C), they are removed from the solid surface. This is a basic concept of the W plasma etching in the fluorinated gases. We can expect the reaction for W etching in the CF_4 plasma to be

Fig. 6. Effect of varying O_2 partial pressure on etch rate of α -W and AZ-1350 in mixed CF_4/O_2 and SF_6/O_2 plasma

Fig. 7. Effect of varying N₂ partial pressure on etch rate of α -W and AZ-1350 in mixed CF₄/N₂ and SF₆/N₂ plasma

D'Agostino (16) has reported that discharges in pure SF₆ yield no stable reaction products in an alumina reactor without Si or SiO₂ substrates. Various investigators (17), on the other hand, reported SF₄, atomic F, F₂, S₂F₂, and SF₂, among the products of SF₆ discharges. Many of these studies were carried out in quartz discharge tubes where the tube wall participated in the reactions. Because of the SiO₂ electrodes used in the present study, one can expect the same products as reported for the SF₆ plasmas.¹ The

¹See Ref. (16).

etching reaction of W films in SF₆ plasma can also be presumed by Eq. [1b].

The etching of W in pure CF₄ plasma is limited by the supply of reactive species (2, 4). Emission spectra study on pure CF₄ plasma has suggested that the F atom emission intensity decreases with increasing reactor pressure (2). Because of the reactant-supply limited mechanism, R_w in pure CF₄ plasma may be expected to decrease with increasing pressure. That is the fact (see Fig. 4). If the pressures are further reduced, R_w will reach a maximum

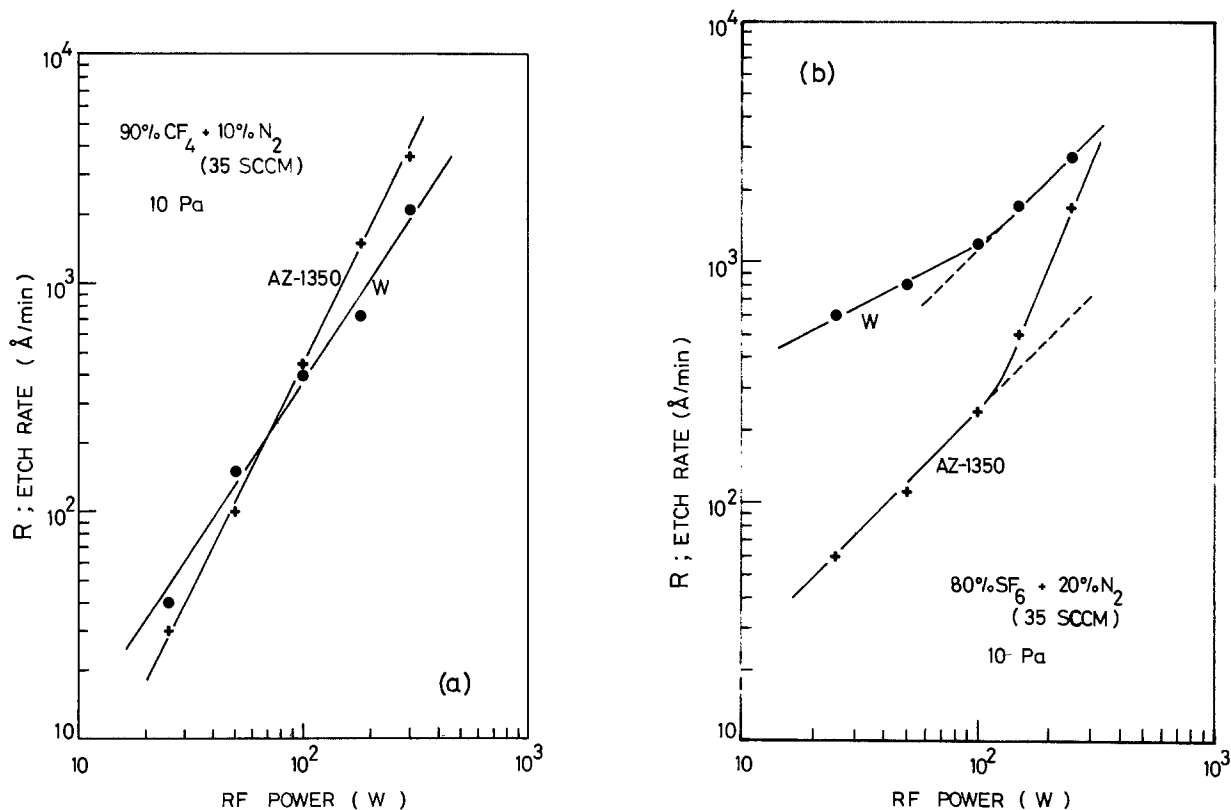

Fig. 8. Etch rate as a function of RF power for α -W and AZ-1350 in 90% CF₄ + 10% N₂ (a) and 80% SF₆ + 20% N₂ plasma (b)

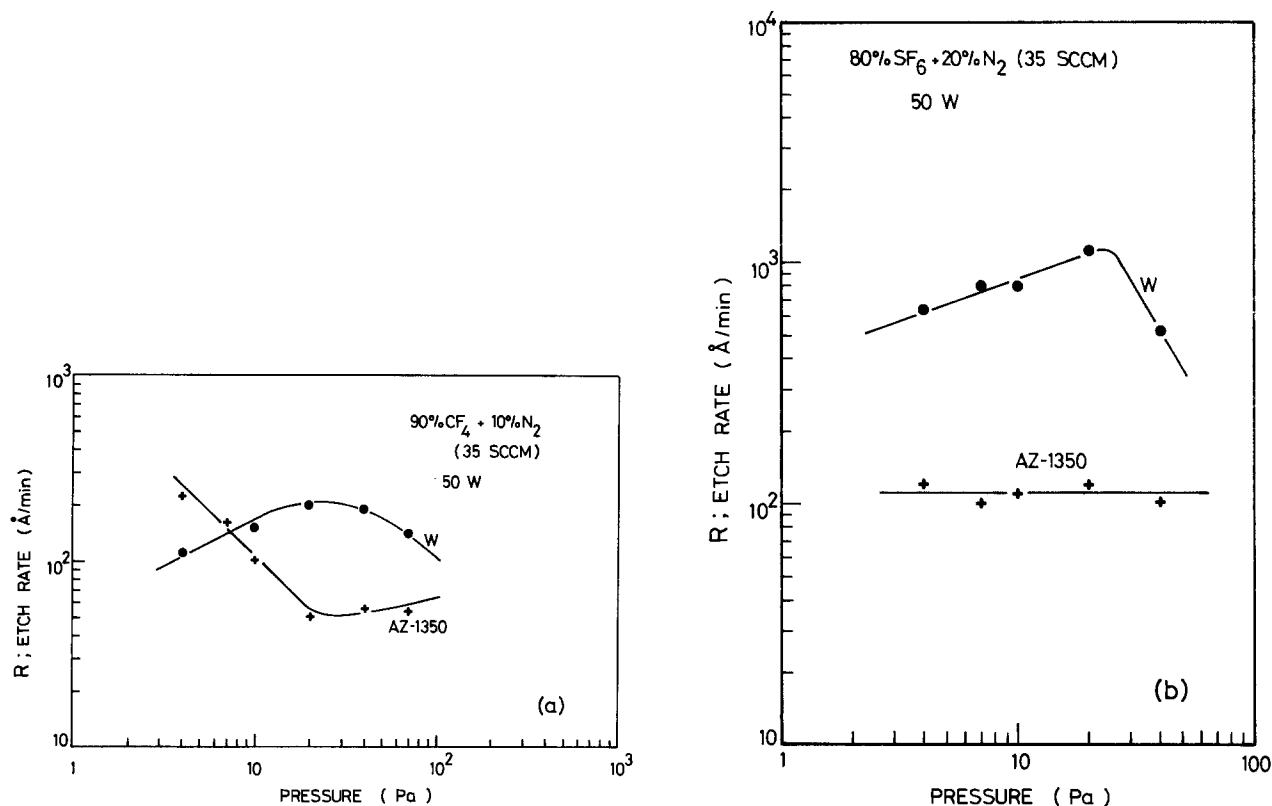

Fig. 9. Etch rate as a function of reactor pressure for α -W and AZ-1350 in 90% CF_4 + 10% N_2 (a) and 80% SF_6 + 20% N_2 plasma (b)

and will then decrease to zero at 0 Pa. We found similar pressure dependence of R_w in the CF_4/Ar and CF_4/O_2 mixtures; in 70% CF_4 + 30% O_2 mixture, for example, R_w increased with increasing pressure, peaking at 10 Pa ($R_w \approx 200$ Å/min), and then decreases with increasing pressure. A decrease in R_w with increasing pressure can also be found in pure SF_6 and 80% SF_6 + 20% N_2 plasmas above 20 Pa (see Fig. 4 and 9).

Noble gas addition, in general, stabilizes and homogenizes reactive gas plasmas that otherwise may be able to provide precise etching control. It can be seen from Fig. 5 that the addition of Ar to CF_4 increases R_w . As one can also see in Fig. 4, R_w in the pure CF_4 plasma increases with decreasing reactor pressure. R_w in the pure SF_6 plasma was constant at pressures up to 10 Pa (see Fig. 4). R_w in the SF_6/Ar system also was constant at Ar percentages from 0 to 60 (see Fig. 5). We have also carried out measurements of R_w and $R_{\text{AZ-1350}}$ as a function of the discharge parameters (RF power, reactor pressure, and gas flow rate) in CF_4/Ar and SF_6/Ar mixtures (30% Ar). The results obtained are very similar to those in pure CF_4 and SF_6 plasmas. It may, therefore, be concluded that the addition of Ar to CF_4 or SF_6 leads no drastic change in the physical and chemical kinetics of the reactions in these etching systems.

Emission or mass spectra from atomic F as a function of feed composition were measured along with the product distribution in CF_4/O_2 and SF_6/O_2 discharges (4, 5, 13, 14, 16, 17). The corresponding etch rate of W films was also reported (4, 5). In the CF_4/O_2 mixture (4, 13, 14), the F atom density increased with increasing O_2 addition, going through a maximum at certain O_2 composition. The etch rate R_w also indicated a maximum at certain O_2 composition (4). However, the maximum of R_w did not coincide exactly with that of the F atom density, where the increase of the F atom with the O_2 addition is accounted for by a sequence of reactions initiating with the production of CF_3 radicals by electron impact and followed by a reaction of CF_3 with oxygen (and further increase of the O_2 addition decreases the F atom density because, probably, of a decrease in electron energy in the plasma). A noncoincidence of these maxima may be explained by the competition between fluorine and oxygen

for active surface sites, as in the case of Si etching with the CF_4/O_2 (13, 14) and SF_6/O_2 mixtures (16). However, the W etch rate decreased monotonically with increasing O_2 addition in the SF_6/O_2 system (3, 4). This trend is in good agreement with the present result (see Fig. 6). In contrast, Tsujimoto *et al.* (5) have recently reported the etching characteristics of W films in SF_6/O_2 mixtures with a parallel-plate SiO_2 reactor, and obtained a maximum of R_w at about 10% O_2 addition, which was lower than the F atom maximum composition (30% O_2 addition). Unfortunately, however, we cannot suggest the reasons for the striking difference in the etching behaviors between Tsujimoto's result and ours [and also those in Ref. (3, 4)].

Clark (18) has found that for Si etching a 50:50 mixture of CF_4 and N_2 is preferable for smooth, uniform, and controllable etching. CF_4/O_2 mixtures and even pure CF_4 tended to pit the surface of crystalline Si, leading it hazed rather than shiny. The CF_4/N_2 mixtures, on the other hand, gave a smoothly etched Si surface. It is shown in Fig. 7 that a small amount of N_2 addition to CF_4 or SF_6 dramatically increases R_w . Moreover, changes in the N_2 addition within a wide range of compositions can be found to have little effect on R_w . The effects of admitting N_2 into the plasma are found to be similar to those of admitting Ar, but are in contrast to those of admitting O_2 . An addition of few tens percent O_2 tends to increase R_w . That is also the case in the CF_4/N_2 and SF_6/N_2 mixtures. We may expect the basic reaction in the CF_4/N_2 plasma to be

and

By the addition of N_2 to CF_4 or SF_6 , the etching of W will occur via a reaction with F radicals, but nitrogen no longer competes with F for active surface sites. Therefore, such mixtures would provide stable, efficient, and controllable etching of the W films. It is quite likely that an analogous mechanism operates during Si etching in 50% CF_4 + 50% N_2 mixture (18).

The etching processes under consideration are far too complex and the available information rather limited to

Fig. 10. Cross-sectional SEM image of a resist-patterned α -W film deposited on GaAs (a), and near top-view SEM photograph of the sample with which resist was stripped (b).

allow a qualitative discussion of the decomposition mechanism. Moreover, it is difficult to obtain a complete explanation of the difference in the etching rates with various plasma and physical parameters (RF power, frequency, pressure, flow rate, temperature, reactor geometry, etc.). Detailed etching mechanisms and plasma chemistry will, thus, be the subjects of a separate study.

Etching Profile

Important factors determining the choice of an etching gas are, generally, the etch rates for the materials, the degree of surface quality and undercutting, the gas chemical aggressiveness toward etching masks, and the desired etching profiles for the relevant purpose. Figure 10a shows the cross-sectional SEM image of a resist-patterned W film. This structure was fabricated as follows. After being degreased, wet-etched, and rinsed in deionized water, a GaAs substrate of (001) surface orientation was coated with 0.45 μm thick, RF sputtered W film (α -phase modification). Next, the 2.5 μm period grating pattern was defined by standard photolithography techniques using 0.5 μm thick AZ-1350 photoresist. This was used as an etching mask for plasma etching. The plasma etching was then done with 90% CF_4 + 10% N_2 mixture at 20 Pa reactor pressure, 35 sccm total gas flow rate, and 50W RF power. As can be clearly seen in the figure, a mesa-shaped structure was formed by stripes etched on the W film while this system gave a reverse-mesa-shaped profile on the photoresist mask. The identical situation is also noted for SF_6/N_2 plasmas. Apparently, the profiles give rise to considerable undercutting near the interface between the W film and photoresist. It is believed that a number of radicals and etching products may be ad-

sorbed on an etching substance. These adsorbed species can recombine with incident etchants, thereby influencing etching reaction at the sidewalls. The species may depend on etching materials in question, in this case, W and AZ-1350, and may interact with each other as the etching proceeds. Such effects will lead to an unusual etching profile, as observed in the present study. Similarly, Tsujimoto *et al.* (5) have found that the degree of undercutting of W films depends surprisingly, on the masking materials, such as AZ-1350, PSG (phosphorus-doped glass), and AZ-1350/PSG.

A near top-view SEM photograph of the sample on which the resist was stripped is also shown in Fig. 10b. Fluorine containing reagents and their mixtures with certain additives did not etch GaAs (12). The photograph in Fig. 10b reveals a high quality GaAs surface without any undesirable roughness or etch pits, and also shows that the etching process did not take part on the surface. The smooth surface appearance of GaAs may indicate the desirability of RIE for use in device applications.

Analysis of RIE-Processed Surface

Surface composition.—Figure 11 shows the SIMS in-depth profiles of the α -W films deposited on GaAs. The samples were unetched (Fig. 11a), etched with pure CF_4 (Fig. 11b), and etched with pure SF_6 (Fig. 11c). A relatively large amount of carbon and oxygen is detected near the W surface throughout the samples. The adsorption of C and O probably occurs primarily after the samples are removed from the chamber, although small concentrations of carbon (CO_2) and oxygen (or H_2O) are present during W sputtering or etching. As the interface between W and GaAs is approached, considerable amounts of C and O are also detected. This is due to the air exposure of GaAs surfaces before W sputtering. Clearly, fluorine exists in the samples etched with both pure CF_4 and SF_6 . The fluorine is a decomposition element of the plasma gas. Furthermore, a large amount of sulfur can be detected in the sample etched with pure SF_6 . In-depth profile studies on the samples etched with the CF_4/N_2 and SF_6/N_2 mixtures also gave the same trends as those described here. The fluorine inclusion is in agreement with Auger electron spectroscopy (AES) by Tang and Hess (4). However, they have detected no Auger signal of sulfur on the W surface during etching in SF_6/O_2 plasmas. This is probably a result of the limited detection limit of an AES rather than the SIMS analysis used in this study.

GaAs surface damage induced by RIE.—Since photoluminescence (PL) is sensitive to defects, this method is sometimes used to study damaged layers (19). Figure 12

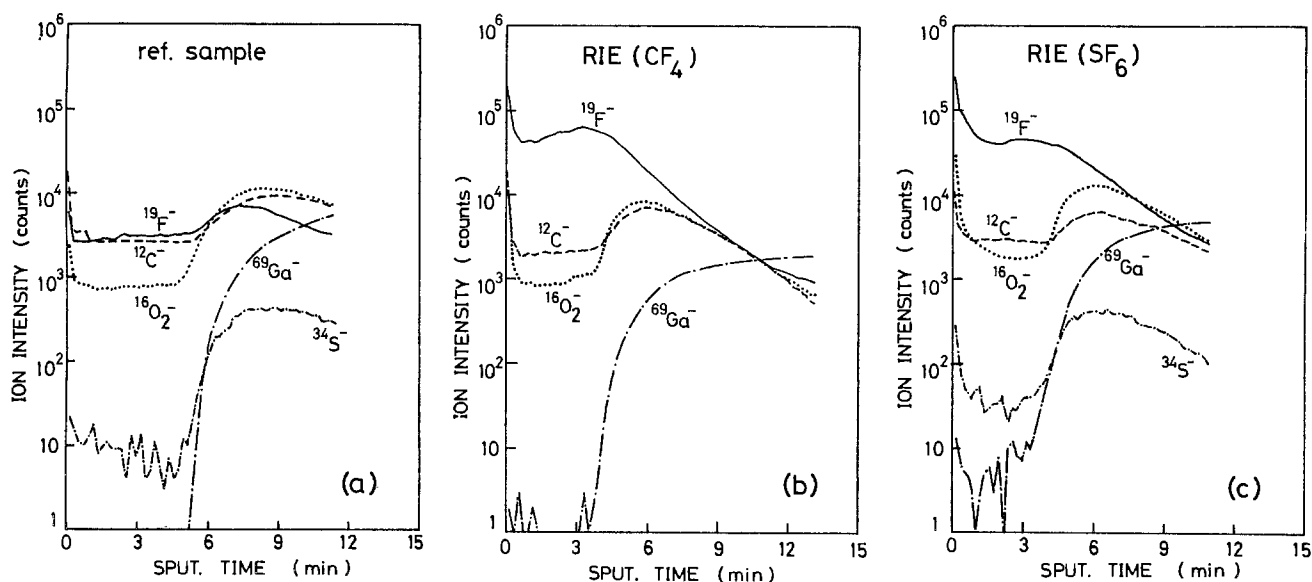

Fig. 11. SIMS in-depth profiles of α -W films deposited on GaAs; (a) unetched, (b) etched with pure CF_4 , and (c) etched with pure SF_6 .

Fig. 12. Photoluminescence peak intensity (~ 1.51 eV) measured at 77 K from GaAs through different processing steps (see text).

shows the PL peak intensity (~ 1.51 eV) measured at 77 K from GaAs through different processing steps; no RIE-processed sample (reference sample), the RIE processed sample, and the wet-etched ($\sim 3000\text{\AA}$) sample after RIE processing. The RIE was done here under the following conditions: SF_6 etching gas, 10 Pa reactor pressure, 35 sccm flow rate, 50W RF power, and 60 min etching time. The samples used were Se-doped GaAs epitaxial layers of $n = 1 \times 10^{17} \text{ cm}^{-3}$.

The surfaces of the samples were excited by a He-Cd laser (4416\AA), and the PL was measured by the conventional method. The RIE was also done with pure CF_4 plasma. The results obtained were similar, as seen in Fig. 12. It is recognized from the figure that the plasma impinging damage which acts as a nonradiative-recombination and/or surface-recombination-velocity reduction centers are produced at the surface of GaAs by the RIE processing. It is also found that the RIE does not lead to a change in the PL spectrum (*i.e.*, only the ~ 1.51 eV peak was observed before and after the RIE processing). In contrast, Kawabe *et al.* (19) have observed relatively large changes in not only the PL intensity, but also the PL spectrum after an Ar ion bombardment of the GaAs surface. After $\sim 3000\text{\AA}$ is removed, almost the same emission intensity as the reference sample begins to appear. The plasma- or ion-bombardment-induced damages can be usually recovered by conventional annealing processes (19, 20).

Furthermore, in order to test the surface quality, Schottky contacts were made on RIE-processed GaAs surfaces and characterized by I-V and C-V measurements (see Fig. 13). The RIE conditions used were the same as those for the PL measurements described above. An evaporated Au metal was used as the Schottky contact. No clear difference was found between the I-V and C-V characteristics between samples with and without RIE-processed GaAs surfaces. For comparison, we also examined Schottky contacts which were fabricated on SiO_2 -sputtered GaAs. An SiO_2 film was deposited with a conventional magnetron-type sputtering equipment at 200W RF power for about 3 min ($\sim 750\text{\AA}$ thick). After removing the sputtered SiO_2 film, the diodes were fabricated in the same manner as described above. The I-V characteristics showed considerably large leakage current. The C-V data taken from the diodes also indicated carrier decrease at a sample surface, in contrast to an almost flat carrier concentration profile obtained from the RIE-processed Schottky diodes. PL measurements also clearly suggested the presence of a damaged layer on the SiO_2 -sputtered GaAs surface. It can, thus, be concluded that distinct damage layer is introduced on GaAs surface

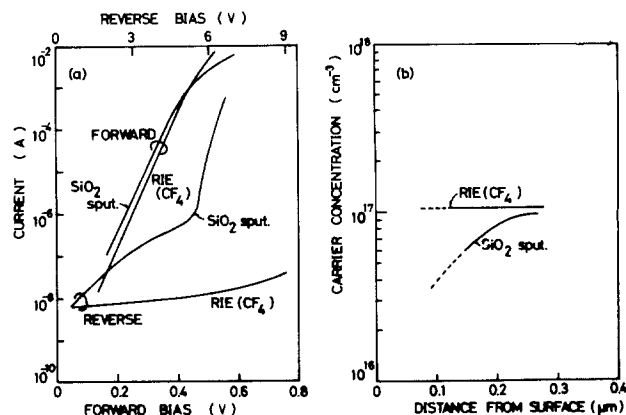

Fig. 13. I-V characteristics (a) and carrier concentration profiles (b) for Au-GaAs Schottky diodes fabricated on the RIE-processed (CF_4) and SiO_2 -sputtered-damaged surfaces.

by the SiO_2 sputtering but is not so clearly introduced by the RIE processing.

Summary

We have studied plasma etching characteristics of sputter-deposited W films on GaAs in a parallel-plate reactor with CF_4 and SF_6 plasmas. Properties of the W films strongly depend upon sputter-deposition condition. The W films sputtered at low Ar pressure ($p \approx 4.5 \times 10^{-2}$ torr) show stable structure, the so-called α -phase modification. When the films are sputtered at higher Ar pressures ($p > 4.5 \times 10^{-2}$ torr), it is possible to identify the presence of the β -phase modification. The reactive ion etching (RIE) characteristics of the sputter-deposited W films strongly reflect such microstructural features. The etch rate of the W films (R_w) is nearly constant in the α -phase region, and it increases abruptly with increasing fraction of the β -phase modification. Etched depth of the α -W films increases linearly with etching time. The α -W/ β -W mixtures, on the other hand, show a clear lag-time effect.

R_w of the α -phase W films strongly depends on the discharge parameters, such as RF power, reactor pressure, and gas flow rate. The etch rate R_w is not strongly dependent upon Ar addition. The addition of O_2 to CF_4 increases R_w considerably, and exhibits a maximum at about 30% O_2 addition. Further increase of the O_2 addition results in a gradual decrease in R_w . On the other hand, the maximum R_w occurs with pure SF_6 discharge and gradually decreases with increasing O_2 additions. A slight addition of N_2 to both CF_4 and SF_6 increases R_w abruptly, and further increase of N_2 shows no stronger effect on R_w (*i.e.*, R_w keeps nearly constant value) within a wide range of N_2 additions. It can be considered that the W etching is controlled by F atoms in the CF_4 plasma and its mixtures, but is not so simple in the cases of the SF_6 plasma and its mixtures.

RIE studies were also simultaneously carried out from an aspect of the etching selectivity between the W films and AZ-1350 photoresists. Relatively large selectivity can be achieved in the CF_4/N_2 and SF_6/N_2 mixtures. The effects of various discharge parameters in the CF_4/N_2 and SF_6/N_2 mixtures on RIE characteristics were also studied in detail with a set of standard etching conditions. Tungsten (R_w) to photoresist ($R_{\text{AZ-1350}}$) etching selectivity extracted from this work, however, should be used with caution. Since SiO_2 and photoresist were simultaneously etched in CF_4 or SF_6 plasmas with an SiO_2 electrode. Oxygen liberated from the SiO_2 electrode would probably enhance the etch rate of photoresist.

The chemical nature of the RIE-processed W surface was examined by SIMS analysis, and presences of C, O, F, and S species on the surface were confirmed. Schottky contacts were fabricated on RIE-processed GaAs surface, and the surface quality was examined by I-V and C-V measurements. No appearance of damage layers was confirmed from these measurements.

Compositional Changes during Alloying of Ohmic Contacts to $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$

ABSTRACT

Auger analysis of alloyed ohmic contacts on n- and p- $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ shows that substantial changes occur throughout a relatively thick interfacial layer during normal alloying cycles. Differences in diffusion of the different semiconductor elements are demonstrated and correlated with their reactivity. It is shown that placing a Cr layer at the semiconductor-contact interface effectively eliminates interdiffusion of the semiconductor and metals at elevated temperatures. Au/Cr metallization coupled with shallow, high dose ion implants gives contact resistances comparable to conventional alloyed contacts without the need for alloying.

A reliable means of producing low resistance ohmic contacts to III-V semiconductors has been the subject of much study (1-4). Commonly used contact metallizations involve the evaporation of a multilayer metal-dopant structure or a metal alloy containing a dopant. This structure is then heated to alloy the metals with the semiconductor surface and diffuse the dopant into the semiconductor producing a region of high carrier concentration at the semiconductor surface. The metallization in contact with this highly doped region results in an ohmic contact. The problems with this technique result from the alloying process. The alloying process causes quantities of the metallization to diffuse deeply into the semiconductor, and several compounds or phases are formed at the metal semiconductor interface. These compounds are not stable even at room temperature (5) and especially at high current densities. For shallow junction devices, the metallization can diffuse into the junction region and destroy the device. Contact degradation is an important means of failure in these devices, also.

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

In order to develop a manufacturable III-V contact technology, a new method of ohmic contact formation must be developed. One approach has been to deposit a layered structure consisting of a dopant layer, e.g., Si or Ge, followed by a refractory metal layer, e.g., Mo, W, or Ta (6, 7) or an amorphous metal layer (8). This structure is then heated as in the case of alloyed contacts. The high melting point of the refractory metals prevent them from forming unwanted compounds at the metal semiconductor interface. These metal layers are typically deposited by sputtering and may be difficult to etch. In addition, they allow only n- or p-type contacts to be formed in a single deposition.

The approach taken here is to create the highly doped region near the semiconductor surface by low energy high dose ion implantation and rapid thermal annealing (RTA). The use of RTA techniques allows high dopant activation to be achieved (9, 10) and at the same time minimizes dopant diffusion. The contact metal consists of a layer of Cr followed by a layer of Au deposited over the implanted regions. This metallization in contact with the highly doped semiconductor surface forms the ohmic

contact. No contact heating is required in this process. Both n- and p-type contacts can be formed in the same Cr/Au deposition. In a previous work, we have demonstrated that the electrical properties of these contacts are comparable to alloyed contacts (11). On n-type material, specific contact resistances of $1.5 \times 10^{-6} \Omega\text{-cm}^2$ for Cr/Au nonalloyed contacts and $2.3 \times 10^{-6} \Omega\text{-cm}^2$ for AuGe/Ni/Au alloyed contacts were achieved. On p-type material, specific contact resistances of $1.4 \times 10^{-4} \Omega\text{-cm}^2$ were achieved for both Cr/Au nonalloyed contacts and Au/Zn alloyed contacts. We now show that the metallurgical properties of these contacts are far superior to those of alloyed contacts.

Auger depth profiling and optical microscopy were used in addition to the electrical measurements described previously (11) to study the effects of heating on alloyed and nonalloyed ohmic contacts to $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. The changes in the composition of the contact layer which result from reactions and diffusion during the alloying process have been investigated with respect to alloying temperatures and time. Differences in the reactive and diffusional behavior of the semiconductor constituents, indium, gallium, and arsenic and the dopants, zinc, and germanium were observed. The differences observed can be explained based on differences in reactivity of the different elements with gold. The extensive reaction which takes place in the Au- $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ alloying process (4) makes the development of a nonalloyed contact technology of particular importance for this semiconductor.

Experimental Procedures

Contact samples were prepared for Auger spectroscopy by using lift-off to pattern $50 \mu\text{m}$ squares of both the alloyed and nonalloyed types of contact metallization. The metallizations were prepared by thermal evaporation onto $1 \mu\text{m}$ epi layers of n-type ($1 \times 10^{16} \text{cm}^{-3}$) $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ grown by liquid phase epitaxy on semi-insulating iron-doped InP. For p-type contact work, p-type regions were produced in these epi layers by selective Be ion implantation at energies of 50, 100, and 225 keV and doses of 5.4×10^{13} , 9.2×10^{13} , and $5.0 \times 10^{13} \text{cm}^{-2}$. The shallow, high dose Si (n-type) or Zn (p-type) implants prior to Cr/Au deposition were done at energies and doses of 50 keV and $3.0 \times 10^{14} \text{cm}^{-2}$ (Si implant) and 120 keV and $1.0 \times 10^{15} \text{cm}^{-2}$ (Zn implant). The implants were annealed using an AG Associates Heatpulse lamp annealing system. The samples were placed face down on a Si wafer, the chamber was

Fig. 1. The time temperature profile used in the rapid thermal annealing of the ion implants.

purged with forming gas, and the anneal cycle completed. The peak temperature was 720°C as measured by a thermocouple mounted alongside the sample. A typical time-temperature profile is shown in Fig. 1. For the p-type measurements, both the Be and Zn implants were annealed at the same time.

Au/Zn contacts were formed by evaporating 1200\AA of an Au 95%/Zn 5% alloy. AuGe/Ni/Au contacts were formed by evaporating first 800\AA of Au 88%/Ge 12% alloy, followed by 200\AA of Ni and 500\AA of Au. Cr/Au contacts were formed by evaporating 200\AA of Cr, followed by 1000\AA of Au. Just prior to loading the samples into the evaporator, a cleaning etch was performed to remove surface oxides. The etch was 10s in buffered HF for the p-type contacts, and for the n-type contacts the treatment was a two-solution etch consisting of a stop solution, 10 ml NH_4OH in 150 ml DI H_2O , and an etch solution, 2 drops NH_4OH , and 2 drops H_2O_2 in 200 ml DI H_2O . The etching sequence for the n-type contacts was 5s in stop, 5s in etch, 5s in stop. For the n-type contacts, the choice of etchant was not critical; either the buffered HF or the NH_4OH based etch were used with equal success.

The contacts to be alloyed were heated in a furnace under a forming gas atmosphere. The alloying procedure was as follows: the samples were loaded onto a quartz boat in the end of the alloying furnace, the furnace was sealed and purged with forming gas, and the samples were slid into the hot zone of the furnace. When the desired temperature was reached, the samples were removed and cooled in forming gas in the end of the furnace tube.

Depth profiles were obtained using an Auger spectrometer¹ equipped with a sputtering gun. The samples were sputtered with a $100 \mu\text{A}$ Ar ion beam accelerated at 4 kV and rastered over a $1 \times 1 \text{mm}$ area. The sputtering rate of Au was measured by sputtering evaporated Au films whose thickness had been determined using a Sloan Dektak II. The sputtering rate of $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ was determined by masking a $5 \mu\text{m}$ line, sputtering for 2 min, and measuring the depth with the Dektak. The resolution of the depth profile can be estimated from the interface abruptness observed on a profile of a contact prior to alloying.

Results

Alloyed contacts.—Profiles of Au/Zn contacts as deposited and after three different alloying cycles are shown in Fig. 2. The lowest alloying temperature investigated was 350°C . Ohmic contacts were obtained by alloying for 6 min at this temperature. The interface is abrupt, with the exception of some outdiffusion of indium into the gold. The gold has similarly diffused into the $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ with a profile which is complementary to the In profile indicating that at this temperature there is

¹Perkin-Elmer Physical Electronics Model 590, digitally upgraded.

Fig. 2. a: An Auger profile of a Au/Zn alloyed contact as deposited. b: After alloying at 350°C for 6 min. c: After alloying at 400°C for 2 min. d: After alloying at 540°C for 2 min.

some In-Au reaction taking place while the other elements are relatively undisturbed. When the temperature is raised to 400°C, more In-Au intermixing is found to have taken place. In addition, a large amount of Zn has accumulated at the contact surface. This temperature produced ohmic contacts with the lowest specific contact resistance. When the alloying temperature is raised to 540°C, a large degree of metal-semiconductor mixing is found to have taken place. Gold was found to migrate 0.5 μm into the semiconductor, and both In and As are found in the contact layer. In addition, a large amount of Ga has migrated to the contact surface.

Similar effects are observed in the case of AuGe/Ni/Au alloyed contacts on $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. Figure 3 shows a depth profile of a AuGe/Ni/Au contact sintered at 420°C for 2 min. Ga has diffused out through the metallization and accumulated on the contact surface. The morphology of the alloyed contacts is always rough. Figure 4b shows a typical photomicrograph of a contact sintered at 400°C. We also found that wire bonding to these alloyed contacts was difficult and unreliable because of the metals (*e.g.*, Ga, Zn) which had accumulated on the contact surface.

Nonalloyed contacts.—A dark field photomicrograph of the Cr/Au contact is shown in Fig. 4a. The contact is perfectly smooth, and the contact morphology did not change with heating.

Composition profiles of nonalloyed Cr/Au contacts before and after heat-treatment are shown in Fig. 5. Even after heating the contact to 500°C for 10 min, very little metal-semiconductor mixing has taken place. In particular, diffusion of semiconductor constituents to the contact surface has been nearly eliminated and gold has not diffused into the semiconductor.

Discussion

During contact alloying, Ga and Zn appear to be diffusing to the contact surface. At the surface, diffusion is against a concentration gradient, a situation which requires a change in phase or chemical environment to drive the process. The accumulation of zinc on the surface of the p-type contacts, for example, could be explained by hypothesizing that Zn reacts on the contact surface. The chemical potential of free zinc on the surface would be less than that in the metallization providing a driving force for Zn diffusion to the contact surface. The diffusion of Ga to the contact surface might be explained using the same mechanism, but with an additional driving force which results from the change in phase of Ga in going from solid form in $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ to Ga liquid (12). A similar situation exists in GaAs, where As reacts with the Au or evaporates from the sample surface while Ga remains as a liquid which accumulates on the contact surface (3).

The alloying process which takes place in $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ has been shown to be more complex than that which exists in the In or Ga binary compounds and even the InGaAsP quaternary compounds (4, 13). This is due to a difference in the reactivity of In and Ga with respect to the gold contact layer. Whereas Ga does not interact with

Fig. 3. An Auger profile of a AuGe/Ni/Au contact after alloying at 420°C for 2 min.

the Au, the complimentary In and Au concentration profiles indicate that In is forming some phase with the Au. Other work has demonstrated the existence of several phases (5, 14) of In-Au compounds in Au based contacts to $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. These compounds have been shown to form at temperatures as low as 160°C (5).

The use of a sandwich contact in this work allows a metal (*e.g.*, Cr) to be used as a diffusion barrier which prevents the In from out-diffusing into and reacting with the

Fig. 5. a: An Auger profile of a Cr/Au nonalloyed contact as deposited. b: After heating at 500°C for 10 min.

Au overlayer, and simultaneously prevents the Au from penetrating into the semiconductor. The appearance of Cr at the contact surface after heating of the nonalloyed contacts indicates that this system is not completely ideal. Other metals, such as Ti and Pt, are known to form diffusion barriers and may also prevent metal-semiconductor intermixing at the $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ -Au interface.

Conclusion

The effects of heating on both alloyed and nonalloyed ohmic contacts to $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ have been investigated. It was shown that the alloying process causes large amounts of dopant and semiconductor constituents to accumulate on the contact surface. The accumulation of these metals on the contact surface make wire bonding more difficult and make shallow junction devices unreliable. It was further shown that these effects can be eliminated by the use of a Cr/Au nonalloyed ohmic contact which can be used on both n- and p-type material. This contact is thermally stable and has a smooth morphology which provides a good surface for reliable bonding.

Evaluation of Silicon Optical Absorption Data for Use in Minority-Carrier-Diffusion-Length Measurements by the SPV Method

Edward S. Nartowitz¹ and Alvin M. Goodman

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

We have examined and evaluated the published data for the optical absorption coefficient α of crystalline silicon as a function of the wavelength λ for use in the measurement of minority-carrier-diffusion length L by the SPV method. We have compared the ASTM-recommended expression for $\alpha(\lambda)$ with (i) Runyan's data on which it is based, (ii) the data of Swimm and Dumas, and (iii) the data of Weakliem and Redfield, and find systematic disagreement that can result in significant differences in the values of L determined by the SPV method. We have proposed (i) a set of compromise data based on an average between the extremes of the published data and (ii) an expression for $\alpha(\lambda)$ that agrees with the compromise data to within about 1%. The use of this expression, $\alpha(\lambda) = [(84.732/\lambda) - 76.417]^2$, where $\alpha(\lambda)$ is per centimeter and λ is in micrometers, reduces the uncertainty in resulting values of L by a factor of approximately two. For $L < 60 \mu\text{m}$, a further reduction in uncertainty can be achieved by lowering the maximum value of λ used for the measurements. Finally, we believe that the compromise data that we propose should be considered as an interim choice pending further experimental results that more clearly remove the present uncertainty in the value of $\alpha(\lambda)$.

The constant-magnitude steady-state surface photovoltage (SPV) method for measuring the minority-carrier-diffusion length, L , utilizes a beam of photons incident on the surface of the semiconductor at an energy just above the bandgap (1, 2). For silicon, the bandgap at 300 K is 1.12 eV, necessitating photon wavelengths less than 1.11 μm (3). The absorbed photons generate electron-hole pairs, some of which diffuse toward the illuminated surface and are separated by the electric field of the surface space-charge region, thereby creating a surface photovoltage, ΔV . As the absorption depth is varied by changing the wavelength of the incident light, ΔV is kept constant by adjusting the intensity of the light. For a homogeneous silicon slab with the geometry illustrated in Fig. 1a, it can

then be shown that

$$I_0 = C[1 + (\alpha L)^{-1}] \quad [1]$$

subject to the conditions

$$\alpha W \gg 1 \quad [1a]$$

$$\alpha w \ll 1 \quad [1b]$$

$$W \gg L \quad [1c]$$

$$w \ll L \quad [1d]$$

$$\Delta p \ll n_0 \quad [1e]$$

Here, I_0 is the intensity of the incident light, α is the op-

tical absorption coefficient, W is the thickness of the silicon wafer, w is the thickness of the surface space-charge region, Δp is the excess minority carrier density at the edge of the surface space-charge region, n_0 is the majority carrier density, and C is a constant. If I_0 is plotted against α^{-1} for each constant-magnitude ΔV point, the result is a linear graph whose extrapolated intercept on the negative α^{-1} axis is L . This is illustrated in Fig. 1b. Thus, the method is critically dependent on a knowledge of $\alpha(\lambda)$.

This method has been applied to the measurement of diffusion lengths in semiconducting materials other than silicon, such as gallium arsenide (1, 4) and indium phosphide (5), where the values of $\alpha(\lambda)$ were separately measured due to the lack of a standard or recommended set of values. For silicon, however, there is an ASTM standard (2) for $\alpha(\lambda)$ which, for the case of stress-relieved silicon, is an empirical fit to data gathered by Runyan (6) in 1967. We refer to this expression for $\alpha(\lambda)$ as the ASTM fit. More recently, absorption data have been gathered on stress-relieved silicon by Swimm and Dumas (7) as well as by Weakliem and Redfield (8). Moreover, Swimm and Dumas point out that their absorption coefficient values are 2-8% lower than those reported by Runyan and up to 16% lower than the ASTM values; they further state that diffusion lengths calculated from their data are approximately 16% greater than those calculated using the ASTM fit.

In the present work, we compare the published absorption data for stress-relieved silicon between 0.70 and 1.05 μm [the ASTM fit (2), the data of Runyan (6), the data of Swimm and Dumas (7), and the data of Weakliem and Redfield (8)]. All of the data considered are based on room temperature measurements. We also compare the values of L calculated using data other than the ASTM fit with the values of L obtained using the ASTM fit, and find significant differences that are strongly dependent on the values of L and the wavelength range covered. In the absence of sufficient objective criteria for selecting one set of absorption data over the other, we generate a set of compromise data which tends to minimize the uncertainty in $\alpha(\lambda)$ and the resultant uncertainty in L . We then compare the resultant L values obtained using the extremes of the $\alpha(\lambda)$ data with the values obtained using our compromise data over various wavelength ranges. We show that the uncertainty in the value of L can be further reduced, especially for low values of L , by an appropriate choice of wavelength range. Finally, we present examples of I_0 vs α^{-1} plots using representative data from measurements of real samples.

Fig. 2. Published values of the optical absorption coefficient for stress-relieved silicon in the wavelength range $0.70 < \lambda < 1.05 \mu\text{m}$.

In addition to the approach described above, we have also considered an alternative procedure. This procedure, which employs averaging fits to the three data sets, is described in the Appendix. The resulting expression for $\alpha(\lambda)$ differs only slightly from Eq. [2].

Comparison of Published Absorption Data and Resultant L Values

The published values of $\alpha(\lambda)$ for stress-relieved silicon between 0.70 and 1.05 μm are shown in Fig. 2. The data of Weakliem and Redfield agree to within 3% with those of Swimm and Dumas, with closer agreement at higher wavelengths. Like the data of Swimm and Dumas, they are consistently lower than either Runyan's data or the ASTM fit, being approximately 3-10% lower than the former and approximately 2-32% lower than the latter. The larger discrepancies with the ASTM fit occur at high wavelengths where the ASTM fit has very little support from Runyan's data.

The maximum percent uncertainty in $\alpha(\lambda)$ was calculated at each wavelength by dividing the difference between the extremes of the data by the minimum value and multiplying by 100. The results are shown in Fig. 3. The maximum percent uncertainty is seen to be a minimum for the region $0.72 < \lambda < 0.88 \mu\text{m}$ and to rise rapidly for $\lambda > 0.88 \mu\text{m}$.

A comparison of diffusion-length values obtained using different sets of absorption data is shown in Fig. 4. Simulated intensities based on Eq. [1], the ASTM fit, and assumed values of L were used in calculating the diffusion lengths from the data of Swimm and Dumas and from the data of Weakliem and Redfield. The symbols L_A , L_S , and L_W denote the values obtained using, respectively, the ASTM fit, the data of Swimm and Dumas, and the data of Weakliem and Redfield. The figure shows that the differences in L resulting from the use of different sets of absorption data depend (i) on the magnitude of the diffusion length and (ii) on the wavelength range over which the data was taken. For data taken over the range $0.826 < \lambda < 1.005 \mu\text{m}$, curve A and B show that diffusion-length values calculated using the absorption data of Swimm and Dumas and of Weakliem and Redfield are approxi-

Fig. 3. Maximum percent uncertainty in α vs. λ . At each wavelength, the maximum percent uncertainty was computed by dividing the difference between the extremes of the published values of α by the minimum value of α and multiplying by 100.

mately 20-25% greater than those calculated using the ASTM fit if $L > 60 \mu\text{m}$. For smaller values of L , the discrepancies are much higher, exceeding 55% for $L < 10 \mu\text{m}$ and exceeding 95% for $L < 5 \mu\text{m}$. Curve C and D show a marked improvement in the agreement for diffusion-length values as a result of gathering data over the wavelength range $0.826 < \lambda < 0.960 \mu\text{m}$. This is not surprising since the percent uncertainty in the absorption data is smaller over that range (Fig. 3). For that range, diffusion lengths calculated from the data of Swimm and Dumas and from the data of Weakliem and Redfield agree with those calculated from the ASTM fit to within 15% for $L > 60 \mu\text{m}$ and to within 28% for $L > 10 \mu\text{m}$. For $L < 10 \mu\text{m}$, the discrepancies again rise rapidly.

Proposed Compromise Values and Their Effect on Diffusion-Length Values

The use of wavelength ranges comprising still shorter wavelengths can further reduce the uncertainties for very small values of L . However, the use of such ranges is restricted by Eq. [1b] which, for example, requires that $\alpha^{-1} \approx 3 \mu\text{m}$ for a sample with a doping concentration of approximately $10^{15}/\text{cm}^3$ and $w \approx 1 \mu\text{m}$. Moreover, for other than small values of L , the I_0 vs. α^{-1} plots must include points with large absorption depths, corresponding to longer wavelengths, in order to define more clearly the line that is to be extrapolated to obtain L . Thus, to measure L , it may be necessary to use absorption data over a wavelength range for which there is significant uncertainty in α .

We feel that, at the present time, there is insufficient justification for choosing one set of absorption data over the others. Therefore, in order to minimize the uncertainty in diffusion-length values obtained using the SPV method, we have generated a set of compromise absorption data by averaging the extremes of the published data at each of the various wavelengths. These data are displayed in Fig. 5 in the form of a plot of $\alpha^{1/2}$ vs. λ^{-1} . A straight line fit, after smoothing the data, yields

$$\alpha(\lambda) = \left[\frac{84.732}{\lambda} - 76.417 \right]^2 \quad [2]$$

where $\alpha(\lambda)$ is per centimeter and λ is in micrometers. The

Fig. 4. A comparison of diffusion length (L) values obtained using three different sets of absorption data, two wavelength ranges, and the same $I_0(\alpha)$ values. L_A , L_S , and L_W are the values obtained using, respectively, the ASTM fit, the data of Swimm and Dumas, and the data of Weakliem and Redfield.

λ^{-1} intercept is $0.902 \mu\text{m}^{-1}$, corresponding to an energy of 1.118 eV which is within 0.1 kT of the bandgap of silicon at 300 K. The rms deviation of this fit from our compromise data is 0.7% for $0.70 < \lambda < 1.04 \mu\text{m}$.

In Fig. 6-8, diffusion lengths calculated using previously published data are compared with those calculated using our compromise data. For $0.826 < \lambda < 1.005 \mu\text{m}$ and $L > 60 \mu\text{m}$, L values calculated using compromise data (L_C) are 10-14% lower than those obtained using the data of Swimm and Dumas (L_S) and 8-10% higher than those obtained using the ASTM fit (L_A), (Fig. 6). Thus, the maximum uncertainty in L is 14% as compared to 25% if the ASTM fit absorption values are used (curves A and B, Fig. 8). Figures 6 and 8 clearly show that for low values of L the uncertainty rises sharply, but through the use of compromise data it is reduced from $> 55\%$ to $> 33\%$ for $L < 10 \mu\text{m}$ and from $> 100\%$ to $> 50\%$ for $L < 5 \mu\text{m}$. For $0.826 \mu\text{m} < \lambda < 0.960 \mu\text{m}$, the use of compromise data re-

Fig. 5. Square root of the compromise absorption coefficients of stress-relieved silicon at 300 K, plotted vs. reciprocal wavelength.

Fig. 6. A comparison between diffusion length (L) values obtained using published absorption data and L values obtained using the compromise absorption coefficients proposed in this paper. L_A , L_S , L_W , and L_C are the values obtained using, respectively, the ASTM fit, the data of Swimm and Dumas, the data of Weakliem and Redfield, and the compromise data. The same $I_0(\alpha)$ values were used for each L determination, and the wavelength range was $0.826 < \lambda < 1.005 \mu\text{m}$.

duces the uncertainty in L to less than 25% for $L > 6 \mu\text{m}$ and less than 12% for $L > 20 \mu\text{m}$ (Fig. 7, 8).

I_0 vs. α^{-1} Plots of Sample Data

Plots of I_0 vs. α^{-1} for sample data are given in Fig. 9-11. Plots using the compromise data for α^{-1} are seen to have r^2 values ranging from 0.992 to 1.000, where r is the correlation coefficient. These values compare favorably with those obtained using either the absorption data of Swimm and Dumas ($0.989 < r^2 < 0.999$) or the ASTM fit to Runyan's absorption data ($0.993 < r^2 < 1.000$).

Some curvature can be present in these plots due to (i) departure from the assumptions made in the derivation of Eq. [1], (ii) surface damage to the sample wafer (9), or (iii) a nonrandom error in the absorption data over a certain wavelength range. If, for example, all the α values were too low for $\lambda > 1 \mu\text{m}$, the plots would decrease in slope for higher values of absorption depth. This appears to occur to a very small extent in the data of Fig. 10 and 11, especially in the plots using the absorption data of Swimm and Dumas. These graphs show a slight concave-downward curvature that cannot be due to surface damage which produces a concave-upward curvature (9). The use of the compromise absorption data results in little concave-downward curvature. However, the curvature present in any of these plots is too slight to offer a criterion for the selection of one set of absorption data over the others. Similarly, the lack of dependence of r^2 values on the choice of absorption data eliminates their use in establishing any such criteria.

Discussion and Conclusions

We recommend the use of compromise absorption coefficients that significantly reduce the uncertainty in the values of L over all wavelength ranges. Further, for the measurement of diffusion lengths larger than approximately $60 \mu\text{m}$, we recommend gathering data over a wave-

Fig. 7. A comparison between diffusion length (L) values obtained using published absorption data and L values obtained using the compromise absorption coefficients proposed in this paper. L_A , L_S , L_W , and L_C are the values obtained using, respectively, the ASTM fit, the data of Swimm and Dumas, the data of Weakliem and Redfield, and the compromise data. The same $I_0(\alpha)$ values were used for each L determination and the wavelength range was $0.826 < \lambda < 0.960 \mu\text{m}$.

length range extending up to but not exceeding approximately $1 \mu\text{m}$ due to the scarcity of absorption data for silicon beyond $1 \mu\text{m}$.

For $L < 60 \mu\text{m}$, a further reduction in the uncertainty of L can be achieved by lowering λ_{max} the maximum value of λ used for the measurements, i.e., by limiting the measurements to a range of λ where there is better agreement among the various sets of $\alpha(\lambda)$ data. For example, if $L \approx 15 \mu\text{m}$, the uncertainty in an experimentally determined value of L due to disagreement between the various absorption data is reduced from about 26% for $\lambda_{\text{max}} = 1.005 \mu\text{m}$ to about 12% for $\lambda_{\text{max}} = 0.960 \mu\text{m}$ to about 6% for λ_{max}

Fig. 9. Plots of I_0 vs. α^{-1} for a "short" diffusion length sample using three sets of optical absorption data. The values of L_A , L_S , and L_C correspond, respectively, to the use of the ASTM fit, the data of Swimm and Dumas, and the compromise data.

Fig. 10. Plots of I_0 vs. α^{-1} for a "medium" diffusion length sample using three sets of optical absorption data. The values of L_A , L_S , and L_C correspond, respectively, to the use of the ASTM fit, the data of Swimm and Dumas, and the compromise data.

Fig. 11. Plots of I_0 vs. α^{-1} for a "long" diffusion length sample using three sets of optical absorption data. The values of L_A , L_S , and L_C correspond, respectively, to the use of the ASTM fit, the data of Swimm and Dumas, and the compromise data.

= 0.880 μm . However, it should be noted that as the range of values used for the measurements is decreased, any uncertainty (experimental error) in the values of the corresponding I_0 values will have an increased effect on the resulting uncertainty in L . A quantitative treatment of minimization of the total error in L due to uncertainties in both α and I_0 would require an overall error analysis that is beyond the intended scope of this paper. Nevertheless, we recognize in a qualitative way the effects of uncer-

tainties in both α and I_0 , and how the selection of the range of λ used for measurements can affect the resultant error (uncertainty) in L .

Finally, the compromise data that we recommend should be considered an interim choice pending further experimental results that clearly remove the present uncertainty in the variation of the optical absorption coefficient of silicon in the wavelength range $0.7 \leq \lambda \leq 1.04 \mu\text{m}$.

APPENDIX

A reviewer of the original manuscript of this paper has suggested an alternative approach to generating compromise $\alpha(\lambda)$ data. In this approach, the data of Runyan (6), Swimm and Dumas (7), and Weakliem and Redfield (8) would be averaged, but the ASTM fit would not be considered. We had originally considered a similar approach, but had discarded it for two reasons: (i) in generating the new $\alpha(\lambda)$ data, it ignores the reality of the ASTM fit which is today's *de facto* standard, and (ii) the various $\alpha(\lambda)$ studies (6-8) do not cover the same wavelength range and do not use the same grid of wavelength values. Nevertheless, we have now calculated an alternative set of $\alpha(\lambda)$ values based on an averaging procedure, and find that these values can be described by an expression having the same functional form as that used for the compromise data with numerical constants that are remarkably close to those of Eq. [2]. The procedure used and the results obtained are described below.

In order to carry out an averaging procedure, it was necessary to have each of the experimental data sets spanning the entire range of interest, 0.7-1.04 μm . The data of Weakliem and Redfield (8) are quite complete in this region, and no special data treatment was necessary; these data are designated $\alpha_w(\lambda)$. The data of Swimm and Dumas (7) cover the range 0.8-1.0 μm , and they give an expression for optical absorption in this region

$$\alpha_s(\lambda) = \left[\frac{85.9}{\lambda} - 77.9 \right]^2 \text{ cm}^{-1} \quad [\text{A-1}]$$

where λ is expressed in micrometers. A least squares fit of Runyan's data (6) to the same functional form gives

$$\alpha_r(\lambda) = \left[\frac{84.765}{\lambda} - 76.271 \right]^2 \text{ cm}^{-1} \quad [\text{A-2}]$$

We then averaged $\alpha_w(\lambda)$, $\alpha_s(\lambda)$, and $\alpha_r(\lambda)$ at 21 points in the interval 0.7-1.04 μm . A least squares fit of those average values gave the expression

$$\bar{\alpha}(\lambda) = \left[\frac{84.801}{\lambda} - 76.594 \right]^2 \text{ cm}^{-1} \quad [\text{A-3}]$$

It is important to note that we have extrapolated $\alpha_s(\lambda)$ and $\alpha_r(\lambda)$ well beyond the wavelength range of the experimental data on which they are based.

A comparison of Eq. [A-3] with Eq. [2] shows very little difference between them. It is also of interest to see how the use of Eq. [A-3] would affect the numerical value of L determined from the experimental data used in Fig. 9-11. Using Eq. [A-3] would have given $L = 9.95 \mu\text{m}$ instead of $L_C = 9.0 \mu\text{m}$ in Fig. 9; $L = 62.7 \mu\text{m}$ instead of $L_C = 60.2 \mu\text{m}$ in Fig. 10; and $L = \sim 179 \mu\text{m}$ instead of $L_C = 172 \mu\text{m}$ in Fig. 11.

Observations of the Temperature Gradient Zone Melting Process for Isolating Small Devices

D. J. Lischner, H. Basseches,* and F. A. D'Altroy

AT&T Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

The temperature gradient zone melting process (TGZM) for doping semiconductors is being investigated for the purpose of using it to create the isolation region in a relatively small geometry thyristor. The small size of the chip puts tougher morphological requirements on this liquid zone process than in past TGZM investigations. We discuss here a number of problems encountered which include enhanced diffusion of the aluminum dopant in the silicon, lateral motion of the molten zone at the edge of the wafer, breakup and smearing of the molten zone, and outdiffusion of the aluminum into the passivating oxide layer.

The thyristor semiconductor device usually contains very deep boron diffusions that are mils in depth and in the case of the triac extends through the thickness of the wafer. It requires days to make in furnaces at high temperatures ($> 1250^{\circ}\text{C}$). It runs around the periphery of the chip and is about twice as wide as its depth; thus, on small chips it takes up a large fraction of the chip area. We report here on our investigations to replace the standard solid-state diffusion method for forming these regions with a liquid-zone method known as temperature-gradient zone melting (TGZM). TGZM is a process by which a liquid zone in or on a solid can be caused to move through or across it by impressing a temperature gradient across the zone (1-6, 9). Here, the solid is single-crystal silicon and the liquid is a silicon/aluminum solution. In practice, the process starts at room temperature with evaporated and photolithographically defined aluminum on one side of the silicon wafer. The wafer is radiatively heated from the other side to temperatures considerably higher ($1000^{\circ}\text{--}1200^{\circ}\text{C}$) than the eutectic temperature to form the molten zone. As a result of the one-sided heating, there is a heat flow through the wafer which imposes the thermal gradient across the molten zone. The faces of the zone are thus at a slightly different temperature ($\Delta T < 0.1^{\circ}\text{C}$) and consequently have slightly different aluminum to silicon ratios with the hotter face having more silicon than the colder face. The resulting silicon concentration gradient causes a diffusion of silicon from the hot face to the cold face, leaving the hotter face undersaturated and the colder face supersaturated. As a result, dissolution of additional silicon occurs at the hotter face while precipitation and epitaxial growth of silicon occur at the colder face with the silicon there incorporating aluminum at the solid solubility limit for that temperature ($\approx 2 \times 10^{19}$ at./ cm^3). Thus the molten zone moves through the wafer, up the temperature gradient, leaving in its wake single-crystal silicon doped with aluminum. Due to the speed with which the zone moves through the silicon, on the order of $10 \mu\text{m}/\text{min}$, wafers can be doped through their thickness in minutes. There is also the further benefit of less side diffusion during the doping step. With TGZM, the concomitant side diffusion is a few microns compared to mils for solid-state diffusion.

TGZM itself is not new. It was first discovered by Pfann in 1955 (2), but was not fully developed due to the introduction of planar technology and oxide masking. Its unique properties, though, have kept it of interest; in par-

ticular, there are the two properties that are being made use of here, speed and the ability to form doped areas that are deeper than they are wide.

In the years 1973-1981, Anthony and Cline (3-9) did much to enhance the understanding of this process through the exploration of various solvent/solute systems, in great detail, and they too used the process for isolating thyristors (8) though their device work dealt mainly with large ($\approx 1/4$ in. diam) high voltage, high power SCR's made with the etched groove and glassivation technology. In contrast, we are discussing here the adaptation of the TGZM process to a small chip made with planar technology.

Wafer Processing Prior to TGZM Step

In this section, we describe the characteristics of and preparation of the wafer leading up to the TGZM step. The wafer is 50 mm in diameter, 10-20 $\Omega\text{-cm}$, n-type material. It is 0.30-0.33 mm thick, but is lapped and polished down to 0.2 mm after TGZM. It has a (1,1,1) orientation. The (1,0,0) orientation was not examined since it is known (6) that only lines of aluminum parallel to the $\langle 110 \rangle$ direction can be TGZM'd without forming discontinuities known as "line breaks." There is not a similar constraint for the (1,1,1) wafer. The surface finish is the usual, one side polished and one side etched where the aluminum is deposited on the polished side. Other surface finishes were tried since it was felt that a less perfect surface would aid the initial wetting and alloying of the aluminum and silicon and thus be more successful with respect to being able to TGZM an aluminum grid through the wafer with minimum line breaks. Wafers with as-cut surfaces on both sides had a far greater number of line breaks than wafers with the usual surface finish, while there was little difference between wafers with the usual surface finish and wafers that had both sides etched. Since a polished surface is likely to be the best from the point of view of being able to make a reproducible aluminum to silicon interface, all other experiments were done with wafers with the usual finish and with the aluminum on the polished side.

The formation of the patterned aluminum film starts with film deposition. The TGZM process requires an unusually thick film, far greater than what is required to dope the silicon. A 0.3 mm thick wafer requires the amount of aluminum in a 0.1 μm thick layer to dope it to its solubility limit. However, it has been found that to be able to TGZM a grid structure with a linewidth of 2-5 mil requires a film thickness greater than $\approx 5 \mu\text{m}$. Less than

*Electrochemical Society Active Member.

that results in erratic success with respect to being able to pass the grid through the wafer with no more than a few line breaks. A Varian E-gun deposition system (Model 3140) was used to form the aluminum layer. It can deposit $\approx 14 \mu\text{m}$ of aluminum from two successive pots without breaking vacuum on 75 two inch wafers in 1.5-2h. Patterning the aluminum into a grid with a 35 or 40 mil step and repeat was done with conventional photolithographic techniques except for the aluminum etch step. The etchant used was the PAN solution, phosphorus acid (1690 ml):acetic acid (340 ml):nitric acid (70 ml) at $55^\circ\text{-}65^\circ\text{C}$. Care had to be taken that excessive undercutting did not occur, and cleared wafers were promptly removed from the etchant and rinsed. Etch time is about 20 min, and while in solution the wafers were rotated 90° every 3 min to ensure even etching. Grid lines running parallel to the solution surface etched $\approx 30\%$ faster than those running perpendicular. During the course of etching, the solution was gently stirred by a magnetic stirrer. As a result of the above procedure, the etched aluminum grid line width is 2.3-2.5 mil as compared to the photoresist line width of 3 mil.

The TGZM Step

The aluminum grid is driven through the wafer at $\approx 1200^\circ\text{C}$ with a temperature gradient across the wafer of $\approx 50^\circ\text{C}/\text{cm}$. This is accomplished in a special in-house-built oven based on a design developed at the General Electric Company and has been described elsewhere (10). At the outset of this investigation, a severe line break and smearing problem was encountered. Figure 1 shows the side of the wafer where the aluminum exits. Two things can be seen, numerous line breaks and smearing of the pattern at the intersections. It should be noted that at that time the common practice was to carry out TGZM in an air ambient. Numerous cross sections taken through the line breaks revealed that they always started on the entrance surface (Fig. 2) implying a mechanism other than that which appears in the literature (6), where it is reported that line breaks occur when the moving line-shaped molten zone lowers its surface energy by splitting and bounding itself by (111) planes. With this mechanism, the line breaks would always occur randomly as the zone moves through the wafer. It was hypothesized that both the line breaks and smearing were due to a cocoonlike oxide that forms over the aluminum at the very start of the TGZM process. As the wafer continues to heat the aluminum, which has the largest coefficient of expansion of any of the phases, appears to rupture out of the cocoon at the intersection (Fig. 3) causing the smearing. The line breaks, however, are thought to be caused by the flow of the molten phase down the grid line and out of the rupture. This transverse motion then in some fashion inter-

Fig. 3. Photograph of entrance side of wafer at a grid intersection. Note the smearing due to escape of molten zone from under the Al_2O_3 cap.

rupts the initiation of TGZM. When an $\approx 1\%$ O_2 in argon ambient was substituted for air, both problems were almost completely eliminated (Fig. 4). Instead of the continuous, impermeable oxide, a flaky oxide forms over the aluminum.

A pure argon ambient cannot be used because a quartz plate immediately above the wafer develops a coating of SiO_2 formed from the evaporation of Si from the wafer and the wafers thermally etch, by which it is meant that the wafers grew Si whiskers and pitted.

For the molten zone to move everywhere perpendicular to the wafer surface, it is required that the temperature gradient be everywhere perpendicular to the wafer sur-

Fig. 4. Photograph of exit side of wafer when ambient during TGZM step was $\approx 1\%$ O_2 in argon.

face. This is in part accomplished by heating the wafer with a radiative flux of sufficient uniformity, and Ref. (10) discusses how sufficient uniformity is achieved in the present oven. However, uncompensated wafers, heated by uniform fluxes of radiation, whether it be one- or two-sided heating as in rapid thermal annealing (10) suffer from lateral temperature gradients that cause the wafer to be cooler at the edge than at the center and this in turn causes the molten zone to move inwards towards the center of the wafer (Fig. 5). This effect is understood (7) and is caused by net radiative losses at the wafer edge. There have been a number of schemes proposed and/or tried to reduce the losses by compensation. For example, it has been suggested that the wafer, during the TGZM step, sit in a hole cut into a large sheet of silicon that is the same thickness as the wafer. It is expected that the inside edge of the hole radiates inwards towards the edge of the wafer sufficient energy to effect compensation of the net loss. Lord has shown through computer modeling (11) that the gap between the wafer and the sheet and the coplanarity of the surfaces of the wafer and sheet must be kept to a fraction of the wafer thickness. This small mechanical tolerance renders this approach impractical. Lien (12) used a thin aluminum ring located on the entrance surface near the edge that was defined along with the aluminum grid during the aluminum etching steps. Here, the heat loss was apparently compensated by the lessened heat loss at the location of the ring, perhaps due to the aluminum's lower emissivity. Though this approach was demonstrated to work, the drawback is the large number of inclusions left in the silicon at the wafer's edge due to the ring's width being tens of mils. Another approach, the authors have developed, uses a thick ring of silicon (3/8 in.) with the wafer hole 1/4 in. larger than the wafer diameter. This eliminates the mechanical tolerance problem associated with the thin silicon sheet approach, but replaces it with the problem of arranging for the ring to have a temperature during TGZM that provides proper heat-loss compensation. When a simple square ring was placed around the wafer (Fig. 6), there was insufficient compensation because the ring had its own very significant edge-loss problem due to its thickness. (The amount of compensation was determined by cross sectioning test wafers and measuring the angle of the molten zone's path.) When a number of such rings are placed side by side and surrounded by silicon blocks, there was additional compensation, but it was still not sufficient. (The wafer, the silicon ring array, and the alumina sheet mentioned below are all supported above the oven floor on pointed quartz pins.) To boost the ring's temperature, 25 mil thick alumina sheets with the same lateral dimensions as the blocks (Fig. 7 and 8) were placed under them to provide thermal isolation from the cold oven floor. (The wafer and ring array are about 1/2 in.

above the oven floor, while the alumina sheet is 3/8 in. above the floor.) This arrangement works as can be seen in Fig. 9. There, the angle of the TGZM path at the wafer's edge is plotted against the height of the wafer above the bottom surface of the silicon ring. It is estimated that the thyristors for which this process was developed can tolerate $\pm 10^\circ$ out of perpendicular TGZM isolation. With that criterion, the wafers then have an allowance of $\pm 1/16$ in. in vertical positioning.

Post-TGZM Wafer Preparation

It is a requirement of our device fabrication process that the wafer's surface be flat and polished. This is accomplished in a few steps. First excess aluminum is removed with the PAN etch. This is followed by a grinding or lapping operation to thin the wafer to within approximately a mil or two of its final thickness. A polishing step then reduces the wafer thickness to $8 \pm 1/2$ mil.

Prior to introducing the wafers into the device fabrication line, they are stained to reveal the location of the grid lines with a short Secco etch. Without this step, mask alignment would not be possible. They then enter the line at the initial oxidation step, and between there and base photolithography step device processing is as usual. At base photolithography, a new mask was introduced which was designed to help overcome the fact that the TGZM grid is not as rectilinear or as evenly spaced as the boron-diffused isolation grid, making mask alignment more difficult. The base-level mask has special alignment features to aid this problem. The base level also has widened grid lines to overcome the aluminum out-diffusion problem which is described next.

After the high temperature, long-time base drive-in step (1215°C, 11h), it is observed that this thick initial oxide lying over the grid lines has grossly changed. Based on appearances alone (Fig. 10 and 11), the SiO_2 has devitrified. This is confirmed by TEM cross-sectional analysis which found areas of the SiO_2 capable of diffracting the electron beam. SIMS analysis has detected aluminum in the oxide above the grid line. This evidence suggests that aluminum has outdiffused from the silicon into the SiO_2 and has catalyzed the conversion of the SiO_2 from the amorphous to the crystalline state. It may also be that the SiO_2 in this region forms aluminum silicate. This last possibility is supported by the observation that it is extremely etch resistant. As mentioned above, at base photolithography, the SiO_2 over the TGZM isolation region is etched away prior to the high temperature long drive-in time of the base drive-in. This procedure eliminates the problem of devitrification.

From this point on in the manufacturing process, device fabrication is normal.

The Enhanced Diffusivity Problem

The initial TGZM-isolated thyristor was designed to accommodate spreading of the isolation region due to diffusion of the aluminum to the extent determined by the temperature and times of processing and the published value of the temperature dependent diffusivity. It was found that the TGZM grid linewidth at the end of the wafer processing was wider than expected. Given that final grid linewidth, it is calculated that the diffusivity of the aluminum at 1260°C was $9.5 \times 10^{-11} \text{ cm}^2/\text{s}$, or about three times the published value. This enhanced diffusivity is likely due to the aluminum concentration being at its solubility limit. It was hoped that with TGZM one could capitalize on the minimal concomitant side diffusion to effect a smaller chip design; however, the found enhanced aluminum diffusivity reduces the advantage.

Device Characteristics

Thyristors made with TGZM isolation regions were in almost all respects normal. The reverse blocking current

Fig. 9. Graph of angle of slant of TGZM zones at wafer edge vs. height of wafer above bottom of silicon ring. Note that magnitude and sign of the angle can be varied and controlled and that an optimum height with little slant can be identified.

Fig. 10. Photomicrograph of oxide over TGZM region after base drive-in. Note fractured appearance.

was a factor of 2-3 times above the usual. Making some simplifying assumptions on the geometry of the junction, the reverse blocking current density of the TGZM isolated part of the junction was $1.9 \times 10^{-3} \text{ mA/cm}^2$, which is 4.4 times greater than the conventional device current density. This figure is still more than an order of magnitude smaller than the specification limit for this device. The increase in current density may in small part be due to the increased size of the space-charge region associated with the TGZM junction being more graded, but the origin of the remainder is unknown. (It is not due to aluminum contamination of the oxide, since SIM analysis has shown that its outdiffusion is confined to immediately over the grid.)

Groups of thyristors with TGZM isolation regions were subjected to all of the same reliability tests that the conventionally designed units experienced. These included bias-humidity, temperature-bias, and temperature cycling tests. They passed all these tests.

Summary and Conclusions

Adapting TGZM to our 40 mil thyristor has required both the improving of the TGZM process itself and the development and alteration of water preparation procedures. With regard to the process itself, gas ambient control is found to be crucial to being able to pass an aluminum grid with a linewidth of a few mils through the wafer with very few line breaks and little to no smearing

Fig. 11. SEM photomicrograph of devitrified oxide over TGZM region taken with wafer inclined to direction of view.

of the pattern. Also, thermal trim rings were developed which correct the nonperpendicular motion of the molten zone at the edge of the wafer. With regards to wafer preparation procedures, an aluminum etching technique was developed for uniformly defining the grid from the relatively thick aluminum starting film, and it was found that a polished silicon surface is one of the two best surfaces to use under the aluminum in minimizing line breaks and smearing. It is observed that the aluminum in the silicon will outdiffuse into a capping oxide during high temperature treatments causing the oxide to devitrify, and that this problem is avoided by removal of the oxide prior to high temperature processing. We also report the unexpected finding of an enhanced diffusivity that is 2-3 times larger than what is reported in the literature. Finally, with TGZM and with the modification and adaptation of various wafer preparation procedures reported on here 40×40 mil thyristors have been made with normal reliability and normal electrical characteristics.

The Composition and Physical Properties of LPCVD Silicon Nitride Deposited with Different $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ Gas Ratios

Paihung Pan* and Wayne Berry*

IBM General Technology Division, Essex Junction, Vermont 05452

ABSTRACT

The composition and physical properties of low pressure chemical vapor deposition (LPCVD) silicon nitride films were studied. The samples were deposited at 770°C with different $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ reactant gas ratios (R) ranging from 2 to 20. Auger electron spectroscopy (AES) showed that the Si/N ratio was about 0.75, and the compositional uniformity as a function of depth was good for all samples. No excess Si clusters were detected by TEM for the samples annealed at 1000°C in N_2 for 5h. Only N—H bonds were observed by infrared (IR) analysis. The amount of N—H bonds in the as-deposited samples was estimated to be about $5 \times 10^{16} \text{ cm}^{-2}$. The normalized N—H absorption peak area was found to increase by increasing R values, while the amount of N—H bonds was found to decrease after annealing at 1000°C in N_2 for 30 min. The plasma etch rates were found to increase by increasing R values and showed a good correspondence to the trend of increasing the N—H bonds. The film stress for all samples was tensile and had a level of $1 \times 10^{10} \text{ dyn/cm}^2$. No difference was observed in the film's ability to act as an oxidation barrier for samples deposited with different R values.

Silicon nitride films are widely used in the semiconductor industry for the applications of passivation (1), gate dielectric in metal-nitride-oxide silicon (MNOS) (2) and storage capacitor in field effect transistors (3), or bipolar memory (4). It is well known that the low pressure chemical vapor deposition (LPCVD) process is superior to the atmospheric chemical vapor deposition (ATCVD) process from the standpoint of film uniformity and mass production. It is also known that the physical and electrical properties of the deposited films rely on the deposition conditions (5, 6). Film stress levels and pinhole density, which are affected by the process parameters, are particularly important when such films are used for passivation. The film composition and its associated structure are fundamental to understanding the etching behavior and the film's ability to act as an oxidation barrier or as a passivation barrier to mobile ions. Stein (7) has previously reported the direct relationship between the Si—H bonding and the MNOS characteristics for the ATCVD film. Additionally, it has been observed (8) that silicon-rich nitride films have higher electrical leakage current and the presence of Si clusters will enhance the charge injection, which makes the films more suitable for the EEROM application (9).

The composition and structure (10-12) as well as electrical properties (13, 14) of LPCVD Si_3N_4 films have been

reported. The purpose of our study is to understand the properties of the LPCVD silicon nitride as a function of the deposition parameters and then relate these properties to the film composition. In this paper, we report on the LPCVD Si_3N_4 film composition (including Si, N, O, and hydrogen), film stress, etch rate, and the film's ability to act as the oxidation barrier. The samples were deposited with different $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ gas ratios (R).

Experiments

Silicon nitride films were deposited in an LPCVD system. The silicon wafer was chemically cleaned immediately before the deposition. All samples were deposited at 770°C with the $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ reactant gas ratio ranging from 2 to 20. The SiH_2Cl_2 gas flow was kept at a constant of 15 sccm.

Film composition (Si, N, and O) of thin samples (~ 50 nm) was measured by using an Auger system with a beam voltage of 5 kV and a current of $1 \mu\text{A}$. An ATCVD Si_3N_4 sample ($n = 2.01$) of 50 nm, which was deposited with $\text{NH}_3/\text{SiH}_4 = 1200$ at 800°C , served as the standard to determine the Si and N concentration. The amount of oxygen in the film was estimated by referencing to the oxygen concentration (66.7 atom percent [a/o]) of a thermal SiO_2 of 50 nm. The Auger depth profile was used to determine the compositional uniformity as a function of depth.

A Fourier transform infrared (FTIR) system was used to analyze the thick samples (~ 500 nm on both sides of wa-

* Electrochemical Society Active Member.

fer). Transmission spectra were obtained with the incident beam normal to the wafer. The raw spectra were then subtracted from the spectra of the silicon substrate. The total absorption peak area measured by the computer was in the range of 200 cm^{-1} . Samples implanted with H^+ ions at an energy of 25 keV and with a dose of $2 \times 10^{17} \text{ ion/cm}^2$ served as the standard to determine the amount of N—H bonds.

A parallel-plate reactor was used to etch the deposited films $\sim 200 \text{ nm}$ thick. In this etching process, power of 400W, temperature of 40°C , and an RF frequency of 13.56 MHz were applied. The flow of CF_4 and O_2 were 135 and 13 sccm, respectively, and the pressure of the reactor was 250 mtorr. The film thickness, before and after etching, was measured by an ellipsometer, and the etch rates were then determined.

Thick films ($\sim 500 \text{ nm}$ on front side of wafer) were used for stress measurement. The film stress was determined at room temperature by using the x-ray topography technique (15). The refractive index for films 50-100 nm thick was measured by an automatic ellipsometer with an incident beam of $\lambda = 632.8 \text{ nm}$. A transmission electron microscope (TEM) was used to identify the presence of the excess Si phase in thin films (20-40 nm).

Results and Discussion

As shown in Fig. 1, the deposition rate and the pressure was found to increase by increasing the R value. Because pumping speed was kept constant in this experiment, the pressure in the reactor increased by increasing the R value. Based on our other study of deposition rate as a function of pressure, we believe the increase in the deposition rates by increasing the R value was due to the pressure increase. The uniformity of film thickness and refractive index, either across a wafer or across a load of 50 wafers, was found to be within 5% and was independent of the R value. The refractive index for all as-deposited samples was 1.99 ± 0.02 . Within experimental errors, no difference in refractive index was found after annealing at 1000°C in N_2 for 30 min.

After the 10 nm thick surface was sputtered away by Ar ions, the Auger spectra for all samples were obtained. Si, Ar, and N peaks were observed but not a trace of oxygen and carbon was detected, which implies that the oxygen concentration in these films was less than the detection limit (0.5 a/o) of this measurement. Since Ar gas was not used during the film deposition, the Ar peak must be caused by the sputtering Ar ions. Assuming that the electron-beam and the ion-beam effects on both the standard ATCVD Si_3N_4 and the deposited LPCVD samples were the same, the average Si/N ratio for all LPCVD samples was found to be 0.75 ± 0.02 . No dependency on the Si/N ratio as a function of R values was found. The Si/N ratios for these samples are listed in Table I.

As shown in Fig. 2, the Auger depth profile indicated that the uniformity of the Si and N concentration as a function of depth was good. A thin layer of SiO_2 films was observed at the $\text{Si}_3\text{N}_4/\text{Si}$ interface which may affect the electrical properties of the metal-insulator-oxide structure. A detailed Auger study of MNOS structure was reported by Johannessen *et al.* (16). Following the report

Table I. The deposition rate, Si/N ratio, amount of N—H bonds, etch rate, and film stress of Si_3N_4 films deposited with different $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ gas ratios (R)

by Pan *et al.* (17), the thickness of this layer was estimated to be about 2-3 nm.

TEM was used to analyze an as-deposited sample and an annealed sample (1000°C in N_2 for 5h). Both samples were deposited with $R = 2$. The TEM diffraction analysis showed diffuse rings for both samples, and no silicon pattern was observed for the annealed sample (Fig. 3a and 3b). The TEM bright field images showed a texture of the film before and after annealing which was 5 and 10 nm, respectively. Both results indicated that the deposited film was amorphous, before and after annealing, and no Si clusters were detected even after annealing for a long time at high temperature. These results and the Auger data of the $\text{Si/N} = 0.75 \pm 0.02$ also indicated that the stoichiometry of these LPCVD samples was Si_3N_4 or very close.

The IR absorption spectrum for a sample, with a thick Si_3N_4 film of about 500 nm on both sides of the wafer, is shown in Fig. 4. The Si—N absorption peak was found to be at 845 cm^{-1} and has the full width at half maximum (FWHM) of 210 cm^{-1} for all samples. No change in either the peak wavenumber or the FWHM value was found after the samples were annealed at 1000°C in N_2 for 30 min. This suggests that the Si—N bonding is nearly the same for both the as-deposited and annealed samples. Since the mass of the hydrogen atom is light and the amount of hydrogen in these samples was small, it was expected that the measured Si—N vibration was not affected by the escape of hydrogen, which was previously bonded to the Si or N atoms.

The N—H bonds at 3350 cm^{-1} were clearly observed for all samples. No trace of Si—H bonds was detected even when the spectrum was expanded 15 times (Fig. 4). This is different from results reported in Ref. (11). As reported in the literature (18, 19), the absorptivity of the S—H bonds is about 1.4 times that of the N—H bonds. This indicated that the amount of the N—H bonds in these films is at least 20 times ($15 \times 1.4 = 21$) that of the Si—H bonds.

Fig. 3. The TEM diffraction pattern for the Si_3N_4 film deposited with $R = 2$. a: As-deposited sample. b: Annealed sample (1000°C , N_2 , 5h).

Fig. 4. The infrared spectrum for a Si_3N_4 film ($R = 2$). The spectrum from $2100\text{--}3500\text{ cm}^{-1}$ was expanded 15 times and is shown in the insert.

When the N—H absorption peak area was normalized by the Si—N absorption peak area, we found that the normalized N—H peak area increased by increasing the R values (Fig. 5). The increase of NH_3 gas flow, which enhanced more H and/or N—H during the deposition, will result in this observation. After annealing at 1000°C in N_2 for 30 min, the N—H bonds were decreased for all samples, but the trend of increasing the normalized N—H peak area by increasing the R values was still observed (Fig. 5). The presence of N—H and the lack of Si—H suggested the presence of Si— dangling bonds. The density of the electron spin resonance (ESR) for the Si— dangling bonds in this Si_3N_4 was of the order of $1 \times 10^{16}\text{ cm}^{-3}$ (20) which is close to the value reported by Makino (10). Similar to the ATCVD Si_3N_4 (7, 21), the presence of Si—dangling bonds will affect the device characteristics.

IR spectra for the samples implanted with hydrogen (H^+) were also obtained. Similar to the report by Stein (7)

Fig. 5. The normalized N—H bonds as a function of R value

Fig. 6. The infrared spectrum for an as-deposited Si_3N_4 film before and after H^+ ion implantation.

for CVD Si_3N_4 , the Si—H bonds at 2200 cm^{-1} were detected (Fig. 6). The normalized Si—H bonds for the as-deposited sample were found to be higher than that of the annealed sample. After implantation, the increase in the N—H bonds for the as-deposited sample is less than that for the annealed sample (Table II). The presence of more N^+ dangling bonds for the annealed samples, due to the escape of hydrogen during annealing, may provide more chance to form N—H bonds and/or provide less chance for the conversion of N—H to Si—H bonds (7, 22) during the hydrogen implantation. The result that the difference in the total weight is nearly the same for both the as-deposited and the annealed samples suggested that a constant amount of hydrogen ion was bonded to Si or N after implantation.

When one defines that $U(\text{N—H})$ and $U(\text{Si—H})$ are the normalized N—H peak area and the Si—H peak area, respectively, one can write equations as

$$U(\text{N—H}) = A(\text{N—H})/A(\text{Si—N}) \quad [1]$$

$$U(\text{Si—H}) = A(\text{Si—H})/A(\text{Si—N}) \quad [2]$$

for samples before implantation. One can also write equations for samples after implantation as

$$U'(\text{N—H}) =$$

$$\frac{A'(\text{N—H}) - (1/2) \times [A(\text{N—H})/A(\text{Si—N})] \times A'(\text{Si—N})}{(1/2) \times A'(\text{Si—N})} \quad [3]$$

$$= [2A'(\text{N—H})/A'(\text{Si—N})] - [A(\text{N—H})/A(\text{Si—N})] \quad [4]$$

$$U'(\text{Si—H}) = A'(\text{Si—H})/[2A'(\text{Si—N})] \quad [5]$$

$$= [2A'(\text{Si—H})/A'(\text{Si—N})] \quad [6]$$

where $A(\text{Si—N})$, $A(\text{N—H})$, and $A(\text{Si—H})$ are the measured absorption peak area for Si—N, N—H, and Si—H bonds, respectively. $A(\text{Si—N})$ and $A'(\text{Si—N})$ are expected to be equal when the measuring condition is the same. The prime (') indicates after implantation. The factor (1/2) in Eq. [3] and [4] came from the fact that the hydrogen only

Table II. The normalized N—H peak area [$U(\text{N—H})$] and Si—H peak area [$U(\text{Si—H})$], before and after H^+ implantation, for the as-deposited and annealed Si_3N_4 films ($R = 10$). $U(\text{N—H})$ and $U(\text{Si—H})$ are defined in Eq. [1], [2], [4], and [6], and $W = 1.4 \times U(\text{N—H}) + U(\text{Si—H})$

	Before I/I			After I/I			$\Delta W =$ $W(\text{Before I/I})$ $- W(\text{After I/I})$
	$U(\text{N—H})$	$U(\text{Si—H})$	W	$U(\text{N—H})$	$U(\text{Si—H})$	W	
As-Deposited	6.03	0	8.44	7.88	3.58	14.61	6.17
Annealed	4.10	0	5.74	6.71	2.72	12.11	6.37

implanted on one layer of Si_3N_4 contributed only one-half of the measured $A(\text{Si}-\text{N})$.

The increase in the N—H and Si—H peak areas can be obtained by subtracting Eq. [4] from [1] and Eq. [6] from [2]. When one assumes that the implanted hydrogen ions are all chemically formed as Si—H or N—H bonds, and defines that U is the amount of N—H bonds represented by the unit normalized N—H peak area, then one can write

$$U = \frac{H}{[U'(\text{N}-\text{H}) - U(\text{N}-\text{H})] + (1/1.4) \times [U'(\text{Si}-\text{H}) - U(\text{Si}-\text{H})]} \quad [7]$$

where H is the total amount of implanted hydrogen which can be obtained by the integration of hydrogen profile in the implanted sample. The factor (1/1.4) came from the ratio of the absorptivity of the Si—H bonds to that of the N—H bonds (12, 13). The amount of N—H bonds [$Q(\text{N}-\text{H})$] and the amount of Si—H bonds [$Q(\text{Si}-\text{H})$] in the sample can then be estimated by using $Q(\text{N}-\text{H}) = U \times U(\text{N}-\text{H})$ and $Q(\text{Si}-\text{H}) = (1/1.4) \times U \times U(\text{Si}-\text{H})$. In order to use this analysis technique, one sample must be implanted with hydrogen.

From the LSS statistical table (23), the projected range was 230 nm and the standard deviation was 50 nm for the implanted H^+ ions with 25 keV. When the gaussian approximation was assumed, one can estimate that the amount of the N—H bonds in these films is in the order of 5×10^{16} bond/cm². The amount of N—H bonds for all samples is listed in Table I. Because the incident beam was normalized to the wafer and the absorption peak area decreased with decreasing the film thickness, the N—H or Si—H bonds are expected to be present inside the film instead of at the $\text{Si}_3\text{N}_4/\text{Si}$ interface, or on the Si_3N_4 surface.

As shown in Fig. 7, the plasma etch rates were found to increase as the R value increased. After the samples were annealed at 1000°C in N_2 for 30 min, the etch rates for all samples were decreased about 2 nm/min. The trend of the etch rates as a function of R values is the same as that of the normalized N—H peak area. As described earlier, the Si/N ratios were nearly the same and the oxygen contamination was very small (< 0.5 a/o) for all samples. These results indicated that the amount of the N—H bonds or total hydrogen in the sample, which will affect the film density and/or the chemical bonding, should play an important role in the process of plasma etching. The lower etch rate of the annealed film was believed to be due to the densifying effect, which reduced the number of the weaker N—H or Si—H bonds (24) of the as-deposited samples and increase the film density. No loading effects were observed for these Si_3N_4 films under the present etching process.

AES and x-ray photoelectron spectroscopy (XPS) were used to analyze the Si_3N_4 surface after plasma etching. The amount of oxygen (about 8 a/o) on the etched surface was found to be slightly less than that on the unetched surface and the depth of the oxygen distribution for both

Fig. 7. The plasma etch rates as a function of R value

the etched and unetched samples was nearly the same. These results indicate that the oxygen plasma mainly promoted the dissociation of the CF_4 (25), rather than oxidizing the Si_3N_4 surface during the process of plasma etching.

Film stress for all samples was tensile and at a level of about 1×10^{10} dyn/cm², which is slightly less than the level for the ATCVD Si_3N_4 (26, 27). A slight decrease in stress was observed by increasing the gas ratio, which is shown in Fig. 8. As described previously, the Si/N ratio and the oxygen in all samples were nearly the same. This suggests that the sample with higher hydrogen, either in the form of N—H or Si—H bonds, increases the relaxation of the intrinsic rigidity. The higher surface relaxation for samples deposited with higher deposition rate (26) may be another reason for this observation.

The ability to act as an oxidation barrier was tested by oxidizing the as-deposited and annealed (1000°C, N_2 , 30 min) samples, in wet O_2 ambient at 1000°C for 2h. Auger depth profiles were then used to determine the oxygen distribution. As shown in Fig. 9, one found that the thickness of the oxidized Si_3N_4 was nearly the same (about 10 nm) for both the as-deposited and the annealed samples, which indicated that the pinhole density was small in the as-deposited samples. The observation of no difference in this ability for the samples deposited with different $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ gas ratios indicates that the stoichiometry for all samples is nearly the same. The shape of the Si LVV Auger spectrum at the oxidized layer/ Si_3N_4 interface was identical to that in the LPCVD oxynitride film. This observation suggested that the initial oxygen atoms replaced some nitrogen sites to form an oxynitride layer. When the nitrogen-rich oxynitride was converted into the oxygen-rich oxynitride or SiO_2 , the oxygen atoms in the ambient then diffused through this layer to react with the

Fig. 8. The film stress of Si_3N_4 deposited with different R values

Fig. 9. The Auger depth profile of the oxidized Si_3N_4 films

Si_3N_4 . The slow chemical reaction of Si_3N_4 with oxidant is believed to be the cause of the slow oxidation rate in Si_3N_4 (28). Both replacement of N with O and diffusion of O were observed during the oxidation of oxygen-rich LPCVD oxynitride. The mechanism of the oxygen diffusion in the oxygen-rich oxynitride may be similar to that in SiO_2 film (29).

Summary

LPCVD silicon nitride films were deposited at 770°C with different $\text{NH}_3/\text{SiH}_2\text{Cl}_2$ gas ratios ranging from 2 to 20. Auger analysis was used to determine the Si, N, and O concentration. Comparing with the standard ATCVD Si_3N_4 sample, the Si/N ratio for the LPCVD samples was found to be 0.75 ± 0.02 and was independent of the R values. No excess Si phases were detected by TEM. The amount of oxygen was found to be less than 0.5 a/o. Only N—H bonds were detected by IR analysis, and the presence of Si dangling bonds was detected by ESR. The normalized N—H absorption peak area was increased by increasing the R values. The amount of the N—H bonds in the as-deposited samples was estimated to be about $5 \times 10^{16} \text{ cm}^{-2}$. The plasma etch rates increased by increasing the R values, and the increase in the amount of hydrogen was believed to be responsible. For all samples, the film stress was tensile and the level was in the order of $1 \times 10^{10} \text{ dyn/cm}^2$. The film's ability to act as the oxidation barrier was nearly the same for both the annealed and as-deposited samples, and no dependence on the R values was found for all as-deposited samples.

Acknowledgments

We would like to thank H. Geipel for the critical reading of this paper. Thanks are given to V. S. Nguyen for the information on ESR, S. Burton for doing plasma etch, and E. Cadwell for doing IR analysis. We also want to thank E. Gardner for the encouragement during the course of this work.

CVD Epitaxial Autodoping in Bipolar VLSI Technology

G. R. Srinivasan*

IBM General Technology Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This paper reviews several aspects of epitaxial autodoping including process effects, flow effects, and the effect of profile tolerance on bipolar device characteristics. Emphasis is placed on the examination of the stagnant boundary layer hypothesis in light of recent evidence. A new derivation of the half-power law that relates the increase in autodoping to an increase in the buried layer area is presented. This law is the limiting law for discrete point sources when they merge to form a continuum.

In high performance bipolar VLSI technology, the trend is toward higher device densities and shallower junctions, both of which are affected by epitaxial autodoping. Autodoping, for example, determines the sharpness of the buried-layer vertical profile, the minimum epitaxial thickness usable for shallow junction devices, and the lateral spacing of the devices. I reviewed the autodoping phenomenon that occurs in CVD epitaxial silicon in 1979 (1), and since then considerable progress has

been made in modeling the hydrodynamic aspects of the dopant redistribution in the epitaxial flow system (2-10). One of the important results of this development as it pertains to the VLSI technology is the theoretical prediction (2), and the subsequent experimental verification (4), of the half-power law which relates an increase in net autodoping due to an increased fraction of the buried layer area in the substrate. Recently, this law has been reconfirmed for substrates containing buried layers of large dimensions (11). The original theory was developed for an array of point sources. In this paper, we will derive

*Electrochemical Society Active Member.

this power law for extended sources, and show that the half power is the consequence of the inverse-distance solution to the flow equation for point sources and its application to a continuum of such sources.

Yet another important outcome of the flow dynamic studies is the finding that for horizontal epitaxial reactor flow systems there is no indication of a stagnant boundary layer (3). This finding has received experimental support recently from direct laser holographic interference observations of the flow in horizontal epitaxial reactors (12, 13) and from theoretical considerations of flow (8).

Further, there have been several recent studies which have examined the interrelationships between autodoping, dopant profiles, and transistor characteristics for bipolar integrated circuits (14-17). In this paper, we will review these flow and device aspects of autodoping in silicon epitaxy.

Process Effects

Autodoping mainly occurs in the pregrowth (prebake) stages of the epitaxial process, and its dependence on prebake parameters (time t_p , temperature T_p) can be described (18) for buried layers by the equation

$$C_A = \alpha \exp(\beta^2 t_p) \cdot \operatorname{erfc}(\beta t_p^{1/2}) \quad [1]$$

where C_A is the maximum concentration in the lateral autodoping peak. If one assumes an Arrhenius behavior for β , which is the ratio of the dopant evaporation velocity to the square root of its diffusivity in silicon such that $\beta = \beta_0 \exp(-\Delta E/kT_p)$, a good agreement between theory and experiment is obtained. Since β contains the evaporation velocity, both the dopant vapor pressure and the reactor pressure are contained in it. The factor α contains both the flow parameters and the growth parameters.

The above equation was derived on the basis that the dopant evaporation kinetics is the controlling mechanism for vapor phase autodoping. The data for arsenic autodoping are consistent with the above model for epitaxial depositions made in a horizontal reactor (18), barrel reactor (15), and vertical pancake reactor (19). More recently, autodoping measurements for epitaxial deposition in a pancake reactor have been reported (20) which show that, while arsenic autodoping is consistent with Eq. [1], phosphorous autodoping shows a different behavior. However, in view of several peculiarities of these data in terms of the differences between the variations of on and off buried layer autodoping with respect to prebake parameters, unexpected growth rate effects, etc., further confirmation is necessary before attempting to model these effects.

The effect of growth rate on autodoping has been modeled using the concept of dopant trapping (1, 18). This trapping model explains the observed increase in autodoping with increased growth rate in terms of the decreased ability of the trapped dopant atoms to diffuse to, and escape from, the rapidly advancing surface.

One of the autodoping effects that is important for integrated circuits is the effect of the initial buried-layer profile, prior to epitaxy. In deriving Eq. [1], an assumption of a rectangular profile was made (18) in order to obtain a closed-form solution to the evaporation equation. Actually, the initial buried layer profile is more complicated, especially if an oxidation-drive-in cycle has been used to form the buried layer. During this cycle, segregation of the dopants into or away from the growing oxide occurs, depending on whether it is a P- or an N-type dopant. For N-type buried layers used in the formation of subcollectors in N-P-N bipolar structures, oxidation cycle produces a dopant pile-up at the SiO₂/Si interface. High performance integrated circuits use high conductivity subcollectors in which the doping is made to the solid solubility limit. Any further pile-up in these buried layers produces mostly electrically inactive dopant and also causes enhanced autodoping.

A method to reduce this pile-up and the consequent autodoping for arsenic subcollectors has been described previously (21). It depends on arriving at a judicious

Fig. 1. Rutherford backscattering profiles of pre-epitaxy arsenic buried layers with identical capsule diffusion, but with two different oxidation-drive-in temperatures. Note arsenic pile-up at the silicon surface for the 970°C case.

choice of the oxidation-drive-in temperature which allows the rate of dopant diffusion to be large relative to the rate of oxidation. Figure 1 shows the Rutherford backscattering (RBS) profiles of arsenic buried layers prior to epitaxy from two oxidation temperatures: 970 and 1100°C. Figure 2 shows the spreading resistance profiles for these two cases, after epitaxy, taken on and off the buried layers. The epitaxial conditions were identical for the two cases: SiCl₄, 1150°C deposition temperature, 0.13 $\mu\text{m}/\text{min}$, AMC 7000 radiantly heated barrel reactor. From the RBS profiles in Fig. 1, we see that raising the oxidation temperature from 970° to 1100°C has virtually eliminated the arsenic pile-up at the substrate surface. The off-buried layer spreading resistance profiles in Fig. 2 show that this increase in oxidation temperature has also reduced the autodoping peak concentration by more than 50%. Further, increased electrical activation of the 1100°C oxidation has decreased the postepitaxial buried layer sheet resistance for the same initial predrive-in profile. VLSI circuitry built on wafers using these two subcollector oxidation temperatures showed that 1100°C temperature produced less parasitic subcollector-isolation capacitance from 970°C (21), which is consistent with the autodoping data.

Flow Effects

Since vapor phase autodoping involves a redistribution of dopant vapor emitted by the buried layer sources in the substrate, it is essential to understand the flow effects in the epitaxial reactor before a quantitative formulation of autodoping can be made. Flow effects have been studied in the past, and these include the TiO₂ smoke visual experiments (22), Raman scattering experiments (23), and mass spectrometry (24). Since the TiO₂ visual experiments, it has become customary to analyze the mass transport in the epitaxial reactor flow in terms of a stagnant boundary layer. Recently, however, there have been two independent studies (3, 13) which show that in horizontal epitaxial reactors which are operated at atmospheric pressure with H₂ as the carrier gas there is no stagnant layer formed. In the first study (3), observations of flow-induced anisotropy in the epitaxial autodoping were made using localized autodoping sources in the wafer. The second study (13) involved direct experimental

Fig. 2. Spreading resistance profiles after epitaxy from wafers used in Fig. 1. Open circles are on-buried-layer profile from 1100°C oxidation-drive-in wafer, and closed circles correspond to off-buried-layer profile from the same wafer. Stars and plus markers indicate corresponding profiles from 970°C oxidation-drive-in wafer, from a separate run.

observation of the flow using laser interference holography.

We shall first consider the autodoping studies. The ability to emit a calculable quantity of dopant vapor into the flow stream from a geometrically defined area on the substrate and to measure its redistribution in the epitaxial layers provides a powerful technique for the characterization of the reactor flow. Also, since the autodoping source is on the wafer surface, one can investigate the stagnant layer, if present, which would be in contact with the wafer. By using different sizes and shapes of the source and placing them in different directions with respect to the flow, the distribution pattern can be related to the flow dynamics through a mathematical model. Such a study was made (3) for an RF-heated, rectangular, horizontal epitaxial reactor which was air cooled. H_2 was used as a carrier gas. The autodoping sources used were arsenic-diffused buried layers of different shapes. The susceptor was inclined at an angle of 3° to the horizontal plane, and a ramp was used at the flow entrance.

The steady-state transport equation for the redistribution of the dopant vapor which is released at a constant rate into a laminar flow of carrier gas of uniform velocity V , along a direction x is given by

$$D_g \nabla^2 C_g - \frac{V \partial C_g}{\partial x} = 0 \quad [2]$$

where C_g is the dopant concentration at any point (x, y, z) in the flow. The above equation can be solved analytically in closed form for either a point source or a line source placed in a direction normal to the gas flow in the wafer plane. If the redistribution were to occur in a stagnant layer ($V = 0$), solutions to Eq. [2] are spherically symmetric for point sources and cylindrically symmetric for line sources.

For a buried layer of finite area, the solution to Eq. [2] has to be integrated over that area. The integration can be evaluated analytically for simple geometries such as a thin rectangular stripe placed in a direction normal to the

flow for which the transport equation reduces to the modified Bessel equation. The details of this procedure are given elsewhere (3). Explicit expressions were obtained for autodoping variation in the downstream and upstream directions. Figure 3 shows that variation. The dots show experimental measurements, and the solid lines are from the theory. It is evident from the data that pronounced flow-induced anisotropy exists in autodoping.

In order to rigorously test the model, anisotropy ratio R , defined as the downstream to upstream autodoping ratio, was calculated. By this procedure, all unknown quantities in the analytical expression for the stripe autodoping drop out, except for the gas diffusivity, D_g , which is calculable from the kinetic theory of gases. When the calculated values of R were tested against the experimental values for different values of x and V , reasonably good agreement was obtained for $D_g = 2.5 \text{ cm}^2/\text{s}$, which was also consistent with the value obtained by the kinetic theory estimation. Figure 4 shows this comparison. Such an agreement found between the theory and experiment provides a strong support to the model assumptions. We note from this figure that the anisotropy ratio varies from about 2 at low flow velocities to about 100 at high flow velocities. Taken together with the observation (2) that the decay length of the dopant redistribution in the reactor flow system at typical flow velocities is of the order of a few millimeters, this pronounced autodoping anisotropy rules out the existence of a stagnant layer of several millimeter thickness as commonly assumed.

We will now consider the study of epitaxial flow which used an entirely different technique, namely holography. The principle of the holography interference technique (12) is to provide two coherent laser beams to traverse the flow under two different flow conditions and to superimpose them for interference. A reference beam (see Fig. 5) provides for the phase synchronization of the two beams. By recording the beam in one condition of the flow on a hologram and using this holographic plate during a different condition of the flow, interference patterns can be generated which can be interpreted in terms of path differences in the laser beam between the two flow conditions. Since the optical path length depends on the integrated refractive index along that path, which in turn depends on the gas density and the temperature,

Fig. 3. Variation of autodoping peak maximum with lateral distance. (SiCl_4 , deposition temperature 1150°C, growth rate 0.13 $\mu\text{m}/\text{min}$, H_2 flow rate 15 liter/min).

Fig. 4. Variation of the autodoping anisotropy ratio with flow velocity as measured at two distances from the stripe buried layer.

one can, in principle, obtain information on the density and/or temperature distribution in the flow along the beam path. By using an optical shutter, real-time observation of the flow development may be studied. This elegant procedure has been used to study the effect of gas velocity and carrier gas species on the flow pattern in a horizontal epitaxial reactor (13). Important observations for horizontal laminar-flow epitaxial reactors which use H_2 as the carrier gas were that when the reactor walls are kept water cooled, the flow patterns are stable and are insensitive to changes in the flow velocity. It was also found that for H_2 at typical epitaxial flow velocities there was little or no turbulence and no convection in the flow. Based on these observations, it was concluded that there is no stagnant boundary layer formed for H_2 carrier gas in a horizontal epitaxial reactor. However, the interference observations suggest a well-developed parabolic velocity profile in this case.

It is of interest to compare the results of the autodoping study with those of the holographic observations. Both studies indicate the absence of stagnant boundary-layer effect in the horizontal epitaxial reactor. Autodoping measurements show a pronounced flow-dependent anisotropy. However, the autodoping analysis assumes a constant and uniform velocity distribution in the flow, while the holography observations imply a parabolic velocity distribution. One way to reconcile this difference is to assume that the vapor transport involves some average flow velocity which can be related to the flow velocity of the input carrier gas. This velocity averaging procedure will be valid only for laminar flows.

Autodoping in VLSI Substrates and the Half-Power Law

We shall now consider the effect due to a large number of autodoping sources that one encounters in a typical

Fig. 5. Schematic diagram of a holographic system. b.s.: Beam splitter. m: Mirror. sp.f.: Spatial filter. l: Lens. h: Hologram. After Ref. (13).

VLSI substrate. For the case of buried layer sources which are so small as to be considered as point sources, the vapor transport equation (Eq. [2]) can be solved and applied to autodoping with the result (2)

$$C_A = (A/r) \exp [(-V/2D_g)(r - x)] \quad [3]$$

where C_A is the autodoping concentration due to a point source at a distance r from it in the wafer plane, A is the proportionality constant, and x is the projection of r along the flow direction. The exponential term in Eq. [3] is the anisotropy factor that modifies the radially symmetric term A/r . Figure 6 shows the autodoping distribution in the wafer plane due to Eq. [3] for $V/2D_g = 1$. For typical deposition conditions, the autodoping extends to several millimeters in the downstream direction and ~ 1 mm in the upstream direction (2).

For a VLSI substrate which contains many thousands of small buried-layer sources, the net autodoping can be calculated by summing the contribution from each of these point sources. By this procedure, it was shown (2) that the net autodoping increases approximately as the square root of the total number n of the point sources on the substrate. The study also showed that the near-half-power law was valid only for the high density arrays of discrete sources separated by distances of less than $10 \mu\text{m}$. For larger separations, the calculation showed a saturation effect, which indicates that the field overlap from these sources is incomplete. The theory also predicted that when $n > 500$ the autodoping variation in the wafer would fall below 5%, thus assuring a uniform autodoping for typical VLSI substrates.

Experimental verification of the half-power law became available subsequently for VLSI wafers which were used for epitaxial deposition in a barrel epitaxial reactor (4). More recently (11), more autodoping data have been published for the deposition in a barrel reactor. These data also confirm the half-power law (see Fig. 7). However, in this latest study, buried layers of large area were used instead of the small ones that are typical of a VLSI pattern. One can intuitively expect the half-power law to be applicable for this case also, although no specific derivation was available. It was speculated that such a power law might be the consequence of the boundary layer in the flow (11). In the treatment that follows, we will present a quantitative formulation of this problem and derive the half-power law for extended sources. We will also show that the half-power law is the limiting law for discrete point sources which are so close to each other as to form a continuum.

Let us consider an extended buried-layer source in the shape of a circle, chosen for symmetry reasons (see Fig. 8). The shape will not really matter, except to simplify the mathematics. The extended source can be considered as a continuous distribution of the point sources, so that the discrete summation of the contribution from each point can be replaced by an integral. For a point source, the so-

Fig. 6. Impurity distribution due to a point autodoping source in a moving stream of gas of uniform velocity V . Dopant vapor diffusivity in the stream is denoted by D_g , and A is a measure of concentration level.

Fig. 7. Autodoping variation with buried layer area [after Ref. (11)].

Fig. 8. A circular autodoping source in which an elemental ring of radius r and width dr is shown.

lution is given by Eq. [3], which includes the asymmetry factor contained in the exponential term. When the point sources merge as to form a continuous distribution, the asymmetry for each point disappears due to extensive field overlap from neighboring points, and the solution reduces to

$$C_A = \frac{A}{r} \tag{4}$$

where C_A is evaluated inside the extended source. For evaluations outside the extended source for which asymmetry remains, procedures as described in an earlier work (3) have to be used to sum the contributions from each point within the extended source.

The continuum effect also reduces the transport equation (Eq. [2]) to a Laplace's equation. It is clear that solution given in Eq. [4] satisfies the boundary conditions

$$C_A = 0 \text{ as } r \rightarrow \infty$$

and

$$-\left[4\pi r^2 D_g \frac{dC_A}{dr}\right]_{r=0} = Q (= 4\pi A D_g)$$

where Q is the steady-state evaporation rate used in deriving Eq. [3].

In order to calculate the total contribution of the continuous distribution of point sources in a circle of radius R , we define an elemental ring of width dr at a distance r from the center (see Fig. 8). The contribution from the sources in this elemental ring as evaluated at the center of the circle is given by

$$dC_A = \frac{A}{r} (2\pi r dr)$$

where $2\pi r dr$ is the area of the ring. The total contribution due to all sources contained in the circular area is then

$$C_T = \int_0^R dC_A = 2\pi AR$$

Relating R to the total area a of the extended source, one obtains

$$C_T = ka^{1/2} \tag{5}$$

where $k = 2\sqrt{\pi} A$. Thus, the total autodoping over the buried layer is proportional to the square root of the area of the buried layer.

Since the above equation was derived from integrating the point source solution, it represents a limiting case of the summation of the discrete point sources when the number density approaches infinity for the continuous distribution.

Before concluding this discussion, it is useful to point out that the original theory of discrete point sources showed a significant departure from the half-power law for interpoint source distances of $10 \mu\text{m}$ or larger. Clearly, for this case, the field overlap from point sources is only partial, and one would expect a saturation effect. This was indeed the prediction from the theory. Such a saturation effect manifests itself when one considers the net effect of several wafers in a single epitaxial run. This loading effect has also been observed for depositions in the barrel reactor (25).

Transistor Profiles

In high performance bipolar transistors, it is desirable to have sharp dopant profiles to reduce the diffusion and parasitic capacitances and the charge storage. The epitaxial process controls only the subcollector (and/or subisolation) buried layer profiles. Figure 9 shows a typical high performance bipolar transistor profile. The subcollector profile can be described by the parameters X_{OD} and X_{AT} . X_{OD} refers to the extent of the dopant outdiffusion in the solid silicon during growth, and it depends on the growth temperature and time and surface concentration in the buried layer prior to growth. X_{AT} is the thickness of the so-called autodoping tail which results from vapor phase autodoping. The shape of this tail depends on the flow and process parameters. Considerable attention is paid to control this autodoping tail, since it determines the minimum epitaxial thickness necessary to form a transistor of given junction depths. It should be pointed out that both the lateral autodoping and the vertical autodoping tail are the consequence of the same vapor phase autodoping phenomenon. In fact, it has been shown (1) that the off-buried-layer autodoping peak and the autodoping tail over the buried layer almost exactly superimpose in the upper layers of the epitaxy. Thus, the same factors that control lateral autodoping control also the autodoping tail in the vertical profile. This point is often not appreciated in literature. Thus, the same measures one takes to reduce lateral autodoping also reduce the vertical autodoping, leading to a reduction of the autodoping tail and a sharpening of the buried-layer profile.

Recently (26), it has been possible to model both the lateral and vertical autodoping profiles using a dopant trapping concept. The salient features of this and other epitaxial profile models are reviewed elsewhere (27).

Fig. 9. Vertical profiles from a high performance bipolar device

Progress has also been made (28) to link the "on" and "off" buried layer profiles through a common adsorption layer.

From a device point of view, the factor that is equally important to the reduction of the autodoping tail is the control of its variation. The following discussion makes this clear. The collector/base (C/B) junction determines the breakdown voltage and the junction capacitance. Since most of the depletion occurs in the autodoping tail region, the extent of this tail determines the depletion layer capacitance. Experimental data from high performance NPN bipolar devices (15) show that this capacitance varies as the square root of the C/B junction concentration in accordance with the abrupt junction theory. Thus, depending on where the C/B junction intersects the autodoping tail the performance of the device varies. To avoid this, the C/B junction is always designed to occur in the flatly doped portion of the epitaxial layer, above the autodoping tail, in order to assure a constant and process-independent C/B junction concentration. This concentration is then determined by the intentional doping level and not by autodoping. However, in order to accommodate the variations in the buried-layer profile which is caused by process variations, a certain minimum thickness X_r (see Fig. 9) of the flatly doped epitaxy is maintained between the subcollector profile and the C/B junction. At high current densities of the order of the maximum drift current density J_c ($J_c = qC_0V_s$, where C_0 is the epitaxial flat doping level and V_s is the saturation velocity of the carriers), base stretching is expected to occur (17). Base stretching essentially widens the intrinsic base, which, in turn, increases the base transit time, and hence increases the device delay. Since the stretching stops at the rapidly rising subcollector profile, it is limited by the thickness X_r . It is therefore desirable to minimize X_r while, at the same time, allowing for the profile variations.

One of the ways to reduce the subcollector variations, and hence X_r , is to reduce the epitaxial growth temperature. At lower growth temperature, the variation in the subcollector outdiffusion profile is expected to be less than that at higher growth temperatures, for a given temperature nonuniformity that exists across the wafer, from wafer to wafer and from run to run. The effect of this variation was calculated (15) for two growth temperatures, 1150° and 1050°C, and for a total temperature nonuniformity of $\pm 10^\circ\text{C}$. The calculations showed that the total tolerance in the epi flat region can be reduced by a factor of 3 by reducing the epitaxial growth temperature from 1150° to 1050°C. Considerable improvement in the transistor speed due to such a reduction in X_r is to be expected on the basis of the limitation to base stretching (17).

The lateral autodoping effects also contribute to the collector isolation capacitance. A detailed analysis of this effect has been carried out for both N- and P-type autodoping in high performance NPN bipolar structures that use combined oxide and diffused isolation (14, 16). The P autodoping modifies the isolation-epitaxy junction, whereas the N-type autodoping shifts the isolation-epitaxy junction toward the P⁺ isolation. These calculations show that the junction capacitance can increase by over 60% due to both types of autodoping in a typical VLSI bipolar application.

The above examples show clearly that autodoping effect should be included as a design constraint in high performance bipolar devices. Also, since autodoping increases in proportion to the square root of the device density, it becomes even more important to take autodoping into account for very large scale integration. One of the effective ways to reduce autodoping is by reduced pressure epitaxy. This works well for N dopants such as arsenic. However, for boron, the reduced pressure is found to increase autodoping (29). Thus, for producing high resistivity P epitaxial films over P⁺ substrates for MOS transistor applications, alternate ways of reducing autodoping need to be used. These include extended prebake (temperature and/or time as indicated by Eq. [1]),

lower growth rates (1), and cap-and-flush techniques. In addition, in order to reduce the buried-layer vertical profile variations, it is desirable to reduce the epitaxial deposition temperature. However, at lower deposition temperatures, the vapor phase autodoping increases (18). The autodoping increase can be minimized by including a high temperature prebake at 1150°C in H₂ prior to the deposition at a lower temperature (15, 19, 27, 30, 31). This high-low epitaxial process has the additional advantage of reducing the epitaxial growth defects by over an order of magnitude compared to that without the 1150°C prebake (14, 15, 27, 30). The defect reduction due to the 1150°C prebake in H₂ was first discovered using the SiCl₄ deposition (30) and it has recently been reconfirmed in a separate study (32). For transistor structures with predominantly N⁺ buried layers, a combination of high-low epitaxial process and reduced pressure epitaxial process offers the advantages of both (33).

Fabrication and Characterization of Epitaxial Heavily Phosphorus-Doped Silicon

Jesús A. del Alamo* and Richard M. Swanson**

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

Phosphorus-doped silicon layers have been grown by epitaxy in a PH_3/SiH_4 system. Doping levels from 2.5×10^{17} to $1.6 \times 10^{20} \text{ cm}^{-3}$ have been obtained. A combination of measurements of electrical resistivity, Hall mobility, and phosphorus concentration by secondary ion mass spectroscopy has yielded accurate values for the electron mobility and the Hall scattering factor. At the lowest doping levels, the phosphorus concentration is proportional to the partial pressure of phosphine in the reactor, while in the high doping regime the dependence is $\sim (p_{\text{PH}_3})^{1/4}$. The growth rate drops by about 20% at the highest doping levels. The defect densities increase quadratically with phosphorus concentration and reach a value of 3000 cm^{-2} at $N_D = 10^{20} \text{ cm}^{-3}$.

The reduction of lateral and vertical dimensions in very large scale integration (VLSI) semiconductor devices requires the doping levels inside the devices to rise so as to provide thin low resistivity layers confined between tightly controlled depletion regions. This trend places increased importance on the accurate characterization of heavily doped silicon.

Material problems have hindered a systematic characterization of heavily doped silicon. Heavy doping studies using diffused or implanted layers suffer from uncertainties caused by their nonuniform doping profiles, while heavily doped as-grown wafers are scarce and inconvenient from a test device point of view. Epitaxially grown heavily doped silicon is a good candidate for carrying out this fundamental study. Epitaxy is a well-known process that produces flat and abrupt impurity profiles, without limitations on layer thickness, and is technologically simple. The doping level, the variable of most interest here, is easy to control.

Epitaxial heavily doped silicon may also be of interest for the fabrication of the base region of VLSI bipolar transistors, if grown under low pressure, low temperature conditions. Its use has already been reported in the fabrication of hyperabrupt IMPATT Si diodes (1).

This paper reports our experience in the growth and characterization of heavily phosphorus doped epitaxial layers. We have reached doping levels of $1.6 \times 10^{20} \text{ cm}^{-3}$, which, to our knowledge, is the highest ever obtained by this technique. In the characterization process, we have measured Hall mobilities and carried out SIMS measurements of the total phosphorus concentration. The outcome of this characterization procedure indicates that the epitaxial material is essentially identical to P-diffused or -implanted Si. We have also measured the Hall scattering factor (2) throughout three orders of magnitude of doping. This parameter establishes the relationship between the conductivity mobility and the Hall mobility.

This paper extends an earlier account of our work (3) and includes new research on the growth and characterization of epitaxial phosphorus-doped silicon.

Experimental Work

All the depositions were carried out in a horizontal, RF-heated epitaxial reactor (Hugle Model HIER II) operating at atmospheric pressure. The quartz reactor tube has an effective cross section of 27 cm^2 above the susceptor. The silicon carbide-coated graphite susceptor is 22.8 cm long and it is tilted at an angle of 2° . This reactor is the same used previously on a fundamental study of silicon epitaxy (4).

Hydrogen was used as carrier gas at a flux of 79 liter/min . Silane was the source of silicon at a partial pressure of 10^{-3} atm except where indicated otherwise. Phosphine was used as dopant source and delivered through a double-dilution system. With PH_3 tanks of 66 ppm, 1%, and 5% in hydrogen, partial pressures from 10^{-8} to $4 \times 10^{-3} \text{ atm}$ were reached in the reaction chamber. With a few exceptions, all depositions were done at a temperature of 1050°C during 10 min. Prior to growth, all wafers were vapor etched in $5 \times 10^{-3} \text{ atm HCl}$ and the carrier gas H_2 during 4 min at 1200°C . The temperature of the substrates was measured with an optical pyrometer calibrated accounting for the emissivity of silicon. The temperature is known within 5°C and was stable during deposition to within $\pm 2^\circ\text{C}$.

The starting material was $\langle 100 \rangle$ boron-doped 0.1-0.2 $\Omega\text{-cm}$ substrates. The 3 in. diam wafers were broken in quarters. One quarter was processed at a time. The cleaning procedure before epitaxy consisted of a standard "reversed RCA" process (5) with a final 50:1 HF dip. After epitaxy the sample was sawed in $7 \times 7 \text{ mm}^2$ die where the characterization was done.

Electrical Characterization

A typical electron profile determined by spreading resistance is shown in Fig. 1. As shown, the carrier distribu-

** Electrochemical Society Active Member.

Fig. 1. Spreading resistance profile of a heavily doped epitaxial layer grown at $P_{PH_3} = 3.5 \times 10^{-4}$ atm.

tion throughout the layer is very flat, and an abrupt transition occurs at the interface with the substrate.

In all samples, the thickness of the layer was measured by the groove and stain method, using a copper sulfate solution (6), and an interferometric microscope. The relative error in the measurement is less than 3%. The difference between the electrical and metallurgical junctions, as determined by spreading resistance or staining, has been calculated by Hu (7). For our box profile, he finds a discrepancy of around 6%.

Great care was taken in the measurement of doping level. First, the sheet resistance was measured at a temperature of 23° by the van der Pauw technique (8) by contacting the four corners of the samples. The measurement was corrected to account for the roll off of the doping level near the junction as seen in Fig. 1 (9). The relative error in the sheet resistance was less than 1%. Multiplying the value of sheet resistance by the layer thickness, measured as described before, the resistivity, ρ , is obtained.

Second, the Hall coefficient, R , is measured using the same van der Pauw configuration in a magnetic field of 1.12 kG. The relative error is smaller than 4%. The Hall mobility is obtained as $\mu_H = -R/\rho$ (8). Since $R = -A/qn$, where q is the electron charge, n is the electron concentration, and A is the Hall scattering factor (10), then $-1/qR = nA$. $-1/qR$ therefore represents the electron concentration in the layer if the Hall scattering factor is equal to unity, as commonly assumed in the literature (A is determined below).

In Fig. 2, we compare our measurements of μ_H vs. $-1/qR$ in some of our epitaxial layers with others re-

Fig. 2. Hall mobility vs. $-1/qR$ measured in this work and by other authors. There are no error bars in our data because they are smaller than the dots themselves.

Fig. 3. Phosphorus intensity vs. sputtering time measured by SIMS in a number of samples.

ported on as-grown (11, 12), diffused (13), and ion-implanted (14) P-doped Si. [The data of Ref. (13) and (14) have been represented by a curve fit reported in Ref. (14) so as to not unnecessarily complicate the figure with their large number of data points.] The agreement among these four sets of data is of the order of our experimental error, i.e., around 4% for the mobility. This finding clearly shows that this epitaxial material displays electrical properties identical to phosphorus-doped silicon fabricated by other methods. This fact remains true even at P concentrations higher than 10^{20} cm^{-3} .

The previously described measurements were carried out in two dies of each sample. The differences in value of $-1/qR$ between dies was less than 5%, showing a very good impurity homogeneity. Some of the samples that had a difference smaller than 2% were selected for secondary ion mass spectroscopy (SIMS) measurement of the total phosphorus concentration. These are the samples shown in Fig. 2.

SIMS analysis was carried out in a CAMECA IMS-3f ion microanalyzer with a 10 keV Cs^+ ion beam at a current of 3 μA . The mass 31 ions (corresponding to phosphorus)

were analyzed from a 30 μm diam area at the center of a crater 400 μm on the side. Some of the phosphorus intensity profiles obtained are shown in Fig. 3. The sputtering etch rate varies from sample to sample around a value of 0.25-0.3 $\mu\text{m}/\text{min}$. We are therefore looking in Fig. 3 at profiles approximately 0.5-0.8 μm deep. Figure 3, like the spreading resistance profile shown in Fig. 1, indicates that the impurity concentration is very flat next to the surface. Deeper profiling was not possible because of a calibration drift in the equipment with time. Because of this same problem, the P intensity in the same sample changed from measurement to measurement and batch to batch. However, the ratio of the P intensity to the Si intensity, the last one measured by means of a Faraday cup, was found to be constant for the same sample throughout all measurements. We assumed this ratio to be proportional to the phosphorus concentration in the layer through a constant denoted as k .

To be able to estimate the P concentration, we extract the value of k by relying on measurements of N_D made by neutron activation analysis (11, 12, 15, 16) by other authors on P-doped Si of similar resistivity values to ours. This process is described in detail in Ref. (2) and will not be repeated here. The constant k is estimated to be within 8%. Figure 4 collects the values of electrical resistivity vs. phosphorus concentration obtained by this procedure, together with those of other authors. The large error bars at low doping levels arise from the gaussian error in P counting (see Fig. 3).

From the data collected in Fig. 4, we can now obtain the conductivity mobility. It is shown in Fig. 5 vs. donor concentrations, together with other measurements from Thurber *et al.* (11, 12). The agreement is again excellent.

The ratio of Hall mobility to conductivity mobility is the Hall scattering factor. Combining Fig. 2 and 5, we can obtain this transport parameter (2), which is represented

Fig. 6. Hall scattering factor vs. $-1/qR$.

Fig. 7. Epitaxial layer growth rate vs. PH_3 partial pressure

in Fig. 6 vs. $-1/qR$, together with some previous determinations of it made in the literature (15-17). It is striking that A , usually assumed to be one, is clearly different than unity in most of the measurement range. In fact, it reaches a value of around 1.3 in the mid- 10^{18} cm^{-3} doping level and decreases to about 0.9 with $N_D > 10^{20}$ cm^{-3} . The theoretical calculations of A predict a value of 1.03 at low doping levels and 0.87 in the degenerate regime (18). These two limits are seen in our measurements that show, for the first time, that A indeed becomes smaller than unity at high doping. The determination of A carried out in this work requires the assumption of $n = N_D$, or, in other words, that all the impurities are located in substitutional position in the Si lattice, and all are ionized. These assumptions have been studied in detail in Ref. (2) and (9) and been found to be fulfilled within our experimental error. The agreement obtained at the high doping end between our measurements of A and the theoretical prediction confirms these assumptions.

Results

Figure 7 plots the growth rate vs. phosphine partial pressure. The growth rate is fairly constant up to a level of around 4×10^{-4} atm, above which it decreases abruptly. Similar results have been found by Gupta (19) in the $\text{AsH}_3/\text{SiH}_4$ and $\text{B}_2\text{H}_6/\text{SiH}_4$ systems. This phenomenon is probably related to the decay in the growth rate of the SiH_4 epitaxy at high temperatures for high SiH_4 partial pressures observed by Duchemin (20). He postulated that homogeneous nucleation occurs in the gas phase that consumes large amounts of SiH_4 , therefore reducing the SiH_4 available for growth. In our experiments, we

observed that, at the highest phosphine levels, a large amount of nucleation occurred, resulting in the deposition of a Si layer on the walls of the reactor.

Figure 8 collects the resulting phosphorus concentration in the epitaxial layer vs. the partial pressure of PH_3 in the reaction tube. A maximum doping level of 1.6×10^{20} cm^{-3} has been reached, which, to the knowledge of the authors, is the highest ever obtained by epitaxy.

For low phosphine partial pressures, the proportionality between the doping level of the growing layer and the phosphine partial pressure is linear. At a p_{PH_3} of about 10^{-6} atm, corresponding to $N_D \approx 3 \times 10^{19}$ cm^{-3} , the doping level goes as the partial pressure to the 1/4 power. A similar phenomenon has been reported by Bloem *et al.* (21, 22). He observes a transition from a linear regime into a square root regime that occurs at a doping level decreasing with increasing temperature (23). The critical point from this 1/2 regime into the 1/4 regime increases with temperature. At our 1050°C growth temperature, these critical concentrations seem to have merged into a gradual transition that almost erases the 1/2 regime.

To study these phenomena in further detail, we plot in Fig. 9 the critical concentrations vs. growth temperatures obtained by Bloem and us. We denote N_{D1} the doping level at which the 1 to 1/2 transition occurs, and N_{D2} corresponding to the 1/2 to 1/4 transition. At $T = 1500$ K, we can only assess a lower limit of N_{D2} from the experiments of Bloem.

As previously mentioned, N_{D1} decreases with the deposition temperature. This behavior is related not so much to the transition as to the linear regime itself, since at any given phosphine partial pressure the incorporation of dopant decreases as the temperature increases. In fact, this has also been observed by Reif *et al.* (24) in the $\text{AsH}_3/\text{SiH}_4$ system in this dilute regime. They observed a slope of 30 kcal/mol, while we observe from Fig. 9 a value of 38 kcal/mol for our PH_3/SiH_4 system. They explained this behavior as arising from the dominance of surface mechanisms as the doping process in their $\text{AsH}_3/\text{SiH}_4$ system (25).

What is striking about this transition from the linear to the square root regime is that, within the measurement error, it occurs at the same phosphine partial pressure throughout the almost 300°C that separates the highest deposition temperature of Bloem and ours. This value is $\sim 10^{-6}$ atm. As postulated by Swanson and Tucker (23) and Bloem *et al.* (21), this square root proportionality arises from the gas phase decomposition of the PH_3 molecule into the phosphorus monomer, P, and phosphorus dimer, P_2 . In computer calculations of the equilibrium partial pressures of all the components of the PH_3/SiH_4 mixture carried out by Bloem *et al.* (21, 22), it is found that the phosphorus dimer becomes the prevalent species

Fig. 8. Phosphorus doping level in epitaxial layer vs. phosphine partial pressure.

Fig. 9. Temperature dependence of the critical concentrations that separate the different regimes of the N_D vs. P_{PH_3} curve. The extrapolated values of n_i , the intrinsic carrier concentration, of Morin and Maita are also shown.

at partial pressures of phosphine of around 10^{-6} atm, this value being rather independent of temperature. The phosphorus dimer is in equilibrium with all the other species, in particular with the phosphorus monomer P which is further postulated to be the only source of dopant that becomes incorporated to the growing layer. Therefore, as the calculations of Bloem show, at around 10^{-6} atm the concentration of phosphorus monomer becomes square-root dependent on the initial phosphine partial pressure, and this behavior determines the P concentration in the epitaxial layer.

The second transition from 1/2 to 1/4 dependence of the P doping level in the growing layer vs. the phosphine partial pressure (N_{D2} in Fig. 9) has been related to the semiconductor becoming extrinsic due to the high concentration of donors (21). We have also noted in Fig. 9 the values of n_i , the intrinsic carrier concentration in silicon, given by Morin and Maita (26). The absolute values of n_i disagree systematically from N_{D2} by about a factor of two; however, the temperature dependence appears very similar. The highest temperature at which Morin and Maita carried out measurements was about 1000 K, the line plotted in Fig. 9 being an extrapolation of their fitting. It is not surprising, therefore, that the absolute values differ, while the slope is similar. An additional source of the difference can be the bandgap narrowing that arises from the high concentration of donors. This phenomenon tends to increase the value of n_i from its low doping value.

We have further studied the dopant incorporation in the epitaxial layer at high doping levels by analyzing the growth rate dependence. Figure 10 shows the resulting value of $-1/qR$ (the actual doping level is around 0.9 times this value) and growth rate vs. silane partial pressure, for a fixed phosphine partial pressure of 3.8×10^{-3} atm. The growth rate is found to be linear with the silane

Fig. 10. Values of growth rate and $-1/qR$ (related to doping level through the Hall scattering factor) vs. silane partial pressure at a fixed phosphine level.

concentration. However, the doping level increases with silane partial pressure until it reaches a maximum beyond which it decreases again. This behavior has been observed and explained by Bloem (22, 27) at lower doping levels. For low silane partial pressures and low deposition temperatures, a trapping of phosphorus atoms at the growing interface occurs if the phosphorus diffusion coefficient is sufficiently small so as to prevent the buried atom from diffusing to the growing surface and escape from it. The phosphorus atom in the solid is not in thermodynamic equilibrium with the gas phase. As the growth rate increases and all donors reaching the surface are trapped, the concentration in the layer decreases since they become buried in a fast growing epitaxial layer. This effect is less pronounced at this very high doping regime than in the low 10^{19} cm^{-3} level at higher temperatures, as observed by Bloem, probably due to the larger phosphorus diffusion coefficient that occurs at high doping levels (28).

Finally, Fig. 11 collects the density of etch pits defined by a 5 min Secco etch and its dependence on doping.

Fig. 11. Density of etch pits defined by Secco etch vs. phosphorus concentration.

There is a strong correlation between doping level and defect density, with the latter increasing roughly on the square of the doping density. The defect seems to be perfect dislocations probably due to strain-induced misfit.

The values here reported, between 100 and 3000 cm⁻² are compatible with the fabrication of the devices for the characterization of minority carrier transport in the heavily doped epitaxial layers. At the time of this writing, vertical and lateral bipolar transistors have been fabricated on these layers, and measurements of hole diffusion length, diffusion coefficient, lifetime, and bandgap narrowing are in progress.

Conclusions

Phosphorus-doped silicon layers have been grown by epitaxy in a PH₃/SiH₄ system. Doping levels as high as 1.6 × 10²⁰ cm⁻³ have been obtained. Electrical characterization of the layers has resulted in detailed measurements of electron mobilities and Hall scattering factor throughout nearly three decades of doping level. A regime in which the phosphorus concentration is proportional to the phosphine partial pressure through a power law with exponent 0.25 has been clearly observed.

Acknowledgments

The authors thank the staff of the Integrated Circuits Laboratory, where all layers were grown. We have benefited from discussions and help from Dr. John Shott, Mr. Richard Crane, Dr. Young Kwark, and Professor Krishna Saraswat. The van der Pauw measurements were carried out in Professor James Gibbons' laboratory. The work was partially funded by the Joint Services Electronics Program. ABSTRACT

A new etching solution, aqueous potassium peroxodisulfate, was developed for etching GaAs. The peroxodisulfate ion is a powerful oxidizing reagent which can extract two electrons and oxidize the GaAs surface. Because this solution is acidic with pH value of 2, it can dissolve the oxidized product. The most significant feature of the solution is that its etching rate is extremely slow, i.e., 150 Å/min, and can be further reduced by adding NaOH to the solution. It is found that adding HCl does not enhance the etching rate but does significantly improve the morphology of the etched surface.

Chemical etching of semiconductors plays an essential role in electron device technology and is, therefore, widely employed in the fabrication of many useful devices, e.g., n-type GaAs Schottky-barrier field-effect transistors (MESFET's) (1). Most power and low noise analog FET's use a recessed gate geometry in which the gate

stripe is placed in an etched slot to locate it slightly below the semiconductor surface (2). The depth, typically 800-2500 Å, to which the gate is recessed is a critical parameter in FET performance. In the past, this etching was almost always done by wet etching using a chemical solution that is composed of an oxidant (H₂O₂) and an acid or

base solvent (3). The strength of the etchant should be adjusted by dilution to provide an adequate etching rate that is sufficiently slow to allow good control over the recess process. Usually, the dilution is so great that reproducibility is a problem. In this paper, we propose a new solution, $K_2S_2O_8 + H_2O$ for etching GaAs that solves the problem.

Experimental

The samples we studied include (i) Si-doped (100) GaAs with carrier concentration in the range of 10^{18} cm^{-3} and (ii) Cr-doped semi-insulating GaAs crystals. In order to measure the etching profile and etching depth, the GaAs surface was first covered with photoresist, and then a $10 \mu\text{m}$ (or $25 \mu\text{m}$) wide stripe window was opened by standard photolithography techniques. The stripes were visually aligned with respect to the (011) or (0 $\bar{1}$ 1) cleavage planes of the sample. The $\langle 01\bar{1} \rangle$ and $\langle 011 \rangle$ directions in the (100) plane were determined by etching a striped test sample along the natural cleavage plane to see whether the channel is V or U shaped (4).

The etching solution was prepared by dissolving 2.7 or 1.4g $K_2S_2O_8$ powder in 50 cm^3 deionized water. Since the solubility of $K_2S_2O_8$ in 50 cm^3 water is 0.875 g at 0°C and 2.65 g at 20°C (5), the prepared etching solution is already saturated for 2.7g case or undersaturated for 1.4g case. Sometimes, acid (HCl) or base (NaOH) was added to the prepared potassium peroxodisulfate aqueous solution to study its effect on etching rate. The temperature of the etching solution was varied between 9° and 70°C to study the activation energy of the etching process. After etching, the photoresist mask was removed and the sample was rinsed in deionized water. Then, the etching depth and etching profiles were measured along the (011) and (0 $\bar{1}$ 1) planes using either an optical microscope or scanning electron microscope (SEM).

Fig. 1. Etching depth as a function of the etching time. Temperature is 20°C .

Results

Figure 1 shows the etching depth as a function of the etching time using four different solutions, i.e., 2.7 and 1.4g of $K_2S_2O_8$ in 50 cm^3 water and 50 cm^3 water + 10 cm^3 HCl, respectively. It is seen that initially the etching rate at room temperature is constant and extremely slow, i.e., $150 \text{ \AA}/\text{min}$, and then gradually the etching rate slows down even further. It is also clear that the etching rate of the 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 H_2O$ (2.7g KH) is almost the same as that of 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 H_2O + 10 \text{ cm}^3 HCl$ (2.7g KHH) solution, but is faster than those of the 1.4g $K_2S_2O_8 + 50 \text{ cm}^3 H_2O$ (1.4g KH) and 1.4g $K_2S_2O_8 + 50 \text{ cm}^3 H_2O + 10 \text{ cm}^3 HCl$ (1.4g KHH) solutions. To etch 800-2500 \AA depth of GaAs using this saturated solution, it takes as long as 5-16 min and, therefore, is very easy to control. The etching depth of the 1.4g KH solution is initially the same as that of the saturated one, but gradually it falls behind. The reason for this is that the 2.7g KH solution is oversaturated and has $K_2S_2O_8$ solid remaining in the solution. The $S_2O_8^{2-}$ ion grabs two electrons and decomposes into two SO_4^{2-} ions; the solid $K_2S_2O_8$ which remains in the solution will then dissolve to supply the $S_2O_8^{2-}$ ions. Therefore, the concentration of peroxodisulfate ion is always constant during the etching process. However, the concentration of peroxodisulfate ion in 1.4g KH solution (undersaturated) decreases gradually during the etching process which results in a slower etching rate after a long etching time.

Figure 2 shows the etching depth as a function of temperature for a period of 60 min. The activation energies were determined to be 10 kcal/mol for 2.7g KH and 2.7g KHH, 8.7 kcal/mol for the 1.4g KH, and 5.5 kcal/mol for the 1.4g KHH solutions.

It is well known that the dissolution process of a solid surface is either reaction-rate limited or diffusion limited. If the former process is the rate-limiting one, the etched depth d will depend linearly on etching time t , i.e., $d \propto t$, however, if the latter process is the dominant one, d is related to t through $d \propto t^{0.5}$ (6). Usually, the diffusion-limited process has lower activation energy than that of the reaction-rate-limited process, for example, Iida and Ito (7) have studied the etching characteristics of (001) GaAs in

Fig. 2. Etching depth as a function of temperature for a period of 60 min.

Fig. 3. The etching shape and etching depth for different etching solutions at room temperature. a: 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 \text{ H}_2\text{O}$. b: 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 \text{ H}_2\text{O} + 10 \text{ cm}^3 \text{ HCl}$.

the $\text{H}_2\text{SO}_4\text{:H}_2\text{O}_2\text{:H}_2\text{O}$ system and obtained activation energies of 6-8 kcal/mol for the diffusion-limited process and 8-11 kcal/mol for the reaction-rate-limited process. Since the etching depth depends linearly on time initially, as shown in Fig. 1, the etching process in these etching solutions is probably controlled by a reaction-rate-limited process at least in the initial few hours. Another way to distinguish which process dominates is to measure the etching rate while stirring. The diffusion-limited process shows a notable stirring effect on the etching rate, while the reaction-rate-limited process does not unless the solution is supersaturated. In 1.4g KHH and 1.4g KH solutions, the etching depths for a period of 60 min are 1.0 μm both with and without stirring, which indicates that the reaction-rate-limited process indeed dominates. In 2.7g KHH and 2.7g KH solutions, however, the etching depth for a period of 60 min is 1.4 μm with stirring and 1.1 μm without stirring, which we believe is not because the diffusion-rate-limited process dominates, but because the solution dissolves more $K_2S_2O_8$ under stirring conditions which enhances the reaction rate.

Figure 3 shows the etching time effect on GaAs along $\langle 011 \rangle$ and $\langle 0\bar{1}\bar{1} \rangle$ directions using 2.7g KH and 2.7g KHH etching solutions, respectively. The etching depth for a period of 20 min is the same, *i.e.*, 3000Å, for either etching solution. The etching profiles using 2.7g KH solution with different etching times are shown in Fig. 3a. A V-shaped etching profile was gradually observed on the $(01\bar{1})$ planes. The etching profiles using 2.7g KHH solution on the (011) planes are shown in Fig. 3b. The top and second figures show an etched step with photoresist protecting a narrow stripe. The third and bottom figures show the U-shaped etching profile which results from etching through a 25 μm wide photoresist window. These etching characteristics are similar to other etching solutions (8).

Figures 4a, 4b, and 4c show the etching effect of KH solution alone, with adding acid (HCl) and base (NaOH), respectively. It is clear that the etching rate is the same for both 2.7g KH and 2.7g KHH solutions, as shown in Fig. 4a and 4b, but the morphology of 2.7g KHH is much better than that of 2.7g KH solution. The etching rate, however, is much reduced to below 10 Å/min by adding NaOH into the solution, as shown in Fig. 4c.

Figure 5 shows the morphology of the etched step of GaAs using 2.7g KHH solution for periods of 20 and 60 min, respectively. In general, the etched surface is very

Fig. 4. Etching characteristics of 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 \text{ H}_2\text{O}$ (a), 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 \text{ H}_2\text{O} + 10 \text{ cm}^3 \text{ HCl}$ (b), 2.7g $K_2S_2O_8 + 50 \text{ cm}^3 \text{ H}_2\text{O} + 10 \text{ cm}^3 (1\text{M NaOH})$ (c) solutions. The etching times are all 90 min.

flat. This indicates that adding HCl removes the oxidized products on the GaAs surface more effectively. We also studied the etching rate of Cr-doped (100) GaAs wafers. It is found that by using 2.7g KHH solution the etching depths for a period of 20 min are the same for both Si- and Cr-doped GaAs, *i.e.*, 3000Å. Therefore, the etching rate is not affected by the conductivities of the wafers.

Discussions

Most etchants are generally composed of an oxidant and an acid (base) solvent. The purpose of the oxidant is to oxidize the substrate. The oxidized products are then dissolved in the acid or base solvent. The peroxodisulfate ion is a powerful oxidizing reagent (9). The reduction potential ΔE for the half-reaction

has been estimated to be 2.01 eV (9). The oxidizing mechanism may be varied with reaction conditions; there is good evidence for the formation of the radical anion $\text{SO}_4^{\cdot -}$ by one-electron reduction (10)

In the absence of inorganic or organic reactants, the $\text{SO}_4^{\cdot -}$ radical anions react very rapidly among themselves to reform $\text{S}_2\text{O}_8^{2-}$ with a second-order rate constant of $3.7 \times 10^6 \text{ M}^{-1}\text{-S}^{-1}$ (11). The radical anion $\text{SO}_4^{\cdot -}$ is stable in acidic

Fig. 5. The etching characteristics of 2.7g $K_2S_2O_8$ + 50 cm³ H_2O + 10 cm³ HCl solution. a: Etching time is 20 min; the etched depth is 3000Å. b: Etching time is 60 min; the etched depth is 9200Å.

Fig. 6. The etching rate does increase by adding H_2SO_4 into $K_2S_2O_8$ + H_2O solution. a: 2.7g $K_2S_2O_8$ + 50 cm³ H_2O + 10 cm³ H_2SO_4 . b: 1.4g $K_2S_2O_8$ + 50 cm³ H_2O + 10 cm³ H_2SO_4 . Temperature is 20°C. The etching time is 20 min.

and neutral solutions, but very unstable in alkaline solution because of fast reaction with hydroxide ions with a large rate constant $7.3 \times 10^7 M^{-1}S^{-1}$ (12)

Since the OH radical is less active than $SO_4^{\cdot-}$, the oxidation process is slowed down. This explains the extremely slow etching rate by adding NaOH into KH solution.

In acidic solution, the peroxodisulfate ion is converted to $H_2S_2O_8$ followed by the hydrolysis to obtain the peroxomonosulfuric acid and sulfuric acid (9)

The final reaction is

The pH value of 2.7g KH is 2, and, therefore, it is an acid solution. It is also found that the etching rate was much enhanced by adding H_2SO_4 into KH solution, as shown in Fig. 6. The etching rates were 1300 and 500 Å/min using one H_2SO_4 + five (2.7g KH) and one H_2SO_4 + five (1.4g KH) solutions, respectively. The etched surface morphology was poor. Since the etching rate was not enhanced by adding HCl into KH solution but the etched surface morphology was much improved, as shown in Fig. 3 and 5, it is concluded that the oxidation process is the etching rate-limited process. From Eq. [1], we can find that increasing the concentration of SO_4^{2-} ion will also increase the concentration of $S_2O_8^{2-}$ ion. Therefore, adding H_2SO_4 will enhance both the oxidation and dissolving rate and thus enhances the etching rate which ends up with a poor surface. The HCl enhances only the dissolution rate but not the oxidation, which improves the morphology of the etched surface.

Conclusions

New etching solutions composed of $K_2S_2O_8$, H_2O , and HCl have been developed for the etching of GaAs. The etching mechanism is believed to entail sequential one-electron transfer oxidations of the GaAs followed by dissolution. The final products should be Ga^{3+} , As^{3+} , SO_4^{2-} . This system has an extremely slow etching rate and results in a high quality surface. To etch 800-2500Å depth of GaAs using 2.7g KHH solution takes as long as 5 to 16 min, and, therefore, it is very easy to control. The etching rate does not degrade much after a long period of etching time, i.e., 3 days. It is thus a reliable and reproducible etching solution.

ABSTRACT

The etching kinetics and electrochemistry of GaAs in aqueous CrO₃-HF solutions were studied. For solutions with a low [HF]/[CrO₃] ratio, etch rates in the dark depend only on the HF concentration and are similar for n-type and p-type GaAs. Illumination strongly increases the etch rate of n-type material but has no effect on p-type dissolution. From current and impedance measurements, it was concluded that Cr^{VI} reduction gives rise to a passivating film on GaAs, which inhibits further hole injection from the oxidizing agent. The limiting quantum efficiencies for Cr^{VI} reduction at illuminated p-type electrodes and for GaAs dissolution at n-type electrodes are significantly greater than unity. At higher [HF]/[CrO₃] ratios the etch rate of both n- and p-type GaAs is determined by Cr^{VI} diffusion in solution. Conclusions concerning the etching mechanism are drawn on the basis of these results.

During the past decade, GaAs and related compounds have become increasingly important for applications in electronic and optoelectronic devices. The crystallographic perfection of these III-V materials directly influences electrical and optical properties and determines device performance and lifetime. One of the most straightforward and powerful methods of defect characterization is, without doubt, wet chemical etching. For GaAs a large number of etchants has been reported (1-4). Most of these etching systems have only been investigated phenomenologically; dissolution rates and surface morphology were studied, but very little attention was paid to the essential chemistry involved.

In this series of papers, a study of the mechanism of the recently developed "DSL-system" for GaAs is presented. DSL refers to "diluted Sirtl-like etchants with the use of light." This system, which is based on CrO₃, HF, and H₂O, has already been described phenomenologically in earlier papers (5-7). With an appropriate choice of solution composition, all crystallographic defects can be revealed in n-type, p-type, and semi-insulating GaAs with high sensitivity. A special feature of this system is that defects are revealed as hillocks on the surface during etching, not only under illumination, but also in the dark. This means that the etch rate of crystallographic imperfections is lower than that of the surrounding material.

Dissolution of GaAs in strongly oxidizing solutions, such as the present CrO₃/HF system, generally takes place via a valence-band process (8, 9). The energy levels of the oxidized states of the redox couple in solution overlap with the valence band of the semiconductor, and holes are supplied to the solid with reduction of the oxidizing agent (8, 9). Localization of holes at the surface of the semiconductor causes rupture of GaAs bonds and results in dissolution. In such "electroless" systems, the rate of reduction of the oxidizing agent, and, consequently, the hole supply to the solid, is equal to the rate of oxidative dissolution of the semiconductor. Since reduction of Cr^{VI} and oxidation of GaAs are potential-dependent reactions, the electrochemistry of the system was studied, together with the etching kinetics, to obtain insight into the mechanism of the etching process. The results of this study are presented in this article. In the second part of this paper, a model is proposed which can explain both the etching and electrochemical results. The morphological aspects of etching in CrO₃-HF solutions will be discussed in a separate paper (10).

Experimental

GaAs crystals, used in this study, were grown by the horizontal Bridgman technique. The wafers were (100)

oriented and supplied by different manufacturers. The n-type samples were silicon doped with a carrier concentration in the range $1.0-2.8 \times 10^{18} \text{ cm}^{-3}$; the p-type samples were zinc doped and had a carrier concentration of $0.8-1.3 \times 10^{18} \text{ cm}^{-3}$. The wafers were first mechanochemically polished. To remove impurities and work damage, various surface pretreatment methods were used. These included anodic polishing in an EDTA electrolyte (11) and etching in H₂SO₄/H₂O₂/H₂O solutions followed, in all cases, by dipping in a diluted HCl solution.

The open-circuit etching kinetics were studied with the same experimental setup as described previously (5). To vary the intensity of the 24 mW, 632.8 nm He-Ne laser at the sample surface, the beam diameter was varied and neutral density filters were used. Homogeneity of the laser spot was maintained within 5% limits. A light power of 150 mW/cm² was used with a spot diameter of 4.5 mm, except for the measurements in which the light intensity was varied. During etching, the solution was not stirred and depletion of solution constituents was not significant. The GaAs samples were partly masked with Apiezon W or photoresist, and the etched depth was measured with a step profiler.

For the electrochemical measurements, both stationary and rotating disk (RDE) electrodes were used. These were mounted in a Teflon cell. Current-potential characteristics were recorded with a Wenking POS73 potentiostat. Impedance measurements were performed with a Solartron 1172 frequency response analyzer using a 10 mV rms signal at 10 kHz. Flatband potentials (V_{FB}) were determined from Mott-Schottky plots (12). A saturated calomel electrode (SCE) was used as a reference, and all potentials are expressed with respect to SCE. A platinum foil served as counterelectrode. A He-Ne laser was also used as light source for the electrochemical measurements.

HF (p.a. grade) was obtained from Merck. In previous work (5), one particular batch of CrO₃ (analar grade), supplied by BDH Chemicals Limited (Poole, England) was used exclusively. In etchants with a low HF concentration ($\leq 2.5M$) containing this CrO₃, the etch rate of n-type GaAs was found to be zero. Subsequent experiments with other batches from BDH (analar grade) and from other suppliers (Merck, p.a. grade and Baker, reagent grade) showed this behavior to be anomalous. The reason for this anomaly is not understood. All etch rates, with the exception of those obtained using the particular batch mentioned above, were reproducible to within 5-10%. The anomalous results with n-type GaAs at low HF concentration are omitted from this work. The electrochemical experiments were performed with CrO₃ (p.a. grade) supplied by Merck. Concentrations are expressed in moles per liter (M).

All measurements were performed at room temperature.

Results

From an extensive study of GaAs etching in CrO_3 -HF solutions reported elsewhere (10), it was clear that the ratio of the HF and CrO_3 concentrations is very important for the etching kinetics. Consequently, the etching and electrochemical results, described in this section, are classified on the basis of this ratio. In the present work, only HF concentrations lower than 10M have been used.

High [HF]/[CrO₃] ratios.—For solutions with [HF]/[CrO₃] ratios > 20, the steady-state open-circuit etch rate of GaAs is independent of semiconductor type and depends linearly on the CrO_3 concentration (Fig. 1). In this range, the HF concentration is not important. The etch rate is sensitive to stirring in the solution. If it is assumed that six holes are required to dissolve one GaAs molecule (13), then the measured etch rate agrees well with that calculated from the diffusion-controlled reduction current of Cr^{VI} , as described below. The etching reaction is obviously determined by diffusion of the oxidizing agent in solution. Consequently, it was not surprising that illumination was found to have no effect on the etching kinetics.

The current-potential curves for n-type GaAs in this range seem to conform to the pattern expected for hole injection from a simple redox system (8). A well-defined cathodic current plateau is observed at potentials positive with respect to the flatband value (Fig. 2). This limiting current depends linearly on the CrO_3 concentration and is directly proportional to the square root of the electrode rotation rate, i.e., cathodic reduction of Cr^{VI} is diffusion controlled. Because of the obvious similarity between curve a of Fig. 2 and the corresponding curve for Ce^{IV} reduction (8), it is tempting to interpret these results in terms of a simple hole-injection mechanism: in the range in which a constant cathodic current is observed, the electron concentration in the space-charge layer is still appreciable, and holes, provided by Cr^{VI} species in solution, recombine with electrons supplied from the bulk (8, 14). At more positive potentials, corresponding to a large band bending, the surface electron concentration is greatly reduced and recombination is no longer possible. The injected holes are held at the surface and cause the solid to dissolve. Since the holes injected from Cr^{VI} are consumed in this reaction, the measured (total) current

decreases to a very low value. The diffusion-controlled hole injection current (curve b) is compensated by the anodic dissolution current (curve c).

However, the results obtained with p-type GaAs show that this description cannot be completely valid. The expected characteristics for a p-type electrode (9) are only observed at extremely high [HF]/[CrO₃] ratios. A current-potential curve for an electrolyte with a concentration ratio of 10⁴ is shown in Fig. 3. At more positive potentials, GaAs is anodically dissolved. At negative potentials, a constant cathodic current is observed. From the dependence of this limiting current on CrO_3 concentration and electrode rotation rate, it can be concluded that the reduction reaction is again limited by mass transport of Cr^{VI} species in solution. In this case, it is clear that the open-circuit etch rate must be determined by the diffusion-

Fig. 3. Current-potential curve for a p-type GaAs RDE in 10⁻³M CrO_3 , 9.0M HF solution at 500 rpm. V_r is the rest potential. Scan rate: 10 mV/s.

controlled reduction of Cr^{VI} . For lower $[\text{HF}]/[\text{CrO}_3]$ ratios (but ones still > 20), the etching kinetics remain unchanged (Fig. 1), but the corresponding current-potential curves deviate considerably from that shown in Fig. 3. The current, which was less well defined, depended strongly on the scan rate, scan direction, and prepolarization potential. Under certain conditions, a current plateau could be observed. However, in most cases a cathodic peak was found at potentials just negative of the rest potential (see results in the following section) and the cathodic current was lower than that expected for a diffusion-controlled process. There seem to be discrepancies, therefore, between the electrochemical results for n- and p-type GaAs and between the electrochemical and etching results of p-type GaAs.

For these CrO_3 -HF solutions, electrode passivation behavior is observed at higher HF concentration. During continued potentiodynamic scanning in the dark, the current gradually decreases. In a 9M HF solution without CrO_3 , the photocurrent at n-type GaAs also decreases in time and a dark layer is formed on the electrode. Removal of this layer and reactivation of the electrode occurs when a small amount of CrO_3 is added to the HF solution. Most probably, the passivating layer consists of an insoluble gallium fluoride $[\text{GaF}_3 \cdot n\text{H}_2\text{O}]$ (15), whose solubility is influenced by the chromium species in solution. Measurements described above were only made at shorter times, for which passivation was not important.

Low $[\text{HF}]/[\text{CrO}_3]$ ratios.—Dark.—For solutions with a $[\text{HF}]/[\text{CrO}_3]$ ratio lower than 10, the open-circuit etch rate of GaAs is practically independent of the CrO_3 concentration but depends strongly on the HF concentration (Fig. 4). A comparison of Fig. 4a and 4b (solid circles) shows that the etching kinetics for p and n-type GaAs in the dark are similar.

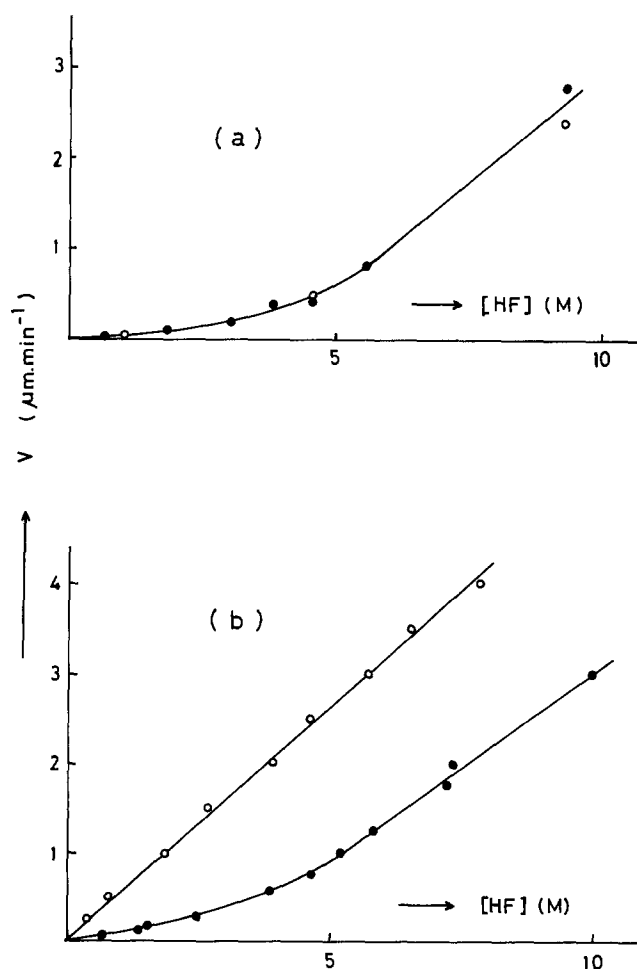

Fig. 4. Open-circuit etch rate as a function of HF concentration for solutions with low $[\text{HF}]/[\text{CrO}_3]$ ratio. Figure 4a refers to p-type, and 4b to n-type GaAs. Solid circles: Dark. Open circles: illuminated.

Fig. 5. Current-potential plot for a p-type GaAs electrode in 1.20M CrO_3 , 1.54M HF solution. Scan rate: 2 mV/s.

The current-potential curve of p-type GaAs (Fig. 5) is markedly different from that observed for very high concentration ratios and more pronounced than that found for lower ratios in the concentration range $[\text{HF}]/[\text{CrO}_3] > 20$. At potentials close to or positive with respect to the flatband potential (see Table I), anodic dissolution of GaAs is evident in the sharply rising current. At potentials negative with respect to the rest potential, the cathodic reduction of Cr^{VI} does not give a diffusion-controlled plateau. Instead, a peak is observed (Fig. 5). At more negative potentials, the current decreases to a very low constant value. This latter value depends on the square of the HF concentration (Fig. 6). The peak is reproducible and is independent of the potential scan direction at lower scan rates. As the cathodic current does not depend on the rotation rate of the electrode, it can be concluded that the reduction reaction is kinetically determined.

Analogous behavior was observed for n-type electrodes in these solutions. Instead of a diffusion-controlled cathodic current, a sharp peak is again observed (curve a in Fig. 7). In contrast to p-type GaAs, the peak shows considerable hysteresis even at very low scan rates: the current observed during the cathodic scan was markedly higher than that observed in the return scan. The peak height was, however, reproducible and independent of the scan rate when the potential was scanned in the cathodic direction. The peak currents for n- (cathodic scan)

Fig. 6. The limiting cathodic current i_{lim} of p-type GaAs (measured at $-0.50V$) as a function of HF concentration for solutions with relatively low $[HF]/[CrO_3]$ ratio. The CrO_3 concentration was constant ($1.20M$).

and p-type electrodes were identical and depended on the square of the HF concentration (Fig. 8). The peak current was considerably lower than the current calculated from the open-circuit etch rate at the same HF concentration. The etch rate was, however, substantially lower than that expected for a dissolution process limited by diffusion of Cr^{VI} in solution.

It is obvious, both from the etching and electrochemical results presented above, that the reduction of Cr^{VI} is seriously inhibited at GaAs electrodes. From the flatband potential measurements given in Table I for an indifferent electrolyte ($0.5M H_2SO_4$) and various CrO_3 -HF solu-

Fig. 7. Curve a is the current-potential curve for an n-type GaAs electrode in $1.20M CrO_3$, $1.54M HF$ solution. Curve b was measured in $0.5M H_2SO_4$ solution. Scan rate: $10 mV/s$.

tions, it follows that the position of the bandedges of the semiconductor is not significantly affected by the presence of HF or chromium containing species in the electrolyte. Since the standard redox potential of the Cr^{VI}/Cr^{III} couple is very positive (16), efficient hole injection from Cr^{VI} is then expected at GaAs electrodes (8, 9, 12). This is obviously not the case. A similar inhibition of the Cr^{VI} reduction has been observed at metal electrodes and has been attributed to the formation of a blocking film on the electrode surface (17-19). From the results presented above, it must be concluded that a film is also formed on GaAs. For an n-type electrode, the cathodic current at potentials negative with respect to the peak begins to increase again (Fig. 7, curve a) before H_2 evolution is normally observed under these conditions (Fig. 7, curve b). This suggests that electrons, which are available in n-type material in the dark at potentials approaching V_{FB} are capable of reducing the blocking layer.

Further evidence supporting the formation of such a layer in these electrolytes was obtained from measurements with a Pt electrode. At potentials negative with respect to the Cr^{VI}/Cr^{III} redox potential, the electrode was clearly passivated, as only a very small constant cathodic current was observed. In contrast to GaAs electrodes, a current peak was not found at low scan rates. The cathodic current at the Pt electrode began to increase markedly at approximately $0V$ (SCE). Since this potential is more than $200 mV$ too positive for hydrogen evolution, the cathodic current must be attributed to reduction of a chromium species. This again indicates a breakdown of the passive layer, analogous to that found with n-GaAs electrodes.

Illuminated.—While illumination has no effect on the open-circuit etch rate of p-type GaAs (open circles in Fig. 4a), dissolution of n-type material is strongly accelerated by light (open circles in Fig. 4b). The etch rate was found to be linearly dependent on the photon flux at low light intensities but tended to a limiting value at high intensities (10). The photoetch rates, shown in Fig. 4b, were measured at high intensity.

Illumination of a p-type electrode has no effect on the current-potential curve in the vicinity of the rest potential but considerably enhances the cathodic current at more negative potentials (Fig. 9, curve a). For comparison, the photocurrent in a $0.5M H_2SO_4$ solution is also given at the same light intensity (curve b). In the latter case, photo-generated electrons give rise to hydrogen evolution at the

Fig. 9. Current-potential plot for a p-type GaAs electrode in 1.20M CrO_3 , 1.54M HF solution under illumination (curve a). Curve b gives the photocurrent in a 0.5M H_2SO_4 solution at the same light intensity. Scan rate: 10 mV/s.

electrode surface. This electron transfer must compete with an effective electron-hole recombination in the surface region (20). A considerable overpotential must be applied to reduce the surface concentration of the majority carriers and thereby the recombination rate, in order for a photocurrent to be observed. In the limiting photocurrent potential range, a quantum efficiency close to unity was found for H_2 evolution in the H_2SO_4 solution, i.e., one electron is transferred per absorbed photon.

The photocurrent curve for the CrO_3 -HF solution differs in two essential respects from that measured in 0.5M H_2SO_4 . First, current onset in CrO_3 -HF solutions is observed at more positive potentials, which suggests that the redox reaction can compete more effectively with the recombination process. However, recombination still dominates the current-potential characteristics at the rest potential. Consequently, etching of p-type GaAs is unaffected by illumination. Second, the limiting photocurrent for a CrO_3 -HF solution is much higher than the corresponding hydrogen current at the same light intensity. This effect is further demonstrated in Fig. 10, which shows the current, measured at -1.0V in H_2SO_4 and CrO_3 -HF solutions, as a function of light intensity. From these results it follows that six to ten charge carriers are transferred for every photon absorbed. This shows that the creation of minority carriers by light has a significant effect on the blocking film at the electrode surface. As already suggested for n-type GaAs, reduction of the film by electrons very likely frees the surface and allows further hole injection into the valence band by the Cr^{VI} species in solution.

The "depassivation" of a p-type electrode by light could be used to get an indication of the thickness of the blocking layer. Under strong illumination, the passivated surface is freed. When the light is switched off, the electrode, of course, repassivates. We measured the current involved in the repassivation as a function of time. The corresponding charge was equivalent to the formation of a thin film at monolayer or submonolayer coverage.

Illumination of an n-type GaAs electrode gave a limiting dissolution photocurrent (Fig. 11), which was the same as that found in a 0.5M H_2SO_4 solution. Both the rest potential and the cathodic peak are shifted to lower potentials with respect to the dark case. The peak current increases slightly with illumination intensity. The hysteresis observed in the cathodic peak is less pronounced under illumination than in the dark and disappears completely at relatively high light intensity (insert in Fig. 11).

Fig. 10. The limiting cathodic photocurrent at -1.0V as a function of light intensity as obtained with a p-type GaAs electrode in 0.5M H_2SO_4 (a) and in 1.20M CrO_3 , 1.54M HF (b) solutions. The light intensity is given in relative units.

It should be noted that in pure CrO_3 solutions no current was observed. Addition of a small amount of HF activated the electrode and the expected limiting photocurrent was measured.

In order to correlate the photocurrent and photoetching experiments with n-type material, the etch rate was measured at various potentials under potentiostatic conditions. Results in Table II are expressed in terms of a quantum efficiency ϕ defined as

$$\phi = \frac{10^{-4} n F \rho (v_1 - v_d)}{60 M i_{\text{ph}}} \quad [1]$$

where v_1 and v_d refer to the etch rates (in microns per minute) under illumination and in the dark at the same potential, ρ and M are the density and molecular weight of GaAs, F is the Faraday constant, and n ($= 6$) is the number of holes required to dissolve one GaAs molecule. Since the quantum efficiency for photoanodic dissolution of n-type GaAs in indifferent electrolyte is close to unity, the limiting photocurrent i_{ph} determined in H_2SO_4 solution was used as a measure for the photon flux in Eq. [1]. The results in Table II show that, in CrO_3 -HF solutions, quantum efficiencies for etching considerably greater than 1 are obtained both at the rest potential and at more positive potentials.

Discussion

At very high $[\text{HF}]/[\text{CrO}_3]$ ratios, the VB reduction of Cr^{VI} is limited by diffusion of the oxidizing agent in solution and the open-circuit etch rate of GaAs is consequently diffusion controlled (Fig. 1). At lower $[\text{HF}]/[\text{CrO}_3]$ ratios but still larger than 20, an apparent anomaly is observed. Although the etch rate of both p- and n-type material is diffusion controlled, the cathodic reduction of Cr^{VI} at p-type electrodes is not limited by mass transport in solution; at n-type electrodes, a clearly defined diffusion plateau current is observed. At $[\text{HF}]/[\text{CrO}_3]$ ratios lower than 10, both the open-circuit etch rate and the Cr^{VI} reduction rate are kinetically controlled.

For this latter range of concentrations, the reduction reaction is clearly inhibited, despite the favorable corre-

Fig. 11. Current-potential curve for an n-type GaAs electrode in 1.20M CrO_3 , 1.54M HF solution under illumination. In the insert, the cathodic peak is given in both scan directions for a light intensity corresponding to a limiting anodic photocurrent of 3 mA/cm^2 . The scan rate for both curves was 1 mV/s .

spondence of redox potential and semiconductor valence band. It was suggested above that this inhibition is due to the formation of a blocking layer on the electrode. Passivation has also been observed by other workers on Pt and other metal electrodes during Cr^{VI} reduction (17-19). This was ascribed to the formation of mixed valence complexes due to partial reduction of hexavalent chromium in dichromate or trichromate ions (18, 19). Hoare suggests, for example, that the reduction of a trichromate ion can lead to complexes containing trivalent and hexavalent chromium entities (19). Such reactions at GaAs can be represented schematically as follows

Using the analogy with metal electrodes, we conclude that such mixed-valence complexes can adsorb and form a blocking layer on GaAs and thus prevent further reduction of Cr^{VI} .

The Mott-Schottky plots for GaAs in these CrO_3 -HF electrolytes were very similar to those measured in 0.5M H_2SO_4 solution (Table I). No significant difference was observed either in the flatband potential or in the slope

Table II. Measured quantum efficiency for dissolution of n-type GaAs in 0.72M CrO_3 , 0.93M HF solution

Potential ^a	ϕ
Of current minimum	0.0
Of current peak	1.3
Rest potential (V_r)	1.7
$V_r + 0.3\text{V}$	3.0

^a These potentials refer to the illuminated electrode. The light intensity corresponded to a limiting anodic photocurrent density of 3 mA/cm^2 .

(expressed here as a calculated donor or acceptor concentration). It therefore seems likely that the chromium ion products of reaction [2] replace the electrolyte anions in the Helmholtz layer. The Helmholtz potential at low pH is determined by adsorption of H^+ ions and does not depend on the nature of the anion in solution. Consequently, the surface complex does not disturb the existing Helmholtz layer. Of course, this is only possible when the surface layer is thin. The transient current measurements with illuminated p-type electrodes, already described, indicate this to be the case.

The surface coverage due to the film is clearly very sensitive to the HF concentration in solution. This is obvious from the strong HF dependence of the etch rate (Fig. 4) and of the cathodic peak current (Fig. 8) for both types of electrode. The constant cathodic current of p-type electrodes at negative potentials also depends markedly on the HF concentration (Fig. 6).

The electrochemistry of the adsorbed film on GaAs displays some unusual characteristics. From the various measurements, it can be concluded that the surface complex is reduced by electrons from the conduction band. The dark cathodic current at n-GaAs begins much sooner than hydrogen evolution (curves a and b, Fig. 7). Illumination of p-GaAs gives a greatly enhanced cathodic current (Fig. 9 and 10). The species responsible for the surface film must, therefore, have energy levels which correspond to the conduction band or the bandgap (20). Since the quantum efficiency for photocurrent at p-GaAs is much greater than 1, reduction of the adsorbed complex must free a surface site at which several holes can be subsequently injected.

A small constant cathodic current is observed on p-type electrodes at potentials negative with respect to the peak value. Since this current is potential-independent but strongly dependent on HF concentration, we assume that the blocking film can be removed by a chemical reaction with HF. This reaction is second order in HF concentration (Fig. 6).

The most intriguing aspect of this system is an apparent coupling of the GaAs oxidative dissolution and Cr^{VI} reduction reactions. For both p- and n-type electrodes, strong passivation sets in only at potentials at which holes are not kept effectively at the surface and GaAs no longer dissolves anodically (Fig. 5 and 7). Most probably, the adsorbed surface complex can react with an intermediate of the GaAs oxidation reaction, thus freeing a surface site and enabling subsequent hole injection by Cr^{VI} . The behavior of the current peak at lower scan rates supports this conclusion. Under these conditions, current hysteresis was observed for n-type GaAs in the dark. The current was much lower for the anodic scan direction (Fig. 7). At potentials slightly negative with respect to the peak, both n- and p-type electrodes are strongly passivated. Upon increasing the potential, band bending conditions become favorable for keeping holes at the surface. For p-type electrodes and n-type electrodes illuminated at high intensity, holes are readily available. Consequently, the GaAs dissolution reaction can be easily initiated. Intermediates from this process can subsequently react with the blocking film, thus depassivating the surface. In these cases, therefore, the establishment of a steady state is expected to be rapid. For an n-type elec-

trode in the dark, holes are not available from the bulk and must be injected by Cr^{VI} in solution. As this process is strongly inhibited by the presence of the passivating film, retardation effects can be significant. In this case, therefore, current hysteresis can be expected even at low scan rates. In the next article, it will be shown that such a coupling of dissolution and reduction reactions can also account for the enhancement of the etch rate of n-GaAs under illumination and for the surprisingly high quantum efficiency (Table II).

At $[\text{HF}]/[\text{CrO}_3]$ ratios higher than ~ 20 , a discrepancy was noted in the electrochemical behavior of n- and p-type GaAs. While the open-circuit etch rate of both materials depends on diffusion of Cr^{VI} species from the bulk solution to the electrode surface, a diffusion-limited current was only found for n-type electrodes. For p-type GaAs, the reduction rate of Cr^{VI} was diffusion limited only at extreme $[\text{HF}]/[\text{CrO}_3]$ ratios. From the discussion above of the results obtained in solutions with a concentration ratio less than 10, it is clear that the reduction of Cr^{VI} at the open-circuit potential of p-type GaAs must be much higher than the cathodic current at more negative potentials. This is obviously also the case for electrolytes with $[\text{HF}]/[\text{CrO}_3] > 20$ in which the concentration ratio is not extremely high. The fact that a reduced cathodic current is not observed for n-type GaAs under similar conditions (Fig. 2) must be attributed to the presence of electrons at the electrode surface. As discussed above, conduction band electrons can reduce the adsorbed complex. This keeps the surface free for subsequent hole injection. Treating the diffusion-limited cathodic current of n-type GaAs in these solutions as a simple example of hole injection into the valence band is, therefore, not justified.

ABSTRACT

A model is presented to describe the dissolution of GaAs in CrO_3 -HF solutions, both in the dark and under illumination. The etching kinetics are shown to be mainly determined by the mechanism of Cr^{VI} reduction at GaAs. An essential feature of the model is the formation of an adsorbed mixed-valence chromium complex which passivates the semiconductor surface. A novel reaction between the adsorbed complex and a surface-state intermediate of the GaAs oxidation reaction is proposed to account for the many surprising aspects of the etching and electrochemical kinetics.

In the first part of this series we described the dissolution of GaAs in CrO_3 -HF solutions (1). It was shown that the HF/CrO_3 concentration ratio determines the etching kinetics; at high values of this ratio, the etch rate depends on diffusion of Cr^{VI} in solution, while at low values etching is kinetically controlled and depends only on the HF concentration. Illumination considerably enhances the

dissolution rate of n-type GaAs but has no effect on p-type material.

In order to gain insight into the etching mechanism, the electrochemistry of the system was investigated. This revealed some unexpected features. The current-potential curves for p- and n-type electrodes have a very characteristic shape at low values of the HF/CrO_3 concentration ra-

tio. The quantum efficiencies for Cr^{VI} reduction at p-type electrodes and for GaAs dissolution at n-type electrodes were significantly higher than 1. On the basis of these results two main conclusions were drawn: reduction of Cr^{VI} gives rise to a blocking film which plays a decisive role in the surface reactions; and this film can be reduced by a surface-state intermediate of the GaAs oxidation reaction, with the result that the surface is "depassivated."

In this paper, the conclusions from the first article are combined with existing ideas on the mechanism of oxidation of III-V materials to give a model which can account quantitatively for many of the electrochemical and etching results. The discussion will be mainly restricted to those cases in which etching is under kinetic or mixed-kinetic control, i.e., to relatively low HF/CrO₃ concentration ratios (1).

Model

Etching of GaAs in CrO₃-HF solutions involves two electrochemical reactions, oxidative dissolution of the solid, and reduction of the oxidizing agent, Cr^{VI}. In the development of a model for the etching system, it is necessary to consider both partial reactions.

Recent work on the dissolution of GaAs suggests a mechanism involving a series of discrete steps (Eq. [1]-[3]) (2-5)

Localization of valence band (VB) holes at the surface results in the rupture of Ga-As surface bonds. The intermediates formed in reactions [1] and [2] correspond to surface states and have energy levels in the forbidden gap (2, 3). The charge transfer steps are accompanied by chemical attack on the weakened bond by a nucleophilic reagent 2X⁻ from solution. Kinetic studies involving competition between oxidation of the III-V material and of a reducing agent in solution have shown that nucleophilic attack very likely occurs after transfer of the second hole (6). On the basis of current and impedance measurements at different HF concentrations (1), it can be concluded that fluoride species do not participate in the anodic dissolution. Rupture of the first Ga-As bond is generally considered to be the rate-determining step (2, 4). Transfer of a further four holes occurs rapidly, and trivalent gallium and arsenic species are formed in solution (7).

On the basis of the electrochemical results presented in the first article, the reduction of hexavalent chromium at GaAs can be represented as follows

Following the example of Hoare (8), who has extensively studied the mechanism of Cr^{VI} reduction at metal electrodes, we consider the trichromate ion, here denoted by {Cr^{VI}-Cr^{VI}-Cr^{VI}}, to be the electroactive species in solution. An exact knowledge of the solution chemistry is not essential since the model can be readily modified to take into account other hexavalent species. Injection of six holes into the valence band of GaAs in step [4] yields an

adsorbed mixed-valence complex which blocks the surface. This surface complex can be reduced by electrons (step [5]), as is clear from the results with p-type electrodes under illumination and n-type electrodes in the dark (1). This implies that the adsorbed species has an energy level distribution corresponding to the bandgap or the conduction band. Since the redox potential of the Cr^{III}/Cr^{II} couple is in this energy range (9), we assume that one of the terminal Cr^{III} atoms is reduced to Cr^{II}; the central Cr^{VI} species, being sterically protected, is not reduced (8). HF is required to remove the reduced complex and free the surface. The unreduced complex can also be removed in a chemical reaction with HF (step [6]), and the liberated Cr^{VI} species subsequently injects three holes into the VB. This explains the small potential-independent cathodic current observed in the dark on p-type electrodes at negative potentials (1).

A clear relationship has been demonstrated between the reduction of Cr^{VI} and the availability of holes at the electrode surface. The reduction reaction is hindered significantly as soon as (photo) anodic dissolution of GaAs stops (1). These results suggest an interaction between the dissolving GaAs and the surface complex. Considering the likely positions of the relevant energy levels, we conclude that a surface-state intermediate of the dissolution reaction is capable of reducing the adsorbed complex, in a manner similar to that suggested above for electrons (step [5])

The reaction of a mixed valence complex with a surface radical yields a reduced complex which is then removed by HF. We consider electron exchange between the adsorbed complex and the surface state to be reversible. An analysis of the etching results leads us to conclude that the rate of reoxidation of the reduced complex is much faster than its rate of decomposition by HF. Equation [7a] can therefore be replaced by [7b]

in which k_7 is an "effective rate constant" describing both steps of reaction [7a].

In the subsequent sections of this paper, the results of p and n-type GaAs will be examined using the complete set of Eq. [1]-[7].

Application of the Model to p-GaAs

Equations for steady state in the dark.—For a p-type electrode in the dark, reaction [5] can be disregarded. Using Eq. [1]-[4] and [6]-[7], the following expressions for p-type GaAs under steady-state conditions are obtained

$$\frac{d\theta}{dt} = k_4 C_{\text{Ox}}(1 - \theta) - k_6 C_{\text{HF}}^n \theta - k_7 C_{\text{HF}}^m N_1 \theta = 0 \quad [8]$$

$$\frac{dN_1}{dt} = k_1 p_s - k_2 p_s N_1 - k_7 C_{\text{HF}}^m N_1 \theta = 0 \quad [9]$$

$$\frac{dN_2}{dt} = k_2 p_s N_1 - k_3 N_2(1 - \theta) + k_7 C_{\text{HF}}^m N_1 \theta = 0 \quad [10]$$

Here, we denote the surface coverage due to the adsorbed complex by θ ($0 \leq \theta \leq 1$), and the surface density of the dissolution intermediates given in Eq. [1] and [2] by N_1 and N_2 (cm⁻²), respectively. C_{Ox} and C_{HF} refer to the

concentration (mol/cm^3) of trichromate and HF species in solution, and p_s is the surface hole concentration (cm^{-3}). It is assumed that the presence of an adsorbed layer on the surface prevents both the Cr^{VI} reduction (reaction [4] and the later stages of GaAs dissolution which require reaction with X^- from solution (reaction [3]). This inhibition is clear from the $(1 - \theta)$ term denoting the free surface in Eq. [8] and [10]. We also assume that the surface hole concentration is given by the Boltzmann equation

$$p_s = p_0 \exp(eV_{sc}/kT) \quad [11]$$

where p_0 is the bulk hole concentration and the band bending V_{sc}

$$V_{sc} = V - V_{FB} \quad [12]$$

is the difference between the applied and flatband potentials.

Kinetic analysis at the rest potential.—The partial currents for reduction of Cr^{VI} (i^c) and oxidation of GaAs (i^a) can be defined according to the reaction scheme [1]–[7]

$$i^c/F = 6k_4C_{\text{Ox}}(1 - \theta) + 3k_6C_{\text{HF}}^n\theta + 3k_7C_{\text{HF}}^mN_1\theta \quad [13a]$$

$$i^a/F = k_1p_s + k_2p_sN_1 + 4k_3N_2(1 - \theta) \quad [13b]$$

At the rest potential V_r , the total current must be zero. Equating i^c and i^a and rearranging with the aid of Eq. [8]–[10], we obtain

$$9k_4C_{\text{Ox}}(1 - \theta) = 6k_1p_s - k_7C_{\text{HF}}^mN_1\theta \quad [14a]$$

From the measured current-potential curves, it is clear that the limiting cathodic current due to reaction [6] is much smaller than the cathodic peak current. Since the current corresponding to the etch rate at the rest potential is larger than the peak current, reaction [6] can be omitted from a consideration of etching at open circuit. Combining Eq. [8] (with $k_6 = 0$) and [14a], we obtain

$$9k_4C_{\text{Ox}}(1 - \theta) = 6k_1p_s - k_4C_{\text{Ox}}(1 - \theta) \quad [14b]$$

The partial currents at V_r can now be derived from Eq. [8], [9], and [14b]

$$i^a = i^c = \frac{18Fk_1k_4C_{\text{Ox}}C_{\text{HF}}^m}{2k_1C_{\text{HF}}^m + 5k_4(k_2/k_7)C_{\text{Ox}}} \quad [15]$$

From Eq. [15], it is immediately clear that, depending on the ratio of C_{Ox} and C_{HF} , the etch rate may be determined either by the oxidizing agent or by HF, provided the values of the rate constants are not too extreme. This is, indeed, found experimentally (1).

At relatively low HF concentration, the second term in the denominator of Eq. [15] is expected to be dominant. The equation then reduces to

$$i^a = i^c = 18/5 Fk_1(k_7/k_2)C_{\text{HF}}^m \quad [16]$$

Figure 1 shows a log-log plot of the measured etch rates at low HF concentration, taken from the first article (1) and recalculated as current density, vs. the HF concentration. Since it was previously shown that the etching kinetics of p-GaAs and n-GaAs in the dark are the same (1), the etch rates for the latter have also been included in the figure. The experimental results agree with Eq. [16] for etch rates differing by an order of magnitude. The slope of the straight line in Fig. 1 is 1.9 ± 0.1 ; this means that reaction [7] must be second order in HF concentration.

Using $m = 2$, Eq. [15] can be rearranged

$$\frac{C_{\text{Ox}}}{i^a} = \frac{1}{9Fk_4} + \frac{5k_2C_{\text{Ox}}}{18Fk_1k_7C_{\text{HF}}^2} \quad [17]$$

From Eq. [17], it follows that a plot of C_{Ox}/i^a as a function of $C_{\text{Ox}}/C_{\text{HF}}^2$ should give a straight line for all etch rates which are not diffusion controlled. The partial current i^a at V_r was again determined from the open-circuit etch rates. The results for p- and n-type materials are plotted in Fig. 2. Considering that the results in this figure represent a wide range of Cr^{VI} and HF concentrations and etch

Fig. 1. The etch rate at open circuit for low HF concentrations, expressed as a current density i^a , is plotted as a function of C_{HF} (see Eq. [16]).

rates extending over two orders of magnitude (1), the fit of Eq. [17] should be considered satisfactory. It can therefore be concluded that the model accounts very well for the etching kinetics at open circuit.

Fig. 2. The etch rate at open circuit, expressed as a current density i^a , is plotted according to Eq. [17].

Determination of rate constants.—In order to calculate the current as a function of potential, it is necessary to know the various rate constants. The constant k_1 is related to anodic dissolution of GaAs. In the absence of the oxidizing agent ($C_{Ox} = 0$), it follows from reaction steps [1]-[3] that

$$i^a = 6Fk_1p_s \\ = 6Fk_1p_0 \text{ at } V = V_{FB} \quad [18]$$

A value of k_1 can thus be obtained from the anodic current-potential curve measured in an indifferent electrolyte. In the present case, Eq. [18] was obeyed and i^a was 1.5 mA/cm^2 at V_{FB} . The resulting k_1 value is given in Table I together with the other constants from the present work.

The term k_2/k_7 can be obtained either from Eq. [16] and Fig. 1 or from Eq. [17] and the slope of Fig. 2. Since k_1 is known, the ratio k_2/k_7 can now be determined. The ratio given in Table I is an average value from the two methods. From Eq. [17] and the intercept of Fig. 2, a value for k_4 can be obtained. This value was found to be not very critical for the further analysis.

At potentials sufficiently negative with respect to V_{FB} , the surface hole concentration is very small. In this range, only reactions [4] and [6] are important. The last term in Eq. [8] can therefore be disregarded and the limiting value of θ can be calculated. The corresponding limiting current $i_{lim} = 9Fk_4C_{Ox}(1 - \theta_{lim})$ is given by

$$i_{lim} = \frac{9Fk_4C_{Ox}k_6C_{HF}^n}{k_4C_{Ox} + k_6C_{HF}^n} \quad [19]$$

At low values of the C_{HF}/C_{Ox} ratio, the limiting current depends only on the HF concentration (1), i.e., $k_4C_{Ox} \gg k_6C_{HF}^n$ and

$$i_{lim} \approx 9Fk_4C_{HF}^n \quad [20]$$

From the experimental dependence of i_{lim} on C_{HF} given in the first article, both n and k_0 can be calculated. Reaction [6] is also found to be second order in HF concentration.

Current-potential curves.—In order to calculate the current in the complete potential range, reaction [6] must be included. The total current is the sum of the partial currents ($i = i^a + i^c$), which are given by Eq. [13]. From the relationship between p_s and θ , which can be obtained from the steady-state Eq. [8]-[10]

$$p_s = \frac{k_4C_{Ox}(1 - \theta) - k_6C_{HF}^2\theta}{k_1 + k_6 \frac{k_2}{k_7} - k_4 \frac{k_2}{k_7} \frac{C_{Ox}}{C_{HF}^2} \frac{(1 - \theta)}{\theta}} \quad [21]$$

the surface coverage can be calculated as a function of p_s . In this way, θ and p_s can be related to the potential via Eq. [11] and [12]. The partial currents, which can also be expressed in terms of p_s and θ (see Eq. [13] and [14]) can therefore be calculated as a function of potential.

Figure 3 shows a calculated curve for a p-type GaAs electrode in a $1.20M$ CrO_3 , $1.54M$ HF solution. For comparison, the measured curve for the same solution is also given (dashed line). Agreement between the two is good: the general form, the cathodic peak height, and the rest potential are predicted by the model. The experimental peak is somewhat broader than expected. This is very likely due to the fact that the Helmholtz potential is not completely constant (10), as is implicitly assumed in Eq. [12]. Figure 4 shows that the calculated dependence of the

Fig. 3. The solid line gives the calculated current-potential curve for a p-type GaAs electrode in $1.20M$ CrO_3 , $1.54M$ HF solution. The rate constants used were the first four in Table I. The dashed line is the measured curve.

peak current on HF concentration is in excellent agreement with that measured experimentally.

A consideration of the partial currents (Fig. 5) shows how the mechanism operates. As long as the surface hole concentration is sufficient to ensure dissolution of GaAs ($V \geq V_{FB}$), reduction of Cr^{VI} is maintained. Reaction of a surface radical with an adsorbed complex according to reaction [7] leads to decomposition of the complex. Three holes are injected from the liberated Cr^{VI} species, and a surface site is freed at which six holes may be subsequently injected (reaction [4]). Since this process involves the injection of nine charge carriers while only four are required to complete the oxidation of the GaAs pair (reaction [3]), the cathodic partial current can exceed the corresponding anodic current; a current peak, indicated by the dashed line in Fig. 5, is observed. At potentials negative

Fig. 4. The cathodic peak current for a p-type GaAs electrode as a function of the HF concentration. The solid line summarizes the measured results from Ref. (1). The points were calculated using the model.

with respect to the peak, the reduction rate of Cr^{VI} decreases rapidly because of the drop in the GaAs oxidation rate resulting from the drastic decrease in p_s . At potentials more positive than the peak value, the cathodic curve tends to a limiting value while the anodic curve continues to rise exponentially. This leveling off of i_c results from an increase in the contribution of reaction [2], whose rate is directly proportional to p_s . This limits the concentration of reactive radicals at the surface and consequently the rate of reaction [7]. It should be emphasized that the limiting cathodic partial current, shown at positive potentials in Fig. 5, is not a diffusion current. The electrode surface is still blocked and the calculated minimum surface coverage is 0.95 in this case.

A comparison of Eq. [15] and [19] reveals the reason for the apparent discrepancy between the etching and electrochemical results reported for p-GaAs in the first article. A diffusion-controlled reduction of Cr^{VI} was only observed at extreme values of the ratio of the HF and CrO_3 concentrations, while the etch rate depended on mass transport in the solution in a much wider concentration range. The limiting cathodic current of Eq. [19] only becomes independent of C_{HF} when $k_6/k_4 \gg C_{\text{Ox}}/C_{\text{HF}}^2$. Since k_6 is relatively small, this is only possible for high $C_{\text{HF}}^2/C_{\text{Ox}}$ ratios. Open-circuit etching becomes solely dependent on the CrO_3 concentration when $2k_1k_7/5k_2k_4 \gg C_{\text{Ox}}/C_{\text{HF}}^2$; this can be expected at much more modest values of $C_{\text{HF}}^2/C_{\text{Ox}}$ since $2k_1k_7/5k_2k_4$ is two orders of magnitude larger than k_6/k_4 (see Table I). This effect is, of course, due to the participation of GaAs surface intermediates in reaction [7] which results in a depassivation of the surface at open-circuit potential.

Etching morphology.—As described in the first article of this series (1) and in previous publications (11, 12), the CrO_3 -HF etchant is, under kinetically determined conditions, very sensitive to defects in both p- and n-type GaAs. Defects generally correspond to crystallographically disturbed areas of the solid. Since such areas are expected to be less noble than the surrounding material (13),

selective corrosive attack should occur when etching is performed in the dark. Enhanced dissolution of defects should therefore lead to etch pits. Surprisingly, this is not observed with CrO_3 -HF etchants: defects are revealed as hillocks. Although etching morphology will be dealt with in considerable detail in a separate paper (14), we shall here consider briefly the reason for this unexpected effect.

As a simple approximation, we equate the high reactivity of defects with enhanced rate constants (k_1 , k_2) for the dissolution reaction of GaAs. We further assume that the defect has a stronger influence on the second hole trapping step (k_2), which involves the final rupture of the bond, than on the first step (k_1). The effect on the etch rate of such changes in the dissolution rate constants can be judged from Eq. [15]. An increase in the ratio k_2/k_1 gives a lowering of the partial anodic current at the rest potential. The corresponding decrease in etch rate results from a heightened preference of the system for reaction [2] compared to reaction [7]. Since this latter reaction involves a depassivation of the surface, the defects are more effectively protected by the adsorbed layer.

Effect of illumination.—When p-type GaAs is exposed to light of the correct wavelength, electrons are generated in the conduction band (CB) and a cathodic photocurrent is observed at negative potentials (1). Measurements in CrO_3 -HF solutions under these conditions show clearly that illumination also affects the rate at which holes are injected into the VB from Cr^{VI} in solution. We attribute the very high apparent quantum efficiencies found in the limiting photocurrent range to reaction [5]. The surface complex is reduced by an electron, and a surface site is freed. A combination of reactions [4] and [5] involving, in the limiting case, the transfer of ten charge carriers per generated electron (i.e., per absorbed photon) accounts very well for the experimental results (1).

Reduction of the surface complex by electrons, either directly via the CB or indirectly via surface states, is obviously more efficient than H_2 evolution. The onset potential for photocurrent flow in CrO_3 -HF solution is considerably more positive than in an indifferent electrolyte (H_2SO_4). Nevertheless, recombination of electrons with holes must also be important at potentials close to V_{FB} . In previous work (9), it was shown that very effective surface recombination at p-GaAs electrodes can effectively compete with charge transfer to the solution. Therefore, illumination has no effect on the current or on the etch rate near the rest potential.

Application of the Model to n-GaAs in the Dark

Steady-state equations.—For oxidative dissolution of n-type GaAs in the dark, holes must be supplied by injection from solution. In addition, the competing reaction involving recombination of injected holes with electrons from the CB must be considered. This reaction becomes important even at potentials considerably positive with respect to V_{FB} , for which the electron concentration at the surface is relatively low. A representation of the hole balance for an n-type electrode in the dark can be given on the basis of the reaction scheme [1]-[7], where j_p is the hole flux at the surface

$$j_p = 6k_4C_{\text{Ox}}(1 - \theta) + 3k_6C_{\text{HF}}^2\theta + 3k_7C_{\text{HF}}^2N_1\theta - k_1p_s - k_2p_sN_1 - 4k_3N_2(1 - \theta) - j_{\text{rec}} = 0 \quad [22]$$

The j_{rec} term describes the recombination process. Despite the fact that injection occurs mainly at the free surface, we assume a uniform surface concentration for the holes. This is justified if the free surface consists of many very small areas. These areas will, of course, change randomly in time. We also assume that the rate constants determined for p-GaAs can be used for n-type electrodes. The validity of this assumption is supported by results of Gomes and Cardon (15), who studied the competition between redox oxidation reactions and anodic dissolution at III-V electrodes. Since identical kinetics are found for

p-type electrodes in the dark and n-type electrodes under illumination, they conclude that the rate constants are, indeed, independent of semiconductor type.

As a first approximation, we use a very simple recombination mechanism. We consider only direct electron-hole recombination at the surface

$$j_{\text{rec}} = k_r n_s p_s \quad [23]$$

As in the case of p-type electrodes, the majority carrier concentration at the surface n_s is described by the Boltzmann equation

$$n_s = n_0 \exp(-eV_{\text{sc}}/kT) \quad [24]$$

where n_0 is the bulk electron concentration. The magnitude of k_r determines the potential at which a transition occurs between recombination and anodic dissolution (16). An estimate of its value can thus be obtained from the photocurrent-potential curve measured in an indifferent electrolyte. When the photocurrent is equal to half its limiting value, dissolution and recombination rates must be equal ($6k_r p_s = k_r n_s p_s$). The measured potential at which this occurs can be used to calculate n_s (via Eq. [12] and [24]) and consequently k_r . The corresponding value is given in Table I.

Current-potential curves.—Using Eq. [1]-[4], [7]-[10], [12], and [21]-[24] and a procedure similar to that followed above for p-GaAs, both the partial and total currents can be calculated as a function of potential. For convenience, reaction [6] was omitted from all calculations on n-type material. As already shown, the current due to this step is negligible compared to the peak current. Reaction [5] involving reduction of the adsorbed complex by CB electrons was also disregarded, since this only contributes to the current at potentials more than 200 mV negative with respect to the peak value (1).

Calculated results are shown in Fig. 6 for an n-type electrode in the same solution as described above for p-GaAs (Fig. 3). The predicted current-potential curve (Fig. 6a) resembles closely the experimental curve measured with n-GaAs in the vicinity of the rest potential (1). Both the magnitude of the calculated current peak and its dependence on HF concentration are identical to those predicted for p-GaAs and thus in complete agreement with the experimental results.

Again, the mechanism can be more readily understood in terms of the partial reactions (Fig. 6b). At extreme band bending, n_s is very low (Eq. [24]) and recombination can be disregarded. Holes injected from solution are used exclusively to dissolve the electrode. The partial currents are, therefore, equal in this range and the total (measured) current is very low. Since j_{rec} is very small, Eq. [22] becomes the same as Eq. [14], which describes p-GaAs at open circuit. The partial currents for n-GaAs in this potential range are the same as for p-type material at $V = V_r$ (compare Fig. 5 and 6b). At more negative potentials, n_s increases and recombination becomes important. The dissolution rate consequently decreases. A corresponding decrease is observed in the partial reduction current (Fig. 6b). As for p-GaAs, only one hole is required to form a surface radical. On reacting with an adsorbed complex, this can free a blocked site. Subsequent multiple hole injection again gives rise to a current peak (Fig. 6a). It should be noted that, in the case of an n-type electrode, the total (external) current results from recombination of injected holes with electrons (16). This current drops to a very low value on the cathodic side of the calculated peak because the hole injection rate decreases drastically. This results from an increasing surface coverage by the adsorbed complex. It should be noted that the cathodic current, shown in Fig. 6a, begins to flow at potentials at which the photocurrent in an indifferent electrolyte reaches its limiting value.

We have, for simplicity, assumed a surface recombination process to analyze the n-type GaAs case in the dark. However, recombination within the space-charge layer seems more likely considering the very strong band

Fig. 6. a: The total current-potential curve calculated for an n-type GaAs electrode in 1.20M CrO_3 , 1.54M HF solution. Direct electron-hole recombination at the surface with a rate constant k_r (Table I) is assumed. b: The corresponding partial curves.

bending involved in the potential range under consideration (16). While the nature of the recombination process may influence the shape of the cathodic peak, its position is always linked to the potential range between photocurrent onset and photocurrent saturation, as observed in an indifferent electrolyte. This has been indicated in the previous section. It can also be shown that the peak current is not dependent on the recombination mechanism, provided that surface intermediates (reactions [1] and [2]) are not involved (see final section).

Etching kinetics.—Using the simple approach as represented by Eq. [22] and [23], it is not possible to calculate the rest potential of the electrode when minority carriers are injected. This potential is determined by a complex combination of factors (17).

An exact knowledge of V_r is, however, not essential for determining the etch rate at open circuit. Under open-circuit conditions, the rates of GaAs oxidation and Cr^{VI} reduction must be equal as the recombination rate must be zero; a nonzero rate would imply electron depletion in the CB. The partial currents at V_r must, therefore, be equal to the potential-independent partial currents shown in Fig. 6b. In order to check that this is the case, we measured the etch rate of GaAs in a 0.72M CrO_3 , 0.93M HF solution as a function of potential. The results in Table II show that the etch rate, determined potentiostatically, has the same potential dependence as that expected from our model (see anodic partial current in Fig. 6b): at potentials positive with respect to V_r , the etch rate is constant and equal to the open-circuit value (this is not a diffusion-controlled rate); at more negative potentials, the etch rate decreases and becomes zero just negative of the cathodic peak value.

Table II. The etch rate of an n-type GaAs electrode, measured in 0.72M CrO₃, 0.93M HF solution, as a function of the applied potential

Potential	Etch rate (nm/min)
Of current minimum	0.0
Of current peak	30 ± 3
Rest potential (V _r)	55 ± 5
V _r + 0.3V	55 ± 5

From the discussion in the previous section, it is clear that the model predicts the same open-circuit etch rates for n- and p-type materials, as is found experimentally. The model, consequently, accounts for the HF concentration dependence of the etch rate.

Application of the Model to n-GaAs under Illumination

Photocurrent-potential curves.—For an illuminated n-type electrode, it is necessary to include a generation term g in Eq. [22] for the hole balance

$$g + 6k_4C_{Ox}(1 - \theta) + 3k_6C_{HF}^2\theta + 3k_7C_{HF}^2N_1\theta = k_1p_s + k_2p_sN_1 + 4k_3N_2(1 - \theta) + j_{rec} \quad [25]$$

It is found experimentally that the current peak occurs at a potential at least 0.5V more positive than V_{FB} (1). Since this implies a strong electric field at the surface and since the penetration depth of the light is small, we assume that all holes created by light reach the surface (9); g then equals the photon flux. Using Eq. [23]-[25], the partial and total curves can again be calculated. The predicted photocurrent-potential curve is similar to that found experimentally (see Fig. 11 of the first article). At positive potentials, a constant anodic current, whose magnitude depends directly on light intensity, results from photoanodic dissolution of n-GaAs. At more negative potentials, the model predicts a cathodic peak, shifted slightly in the negative direction with respect to the peak in the dark. The calculations also show that this shift is more pronounced at higher light intensity. The predicted peak height under illumination is, however, the same as in the dark and is independent of light intensity. The measured peak showed a weak dependence on photon density (1).

The mechanism of photoetching.—Although the model based on direct electron-hole recombination at the surface accounts reasonably well for the observed current-potential curves, it cannot explain the increase in etch rate at the rest potential during illumination. At V_r , the electrons generated by light at a rate g must be consumed at the same rate, to maintain electrical neutrality in the CB. As generation and recombination rates must be equal ($g = j_{rec}$), Eq. [25] becomes intensity independent at the rest potential and no effect of light on the etch rate can be expected. This also holds for more elaborate models involving recombination centers either at the surface or in the space-charge layer.

In general, two common mechanisms could account for photoetching of n-GaAs at open circuit. In the first, holes generated by light are used for dissolution of the electrode, while the majority carriers, electrons, reduce an oxidizing agent from solution. We do not have such a reduction reaction in the present case. The contribution from reaction [5], the reduction of the surface film by electrons, is too small at the rest potential to account for the increase in etch rate due to light. The second mechanism involves a displacement of the semiconductor bandedges by illumination (10). In this way, hole injection from an oxidizing agent into the VB or surface states, which cannot occur in the dark, may become possible under illumination. A significant shift in the bandedges due to injection from solution or illumination was, however, not observed in this work (Table I of the first article).

To account for photoetching of n-GaAs in CrO₃/HF solutions, a different recombination mechanism was consid-

ered (5), in which the intermediates of the GaAs dissolution reaction act as electron traps

Since these reactions influence the concentration of the radical intermediate responsible for freeing the surface (reaction [7]) they should affect the etch rate. Such a recombination mechanism may not be excluded for the dark case. The rest potential under illumination, however, was found to be more than 100 mV more negative than in the dark (1). The band bending is therefore less extreme and a surface recombination mechanism of the type indicated in Eq. [26] and [27] is even more probable. Normally, one would not expect the second step to be very likely. However, it must be remembered that the intermediate is formed under the blocking layer and nucleophilic attack by X⁻ (reaction [3]) is severely hindered. Analogous recombination steps have been suggested previously by Gomes and co-workers for photoanodic dissolution of n-type III-V electrodes (18, 19).

Equations [9] and [10] now become

$$\frac{dN_1}{dt} = k_1p_s - k_2p_sN_1 - k_7C_{HF}^2N_1\theta - k_8N_1n_s + k_9N_2n_s \quad [28]$$

$$\frac{dN_2}{dt} = k_2p_sN_1 - k_3N_2(1 - \theta) + k_7C_{HF}^2N_1\theta - k_9N_2n_s \quad [29]$$

For convenience in the calculations, we limit ourselves to the case in which all recombination occurs via such a mechanism; the independent j_{rec} term in Eq. [25] is therefore omitted. With the aid of Eq. [8], [24], and [25]-[29] and some straightforward though tedious mathematics, expressions for θ , p_s , k_8N_1 , and k_9N_2 can be obtained as a function of n_s and thus of V_{sc} . Apart from the known parameters, these expressions contain two new terms k_7/k_8 and k_9/k_3 . The former ratio determines the potential at which n-GaAs begins to dissolve when holes are injected from Cr^{VI} in the dark. Its value can be allocated accordingly. The ratio k_9/k_3 must be chosen arbitrarily.

Typical results of such a calculation are given in Fig. 7a. The solid curve shows the total current under illumination as a function of potential. The general form is very similar to that of the measured curves (1). The cathodic peak is shifted with respect to its position in the dark (dashed curve) and illumination enhances slightly the peak current, in agreement with the experimental results. In Fig. 7b the calculated quantum efficiency for dissolution of GaAs, ϕ , defined as

$$\phi = (i_{diss}^* - i_{diss})/gF \quad [30]$$

is plotted as a function of potential; i_{diss}^* and i_{diss} refer to the calculated current densities for GaAs dissolution under illumination and in the dark at the same potential. From this figure, it is clear that a quantum efficiency in excess of one can be expected not only at positive potentials but also at the rest potential, as indicated. A similar result was found experimentally in the potentiostatic etching experiments reported in Table II of Ref. (1). The experimental values were, however, higher than those shown in Fig. 7.

This recombination mechanism is clearly too limited to account quantitatively for all the results observed with illumination. However, the qualitative and semiquantitative agreement between predicted and measured results supports the assumption that dissolution intermediates must play an important role in the electrochemistry of n-type GaAs electrodes illuminated in CrO₃-HF solutions.

Fig. 7. a: The solid line gives the calculated current-potential curve under illumination for an n-type GaAs electrode in 1.20M CrO_3 , 1.54M HF solution. The dashed line represents the dark case. Recombination is assumed to occur via surface intermediates of the GaAs oxidation reaction. The ratio k_7/k_8 is given in Table I. The ratio k_9/k_3 is assumed to be $2.5 \times 10^{-9} \text{ cm}^3$. b: The calculated quantum efficiency for dissolution of GaAs as a function of potential for the case described in Fig. 7a. The light intensity used corresponds to a flux of $2.1 \times 10^{-8} \text{ mol/cm}^2\text{-s}$.

Summary

The model proposed in this paper for the dissolution of GaAs in CrO_3 -HF solutions involves two important features.

The first is the partial reduction of a hexavalent chromium species in solution results in the formation of an adsorbed mixed-valence complex on the semiconductor surface. This acts as a blocking layer which inhibits both the further injection of holes from Cr^{VI} and the dissolution of GaAs.

The second is that the adsorbed complex can be reduced by a radical intermediate of the GaAs oxidation reaction. The reduced form is then removed from the surface by HF from solution.

An analysis of the kinetics of the partial reactions leads to equations for the etch rate and the current as a function of applied potential.

With regard to etching, the model can explain the following observations: the etch rates of p- and n-type GaAs in the dark are the same; etching changes from kinetic to diffusion control when the ratio of the HF and CrO_3 concentrations is increased; the etch rate of p-type GaAs is not influenced by illumination; and crystallographic defects are revealed as hillocks.

The model accounts very well for the electrochemical results with p-type GaAs: the form of the current-potential curves, including the characteristic cathodic

peak, is explained; the positions of both the rest potential and the peak maximum are predicted; the magnitude of the current peak and its dependence on HF concentration are accounted for quantitatively; and the very high apparent quantum efficiency for the cathodic photocurrent can be understood.

For n-type electrodes, recombination of holes injected by Cr^{VI} with CB electrons must also be taken into account. The essential results for n-type GaAs in the dark can be explained with the aid of a simple model involving direct electron-hole recombination at the surface. The general form and the position of the current-potential curves is accounted for. The peak current is shown to be identical to that of p-type GaAs and to have the same HF concentration dependence.

This simple recombination model failed, however, to explain the results obtained with n-GaAs under illumination. Since, in this case, the rest potential is shifted to values more negative than that observed in the dark, it was concluded that recombination of electrons and holes occurs via surface intermediates of the GaAs oxidation reaction. Although this mechanism predicted a higher cathodic peak current in the dark than was experimentally observed, it could account for the results under illumination. The form of the calculated photocurrent-potential curves agrees with that measured experimentally; the shift of the potential of the cathodic peak from its dark value to more negative potentials at increasing light intensity is predicted; the increase in the magnitude of the peak current with increasing light intensity is explained; and a quantum efficiency greater than one for dissolution of n-GaAs both at open-circuit and more positive potentials can be understood in terms of the model.

ABSTRACT

Quantitative data are presented on the infrared (IR) absorption of interstitial oxygen in oxygen-rich silicon using Fourier transform spectroscopy. Besides the well-known 515 and 1106 cm^{-1} room temperature IR bands, due to the symmetric and antisymmetric vibrations of the Si_2O entity, respectively, three other bands at 1227, 1720, and 1013 cm^{-1} are reported, whose intensities are scaled with those of the 515 and 1106 cm^{-1} bands. The band at 1227 cm^{-1} has often been confused with an oxygen precipitate band observed at 1225 cm^{-1} in annealed silicon. Evidence is given that the 1227 cm^{-1} band is related to interstitial oxygen. It is also shown that another band at 1720 cm^{-1} is a combination of the antisymmetric mode of Si_2O with a phonon combination of the silicon lattice. A weak band at 1013 cm^{-1} is reported for the first time, and it is attributed to an overtone of the 515 cm^{-1} mode.

Oxygen dissolves in silicon near the melting point (1420°C) up to concentrations of about 2×10^{18} at./ cm^3 by forming two strong Si—O bonds with nearest-neighbor Si atoms (1). In this position, the oxygen atom is termed to be interstitial and noted O_i . This implies a distortion of the lattice as the mean distance between the two Si atoms increases from 0.234 nm in the unperturbed lattice to 0.320 nm when bound through the oxygen atom. Near the melting point, this distortion is somewhat reduced by the generation of Frenkel pairs, but their production rate decreases with temperature and the lattice strain of oxygen-rich Czochralski-grown (CZ) silicon (2) increases with the cooling down of the crystal. A possible channel for global lattice relaxation of the crystal is the precipitation of some form of silica. (It must be pointed out that precipitation of silica produces local strains because of the volume misfit between silicon and silica. These local strains can, in turn, be relaxed by other mechanisms whose discussion is beyond the scope of this paper.) The precipitation kinetics of O_i is such, however, that the O_i concentration at room temperature in most as-grown CZ Si crystals is of the same order of magnitude as that near the melting point, despite the fact that its solubility is of several orders of magnitude less than that at the melting point. It is commonly admitted that, during the cooling down of the CZ Si crystals, precipitation of oxygen can occur (3), especially for crystals with large diameters. This point will be clarified here.

Infrared (IR) vibrational spectroscopy can reveal the presence of dispersed oxygen as well as that of silica precipitates (O_p) produced under deliberate high temperature annealing (4). This technique can allow one to determine the respective amount of each phase if what is due to O_i and what to O_p has been identified unambiguously. This task is complicated by the fact that the most intense IR bands associated with O_i and O_p occur in the same spectral range (950–1250 cm^{-1}), and one of the purposes of this paper is to clearly present what is due to interstitial oxygen since recently, the wrong attribution of a weak absorption band in as-grown CZ Si has led to the statement that silica absorption could be detected in this material. The other purpose is to try to summarize all the features of the room temperature absorption of O_i in silicon, including a discussion on the origin of an O_i -related band

observed at 1720 cm^{-1} and the attribution of another weak band at 1013 cm^{-1} .

Experimental

Different samples about 4 mm thick were cut from a (100)-oriented B-doped CZ slice with $N_a - N_d = 1 \times 10^{15}$ cm^{-3} and $[C_s] = 2 \times 10^{16}$ at./ cm^3 . This slice had been annealed for 2h at 650°C. The spectra shown here have been obtained with a BOMEM DA3.01 Fourier transform spectrometer, using a float-zoned sample with the same free carrier concentration as a reference. The measurements have been performed at $(293 \pm 1)\text{K}$ or at lower temperature using a continuous flow liquid helium cryostat, and they were reasonably independent of the samples. In the determination of the extrinsic absorption coefficient, the effect of multiple reflections is taken into account (5). Neglecting this effect leads to an overestimate of the absorption coefficient, an error which increases for the small values of this coefficient. This must be reminded since we compare values of the absorption coefficient which can differ by two orders of magnitude. No correction has been made for the phonon and free-carrier absorption. The O_i concentration using the ASTM F121-80 norm is 9.9×10^{17} at./ cm^3 . A series of recent independent analyses has shown that the RT calibration factor recommended by the ASTM and the DIN (2.45×10^{17} at./ cm^2), based on the analyses of Graff *et al.* (6), was underestimated and that a value of 3.0×10^{17} at./ cm^2 was more realistic (7).

Results and Discussion

The first extensive studies of the IR absorption of oxygen in silicon after those of Kaiser and Keck (8) were made by Hrostowski (9). They demonstrated that the absorption in as-grown material was characteristic of an Si_2O quasi molecule, today denoted O_i . We consider the so-called 515 and 1106 cm^{-1} O_i -related bands, and we present quantitative data on these bands as well as on weaker bands also related to O_i .

The 515 cm^{-1} band is actually observed at 514.0 cm^{-1} at RT, and it shifts at 517.8 cm^{-1} at liquid helium temperature (LHT). It is due to a symmetric vibrational mode of Si_2O . Although guessed by the first investigators, some doubts had been cast on this attribution (3), but a comprehensive study of the stress-induced dichroism of this band compared with that of the 1106 cm^{-1} band by

* Electrochemical Society Active Member.

Stavola (10) has confirmed the early attribution. The resonance of the 515 cm^{-1} band with the phonon spectrum of Si is responsible for its asymmetric shape, characteristic of a resonance between a discrete transition and a continuum (Fig. 1a). This is also the probable reason for the absence of an isotopic shift due to oxygen (9). This band can be a useful probe of the O_i concentration in annealed silicon containing silica precipitates because of its relative sharpness ($\text{FWHM} \approx 7.6\text{ cm}^{-1}$) and of the weak intensity of the silica precipitates band in this spectral region (10). When measuring the maximum absorption coefficient of this band using the high frequency background as a base line, its ratio to the maximum absorption coefficient of the 1106 cm^{-1} band (this will be hereafter referred to as the relative intensity) is 0.26 ± 0.03 . This figure is an average of measurements made on different Si samples with negligible oxygen precipitation, and the maximum absorption coefficient of the 515 cm^{-1} band can be used to measure $[O_i]$ using calibration factors of $9.4 \times 10^{17}\text{ at./cm}^2$ (ASTM F-121 1980) or $1.25 \times 10^{18}\text{ at./cm}^2$ to comply with Ref. (7).

Figure 1b shows the strong RT absorption of O_i peaking at 1107.7 cm^{-1} , known as the 1106 cm^{-1} band. It can be ascribed to transitions involving the antisymmetric stretching mode (ν_3) of the Si_2^{16}O group starting from thermally excited states of a low frequency anharmonic vibrational mode or a quasi-free rotational mode of the oxygen atom

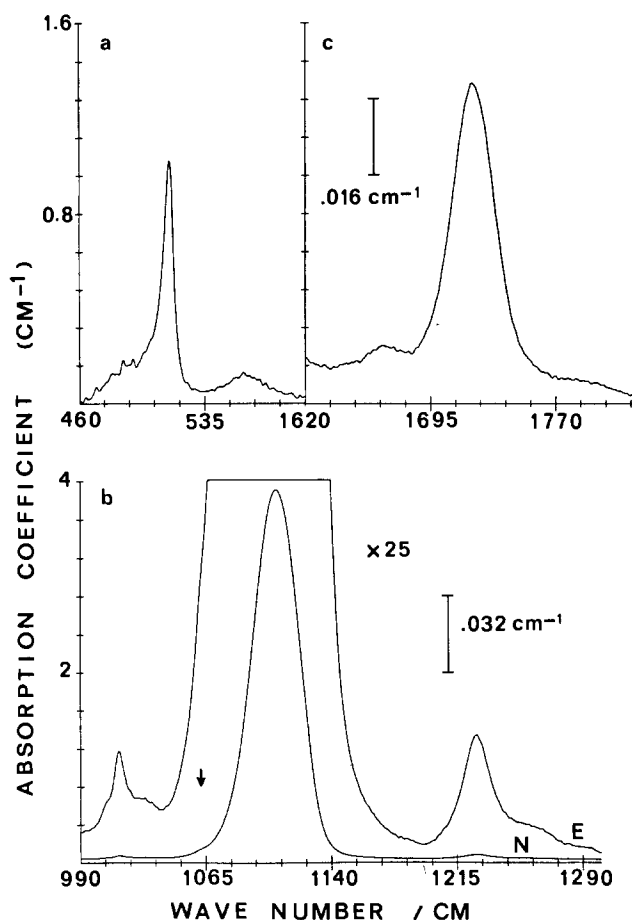

Fig. 1. Absorption coefficient of O_i in a B-doped silicon sample at $(293 \pm 1)\text{ K}$. $[O_i] = 1 \times 10^{18}\text{ at./cm}^3$. The spectral bandwidth (2 cm^{-1}) and the abscissa scale ($15\text{ cm}^{-1}/\text{division}$) are the same for the three spectra. a: The band at 514 cm^{-1} . Note the asymmetric shape and the weak background feature near 560 cm^{-1} . The integrated intensity (l.i.) between 474.5 and 534 cm^{-1} is $(11.8 \pm 0.6)\text{ cm}^{-2}$. b: The bands at 1013 , 1108 , and 1227 cm^{-1} . The ordinate scale for b corresponds to spectrum N. Spectrum E has been expanded by a factor of 25 with respect to spectrum N. The ^{18}O absorption, detected as a shoulder on the low energy side of the 1108 cm^{-1} band, is marked by an arrow. The l.i. is $(136 \pm 1)\text{ cm}^{-2}$ between 1035 and 1185 cm^{-1} . c: The band at 1720 cm^{-1} . The scale expansion with respect to spectrum N of b is 50.

among equivalent minima. The full width at half maximum of the envelope is 33 cm^{-1} , but the individual components are expected to be sharper. The maximum of the envelope is resolution-independent for a spectral band width (s.b.w.) less than 4 cm^{-1} . For a s.b.w. of 8 cm^{-1} , a small decrease of the peak absorption is observed, however. This fact is not in contradiction with individual components having natural widths $\approx 5\text{ cm}^{-1}$ separated by the same quantity. A study of the shape of the envelope as a function of the s.b.w. and of the temperature between 250 and 350 K could help to elucidate this point. In the absence of silica precipitate, the ratio of the peak absorption to the integrated intensity of the 1106 cm^{-1} band is $(2.86 \pm 0.06) \times 10^{-2}\text{ cm}$, and this is a supplementary indication that this band is an envelope.

An asymmetry observed on the low energy side of the 1106 cm^{-1} band is attributed to the ν_3 mode with ^{18}O . (The natural abundance of ^{18}O is 0.002 times that of ^{16}O .) Drastic base-line correction provides a peak value of $(1059 \pm 1)\text{ cm}^{-1}$ for the ^{18}O band, in agreement with the value of 1058 cm^{-1} obtained with an ^{18}O -enriched sample (9). A band at 1013 cm^{-1} and a weaker shoulder at 1006 cm^{-1} are also observed in all the OR samples with a relative intensity of $(6 \pm 2) \times 10^{-3}$. They are seen in the left side of Fig. 1b. A weak band is also observed at the same position (1012.5 cm^{-1}) at LHT; this band was also reported without comment by Oerhlein *et al.* (11). There is a correlation between these bands and the O_i concentration but not with the carbon or boron concentration. Under annealing at 450°C for a relatively long time, these bands broaden and their structure is not so well defined. Bean *et al.* (12) quote a weak band at 1004.1 cm^{-1} in electron-irradiated OR Si after annealing at 450°C . We have indeed observed local mode absorption at 1005.2 and 1011.1 cm^{-1} at room temperature in electron-irradiated OR Si after short-time annealing in the 450°C range. These bands shift to 1006.7 and 1012.2 cm^{-1} at low temperature. The band and the shoulder reported above are certainly different from these oxygen defect-complex bands since the former are still observed after a high temperature (1350°C) redissolution treatment. Bands near 1006 cm^{-1} at ambient have also been associated by Chrenko *et al.* (13) to interstitial lithium trapped electrostatically by the O_i atom in Li-diffused Si, but these bands shift by $\approx 8\text{ cm}^{-1}$ toward high frequencies at low temperature and they do not seem to be related to the bands observed here.

The sharpness of the 1013 cm^{-1} band at room temperature makes its assignment to a combination of the 515 cm^{-1} mode with a phonon mode unlikely, but it could be an overtone of this mode. The absence of a frequency shift between room temperature and LHT could be explained by a change of the anharmonicity of the mode with temperature.

The band at 1227 cm^{-1} best seen on the right side of spectrum E in Fig. 1b is common to all the OR Si samples with a relative intensity of $(11 \pm 2) \times 10^{-3}$. This band should not be confused with the band at 1225 cm^{-1} observed in OR Si after high temperature annealing, which is associated with some kind of silica precipitate (4). Figure 2 shows the 1225 cm^{-1} precipitate band at room temperature in a sample identical to that used to obtain the spectra of Fig. 1 after a two-step annealing: in the first step, 95% of O_i present in the sample was precipitated; in the second step, 50% of the oxygen was redissolved and the 1225 cm^{-1} precipitate band appears clearly. From a comparison of the intensities of the 515 and 1106 cm^{-1} bands in the spectrum of Fig. 2, a contribution of the silica absorption at 1106 cm^{-1} of 17% (0.38 cm^{-1}) to the maximum absorption coefficient at this wave number is calculated. This precipitate band which can generally be observed after preannealing at 600°C followed by annealing at 900°C has long been ascribed to the presence of cristobalite, but this attribution has recently been questioned (14). An important point is that, contrary to the 1227 cm^{-1} band, the shape and the intensity of this precipitate band remain practically unchanged between room temperature and LHT.

Fig. 2. Absorption coefficient of O_i and O_p in an annealed sample identical to that of Fig. 1. The spectral bandwidth is 2 cm^{-1} . Note the precipitate band near 1225 cm^{-1} . $[O_p] \approx 5 \times 10^{17} \text{ at./cm}^3$ is inferred from this spectrum.

The 1227 cm^{-1} band, on the other hand, is a combination band involving the ν_3 mode of the Si_2O group. This band shifts at 1205.8 cm^{-1} at LHT. The 1205.8 cm^{-1} band has been ascribed by Bosomworth *et al.* (15) to a combination band of the ν_3 mode with a two-quantum excitation of a low frequency anharmonic motion of the oxygen atom tunneling through a potential barrier built by the two silicon atoms of the Si_2O group. This motion is a two-dimensional analog of the low frequency inversion motion of nitrogen tunneling through the potential built by the three hydrogen atoms in the ammonia molecule. In the harmonic oscillator description, it can be visualized as a $|0,0,0\rangle \rightarrow |1,2,0\rangle$ transition where the first number from the left refers to the excitation number of the ν_3 mode, the second one to the excitation number of the low frequency oscillator, and the one at the right to the l value of this oscillator. Aside from the 1205.8 cm^{-1} , a second component at 1216.8 cm^{-1} appears above 15 K and it can be similarly ascribed to a $|0,1,1\rangle \rightarrow |1,3,1\rangle$ transition. (With this labeling, the strong 1136.4 cm^{-1} observed at LHT is a $|0,0,0\rangle \rightarrow |1,0,0\rangle$ transition.) At room temperature, it is expected that the quasi-free rotational motion of the oxygen atom about the Si-Si axis can compete with the low temperature vibrational motion.

The observation of the 1227 cm^{-1} band has been sometimes related to the presence of some kind of silica precipitates in as-grown material. We have tried indeed to measure the concentration of precipitated oxygen in the slice from which the IR sample has been cut. A redissolution experiment (5h at 1350°C in argon ambient followed by room temperature quenching at $\approx 100^\circ\text{C/s}$) on an adjacent sample showed, after removing of $200 \mu\text{m}$ of material on each side of the sample, an increase of the intensity of the 1106 cm^{-1} band by 2%, *i.e.*, by $2 \times 10^{16} O_i \text{ at./cm}^3$. Besides this point, no differences were found in the room temperature spectra of both samples, indicating that in the as-received sample about 98% of the oxygen was already present in the interstitial form.

Figure 1c shows a vibrational band associated with O_i and located at 1720.1 cm^{-1} at room temperature with a relative intensity of 0.016. This band has previously been reported by Lappo and Tkachev (16). The energy difference between this band and the 1106 cm^{-1} band is 612.4 cm^{-1} . (See Table I for the exact position of the bands at 293 K.) At LHT, this band shifts to 1748.6 cm^{-1} ; above 20 K, two new bands appear with decreasing intensities at 1741.2 and 1735.5 cm^{-1} . These bands have also been reported by Krishnan and Hill (17). Their separations from the "hot" bands at 1128.3 and 1121.7 cm^{-1} which are associated (18) with the 1136.4 cm^{-1} band are 612.9 and 613.8 cm^{-1} , respectively. We have checked that the 1720 cm^{-1} band was not correlated with carbon. This band was ascribed by

Table I. Characteristics of the infrared bands associated with interstitial oxygen in silicon at 293 K for a spectral bandwidth of 2 cm^{-1} . The relative intensities are measured taking into account the reflection losses

Lappo and Tkachev to the combination of two vibrational modes of the Si_2O group, namely, the symmetric one producing the 515 cm^{-1} band and a mode they ascribe to what we label the 1227 cm^{-1} band. The agreement on the frequencies is fair at room temperature, but the LHT results destroy the argument. We propose that this line is due to a combination of the ν_3 antisymmetric mode of the Si_2O group with the two-phonon combination TA + TO at the X point of the Brillouin zone (19). This two-phonon combination is IR active, and it gives rise to the strongest absorption (apparent intensity $\approx 10 \text{ cm}^{-1}$) in the multiphonon spectrum of silicon. The frequencies of this combination are (610 ± 1) and $(613 \pm 1) \text{ cm}^{-1}$ at room temperature and LHT, respectively, but we are unable to detect this difference in our measurements. From the FWHM of the 1720 cm^{-1} band, we infer that the phonon mode distribution is sharp and this is confirmed by the LHT results where the FWHM of the 1748.6 cm^{-1} band is 3.6 cm^{-1} against 0.6 cm^{-1} for the ν_3 band at 1136.4 cm^{-1} .

Conclusion

Two O_i -related IR vibrational bands have been known for a long time in OR silicon. It has been shown here that three other weak vibrational bands are also related to O_i , and that one of them reveals a coupling between the ν_3 mode and the phonon spectrum of silicon. Waldner *et al.* (20) had made similar observations in the study of the local mode absorption of Li B pairs in silicon. One of the bands analyzed here has been previously ascribed to a silica precipitate. The present work rules out this possibility and its consequences. A point which has not been discussed is the origin of a weak and broad band observed at 560 cm^{-1} . This band can be seen in Fig. 1a, where the reference sample contains the same boron concentration as the CZ sample: so, its attribution to a local mode of boron seems unlikely. The presence of this band after redissolution of oxygen seems to preclude its attribution to a silica mode, and its possible relation with oxygen deserves further investigation.

Acknowledgments

We are grateful to Professor J. W. Corbett for having brought Ref. (7) to our attention. The preparation of the samples for the high temperature annealing was performed by S. Squelard.

A Modeling Study of Superficial Topography for Improved Lithography

L. K. White*

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

The contour coating properties of spun-on resist films on topography can influence the lithographic definition of features. In some cases, it is desirable to take these effects into consideration in the layout of a device. Superficial topography, ST, around the perimeter of critical features and large arrays where space permits can improve the uniformity of the spun-on coating contour. A computer simulation procedure is used to design the ST and examples presented for a real device structure coated with representative spun-on positive resist coating. The same ST can also reduce the effects of radial flow-induced coating anomalies that can, in some cases, produce different contours at every location on the substrate. Even planarization sublayers in multilayer resist processes cannot always effectively planarize large arrays relative to a flat expanse. ST can play a beneficial role in many lithographic processes using spun-on films that coat topographical features.

Spun-on resist coatings are the dominant imaging material for IC lithographic processing. Spun-on polymer coatings are also being used more frequently in etchback planarization processes (1) and as passivation coatings. As critical dimensions approach the step heights of the topography, the topography (contour) coating properties of these spun-on coatings become an increasingly important aspect of all these processes. The spun-on coating thickness on topographical features is strongly influenced by the feature size. Different spun-on solutions and spin processes can produce different contour coating properties. Film shrinkage and, in some cases, thermal flow during subsequent cures of the film also influence the coating properties. The spun-on coating thickness on topography is further complicated by adjacent topography which can produce significant changes in the coated contour (2). In large, complex repetitive arrays, the interaction of the edge features of the array with the flat expanse produces significant coating thickness variations. Furthermore, radial flow-induced coating anomalies can actually produce different coating contours, depending on the radial position and orientation of the topography (3, 4).

For lithographic definition of the spun-on resist films, coating thickness variations can greatly influence the final patterned dimensions (5, 6). On highly reflective substrate materials with conventional positive resists and optical g-line exposure (436 nm), standing wave interference phenomena typically produce linewidth deviations as large as 0.5 μm with a 0.0650 μm change in resist thickness. In reality, the exact linewidth deviations may be different depending on the exact thickness change, the substrate reflectivity, resist contrast and processing, and the resolving power of the projection printer relative to the mask dimension. In the past, lithographic considerations in a device layout have concentrated on maximum step height of the topography, minimum line, space, pitch, and contact hole dimensions, and placement accuracies of

interlevel overlays. In this work, we propose that, in some cases, the actual configuration of the topography should be considered to accommodate the contour coating properties of spun-on films during device fabrication. To maintain process latitude and improve yields, spun-on coating thicknesses on topographical features need to be adequately controlled. These considerations become most significant for fine-lined lithography, (*i.e.*, design rules less than 2 μm). Sometimes, it is actually desirable to add topography that serves no electrical function to a design. This topography we shall call superficial topography, ST. The ST can be a permanent structure or a temporary one depending on subsequent processing and space considerations. ST appears to have its most immediate and obvious application at the edge of large complex arrays. The use of ST can improve the coating thickness uniformity on topographical features at the edge of and within the array. A computer simulation technique can be used to design the ST. The same ST can reduce the effects of radial flow-induced coating anomalies.

Designing Superficial Topography

The spun-on film contour coating simulation procedure has been described in detail elsewhere (2-4) and is based on the application of a low pass frequency filter to the uncoated contour (topography). This procedure involves expressing the uncoated contour in the frequency domain, that is, in terms of its Fourier coefficients, a_{nm} and b_{nm} . The spun-coated contour, $T_c(x,y)$, can be approximated as shown below

$$T_c(x,y) \approx \sum_{n=0}^j \sum_{m=0}^k w_n w_m a_{nm} \cos\left(\frac{2\pi nx}{N} + \frac{2\pi my}{M}\right) + w_n w_m b_{nm} \sin\left(\frac{2\pi nx}{N} + \frac{2\pi my}{M}\right) \quad [1]$$

where N and M are the total number of points that span the x and y coordinates. w_n and w_m are the frequency

* Electrochemical Society Active Member.

weighting factors for the x and y coordinates (*i.e.*, the frequency filter). j and k equal $N/2$ and $M/2$, respectively.

The same frequency filter is used for both x and y coordinates. It is determined empirically by measuring the step heights of coated isolated line features. The nonunity weighting factors (w_n and $w_m < 1.0$) that make up the low pass frequency filter are proportional to the logarithm of the period. Two parameters are used to define the filter, P_{\min} and α . P_{\min} represents the minimum period that has weighting factor equal to one and suggests the range of the feature-feature interaction. α is the slope of weighting factor-logarithm period curve and reflects the conformality of the coating. An α parameter of zero would represent a perfectly conformal coating.

For three-dimensional simulations, it is sometimes desirable to include the effects of film shrinkage. Assuming film shrinkage is proportional to thickness, changes in the measured step heights for coated topographical features can be computed according to the relationship shown below

$$H_b = (1 - 1/c) H_i + H_a (1/c) \quad [2]$$

where, H_b is step height before shrink, H_a is the step height after shrink, H_i is the initial uncoated step height, and c is the shrink factor. By measuring thicknesses before, T_b , and after, T_a , curing of the film, the shrink factor is determined as the fraction of the original thickness, T_a/T_b . Figure 1 shows a schematic of the before and after shrink contours and denotes the relevant parameters.

The shrinkage correction can easily be applied to the computed frequency weighting parameters

$$w'_n = (1 - 1/c) + w_n (1/c) \quad [3]$$

w'_n is the shrink-corrected weighting parameter and w_n the normal after-shrink parameter. The normal, after-shrink, frequency weighting parameters are determined from the isolated-line test pattern. Shrink-corrected, w'_n and w'_m , weighting parameters are computed, and a coating contour is calculated from these parameters. The film thickness used is the T_b thickness. The shrink factor is applied to these thicknesses, and the resulting thicknesses are added to the initial uncoated topography to give the shrink-corrected contour. Simulations done without a shrink-correction procedure produce reduced film thicknesses on top of topographical features (*i.e.*, lower step heights and a less conformal coating).

Figure 2a shows the corner portion of a silicon-on-sapphire (SOS) epi-island layout. The step height of the islands is $0.56 \mu\text{m}$. Gates are defined across the islands through the notches on the edge of the islands. The size of the islands is $12 \times 18 \mu\text{m}$. The gaps between the islands are $7 \mu\text{m}$ in the horizontal direction and $2 \mu\text{m}$ in the vertical direction. For this layout, only the gate definition on top of the islands is critical and the space between gates is much larger than the gate length (*i.e.*, width of defined line). Solid, dotted, and dashed lines show where the coating contour cross sections are displayed for the first, second, and fifth rows of gates, respectively. In Fig. 2b and 2c, the ST configurations that we have considered at the edge of the array are denoted by the slash-filled lines.

Table I summarizes the simulation parameter, solution properties, and coating conditions for a few spun-on positive resist films. Figure 3 shows computed shrink-corrected coating contour for the various rows of gates in the epi island layouts, a, b, and c, shown in Fig. 2. The epi island arrays are typically defined by a 512×512 array of

Fig. 1. Schematic of before shrink and after shrink contours

Fig. 2. Epi island layout with and without superficial topography

points spaced at $1 \mu\text{m}$ intervals. The frequency weighting parameters that correspond to a softbaked OFPR 800 coating ($\alpha = 0.60$, $P_{\min} = 200 \mu\text{m}$) were used for all the topographical configurations assuming a 0.90 shrink factor. The computation typically requires 3 min of CPU time on an IBM mainframe computer and a 4 Mbyte machine. These simulated contour traces show thickness variations at the edge of, between, and on top of the islands. The contour height (Y-axis) represents the height of the simulated profilometer trace relative to the uncoated flat expanse. For these designs, only the coating thickness on top of the islands is critical for gate definition. Large thickness variations at the edge of a feature are always present with conventional novalac resin-based positive

resist systems. The ST presented here is only designed to control the resist thickness on top of the epi islands. If pattern definition were important between the islands, thickness variations between the top and bottom of the steps would also be important.

Table II summarizes thickness variations between and within the rows of gates on top of the epi islands for the layouts. For the spin-coated layout without ST (Fig. 3a), the maximum thickness variation between the top of islands is 950Å. The second layout with ST consisting of a 10 μm line spaced 10 μm from the edge of array reduces the maximum thickness variations to 450Å. The third layout with ST further reduces the maximum thickness variations to 250Å. The top section of ST has been widened to 15 μm and is spaced only 5 μm from the edge of the array.

The design of ST depends not only on the layout, but also on the resist material and spin process used. Figure 4 shows additional coating contour simulations for the layout shown in Fig. 2a and 2c. The frequency weighting parameters used are $P_{\min} = 400 \mu\text{m}$ and $\alpha = 0.53$, which may be representative of an HPR 206 coating. No shrinkage correction is used in the simulation. For softbaked positive resist films, a 0.85-0.90 shrink factor does not appreciably change the simulated relative thickness variations on top of the islands; however, small detectable thickness variations between the top and bottom of the simulated

Fig. 4. Simulated contour traces for epi island layout for $P_{\min} = 400$, $\alpha = 0.53$.

contours are present. A shrink-corrected contour (Fig. 3) appears to produce a less smoothed simulated contour. Corners and edges of topography appear more prominent in the shrink-corrected contours. Without ST, the maximum thickness variation on top of the islands is 1100Å. Even with the ST shown in Fig. 2c, the maximum thickness variation is only reduced to 650Å. A more substantial ST is necessary for this particular spun-on coating to reduce thickness variation on top of the islands even further. The configuration of the superficial topography that appears to be most effective in reducing thickness variations tends to match the periodicity within the complex array itself. The simulation also suggests that, at least for this layout, spun-on positive resist coating materials and processes that exhibit longer effective ranges (larger P_{\min} values) tend to produce greater thickness variations within the array.

In practice, it is desirable to keep the thickness variations on top of the islands around a third of the distance between the maximum and minimum standing wave exposure intensity nodes. Thus, for a g-line (436 nm) exposure system, the thickness variation should be around 210Å. For the worst possible case, the standing wave-induced dimensional deviation is approximately halved. Further reduction in these dimensional deviations can be obtained by still tighter thickness control or in some cases by reducing substrate reflectivity. This type of ST is only used to control the maximum resist thickness on top of the islands. The thickness variations at the edge of the island are still present. These edge thickness variations are typically 1200Å, and the presence of a standing wave maximum intensity node is unavoidable. Necking at steps on reflective topography needs to be addressed by other resist processing techniques, such as multilayer resist processes (7, 8). Although these multilayer processes address resist thickness changes within an individual island, they do not necessarily address thickness variations between islands. Even with a thick planarization sublayer, a group of small features tends to behave as a single large feature and little planarization is possible between the flat expanse and the array. Note that, if the spun-on coatings shown in Fig. 3 and 4 had been used as planarization sublayers, the initial uncoated step height of 0.56 μm would have only been reduced to 0.42 and 0.39 μm relative to the flat expanse, respectively. Thus, superficial topography can be important even in multilayer resist processing schemes.

Effect of Radial Flow-Induced Coating Anomalies

The simulations in the previous section only apply for situations where radial flow-induced coating anomalies do not play a prominent role. These anomalies influence the contour coating and thickness variations at various

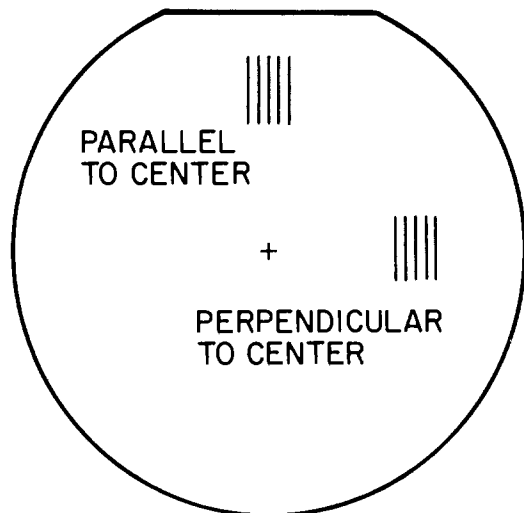

Fig. 5. Schematic of \parallel and \perp orientations with respect to flow from wafer center.

orientations and positions with respect to the centrifugal center of the wafer. Figure 5 shows a schematic of lines oriented parallel (\parallel) and perpendicular (\perp) to the flow of material from the centrifugal center of the wafer. Figure 6 shows profilometer traces that illustrate how coating contours are influenced by the orientation of the feature with respect to the wafer center. Isolated-line features, 40 and 5 μm wide, coated with HPR 206 at a 6 krpm spin speed are shown. The circled "x" denotes the \parallel orientation, and the arrow the direction of flow from the wafer center at the \perp orientation. The numbers above the traces indicate the maximum measured step height in microns, and the numbers below the traces the feature size. The original step height for the feature was 1.01 μm . The profilometer traces for the \perp orientation were taken 25 mm from the center of a 3 in. diam wafer.

Step heights are increased for the \perp orientation, and a buildup of material on the sidewall of the step produces an asymmetrical shape for the coated line feature. The buildup always occurs on the sidewall oriented toward the wafer center. The maximum step height for the orientation does not occur in the center of the cross section of the line but is displaced toward the wafer center side of the line. The edges and corners of features are thus coated differently, depending on whether the edge is adjacent to or opposite the wafer center. When coating failures occur (*i.e.*, thin or no film coverage of a feature), they tend to be located at edges opposite the wafer center, downstream from the radial flow.

Fig. 6. Profilometer traces of coated isolated-line features at \parallel and \perp orientations.

Radial flow anomalies are more complex than depicted by these two orientations. Intermediate orientations between \parallel and \perp have a complex coating behavior. The \perp orientations themselves have a radial dependence, which essentially introduces a positional dependence for every feature with respect to the centrifugal center (*i.e.*, all features on the wafer can be coated differently). These radial flow anomalies become greater the further away features are from the centrifugal center of the substrate. Larger diameter substrates will show even greater anomalies at their edges. In the center of the substrate, the radial flow anomalies are small and, in terms of the coating contours of line features, the \perp orientations begin to resemble the \parallel orientations.

The flow-induced coating anomalies within large complex three-dimensional arrays can also be significant. Since a group of small features seems to behave as a large feature, the upstream side of the array tends to show thickness buildup and the downstream sides thickness thinning. An example of this effect is shown in Fig. 7 for $10 \times 10 \mu\text{m}$ line-space gratings at \perp orientation and at the center of the substrate. The resist coating is OFPR 800 spun on at 6 krpm, and the uncoated step height is 0.44 μm . The A value represents a coated step height measurement in microns for the first line feature, and the B value the coated step height of a line feature within the array. Although there is some noise present in the B step heights, the difference between A and B step heights is reproducible from wafer to wafer at the same contour trace positions.

The arrows on the figure show the direction of flow from the radial center of the substrate. The middle trace was taken near the centrifugal center of the substrate, and the radial flow induced coating anomalies are expected to be small. Both sides of this grating exhibit the same A and B step heights. In terms of minimizing thickness variations across the whole array, the center positions are always superior. These positions produce coating contours that have small radial flow anomalies, and they are predicted with reasonable accuracy by our simulation procedure. All \parallel orientations of the grating would produce a similar coating contour. The upstream side of the array at a \perp orientation away from the center position (top of Fig. 7) shows the smallest difference between the A and B

Fig. 7. Profilometer traces of coated $10 \times 10 \mu\text{m}$ grating features at \perp orientations.

step heights. The first line feature exhibits a thickness buildup effect relative to the center trace. The downstream side of the same array away from center position (bottom of Fig. 7) shows the largest difference between the A and B step heights. The first line feature shows a thickness thinning relative to the step height within the array. For this coating, the first line feature on the back side of the array exhibits the most substantial thickness change. This observation suggests that thickness variations produced by radial flow anomalies in some cases may actually exceed those predicted by our contour simulation routine. The exact magnitude of these thickness variations depends on the radial position of the \perp orientation, but the largest radial flow-induced coating anomaly usually occurs at the first feature in the complex array. Superficial topography around the perimeter of the array would help minimize this coating anomaly.

It should also be pointed out that radial flow anomalies can also change the coating contour within the array. The B step heights in presence of radial flow are different from those in the center of substrate and at a parallel orientation. Superficial topography cannot correct this type of coating anomaly. It is important to minimize radial flow-induced coating anomalies during the spin coating process so that topographical features do get coated uniformly and coating failures are minimized. Devices with high step heights and large or long feature sizes are more susceptible to these coating anomalies. Low spin speeds and careful selection of coating materials can be used to minimize, but not eliminate, these effects (3, 4).

This effect, however, is expected to be much smaller for three-dimensional arrays that have both a finite width and length. Smaller feature sizes and more broken arrays produce less substantial radial flow-induced anomalies. In any case, ST around the perimeter of complex arrays can only improve the situation. Since radial flow-induced coating anomalies increase with distance from the center, larger diameter substrates could conceivably benefit more from the use of ST.

Summary

The use of superficial topography to improve coating contour and thickness uniformity at the edge of complex arrays has been proposed. Since a group of small features

tends to act like a single large feature, edge features of an array effectively coat differently during the spin coating process than the same feature within an array. In the absence of large radial flow-induced coating anomalies, the configuration of the superficial topography can be constructed by computer simulation techniques. Different spun-on coatings and topography configurations require different ST to obtain the most uniform coating contours. Films and coating processes that produce long ranges for feature-feature interaction tend to require more substantial ST configurations. Radial flow-induced coating anomalies can produce greater coating nonuniformities within an array. The larger anomalies also tend to occur at the edge of the arrays and on the downstream side of the array. ST also helps reduce these coating difficulties. ST can also be beneficial in multilayer resist processes that employ planarization sublayers, since the sublayers cannot effectively planarize a large array relative to a flat expanse. The contour coating properties of the spun-on resist films used to define critical lithographic levels and spun-on sacrificial films used in planarization etchback procedures are an increasingly important aspect of device processing. Careful consideration of these properties can improve yields, process latitude, and, in some cases, even device performance.

Studies of the Vaporization/Decomposition of Alkali Sulfates

K. H. Lau, R. D. Brittain,* R. H. Lamoreaux,* and D. L. Hildenbrand

SRI International, Menlo Park, California 94025

ABSTRACT

To complement a previous study of the vaporization behavior of K_2SO_4 , the vaporization of Li, Na, Rb, and Cs sulfates has been studied by mass spectrometry and the torsion-effusion method to determine the total pressures, molecular weights, and compositions of the effusing vapors. Both molecular vaporization of M_2SO_4 and dissociation contribute to the vaporization flux. For Na, Rb, and Cs sulfates, the decomposition reaction is $M_2SO_4(s) = 2M(g) + SO_2(g) + O_2(g)$. From the difference between the measured total pressures and calculated decomposition pressures, the contributions attributable to molecular vaporization of Na_2SO_4 , Rb_2SO_4 , and Cs_2SO_4 are about 37, 75, and 95% of the total pressures over the respective sulfates in the temperature ranges of our measurements. Vapor molecular weights determined from simultaneous torsion-effusion and mass-loss measurements are in close agreement with the compositions inferred from the pressure data. Decomposition of $Li_2SO_4(s)$ occurs by the reaction $Li_2SO_4(s) = Li_2O(s) + SO_2(g) + 1/2 O_2(g)$; the Li_2O reacts with the remaining Li_2SO_4 to form a liquid solution phase of unknown Li_2O activity. Li_2SO_4 sublimation accounts for about 0.3% of the pressure over Li_2SO_4 . The derived heats of sublimation in kilojoules per mole at 298 K were determined to be 388.4 ± 4.1 for Li_2SO_4 , 364.0 ± 1.3 for Na_2SO_4 , 340.2 ± 2.8 for Rb_2SO_4 , and 320.1 ± 2.0 for Cs_2SO_4 . Values of the entropies of the gaseous sulfate molecules were derived from slope heats and absolute pressures and are compared with values calculated from molecular constants.

Metal sulfate chemistry is important in technologies such as sulfur removal from combustion gases and high temperature energy generation and conversion. In most of these applications, the high temperature vaporization behavior of sulfates is of particular concern, but the basic

*Electrochemical Society Active Member.

thermodynamics and kinetics needed to treat the technical problems are not adequately known. In the case of alkali sulfates, serious discrepancies exist among sources in the literature not only as to total pressures but in regard to the relative importance of the various vaporization processes.

The vaporization of alkali sulfates is complex in that a variety of condensed and vapor phase products may be observed under appropriate conditions. The vaporization behavior may be described as combinations of conceptually simpler individual processes such as molecular vaporization

congruent decomposition

and incongruent decomposition, which results in changes in the condensed phase composition. One incongruent vaporization reaction that may be postulated is

but various condensed phases, both pure compounds and solutions, are possible products.

Previous studies reported that reaction [2] is the principal decomposition mode of Na_2SO_4 (1-3), K_2SO_4 (1, 4), Rb_2SO_4 (1, 5), and Cs_2SO_4 (1, 5); no evidence of incongruent vaporization was found. The percentage of the total vapor pressure attributable to molecular vaporization was not established precisely in most studies, but was reported to increase with the atomic weight of the cation from about 14% for Na_2SO_4 (2) to nearly 100% for Rb_2SO_4 and Cs_2SO_4 (5).

Although several studies of Li_2SO_4 vaporization have been reported, the results are in poor agreement. A mass spectrometric study (1) indicated vaporization according to the decomposition reaction [2], with no molecular sulfate detected, but a later mass-effusion and transpiration study (6) gave indirect evidence for a lithium containing vapor species, presumably $Li_2SO_4(g)$, as the major component of the vapor. This latter study also found evidence of incongruent vaporization, presumably by reaction [3], but concluded that it could not be the major vaporization process.

With the exception of condensed phase solutions, reliable thermodynamic data are available for the various decomposition processes, so that equilibrium decomposition products under neutral vaporization conditions may be predicted from these data. Sulfates of Na, K, Rb, and Cs are calculated to decompose by reaction [2], in agreement with the experimental results. Bonnell and Hastie (7) showed that the $Na(g)$ pressures observed over Na_2SO_4 under neutral vaporization conditions implied that the activity of condensed Na_2O was less than about 10^{-5} . This conclusion agrees with thermodynamic calculations that predict a $Na_2O(g)$ partial pressure of 2×10^{-14} bar for the dissociation of Na_2SO_4 under neutral conditions at 1200 K, whereas the $Na_2O(g)$ pressure over pure $Na_2O(s)$ under similar conditions is predicted to be 2×10^{-8} bar. Similar conclusions can be derived for the decomposition of K_2SO_4 , Rb_2SO_4 , and Cs_2SO_4 . However, under neutral conditions Li_2SO_4 is calculated to decompose primarily by reaction [3]; whether the condensed phase product is a pure substance or a solution is a matter for experimental determination.

A previous study in this laboratory (4) used Knudsen cell mass spectrometry and torsion-effusion vapor pressure measurement to investigate the vaporization behavior of K_2SO_4 . Molecular sublimation accounted for about 63% of the total vapor pressure under the experimental conditions; congruent decomposition by reaction [2] accounted for the remaining pressure. The enthalpy of sublimation at 298 K was 361.9 ± 6.3 kJ-mol⁻¹. The entropy derived from mass spectrometric second-law measurements and torsion-effusion total pressures was 13.8 J-mol⁻¹-K⁻¹ larger than tabulated values calculated from partially estimated molecular constants.

The present studies were undertaken to resolve discrepancies in the earlier data, to obtain quantitative information on the relative importance of molecular vaporization and dissociation, and to derive accurate thermodynamic data for the gaseous sulfates. To this end, the basic approach was the same as in our study of K_2SO_4 vaporiza-

tion. Total pressures were determined by the torsion-effusion method, a purely mechanical technique that requires no knowledge of vapor composition to evaluate total pressures. Partial pressures attributable to decomposition species were calculated using literature thermodynamic data, and the partial pressures due to M_2SO_4 molecules equated to the difference between total and decomposition pressures. Vapor molecular weights, \bar{M}_w , determined from simultaneous torsion-effusion and mass-loss measurements provided a check on our interpretation of the vapor composition. The mass spectra of the effusing vapors were studied in detail, and thermodynamic data were derived for the molecular vaporization and decomposition processes.

Experimental

Mass spectrometric studies were done in the 12 in. radius, 60° sector magnetic instrument equipped with a Knudsen cell source (8). Details of the platinum effusion cell, cell holder, and Pt, Pt-13% Rh thermocouple, and of the experimental technique have been given previously (8). Measurements of the temperature dependence of pressure and ion intensity were made by varying the temperature randomly; however, the data are tabulated in order of ascending temperature so that trends may be more readily identified.

The torsion-effusion apparatus and the associated microbalance, which have been described previously (9-11), were the same as in our K_2SO_4 vaporization study (4). Pt-30% Rh alloy effusion cells with orifice diameters of 0.06 and 0.11 cm and capped with tapered, Pt-coated alumina plugs were used. The system performance was checked against the vapor pressure and molecular weight of KCl, both cells giving results within 5% of the accepted values (12).

The measurements were made using high purity, anhydrous Mallinkrodt AR-grade Na_2SO_4 , Alfa ultrapure $Li_2SO_4 \cdot H_2O$ and Rb_2SO_4 , and Cerac/Pure Cs_2SO_4 . The $Li_2SO_4 \cdot H_2O$ was dried by heating for 2h at 463 K in N_2 . No obvious impurities were found in the mass spectrum, and essentially no outgassing was observed on heating the specimens to measurement temperatures in the torsion-effusion apparatus. In view of the pronounced tendency of molten Na_2SO_4 to wet the walls and to creep out of the effusion cell container, as observed by Kohl *et al.* (13) and in our own preliminary experiments, we charged the cell with a mixture of the solid sulfate and high surface area platinum powder. The inert Pt powder provided a large internal wicking area that confined the molten sulfate by surface tension; two different loadings showed the vapor pressure of the liquid to be independent of the Na_2SO_4/Pt ratio in the region investigated. This technique proved highly effective in eliminating the creep problem in the Na_2SO_4 measurements. Studies on the other sulfates were made at temperatures below the melting points.

Results

Vapor mass spectra.—The mass spectra were examined to obtain quantitative information on the molecular species in the vapor. Table I presents the threshold appearance potentials, neutral precursors, and relative ion intensities at 30 eV ionizing energy. Appearance potentials were evaluated by the vanishing current method. The close agreement of threshold ionization potentials of Na^+ , Rb^+ , Cs^+ , O_2^+ , and SO_2^+ with the spectroscopic ionization potentials (IP) of the corresponding neutrals Na (IP = 5.14 eV), Rb (IP = 4.18 eV), Cs (IP = 3.89 eV), O_2 (IP = 12.08 eV), and SO_2 (IP = 12.34 eV) indicate that the ions are formed by simple ionization processes near threshold. Because of the low appearance potentials of the ions $Li_2SO_4^+$, $Na_2SO_4^+$, $Rb_2SO_4^+$, and $Cs_2SO_4^+$, the corresponding neutrals are also regarded as parent species. At higher ionizing energies, a substantial fraction of the M^+ signal must result from dissociative ionization of M_2SO_4 . Our threshold appearance potentials for $Rb_2SO_4^+$ and $Cs_2SO_4^+$ are about 1 eV lower than those reported by Ficalora *et al.* (1), but agree closely with that of Kohl *et al.* (13) on

^a Not measured.

Na_2SO_4^+ ; Ficalora *et al.* (1) did not detect Li_2SO_4^+ or Na_2SO_4^+ . The species Na_2O^+ , Rb_2O^+ , and Cs_2O^+ , whose measured appearance potentials are far greater than those measured by Hildenbrand and Murad (14) for Na_2O^+ over $\text{Na}_2\text{O}(\text{s})$ (5.5 eV), by Norman and Winchell (15) for Rb_2O^+ (4.9 eV) and Cs_2O^+ (4.6 eV), and by Gorokhov (16) for Cs_2O^+ (4.45 eV), are clearly fragment ions. We found no evidence for molecular SO_3 , reported to be present in other studies.

On the basis of the observed ion signals and the AP data, we conclude that the major species in the vapor effusing from $\text{Na}_2\text{SO}_4(\text{s,l})$, $\text{Rb}_2\text{SO}_4(\text{s})$, and $\text{Cs}_2\text{SO}_4(\text{s})$ are the M_2SO_4 molecular sulfates, the M gaseous alkali metal atoms, SO_2 , and O_2 ; the major species effusing from $\text{Li}_2\text{SO}_4(\text{s})$ are SO_2 and O_2 plus a small amount of molecular Li_2SO_4 . No $\text{Li}(\text{g})$ is detected in the latter. Thus, decomposition by reaction [2] and molecular vaporization by reaction [1] contribute to the vaporization of Na, Rb, and Cs sulfates, whereas Li_2SO_4 vaporizes primarily by decomposition according to reaction [3] with a small contribution from direct sublimation.

To obtain second-law information for the molecular vaporization process, the temperature dependences of the intensities of M_2SO_4^+ species were measured. Second-law heats were derived from least squares analysis of $\log(I^+T)$ as a function of reciprocal temperature, with the results shown in Table II. As a check on this procedure, the decomposition processes were also studied by monitoring M^+ and/or SO_2^+ , for comparison with the established reaction thermodynamics.

Total vapor pressures and vapor molecular weights.—The torsion-effusion total vapor pressures obtained with cells PR-1 and PR-2 and the vapor molecular weights, \overline{M}_w , evaluated from simultaneous torsion and gravimetric effusion experiments are summarized in Tables III, IV, and V. Individual vapor pressures are plotted in Fig. 1-3 as $\log P$ vs. $1/T$. Constants for the effusion cells are included in Table V.

For Na_2SO_4 , a few torsion-effusion measurements were also made on the solid phase, and these are shown in Fig. 1. Several of these were made on a fresh sample of crystalline Na_2SO_4 , and several on the Na_2SO_4 -Pt mixture after completion of the measurements on the liquid. The two sets are in reasonable agreement and join well with the liquid phase pressures at the melting point, indicating that the Pt "wicking" technique gives satisfactory results.

No total pressure measurements are reported for Li_2SO_4 since the mass spectrum indicated only a minor contribution (< 1%) from molecular sublimation. Also, as noted below, it is likely that the oxide product formed in this

case is present at reduced activity, thereby complicating the interpretation. For comparison purposes, a few preliminary torsion measurements on Li_2SO_4 indicated a total pressure of 7×10^{-8} bar at 1115 K.

Na_2SO_4 pressures measured with the 0.06 cm diam orifice were about 60% higher than those determined with the larger orifice. A similar orifice-size dependence

was found for K_2SO_4 (4). The difference was about 25% for Rb_2SO_4 but was negligible for Cs_2SO_4 . The orifice effect is attributable to undersaturation of the vapor resulting from a kinetic barrier in the vaporization process. The Whitman-Motzfeldt model (11, 17-19) was used to extrapolate the data for Na_2SO_4 and Rb_2SO_4 to zero orifice area to give the equilibrium pressures shown in Fig. 1 and 2; no extrapolation was necessary for the Cs_2SO_4 data. This extrapolation yielded the proportionality constants between steady state and equilibrium pressures for the several cells and samples shown in Tables III, IV, and V. Also shown in Fig. 1-3 are the calculated decomposition pressures for reaction [2]; because of the restriction of congruent vaporization, the calculated partial pressures of M, SO_2 , and O_2 within the effusion cell are not in the integral ratios of 2:1:1 but are adjusted on the basis of their molecular weights so that mass effusion yields stoichiometric M_2SO_4 . In each instance, the total equilibrium pressure is

ing with the atomic weight of the metal. The quantitative implications of the molecular weight data toward vapor composition will be discussed in a subsequent section.

Residual solid phases.—After the effusion runs, cell residues were examined by x-ray diffraction analysis. Except for the case of Li_2SO_4 , sulfates identical to the starting materials were detected, but no oxides or hydroxides were found; aqueous solutions of the residues had the same pH values as comparable solutions of the starting sulfates. These results indicate that these sulfates vaporize congruently, in accord with the observations of Cubicciotti and Keneshea (3) for Na_2SO_4 and of Cubicciotti (5) for Rb_2SO_4 and Cs_2SO_4 ; identical behavior was observed for K_2SO_4 (4).

Examination of the effusion cell after the exploratory measurements on Li_2SO_4 revealed partial melting of the contents, although the cell temperature had been kept below the Li_2SO_4 melting point, 1132 K. The pH of an aqueous solution of the cell residue was 9.5. There are, apparently, no phase diagram data in the literature for the Li_2SO_4 - Li_2O system. The analogous Li_2CO_3 - Li_2O system (20) has a eutectic at 13 mole percent Li_2O and 978 K, 28 K below the Li_2CO_3 melting point. The evidence for partial fusion during incongruent vaporization below the melting point of either Li_2SO_4 or Li_2O suggests that Li_2SO_4 has a similar phase diagram and that vaporization above the eutectic temperature produces a solution with unknown equilibrium values of Li_2O composition and activity. As only a small fraction of specimen was vaporized in our

measurements, Li_2SO_4 was present in excess, and its activity in the effusion cell remained essentially unity; the activity of Li_2O in liquid solution was less than unity. In accordance with the law of mass action as applied to reaction [3], the pressure observed in the exploratory run, due primarily to SO_2 and O_2 , is higher by a factor of five than that calculated from literature thermodynamic data (21) for the case of unit activity for $\text{Li}_2\text{O}(\text{s})$.

Determination of vapor composition.—It is difficult to derive accurately the vapor composition from mass spectra alone, because of uncertainty in the relative ionization cross sections of the various neutrals and because of possible effects of fragmentation on species such as Na^+ , Rb^+ , and Cs^+ . However, with both total pressures and molecular weight data available, vapor composition can be determined quantitatively by two independent routes. From the pressure data alone, the difference between the total pressure, P_T , and decomposition pressure, P_D , is the molecular pressure $P(\text{M}_2\text{SO}_4)$. The quantity $P(\text{M}_2\text{SO}_4)/P_T$ is then the fractional contribution of molecular vaporization to the total pressure. Values of P_T taken from the derived equilibrium pressures, of P_D calculated from thermodynamic data, and of $P(\text{M}_2\text{SO}_4)$ obtained by difference are listed at even temperatures in Table VI.

Alternatively, the vapor molecular weight data can be used to define vapor composition. The overall sulfate vaporization process can be described by the expression

where the stoichiometric coefficient b can be used to quantify the contributions of the two processes. For effusion of a complex vapor, the vapor molecular weight \bar{M}_w determined from simultaneous torsion and gravimetric Knudsen measurements is a weight average value related to the values for the individual species by the expression

$$\bar{M}_w = [\sum m_i(\bar{M}_w)^{-1/2}]^{-2} \quad [5]$$

Table VII. Comparison of derived molecular vaporization pressures and vapor molecular weights

M_2SO_4	From total pressures ^a			From molecular weights		
	b	$P(\text{M}_2\text{SO}_4)/P_T$	\bar{M}_w (calc)	b	$P(\text{M}_2\text{SO}_4)/P_T$	\bar{M}_w (meas)
Na_2SO_4	0.47	0.37	68	0.48	0.36	67
K_2SO_4	0.23	0.61	116	0.26	0.59	110

^a Uncertainty ± 6 kJ·mol⁻¹.

^b Ref. (22).

^c Ref. (23).

where m_i and $(Mw)_i$ are the mass fraction and molecular weights of the i gaseous species. For the overall sulfate vaporization/decomposition process expressed as reaction [4], the observed molecular weight can be related to the coefficient b in the following way

$$\overline{Mw} = \left[\frac{Mw(M_2SO_4)}{(1-b)Mw(M_2SO_4)^{1/2} + 2bMw(M)^{1/2} + bMw(SO_2)^{1/2} + bMw(O_2)^{1/2}} \right]^2 \quad [6]$$

The ratio $P(M_2SO_4)/P_T$ evaluated from the pressure data is also related to \overline{Mw} and b by the expression

$$P(M_2SO_4)/P_T = \left[\frac{(1-b)Mw(M_2SO_4)^{1/2}}{(1-b)Mw(M_2SO_4)^{1/2} + 2bMw(M)^{1/2} + bMw(SO_2)^{1/2} + bMw(O_2)^{1/2}} \right] \quad [7]$$

Therefore, the pressure data alone can be used to derive values of b and then \overline{Mw} for comparison with the directly measured values of \overline{Mw} or, conversely, the latter can be used to evaluate the ratio $P(M_2SO_4)/P_T$ and checked for consistency with the value derived directly from the total pressure measurements.

In Table VII, the pressure ratios $P(M_2SO_4)/P_T$, the average vapor molecular weights \overline{Mw} , and values of the coefficient b obtained by the two different methods are seen to be in remarkably good agreement, giving a high degree of confidence in the vapor composition information. Also included for completeness are results obtained earlier on K₂SO₄ (4). There is a smooth progression from 37% molecular vaporization for Na₂SO₄ to 95% for Cs₂SO₄.

For Li₂SO₄, where the fraction of molecular sublimation was too low to yield meaningful results by the approach described above, an approximate value of $P(Li_2SO_4)/P_T$ was derived from the vapor mass spectrum and a pressure calibration constant based on the vapor pressure of gold. The Li₂SO₄⁺ and SO₂⁺ signals at 1115 K yielded the values $P(Li_2SO_4) = 2 \times 10^{-10}$ bar, $P(SO_2) = 7 \times 10^{-8}$ bar, and $P(Li_2SO_4)/P_T = 0.003$. The estimated SO₂ pressure is in accord with the preliminary torsion value and about a factor of five higher than that calculated for unit activity of Li₂O(s), as expected from the partial melting of the sample and dissolution of Li₂O in Li₂SO₄ at temperatures below the melting point of the sulfate.

Thermodynamics of $M_2SO_4(g)$ species.—The enthalpy change of a reaction is usually calculated from the temperature derivative of the equilibrium constant by the "second-law method" or from individual values of the

^c Calculated values taken from literature sources discussed in the Appendix.

equilibrium constant by the "third-law method," which is based on knowledge of the absolute entropies of reactants and products. For alkali sulfate vaporization, we defin-

itely prefer the second-law method. The spectroscopic and molecular constant data for the gaseous alkali sulfates are still quite incomplete, although the available data have been reviewed and extended with estimates so as to calculate tables of thermodynamic functions (22, 23). The major uncertainties involve the low frequency deformation vibrations and modes involving the metal atoms, leading to uncertainties on the order of ± 17 J·mol⁻¹·K⁻¹ in the calculated entropies at 298 K (22).

In Table VIII are listed the standard enthalpies of sublimation at 298 K of the molecular sulfates derived from the second-law analysis of the M₂SO₄⁺ ion signals. Values for K₂SO₄ from our earlier work (4) are included for completeness, as are previous values from the literature. Heat capacities and enthalpy increments above room temperature are less sensitive to errors in molecular constants than are the entropies and Gibbs energy functions; therefore, the uncertainties associated with the second-law method are smaller than for the third-law procedure for these molecules. For Na₂SO₄, our selected value is based on the liquid phase measurements because of uncertainty over which of the several polymorphic solid phases is involved and the slow rate of transformation between these phases. The standard enthalpies of formation of M₂SO₄(g) shown in Table VIII were based on the enthalpy of sublimation results of this work and values for the solids (22, 23).

The absolute entropies of the gaseous alkali sulfates were derived from the second-law heats of sublimation and derived values of the M₂SO₄ partial pressures at the

experimental temperatures. The results are shown in Table IX along with corresponding values from the literature (22, 23).

Discussion

Our vapor composition data are consistent and are felt to accurately define the relative contributions of molecular vaporization and decomposition to the total vapor pressures of the alkali sulfates. There are, however, some significant differences between these results and those reported earlier. For Na_2SO_4 , results reported before 1979 are reviewed in the JANAF Tables (22), which give a selected value of $P(\text{Na}_2\text{SO}_4) = 1.3 \times 10^{-7}$ bar at 1200 K, compared to our derived value of 3.19×10^{-7} bar; the JANAF value is equivalent to 20% molecular vaporization, compared to 37% found in this study. The subsequent Knudsen effusion results of Halle and Stern (2) which yielded $P(\text{Na}_2\text{SO}_4) = 4.2 \times 10^{-6}$ bar at 1200 K and 14% molecular vaporization are clearly too low. For Rb_2SO_4 and Cs_2SO_4 , Cubicciotti (5) reported less than 1% decomposition in this same temperature region, based on failure to find any evidence for elemental Rb or Cs in the collected effusate. However, these results could have been biased by low sticking probabilities for the alkali atoms on the cool glass collector surface; such behavior has been observed for Mg atoms (24), and we have observed similar behavior for Zn atoms on numerous occasions over the years. It is interesting to note in retrospect that Cubicciotti's comparison (5) of observed effusion data and calculated decomposition pressures indicated about 5% dissociation for Cs_2SO_4 and 20-30% for Rb_2SO_4 , in close agreement with our findings, but this information was discounted as less reliable than the effusate collection results.

The Knudsen effusion data of Cubicciotti (5) on Rb_2SO_4 , when corrected slightly for dissociation, give $P(\text{Rb}_2\text{SO}_4) = 1.5 \times 10^{-6}$ bar at 1200 K, in good agreement with our value of 1.29×10^{-6} bar; similarly, correction of the effusion results of Jagannathan and Wyatt (6) yields $P(\text{Rb}_2\text{SO}_4) = 2.2 \times 10^{-6}$ bar at 1200 K, also in accord with our results. Selected values for Cs_2SO_4 in the JANAF Tables (22), based largely on the effusion data of Cubicciotti (5), lead to $P(\text{Cs}_2\text{SO}_4) = 8.5 \times 10^{-6}$ bar at 1200 K, close to our derived value of 8.18×10^{-6} bar.

Jagannathan and Wyatt (6) concluded correctly that Li_2SO_4 vaporizes incongruently by decomposition to $\text{Li}_2\text{O}(s)$, but their further conclusion that decomposition cannot be the major vaporization process is way off the mark, for unknown reasons. As suggested by Kohl *et al.* (13), interaction of the sulfate samples with alumina-lined tantalum cells may well be responsible for the absence of Li_2SO_4^+ and Na_2SO_4^+ in the mass spectra reported by Ficalora *et al.* (1).

A useful measure of the reliability of the second-law slope heats is given in the comparison of measured decomposition enthalpies derived from parent M^+ and SO_2^+ signals with those calculated from established thermodynamic data. Such a comparison cannot be made for Li_2SO_4 because of the dissolution effects and unknown Li_2O activity mentioned earlier, but in each other instance the M^+ and SO_2^+ second-law values are well within 6 kJ-mol⁻¹ of the calculated values per mole of gas. Comparison of our derived sublimation enthalpies with previous selected values in Table VIII shows the largest deviations for Na_2SO_4 and K_2SO_4 , where those values (22, 23) were obtained primarily from third-law analyses.

As seen in Table IX, the agreement between experimental and calculated entropies is within the estimated error limits in all cases. While the agreement is quite good for Rb_2SO_4 and Cs_2SO_4 , the results indicate that some revision of the estimated frequencies for Li_2SO_4 , Na_2SO_4 , and K_2SO_4 is in order.

Our effusion measurements on Na_2SO_4 , K_2SO_4 , and Rb_2SO_4 showed a pronounced and reproducible dependence on orifice size, while no such effect was observed for Cs_2SO_4 . This orifice-size dependence is generally associated with a kinetic barrier arising from structural or

orientational changes during the transfer from condensed to vapor phase. The decomposition process would clearly require major structural changes during this transition and could be the major contributor to such a kinetic barrier. The absence of an observable orifice-size effect in Cs_2SO_4 , which shows the smallest degree of decomposition, is in line with this reasoning.

Assembled in Table X at a common temperature for ease of comparison are the molecular sublimation and decomposition pressures, and the molar enthalpies and entropies of sublimation. The decomposition pressures show remarkably little variation through the series, while the enthalpies of sublimation show the expected decrease for the heavier salts, leading to higher molecular sublimation pressures.

ABSTRACT

High doses of Sb implanted in silicon and then annealed at a temperature range between 800° and 1200°C cause Sb precipitation and extrinsic diffusion. Sb precipitation has not been completed at temperatures between 800° and 1000°C for 60-400 min duration; a supersaturation of substitutional Sb is detected under the same conditions. The oxidation of such samples causes Sb segregation and anomalous oxide growth. Residual crystal damage after annealing can be observed.

Antimony is a suitable element to study simultaneously diffusion and precipitation in silicon for Sb has a low solubility limit in silicon. A Sb-doped silicon dioxide source is frequently used for the study of antimony diffusion in silicon (1-3). In most of these cases, the Sb concentration in silicon is then just above its solubility limit. These Sb profiles differ from ion-implanted profiles. Sb ion implantation at high doses turns the implanted silicon layer amorphous. The solid phase epitaxy (SPE) growth of this amorphous layer induces a high metastable substitutional antimony concentration at suitable temperatures (4-6). This metastable concentration is far above its solubility limit. After SPE and at temperatures greater than 800°C, antimony precipitation occurs (5, 7).

Experimental results of antimony-implanted silicon annealed at a temperature range between 800° and 1200°C in N₂ or dry O₂ are presented in this work. The behavior of antimony precipitation and diffusion is discussed.

Experimental

FZ <100> silicon crystals of p-type (20 Ω-cm) were implanted with ¹²¹Sb⁺ at room temperature. The implantation energy ranged from 30 to 120 keV, and the dose from 10¹³ to 3 × 10¹⁵ cm⁻². The samples were annealed in N₂ or dry O₂ at 900°-1200°C for 15-120 min. The chemical antimony concentration was measured by SIMS and RBS. The RBS method was also used to determine the substitutional Sb concentration. The SIMS measurements were carried out using a CAMECA IMS-3F ion probe. The electrically active Sb was determined by the four-point probe method combined with anodic oxidation. The measurement error in the concentration was less than 20% for SIMS and less than 30% for electrical measurements. In the depth, the measurement error was less than 10% for both kinds of measurement.

Results and Discussion

Figure 1 shows the RBS measurements of an antimony-implanted and -annealed sample (120 keV, 3 × 10¹⁵ cm⁻², 1000°C, 60 min, in N₂). The figure shows the random and the aligned spectrum of this specimen. For comparison, a

<100>-aligned reference signal of an unimplanted silicon crystal is given (broken line). The higher aligned RBS signal (circles) of Si suggests that after annealing the silicon sample still contains residual damage. The random (squares) and aligned (circles) RBS spectrum for Sb shows that a part of Sb is not substitutional. This not substitutional part can be correlated with the SIMS measurement in Fig. 2. The measured sample in Fig. 2 (curve 2) is the same as in Fig. 1. In this figure, the measured implantation profile (curve 1) prior to annealing is also shown. Below a concentration of ≈ 6 × 10¹⁹ cm⁻³, the annealed profile broadens because antimony diffusion occurs. Above this concentration, the antimony atoms are immobile. Therefore, in this concentration range diffusion does not take place. Curve 2 indicates that the immobile Sb makes up ≈ 70-80% of the implantation dose (area of profile above 6 × 10¹⁹ cm⁻³).

Furthermore, the earlier RBS measurement (Fig. 1) shows that these atoms are not found on substitutional sites. Therefore, it can be concluded that these immobile antimony atoms are precipitates. The concentration of 6 × 10¹⁹ cm⁻³ at which Sb diffusion takes place is higher than the Sb solubility limit of ≈ 4 × 10¹⁹ cm⁻³ (8). Therefore, Sb diffusion occurs before the precipitation process reaches its thermodynamical equilibrium. Moreover, the substitutional antimony concentration may be far above its solubility limit as shown in Fig. 3. The upper profile (curve 1) in Fig. 3 shows the total Sb concentration (solid circles) and the substitutional electrically active concentration (open circles) of a further antimony sample (50 keV, 3 × 10¹⁵ cm⁻², 900°C, 60 min in N₂). At 900°C, the solubility limit of Sb is ≈ 3 × 10¹⁹ cm⁻³ (8). The maximal electrically active concentration shown in Fig. 3 is ≈ 7 × 10¹⁹ cm⁻³. In this case, the substitutional antimony concentration is more than a factor two above the corresponding solubility limit and outside the limits of our experimental measurement error. Therefore, it may be concluded that a supersaturation of substitutional antimony atoms exists and that the precipitation has not reached its thermal equilibrium. This conclusion will be clearly supported later in this paper by the comparison of antimony pro-

Fig. 1. Random (squares) and $\langle 100 \rangle$ -aligned (circles) RBS spectrum (1, 7 MeV, He^+) of a Sb implanted (120 keV , $3 \times 10^{15} \text{ cm}^{-2}$) and annealed (1000°C , 60 min, N_2) sample. For comparison, the $\langle 100 \rangle$ -aligned signal (dotted line) of an unimplanted specimen is given.

files annealed at different temperatures as in Fig. 6, which shows that the shoulder concentration increases as

Fig. 2. SIMS measurement of an implanted (squares) (120 keV , $3 \times 10^{15} \text{ cm}^{-2}$) and then annealed (solid circles) (1000°C , 60 min, N_2) Sb-doped sample. The annealed sample is the same as in Fig. 1.

Fig. 3. Sb implantation at 50 keV for $3 \times 10^{15} \text{ cm}^{-2}$ (curve 1) and for 10^{13} cm^{-2} (curve 2). Annealing at $T = 900^\circ\text{C}$ for 60 min (curve 1) and for 120 min (curve 2) in N_2 . In this figure, the SIMS measurement (solid circles, squares) of both curves and the electrical measurement (circles) of curve 1 are shown.

Fig. 4. Sb implantation carried out at 50 keV for a dose of $3 \times 10^{15} \text{ cm}^{-2}$. The annealing was carried out in N_2 , at $T = 800^\circ\text{C}$, for 120 min. In this figure, the SIMS (solid circles), RBS (triangles), and electrical measurements (squares) are given.

the temperature decreases. This experimental result supports the idea that by annealing of high implantation doses the solid phase epitaxy (SPE) causes a high supersaturation of substitutional antimony in silicon. After further annealing Sb precipitation takes place (5, 6).

Fig. 5. Sb implantation with the same parameters as in Fig. 3 (50 keV, $3 \times 10^{15} \text{ cm}^{-2}$, curve 1). The annealing was carried out in N_2 at 1200°C for 15 min.

Fig. 6. The SIMS profiles of Fig. 3 (curve 1) (solid circles), Fig. 4 (squares) and Fig. 5 (triangles) are shown.

The decrease of the carrier concentration (n) toward the surface in Fig. 3 cannot be explained with accuracy yet. The possibility of a measurement effect as reported in Ref. (9, 10) by the electrical measurement of As profiles implanted through a oxide cannot be excluded. This, however, does not affect the above conclusions because the main objective of the electrical measurements in this work is to show that the concentration at the shoulder profile is also electrically active being a further support of the presence of substitutional antimony at this level

Fig. 7. Thermal annealing of an Sb-implanted sample (80 keV, $3 \times 10^{15} \text{ cm}^{-2}$). A thermal oxidation was carried out at 800°C in dry O_2 for 400 min followed by annealing in N_2 for 15 min. The dashed vertical line represents the SiO_2/Si interface.

(which can diffuse before the precipitation reaches its thermodynamical equilibrium).

Curve 2 in Fig. 3 shows the profile of another antimony sample implanted at 50 keV with a dose of 10^{13} cm $^{-2}$ and annealed at 900°C for 120 min in N $_2$. The maximal antimony concentration of this sample is lower than its solubility limit at this temperature.

A high substitutional antimony supersaturation can be reached by annealing high Sb implantation doses at low temperatures, as shown in Fig. 4. A specimen was annealed at 800°C for 120 min with the same implantation parameters as the sample in Fig. 3 (curve 1). The SIMS (solid circles), the RBS (triangles), and the electrical (squares) measurements are shown. The electrical profile shows a sharp change in the carrier concentration at a depth of ≈ 50 nm. It cannot be discerned if this jump in profile arises from the damage in the crystal. Nevertheless, a broadening of the total antimony concentration profile at $\approx 4 \times 10^{20}$ cm $^{-3}$ is recognizable. This broadening can be clearly seen by comparing the profile in Fig. 3 (curve 1) and the profile in Fig. 4 as done in Fig. 6. Consequently, Sb diffusion at 800°C for 120 min takes place. The substitutional electrical Sb concentration is at least by a factor ≈ 3 above its solubility limit at 800°C. This indicates that the precipitation process at this temperature is slow and has not been concluded. Moreover, this high substitutional antimony supersaturation supports the model in Ref. (5, 6) mentioned earlier.

Annealing at higher temperatures of high Sb-implanted doses was also carried out. A specimen with the same implantation parameters as in Fig. 3 (curve 1) was annealed at 1200°C for 15 min in N $_2$. The measured antimony profile is shown in Fig. 5. The peak in the profile at which the precipitation is located is considerably smaller than in Fig. 2-4. The concentration of $\approx 6 \times 10^{19}$ cm $^{-3}$ at which the tail of the profile begins corresponds with the solubility concentration of Sb at 1200°C (8). Here, the precipitation appears to reach its equilibrium value. The occurrence of supersaturated substitutional antimony is clearly seen by comparing the samples of Fig. 3 (curve 1), 4 and 5 as shown in Fig. 6. From this figure, it may be concluded

Fig. 8. Sb implantation at 80 keV for 3×10^{15} cm $^{-2}$. Thermal oxidation was carried out at 1000°C in dry O $_2$ for 40 min followed by annealing in N $_2$ for 15 min. The interface SiO $_2$ /Si is given by the vertical dashed line.

Fig. 9. The implantation parameters are the same as in Fig. 7 and 8. Thermal oxidation was realized in dry O $_2$ at 1200°C for 5 min. Then the sample was annealed in N $_2$ for 15 min. The interface SiO $_2$ /Si is given by the vertical dashed line.

that the supersaturation of Sb increases at lower temperature. Also, the antimony concentration level at which the diffusion takes place is increased by lowering the temperature.

In the following, we describe Sb high dose-implanted silicon specimens which were annealed in oxidizing atmosphere. The samples were implanted at 80 keV with doses of 3×10^{15} cm $^{-2}$. The annealing was performed in dry O $_2$ at 800°C for 400 min (sample 1), at 1000°C for 40 min (sample 2), and at 1200°C for 5 min (sample 3). Then, the samples were annealed at the respective temperature in N $_2$ for 15 min. This last annealing step causes only a

Fig. 10. The thermal oxide thickness of the doped samples 1, 2, and 3 are compared with the respective thermal oxide thickness of the undoped samples 1', 2', and 3'.

further diffusion and precipitation of Sb. At the same time, undoped samples (1', 2', 3') were treated using the respective annealing parameters. The measurements were performed by SIMS avoiding the matrix effect at the SiO₂/Si interface (12, 13). Figure 7 (sample 1), Fig. 8 (sample 2), and Fig. 9 (sample 3) show the antimony concentration profiles in oxide and in silicon. The antimony precipitation and diffusion in these figures show a similar behavior as discussed earlier. Although not much is known about the segregation of Sb at Si/SiO₂, it is assumed that Sb piles up during thermal oxidation in silicon (14, 16). Therefore, the Sb segregation coefficient ($m = C_{(Si)}/C_{(SiO_2)}$) is greater than 1 at the SiO₂/Si interface. However, in Fig. 7-9, $m = 1$ for all three cases, probably because the antimony precipitates influence the Sb segregation. The thickness of the thermally grown oxide is not the same on the Sb doped and undoped specimens. This is shown in Fig. 10. The reason for this deviation cannot be given.

Summary and Conclusions

At higher Sb implantation doses at annealing temperatures between 800° and 1000°C, the antimony substitutional concentration exceeds its solubility limit at these annealing temperatures for times up to 400 min. The amount of Sb substitutional supersaturation is the larger the lower the temperature. At 1200°C after 15 min, Sb precipitation has reached its equilibrium value. At the same time that antimony precipitates, extrinsic Sb diffusion takes place. RBS measurements show residual crystal damage caused by Sb ion implantation and/or antimony precipitation. The Sb segregation coefficient for the SiO₂/Si system does not follow the expected behavior. Moreover, an anomalous thermal oxide growth can be observed.

Effect of Oxidation Ambient on the Electrical Properties of Thin Silicon Oxide

Richard G. Cosway*

Motorola, Incorporated, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

Beneficial effects of growing oxide, particularly gate oxide, with some chlorine present have been known for some time. Monkowski's paper (1) provides an excellent review of these effects which include better passivation, minority carrier lifetime enhancement, improved dielectric breakdown characteristics, increased growth rate, and stacking fault suppression over oxides grown in dry O₂.

The purpose of the present investigation was to see if some of the same benefits realized for thicker oxides grown in an HCl containing ambient still apply to thinner (150Å) oxides.

Experimental

The starting material was Czochralski-grown, 75 mm, silicon wafers of <100> crystal orientation phosphorus

*Electrochemical Society Active Member.

doped to 7.5-12.5 Ω-cm. Immediately prior to each run, the diffusion tube, boat, and push rod were cleaned in 10 volume percent (v/o) HCl, 90 v/o N₂ for 1h at 1000°C. All oxidations were carried out at 900°C in a 150 mm quartz tube. Dry O₂ runs had an O₂ flow rate of 10 liter/min, while torch runs had O₂ and H₂ flow rates of 6 and 10 liter/min, respectively. HCl runs used no HCl during the first half of the oxidation cycle and 0.3 liter/min during the last half. Immediately following oxidation, wafers were annealed in N₂ at 900°C for 1h.

Oxide thicknesses were measured on an IBM 7840 film thickness analyzer. Electrical measurements were made on capacitors formed by depositing aluminum (dc magnetron) through a shadow mask to give a nominal size of 7.5 × 10⁻³ cm². The back oxide was stripped and aluminum was deposited so as to give good ohmic contact. The front

and back aluminum was then annealed for 30 min in 5 v/o H_2 , 95 v/o N_2 at 450°C.

C-V plots contained three traces: (i) unbiased, (ii) biased for 1 min at 200°C at 4.5V, and (iii) biased for 1 min at 200°C at -4.5V. Total flatband voltage shifts were obtained by taking the difference between the leftmost and rightmost traces at flatband.

Breakdown voltages were measured using a Tektronix Model 576 curve tracer. The dc voltage was ramped manually until the capacitor ruptured.

Leakage currents were obtained using an HP 4140B picoammeter. Interface-trapped charge values (reported as the density of states at mid bandgap) were obtained from quasi-static C-V measurements using the HP 4140B picoammeter.

Results

Table I shows that oxidation in O_2/HCl gives higher C-V shifts than oxidation in dry O_2 . Wafers oxidized in H_2O/HCl did not give enough good C-V traces to enable a statistically significant evaluation. Most of the capacitors produced in H_2O/HCl were broken down by the bias-temperature-stress of 4.5V at 200°C for 1 min. From the results in Table I, which give the average values and standard deviation from three runs (2 for O_2/HCl) 2 wafer/run and 2 capacitor/wafer, H_2O appears to give a greater total C-V shift than O_2 .

The higher C-V shifts for the O_2/HCl and H_2O oxidations were mostly due to a negative shift after positive BTS (i.e., trace 2 is shifted to the left of trace 1). This may be due to the enhanced equilibrium alkali concentration within the tube in the presence of H_2O and/or HCl (2). Creation of interface traps in the presence of H_2O (3, 4) may also be related to the higher C-V shift. Note that some H_2O is present during the HCl/O_2 oxidation due to the decomposition of HCl .

Table I also shows that yield is determined mainly by oxidant and that the presence of HCl has minimal effect. The yields ($> 10 \text{ MV}\cdot\text{cm}^{-1}$) exclusive of tertiary defects from three runs (two for O_2/HCl) 2 wafer/run and at least 15 capacitor/wafer are shown for each ambient. Comparisons were made among the various ambients using statistical analysis which showed (i) O_2 can be considered equivalent to O_2/HCl and H_2O can be considered equivalent to H_2O/HCl , (ii) H_2O appears to give greater yield than O_2 , and (iii) with 90% confidence, H_2O/HCl gives greater yield than O_2/HCl . The higher yield obtained from H_2O oxidation may be caused by the micropores being filled by OH groups to give more uniform electric fields (3) than would be the case for oxides grown in dry O_2 .

The cumulative failures as a function of applied field is shown in Fig. 1, where it can be seen that the O_2/HCl ambient yields oxides with the most cumulative failures below 11 $\text{MV}\cdot\text{cm}^{-1}$, while oxides grown in H_2O/HCl have the lowest cumulative failure up to 15 $\text{MV}\cdot\text{cm}^{-1}$.

Leakage currents measured at 5 $\text{MV}\cdot\text{cm}^{-1}$ (7.5V for 150Å oxides) gave less than 0.5 $\text{nA}\cdot\text{cm}^{-2}$ for all ambients, and for those capacitors breaking down at $> 10 \text{ MV}\cdot\text{cm}^{-1}$ the average breakdown field was approximately 12.5 $\text{MV}\cdot\text{cm}^{-1}$.

The interface-trapped charge, Q_{it} , for the various ambients is also shown in Table I. All values are the same order of magnitude, with the O_2/HCl oxides yielding the

Table I. Summary of electrical properties for 150Å oxides

Additive	Oxidant	Total flatband shift (mV)	Yield $> 10 \text{ MV}/\text{cm}$ (%)	Interface-trapped charge ^a ($\text{cm}^{-2}\cdot\text{eV}^{-1}$)
No HCl	O_2	13 ± 3	88.4 ± 7.2	3×10^{11}
HCl	O_2	24 ± 7	86.3 ± 12.1	6×10^{11}
No HCl	H_2O	40 ± 26	93.0 ± 9.2	4×10^{11}
HCl	H_2O	—	96.9 ± 6.3	3×10^{11}

^a Determined from the density of states at midbandgap.

Fig. 1. Cumulative failures as a function of applied field for 150Å oxides grown in various ambients.

highest value of $6 \times 10^{11} \text{ cm}^{-2}\cdot\text{eV}^{-1}$. This may be explained by the findings of Kriegler (5), wherein the use of dry HCl was shown to lead to damage of the silicon surface.

The data for H_2O and H_2O/HCl oxidation were presented only for completeness, since the growth rate in these ambients are too rapid to enable good process control for 150Å oxides.

Discussion

The increased oxide growth rate reported to occur when HCl is present (6) was not observed in the present study. This is probably because the growth takes place in the linear regime of oxidation for these thin films where the HCl was shown to have no effect. The effect of HCl on stacking faults and minority carrier lifetimes was not examined in the current study.

While the passivating properties of the oxides were not measured by intentional contamination, the as-grown films produced in O_2 seemed to contain less alkali impurities (from flatband shifts) than those produced in O_2/HCl (Table I). The as-grown impurity level may be more important than the passivating properties of the oxide for future VLSI applications where downstream processing will be cleaner than today's.

It is possible that cleaning the tube at a considerably higher temperature may reduce the alkali levels observed for the films grown in O_2/HCl ; however, this was not investigated.

The breakdown characteristics of the dry O_2 oxides appear equivalent to those for O_2/HCl oxides (Table I). This, coupled with the arguments presented above, shows that oxides grown in dry O_2 may well be the gate oxides of the future.

By growing oxides in dry O_2 only, retaining HCl solely as a tube cleaning agent, the problems of HCl corrosion can be minimized. Since precise control of HCl flow rate is not necessary for tube cleaning, it can be plumbed to the furnace separately from the other process gases and, as such, can be kept away from the expensive furnace parts that it may corrode.

Another approach is to use an alternate chlorine source to HCl such as TCA (1,1,1-trichloroethane). While this limits the corrosive problems within the gas cabinet, the potential formation of toxic gases (7), explosion potential (8), as well as poorer oxides grown under these conditions (9) make this alternative less than optimal.

Conclusions

The current investigation has shown that the presence of HCl during growth of thin (150Å) oxides materially affects neither the yield ($> 10 \text{ MV}\cdot\text{cm}^{-1}$), average breakdown field above 10 $\text{MV}\cdot\text{cm}^{-1}$, nor the leakage current. For dry oxidation, the presence of HCl actually increases the total flatband shift and slightly increases the interface-trapped charge. H_2O has been shown to give higher yield but worse C-V shifts than O_2 .

Thus, it is feasible to grow thin oxides in dry O₂ only, still utilizing HCl for tube cleaning, however.

Acknowledgments

I would like to thank C.-E. Wu for his valuable contributions to this work including data analysis. I would also like to thank John Seeger for providing the metal deposition, Ginger Stapleton for providing the leakage current and quasi-static C-V measurements, and Fran Sanchez for providing the breakdown and high frequency C-V measurements.

Effects of Surface Oxide on Leakage Current of Magnetron-Sputtered Ta₂O₅ on Si

Shunji Seki, Takashi Unagami, and Osamu Kogure

Nippon Telegraph and Telephone Corporation, Ibaraki Electrical Communication Laboratories, Tokai, Ibaraki 319-11, Japan

In recent years, tantalum pentoxide (Ta₂O₅) films have attracted much interest for use as storage capacitors in large-scale integrated memory cells and as gate insulators in MOS devices. The higher dielectric constant for Ta₂O₅ films, compared with that for SiO₂ films, makes them attractive for these devices. For these applications, Ta₂O₅ films were prepared by chemical vapor deposition (CVD) and thermal oxidation of a deposited Ta film (1, 2). In these investigations, it has been shown that these films show very high leakage current, and that low temperature heat-treatment around 400°C results in a significant deterioration in the resistivity of Ta₂O₅ films, especially with aluminum electrodes in place. In order to reduce the leakage current, dual-dielectric structures such as Ta₂O₅/SiO₂ have been fabricated. It has been demonstrated that thermal oxide grown by interfacial oxidation between Ta₂O₅ and the silicon substrate reduces the leakage current in the Ta₂O₅ (30 nm)/SiO₂(12 nm)/Si structure (3). However, in this dual-dielectric structure, the effective dielectric constant of the dual-dielectric film is less than 10 due to the existence of the low dielectric constant SiO₂ between Ta₂O₅ and Si. Therefore, Ta₂O₅ films with high dielectric constant and low leakage current are necessary if these films are to be used in electronic devices.

The authors have demonstrated that a low dielectric constant transition layer formed at the silicon interface plays a key role in determining the electrical properties of RF magnetron-sputtered Ta₂O₅ on Si (4). This transition layer can be formed as a result of the interaction between the sputtered particles and the silicon substrate in the initial stage of Ta₂O₅ formation. The present work explores the role of surface oxide on the silicon substrate prior to sputtering deposition in the formation of the transition layer at the interface and the electrical characteristics of the deposited film. This note indicates that the surface oxide exerts an important effect on the leakage current and dielectric properties of Ta₂O₅ films deposited on Si.

Experimental

Leakage current characteristics were measured by using an Al/Ta₂O₅/Si capacitor. Single-crystalline silicon wafers (p-type, <111>-oriented and 2 Ω-cm) were used as substrates. These substrates were cleaned by a mixture of H₂SO₄ and H₂O₂ (volume ratio of H₂SO₄/H₂O₂ = 4/1), and then rinsed in deionized water. Immediately before being installed into the sputtering chamber, the substrates were

dipped into dilute HF to remove the oxide formed during the previous processing steps. Surface oxide thickness at the silicon surface prior to sputtering was adjusted to 1.8 nm (sample A) and 2.5 nm (sample B) by oxidation in the plasma. Surface oxide thickness was measured by ellipsometry and the contact angle of water drops on the surface (5). On these substrates, Ta₂O₅ films were fabricated using an RF magnetron sputtering system. The Ta₂O₅ target was of 10 cm diam and 5 mm thickness. The sputtering was performed in a mixture of argon and oxygen (partial pressure ratio of Ar/O₂ = 90/10). The deposited film thickness was determined by ellipsometry at the wavelength of 632.8 nm. Electron-beam-evaporated aluminum was used for electrodes. Prior to measurements, these MOS capacitors were annealed at 450°C in a hydrogen ambient. After annealing, leakage current characteristics were measured in a dark, shielded box. A negative external voltage was applied to the aluminum electrode in these measurements. In addition to these measurements, dielectric properties of the Ta₂O₅ films were also measured. These measurements were performed for more than 50 capacitors fabricated on the same silicon substrate.

Results and Discussion

Figure 1 shows typical leakage current characteristics for sample A and B. A drastic change can be seen in the leakage current characteristics. The film thickness of sample A is 70.5 nm, and that of sample B is 60 nm. The leakage current in sample A is more than eight orders of magnitude lower than that in sample B when an external electric field of 1 MV/cm is applied. The leakage current in sample A is 1.5×10^{-9} A/cm² at 1 MV/cm. The dielectric breakdown strength is more than 6×10^6 V/cm. It should be noted that this capacitor was annealed in a hydrogen ambient at 450°C with aluminum electrodes on the Ta₂O₅ film. This result clearly indicates that the surface oxide on the silicon substrate prior to sputtering plays a key role in determining the leakage current characteristics, since Ta₂O₅ films in both samples were deposited under the same sputtering conditions.

Figure 2 indicates frequency dispersions in the capacitance of sample A and B. Capacitance was measured at an external bias voltage of -5V applied to the Al electrode. Capacitances at each frequency were normalized by the capacitance measured at 1 MHz. No frequency dispersion

Fig. 1. Current-voltage characteristics of sample A and B. Surface oxide thickness of sample A is 1.8 nm, and that of sample B is 2.5 nm.

Fig. 2. Frequency dispersion in the capacitance of sample A and B.

has been observed for sample A in the range of 1 kHz-1 MHz. On the other hand, a large frequency dispersion has been observed for sample B. The dielectric constant of sample A is calculated to be 16.5 at 1 MHz. This higher dielectric constant, compared with that of dual-dielectric

structures, makes RF magnetron-sputtered Ta₂O₅ films more attractive for application to electronic devices. Dielectric loss of the film at 1 kHz was less than 0.1% in sample A, but was more than 10% in sample B. These results indicate that high quality Ta₂O₅ films can be obtained on Si by controlling the thickness of the surface oxide.

In addition to the above-mentioned leakage current and dielectric characteristics, a remarkable change was observed in film thickness and index of refraction depending on the surface oxide thickness. When Ta₂O₅ film was deposited on Si substrates with different surface oxide thicknesses for the same sputtering period under the same sputtering conditions, the thickness of the film deposited on the Si substrate with 1.8 nm thick surface oxide was 72 nm, while that of the film deposited on Si with 2.5 nm thick surface oxide was 61.5 nm. The effective indexes of refraction for the films deposited on the former and the latter substrates were 2.04 and 2.12, respectively. This remarkable change in the film thickness and index of refraction might be due to the effect of surface oxide thickness on the transition layer formation mechanism in the initial stage of Ta₂O₅ formation on silicon.

Conclusion

It has initially been indicated that surface oxide prior to sputtering plays a key role in determining the leakage current and dielectric characteristics of magnetron-sputtered Ta₂O₅ on Si. By reducing the surface oxide thickness to as low as 1.8 nm, the leakage current after annealing becomes about 1×10^{-9} A/cm² at 1 MV/cm. The dielectric breakdown strength is more than 6×10^6 V/cm. Furthermore, dielectric constant reaches 16.5, which is much higher than that of the dual-dielectric structure. No frequency dispersion was observed in the film capacitance from 1 kHz through 1 MHz, and dielectric loss of the film was lower than 0.1% at 1 kHz. These results clearly demonstrate that high quality Ta₂O₅ films with high dielectric constant and low leakage current can be obtained on Si with magnetron sputtering by controlling the surface oxide thickness prior to deposition.

Preparation of Thin ($0.6 \mu\text{m}$) Continuous Monocrystalline Silicon over SiO_2

L. Jastrzebski,* J. F. Corboy, R. Pagliaro, Jr., and R. Soydan

RCA Laboratories, Princeton, New Jersey 08540

Silicon-on-insulator (SOI) technology is a technique under development to obtain monocrystalline silicon over SiO_2 islands, which can be used as an alternative to SOS (1). If this technology can be successfully accomplished in an economical fashion to provide VLSI-quality layers (2), device problems such as latchup (3) and bird's beak (4) can be eliminated wherever this growth technique is applicable.

Several SOI approaches are currently under investigation [for the assets and liabilities of the various approaches see, *e.g.*, Ref., (5)]. With some of the SOI techniques, it is difficult to provide a thin ($\sim 0.5 \mu\text{m}$) silicon layer over oxide islands. For SOI films obtained by epitaxial lateral overgrowth (ELO), a monocrystalline silicon layer is grown by selective CVD from the openings in the oxide mask (deposition conditions are chosen to prevent silicon nucleation over the oxide during homoepitaxial growth) (5-8). The epi layer grows vertically until it is level with the SiO_2 mask and then laterally over the SiO_2 mask as it continues its vertical growth. Growth is continued until the growth fronts, seeded from opposing windows, meet to form a continuous film of silicon. The minimum thickness at which an acceptably smooth, continuous, epitaxial film is obtained depends on the lateral to vertical growth rate ratio (overgrowth ratio) and the width of the SiO_2 islands. Although overgrowth ratios of 10:1 (6) and 40:1 (7) have been reported, low defect densities in ELO films have been reported only for films prepared at a 1:1 ratio (8). If the final SOI film thickness is greater than required for successful circuit applications, *e.g.*, for use as an alternative to $0.6 \mu\text{m}$ thick SOS films, the SOI film could be thinned to the desired thickness by oxidation. Although in the present work we discuss the application of oxide thinning to SOI films obtained by the ELO process, this approach could be used for any SOI film which is too thick for a given device fabrication process. We believe that oxidation thinning is a reliable, economical technique to obtain, in a reproducible way, uniform films of desirable thicknesses ($\sim 0.5 \mu\text{m}$) with smooth surfaces.

The substrates were (100)-oriented silicon patterned with stripes of $0.65 \mu\text{m}$ thick, $6.0 \mu\text{m}$ wide SiO_2 with $6.0 \mu\text{m}$ wide exposed silicon regions between the SiO_2 stripes. The epitaxial films were prepared in a chemical vapor deposition reactor (AMC 7900) at 1050°C at 760 torr using a mixture of SiH_2Cl_2 , HCl , and H_2 . The deposition process was a two-step growth cycle (9). The samples described in this paper were grown at approximately $0.3 \mu\text{m}/\text{cycle}$ for 21 cycles, to give $6 \mu\text{m}$ thick ELO films.

After epitaxial growth, the wafers are removed from the CVD reactor and thinned by oxidation at 1100°C in HCl steam. A maximum of $2.1 \mu\text{m}$ of oxide was grown during each oxidation step, after which the wafers were removed from the oxidation furnace and the SiO_2 film was stripped in buffered HF . When additional silicon thinning was required, the wafers were cleaned and oxidized again. The amount of silicon removed by oxidation was calculated using the formula (10) $t_{\text{Si}} = 0.45t_{\text{ox}}$ (where t is thickness).

Cross-sectional SEM micrographs of the as-grown SOI structure and the structures obtained after each thinning are shown in Fig. 1. The flat continuous nature of the silicon film over and between the SiO_2 strips is evident in Fig. 1E and 1E'. It is clear that the SOI layers thinned to 3.2 , 1.6 , 1.1 , and $0.6 \mu\text{m}$ have the same flatness as the as-grown film

According to our experience, it is not currently possible to obtain continuous $0.6 \mu\text{m}$ thick epitaxial silicon films over $0.6 \mu\text{m}$ thick (or thicker), $6.0 \mu\text{m}$ wide (or wider) SiO_2 using only an epitaxial CVD technique. By combining a CVD growth technique that provides epitaxial silicon with a post epi thinning technique, "oxidation," we are able to obtain this structure.

The process of the oxidation of silicon is well documented (11, 12). The oxidation conditions used to obtain the data presented in this paper were used to demonstrate only the feasibility of oxidation as a thinning technique, and not the practicality of the technique. A practical method of removing 5 - $10 \mu\text{m}$ of silicon would be to use a high pressure (13-15) oxidation procedure.

The time required to grow 0.5 , 1 , 2 , 3 , 4 , 5 , and $6 \mu\text{m}$ of SiO_2 , which corresponds to the removal of 0.22 - $2.7 \mu\text{m}$ of silicon, is given in Table I for oxidation performed at various temperatures in steam at atmospheric pressure and at 20 atm. The columns labeled I and II represent the total time required to remove the amount of silicon shown in the right-hand column, using one oxidation step or two separate but equal length steps (the first oxidation step is followed by oxide removal).

The most practical way of performing thinning by oxidation is to use high pressure (~ 20 atm). From an economical standpoint, the thinning should be performed at high temperatures (1200°C), since the oxidation time is short. If diffusion of impurities need be taken into consideration, as in the case of vertically integrated (three-dimensional) structures, the thinning by oxidation should be carried out at low temperature, high pressure, and with repetitious oxidation steps. For example, during the thinning of $2.25 \mu\text{m}$ of silicon by oxidation at 800°C , at 20 atm, using two successive oxidation steps the impurity

movement (\sqrt{Dt}) is kept to a minimum (D is the diffusion constant of an impurity, and t equals time). The impurity redistribution will be 0.015 μm for boron and 0.005 μm for arsenic using $D_B = 3 \times 10^{-3}$ and $D_{As} = 1 \times 10^{-3}$ $\mu\text{m}^2/\text{h}$. This amount of diffusion will not significantly affect already made devices previously fabricated in the first level of the circuit.

Another issue is the reproducibility and uniformity of SOI films thinned by oxidation. Oxidation is a standard step used by IC processing and the reproducibility of the oxide thickness is controlled to within about $\pm 1\%$ during oxide formation. Also, the uniformity of the oxide across a wafer is $\leq \pm 1\%$. Therefore, the major variations in the thickness of the thinned SOI film during oxidation are associated with the as-grown epitaxial film uniformity and reproducibility. To date, there are not sufficient data on the reproducibility of the ELO process, but the results collected so far indicate that uniformity across the wafer (for identical patterns) is similar to the homoepitaxial layers which is about $\pm 5.0\%$ [for a detailed discussion, see Ref. (16)]. Since this thickness variation will be reflected during thinning, a 6 μm thick SOI film thinned to 0.5 μm will have a ± 0.30 μm thickness variation. For CMOS applications (17), approximately 3 μm thick ELO films overgrowing 3 μm wide SiO₂ islands will be used, and in this case the thinned film thickness variation will be about ± 0.15 μm , which is acceptable for any VLSI application.

We propose that thin (0.6 μm), acceptably smooth, continuous silicon over and between SiO₂ layers can be obtained in an economically viable fashion if CVD growth is combined with thinning by oxidation. This process uses a reliable, economically viable approach to obtain, in a reproducible way, uniform films of desired thicknesses. When combined with high pressure oxidation it can also be used for vertically integrated (three-dimensional) circuits.

The Fabrication of CMOS Structures with Increased Immunity to Latchup Using the Two-Step Epitaxial Process

L. Jastrzebski,* J. F. Corboy, R. Soydan, R. Pagliaro, Jr., and C. Magee

RCA Laboratories, Princeton, New Jersey 08540

Latchup between p and n transistors in CMOS circuits is one of the primary problems that has to be overcome before the spacing between n and p transistors can be

*Electrochemical Society Active Member.

substantially reduced (1,2). Trenching and the use of heavily doped substrates are currently used to reduce latchup between n and p regions (3). Trenching puts a physical barrier between the n and p regions, whereas

Fig. 1. Processing sequence for a latchup-resistant structure using an epitaxial lateral overgrowth technique.

heavily doped substrates provide a high conductivity, low minority carrier region thereby reducing the minority carrier flow between n and p transistors (4). Currently, 15 μm thick epi layers are being used. This thick epi layer is required to prevent the impurities that out-diffuse from the heavily doped substrate, during well drive, from reaching the bottom of the well region. Due to crystallographic defect generation and practical considerations with present trench technology, only 1-2 μm deep trenches (5) are possible. This leaves a region approximately 13-14 μm thick above the substrate-epi layer interface through which latchup can occur.

Other approaches are being sought to improve CMOS circuits resistant to latchup. One approach is based on

Fig. 2. SEM cross-sectional photomicrograph of n^- and p^- epi layers separated by oxide. The oxide has been removed to enhance clarity in this micrograph.

megaelectronvolt implanting a heavily doped region underneath the well (6), which allows one to have close spacing between the heavily doped regions and the well. Another approach is SOI/SOS technology (7, 8), which yields a totally isolated silicon island. In this paper a new approach to obtain latchup resistant structures is reported. This approach is based on a two-step epitaxial lateral overgrowth (ELO) (9, 10) process. The processing steps are shown in Fig. 1. First, a thin 400 \AA thick oxide (800 $^\circ\text{C}$ in HCl steam) and an 800 \AA thick nitride are grown. A photolithographic pattern corresponding to n or p regions is defined in the photoresist and etched into the $\text{Si}_3\text{N}_4 + \text{SiO}_2$ mask. Subsequently, the first ELO growth step is performed (Fig. 1A). Growth is carried out at 1050 $^\circ\text{C}$ at 100 torr using SiH_2Cl_2 , dopant, and HCl in H_2 in a radiantly heated barrel reactor. The deposition process is a series of two-step cycles. One cycle consists of a deposition step and an etch step. In the deposition step, SiH_2Cl_2 , dopant, and HCl are added to the H_2 carrier for 1 min. At the end of the deposition step, the SiH_2Cl_2 and dopant are removed from the gas stream and the etch step (second step) begins and continues for 1.5 min. The epi layers are grown at a rate of approximately 0.43 $\mu\text{m}/\text{cycle}$ for eight cycles. Dopant is excluded from the first cycle, and the system is purged for 10 min between the first and second cycles to reduce autodoping. Dopant is added to cycles two through eight, and no purge is used between these cycles.

The CVD deposition conditions are such that no silicon nucleates on the Si_3N_4 , but selectively grows in the area of exposed silicon (10), giving the structure shown in Fig. 1A. Subsequently, the epi layer is oxidized at 1050 $^\circ\text{C}$ for 1h in HCl steam to form 1.0 μm of oxide (Fig. 1B). This oxidation step is followed by a wet nitride etch and a "short" wet oxide etch to remove the 800 \AA Si_3N_4 and the 400 \AA SiO_2 layers (Fig. 1C), exposing substrate regions which are not covered by the first epi layer. Subsequently, a second selective epitaxial growth step is performed (Fig. 1D) identical to the first epi growth with the exception of using the opposite conductivity dopant type. After the second growth, the oxide is removed and the wafers are put through the remaining portion of a standard CMOS process.

The n^- and p^- epi layers are isolated from each other by an oxide layer which extends from the epitaxial surface to the $\text{Si}_3\text{N}_4/\text{SiO}_2$ pattern layer on the heavily doped

Fig. 3. SIMS profiles of the antimony concentration in the second epitaxial layer (broken line) and in the first epitaxial layer (solid line) after deposition.

substrate surface. A SEM cross-sectional micrograph of the resulting structure is shown in Fig. 2. This structure is not planar. A dip of about $0.8 \mu\text{m}$ exists on the surface in the regions where the two epi layers meet. This nonplanarity should not be an important obstacle in the application of this technology since during SOS processing island edges $\sim 0.6 \mu\text{m}$ high can be tolerated.¹ SIMS profiles of the antimony concentration in the epitaxial layer, which was incorporated via autodoping and out-diffusion from the substrate during the CVD growth process, are shown in Fig. 3. The antimony impurity gradient that extends from the heavily doped substrate into the p^- and n^- epitaxial regions shows a drop in concentration from 10^{18} to 10^{16} cm^{-3} over a distance of $0.3 \mu\text{m}$ in the second epi layer and $0.7 \mu\text{m}$ in the first epi layer. (The first epi layer is exposed to both epi layer temperature cycles.) Since a "well drive" is not required and only low temperature steps are needed to complete the CMOS process, one can expect that these gradients will not be significantly changed during subsequent steps required to complete the CMOS process.

The proposed structure should avoid all of the most significant device problems encountered during ELO, such as high leakage along the interface formed by the ELO film overgrowing an oxide. This interface is different from the interface formed by oxidation of silicon. The leakage along the ELO/oxide interface especially affects performance of NMOS transistors giving leakage in order of $10^{-9} \text{ A}/\mu\text{m}$. It is less apparent in PMOS devices, in which it is usually three orders of magnitude lower (10-12). In the two-step ELO process described, this problem is eliminated by depositing the p^- epi layer first and then thermally oxidizing it. The n channel transistors fab-

¹Also notice that surface nonplanarity is a gradual one; this type of nonplanarity does not affect continuity and definition of poly and metal lines.

ricated in this silicon will be in contact with a "post-epi" thermally grown oxide, not in silicon grown over a SiO_2 layer. The less susceptible p transistors will be made in the second epi layer (n^-) that overgrows the thermally grown oxide. In this way neither the n - or p -channel transistors will be affected by sidewall leakage.

A Rechargeable All-Solid-State Sodium Cell with Polymer Electrolyte

K. West, B. Zachau-Christiansen, T. Jacobsen,* and S. Atlung*

Fysisk-Kemisk Institut, The Technical University of Denmark, DK 2800 Lyngby, Denmark

INTRODUCTION

Secondary lithium cells with intercalation or insertion materials as positive electrodes are now an extensively studied subject. However, only few papers covering the corresponding sodium systems have yet appeared. Ostensibly this is due to the lack of reversible sodium/electrolyte half-cells functioning below 200°C. At higher temperatures most electrode materials will react via displacement reactions, which generally have lower electrode potentials and do not possess the inherent reversibility of intercalation reactions.

Liquid organic electrolytes consisting of NaI dissolved in propylene carbonate have been used for electrochemical preparation of sodium intercalated TiS_2 (1,2). The Exxon group has cycled both Na/ TiS_2 and Na/ MoS_3 using sodium triethyl (N-pyrrol) borate dissolved in 1,3-dioxolane as electrolyte (3,4). Most other groups have chosen to use two-electrolyte systems with an ionic conducting ceramic membrane. This membrane separates molten sodium from the liquid electrolyte forming contact to the active material in the positive electrode (5).

In this communication cycling of a cell with solid sodium in contact with a polymer electrolyte and with amorphous MoS_3 as positive electrode is reported.

EXPERIMENTAL

Amorphous MoS_3 was prepared by thermal decomposition of $(\text{NH}_4)_2\text{MoS}_4$ as described by Jacobson *et al* (3).

Sodium electrodes were made by pressing a layer of sodium onto a Ni foil, using polyethylene sheets to aid the spreading. In this way smooth layers of

sodium with thicknesses between 50 μm and 100 μm were obtained.

Polymer electrolyte sheets ($\approx 30 \mu\text{m}$) were prepared by evaporation of acetonitrile solutions of poly-(ethylene oxide) (PEO) and the proper amount of NaI, recrystallized from acetonitrile and vacuumdried at 180°C. The PEO (WSR 301 Polyox, MW = $4 \cdot 10^6$, BDH) was used as received. The films were prepared and handled in an argon filled dry box. The NaI concentration in the films used corresponded to a Na/O ratio of 1:10. With this electrolyte, the operating temperature of the cell is confined to the interval between 98°C (melting of sodium) and 65°C, as the electrolyte conductivity decreases rapidly below this temperature.

Composite MoS_3 electrode films ($\approx 50 \mu\text{m}$) with the overall composition: 72 w/o MoS_3 , 20 w/o PEO, and 8 w/o NaI were prepared by evaporating acetonitrile suspensions/solutions of the ingredients onto nickel foils. In some cases graphite was added as conductive diluent, but no improvement of cell performance at these very low current densities was achieved.

The cell was mounted with spring load in a Ni-plated brass container sealed with a viton O-ring. This container was heated in air to 90°C in a Buchi TO-50 oven.

RESULTS

The first two cycles of the cell

Na / PEO-NaI (10:1) / MoS_3

are shown in fig. 1. The current density used for discharge and charge was 15 $\mu\text{A}/\text{cm}^2$ in these cycles, corresponding to a stoichiometric discharge time of 45 h. The cell was discharged to 1.5 V.

*Electrochemical Society Active Member.

ABE

Fig. 1. Initial cycles of the cell Na/NaI-PEO (10:1) / MoS_3 at $15 \mu\text{A}/\text{cm}^2$. Charge recalculated as $X = \text{Na}/\text{Mo}$ based on total Mo-analysis of cell.

and recharged to 2.6 V *vs* Na. It is seen that the coulombic cycling efficiency (the ratio between discharge and charge capacity) is considerably less than unity, possibly due to disproportionation of the electrolyte. An advantage of using iodide-containing electrolytes in alkali metal batteries might be that the iodine liberated during overcharge recombines with the alkali metal and thereby scavenges the negative electrode of developing dendrites.

The discharge curve is smooth as expected for an amorphous electrode material, and 1.4 Na/Mo is inserted during the first discharge. Previously discharge capacities of up to 3 Na/Mo have been achieved (4), but the capacity has been shown to be sensitive to the details of the MoS_3 synthesis (6). The stoichiometric capacity calculated from the first discharge is 290 Wh/kg.

The development of the discharge capacity upon cycling is shown on fig. 2. The charge and discharge current used was $150 \mu\text{A}/\text{cm}^2$ in cycle 3 to 9, and $15 \mu\text{A}/\text{cm}^2$ in the other cycles. Despite the rapid decrease in cell capacity, a total number of 10 Na/Mo have been cycled during the lifetime of this cell, and the available amount of sodium has been cycled 1.5 times. This shows that, even close to its melting point, sodium forms a sufficiently

Manuscript submitted July 11, 1985; revised manuscript received Oct. 3, 1985.

Fig. 2. Discharge capacity as function of cycle number. The total number of Na cycled per Mo is also shown.

stable interface with a PEO-electrolyte to allow reversible operation of this electrode. Possibly the formation of a passive sodium ion conducting film on the interface is responsible for this stability.

It is thus concluded that solid state sodium batteries might be feasible by extension of lithium battery technology, especially when electrolytes with better conductivity and more reversible electrode materials are developed.

Li-Al/FeS₂ Cell with LiCl-LiBr-KBr Electrolyte

Thomas D. Kaun*

Argonne National Laboratory, Chemical Technology Division, Argonne, Illinois 60439

With its high theoretical specific energy and low resistivity electrolyte, the Li-Al/LiCl-KCl (m.p. 352°C)/FeS₂ cell has long been projected to be capable of very high performance (1). However, the cell, which is operated at temperatures of 425 to 450°C, has an unacceptably high capacity-decline rate of 0.10-0.25%/cycle (2) due to sulfur migrating from the positive electrode into the separator region and depositing there as Li₂S (3). Earlier attempts to reduce this capacity-decline rate concomitantly reduced cell performance (2).

In this study, two major changes from the earlier cells were evaluated: 1) a novel electrolyte, 25 mol% LiCl-37 mol% LiBr-38 mol% KBr (m.p. 310°C) (4), and 2) a higher loading density (2.4 vs. 1.5 Ah/cm²) for the FeS₂ electrode, which was then operated only on its higher-voltage (1.75 avg. V), or "upper-plateau", reaction:

(This reaction is actually a series of three consecutive reactions.) (8) In this mode of operation, the electrode will be designated a dense, upper-plateau (U.P.) FeS₂ electrode. In a conventional "two-plateau (T.P.)" FeS₂ electrode, the lower-voltage (1.33 avg. V) reaction also is used. This reaction is:

Experimental

A sealed prismatic bicell was employed to duplicate earlier test cells that had been used in evaluating the performance of Li-Al/LiCl-KCl/FeS₂ cells (2). The electrodes (8.7cm high x 6.3 cm wide) were contained behind perforated-sheet current collectors--molybdenum for the central FeS₂ electrode and 1008 steel for the two Li-Al electrodes. The electrode area, based on the separator, was 100 cm².

The iron disulfide electrode contained FeS₂ with 15 mol% CoS₂ additive for a total theoretical capacity of 25.2 Ah (on the upper plateau). The slurry-formed LiAl electrode (5) contained 53 at% Li-Al alloy for 35 Ah capacity with 0.9 Ah/cm² loading density. Cells were assembled with a 8N powder feedthrough seal and were subsequently operated in an argon glovebox. Cycle-life testing at a 8-h charge rate (25 mA/cm²) and 4-h discharge rate (50 mA/cm²) was controlled between voltage cutoffs of 2.05 and 1.25 V, respectively. A Ni/Ni₃S₂ reference electrode indicated working-electrode potentials during the deep-discharge cycling. Current interrupts of one second duration were used to evaluate electrode and cell resistances. Power measurements were derived by integrating constant-current pulses (10-100 A) of 15-s duration.

Results and Discussion

The Li-Al/U.P.-FeS₂ cell having LiCl-KBr-LiBr electrolyte and operated at 397°C + 5°C had 50% higher energy and power density than Li-Al/T.P.-FeS₂ cells having LiCl-KCl electrolyte and operated at 427°C. The voltage-capacity curves of the two cells (each of 25.2 Ah capacity) are presented in Fig. 1. Energy density at 50 mA/cm² was

enhanced as a result of approximately 50% higher utilization of the capacity and a 10% higher average discharge voltage. The energy density at higher discharge rates, 100 and 150 mA/cm², showed even greater improvement with the utilization of theoretical capacity ranging from 85 to 65% (Fig. 2). The specific power at 80% depth of discharge (DOD) was also enhanced by approximately 50% for the new cell because the voltage at that point in the discharge was about 0.3 V higher than that of a cell with a T.P.-FeS₂ electrode. (Six cells of 1-Ah capacity have confirmed these improvements.)

The improved power and energy densities of the iron disulfide electrode at the reduced operating temperatures of 388 to 427°C are believed to be caused by two factors. One is improved electronic conductivity of the electrode. According to the Bruggeman equation (6)

$$K_m = (1 - f)^{3/2} \quad [3]$$

where K_m = bed conductivity/dense body conductivity and f = electrolyte fraction, the increased electrode loading density (from 32 to 50 vol %) would double electronic conductivity of the iron disulfide electrode. The second factor is an increased "dynamic range" with the LiCl-LiBr-KBr electrolyte. At 400°C, this electrolyte has a liquidus that extends over a Li⁺/K⁺ ratio of 1.25 to 2.6; for LiCl-KCl, the range is only 1.25 to 1.81. The broader liquidus for the LiCl-LiBr-KBr electrolyte would tend to prevent salt crystallization; it has been postulated that the crystallization of LiCl-KCl impedes operation (7).

The capacity utilization vs. cycle number for U.P. FeS₂ cell is shown in Fig. 3 (the coulombic efficiency of the cell is 99+%). Its utilization is 89% at 50mA/cm², based on a revised cell capacity (24 Ah) from a lower than assumed CoS₂ purity. The cell capacity has been constant through more than 230 cycles and 3000 hours, and the cell voltage vs. capacity curve has remained unchanged (as in Fig. 1) during this time. In this test, the cell was charged at 25 mA/cm² to a charge cutoff voltage of 2.05V. These values are greater than those that could be used with the Li-Al/LiCl-KCl/T.P.-FeS₂ cell while maintaining stable capacity (2). Electrode potentials (vs. the Ni/Ni₃S₂ reference electrode) indicate that both electrodes, LiAl and FeS₂, mutually attain full charge. The discharge capacity is limited by the upper-plateau capacity of the positive electrode.

Apparently, both time-related and cycle-related capacity-loss mechanisms have been overcome in this cell. Considerable attention has been given to gaining understanding of these mechanisms for FeS₂ in LiCl-KCl. Preto et al. (8) indicated that capacity loss for FeS₂ in LiCl-KCl is due to its complex electrochemistry involving formation of non-equilibrium species. Additionally, thermal decomposition and solubility in LiCl-KCl of discharge reaction species have also been found to be causes of capacity loss in the disulfide electrode (9). For the dense U.P.-FeS₂ electrode in LiCl-LiBr-KBr, the reduced operating temperature and increased electrode-bed conductivity would promote capacity stability according to these understandings.

Key Words: fused salt, lithium cell, disulfide electrode

Conclusion

The use of the dense U.P.-FeS₂ electrode and LiCl-LiBr-KBr electrolyte, which allows a cell operating temperature of 397°C, has eliminated disulfide electrode capacity loss and increased cell performance significantly. Based on a 250 Ah multiplate cell, we expect a specific energy greater than 150 Wh/kg at the 4-h rate and specific power of greater than 150 W/kg at 80% DOD. The expected cycle life of greater than 1000 cycles is comparable to that of the LiAl/FeS cell (10).

The Extent of the Phenomenon of Oscillatory Anion Incorporation in Alumina Barrier Films

D. L. Cocke,* C. A. Polansky, D. E. Halverson, S. M. Kormali, C. V. Barros-Leite, O. J. Murphy,* E. A. Schweikert, and P. Filipus-Luyckx

Department of Chemistry, Texas A&M University, College Station, Texas 77843

The recent observation of oscillatory incorporation of tungstate into anodically grown alumina films (1) has now been extended to include several other anions, such as MoO_4 , MnO_4 , and CrO_4 . This confirms the general nature of the phenomenon, which is the first electrochemically produced oscillation in the solid state. The observation has extremely important ramifications to electrochemical studies on passivity, general electrochemicals and anodic growth mechanisms.

Incorporation of anions into electrochemically grown alumina films is being studied in an effort to determine their effect on the structure (2,3,4), electronic properties (5,6) and stability (2) of the alumina formed. The determination of the distribution of anions in these films is currently being unraveled (2,7). It has been shown through the use of electron microscopy (STEM) that initially the entire film is amorphous, and incorporation of anions into the alumina stabilizes the amorphous structure to the process of dehydration and subsequent crystallization by the electron beam (4). The general structure of electrochemically grown barrier alumina films has been reported to consist of an inner region, which is relatively pure (7), and an outer region, which is thought to be a uniform structure, containing species from the anions present in solution (8,9).

Sharp, et al. (6), have established that the properties of the films are dramatically affected by these anion residues. The incorporation of tungsten species into anodic alumina films resulted in a surprising structure (1). Through the use of alpha and argon backscattering, the tungstate species were found (1) to be incorporated periodically in the alumina structure, suggesting an oscillatory mechanism for formation of the film. This communication de-

scribes the incorporation of three additional anionic species into alumina films.

The anodic oxide films were grown galvanostatically at various current densities on highly polished aluminum discs in 0.15 M borate buffer solutions (pH = 8.4), which also contained either 0.5 M $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$, 0.5 M $\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$, 0.5 M $\text{Na}_2\text{CrO}_4 \cdot 4\text{H}_2\text{O}$ or 0.5 M KMnO_4 . The film growth was stopped when the cell voltage reached 72 V. The film thicknesses were calculated to be approximately 1000 Å, using a growth rate of 14 Å/V (5). Two types of Rutherford backscattering data were taken on the films exposed to MoO_4 or WO_4 species; a variable energy cyclotron with a collimated 40 MeV Ar^{4+} ion beam (Texas A&M University) and a Van de Graff accelerator employing a collimated beam of 2 MeV He^{2+} ions (Rio de Janeiro). Only the latter was used on the CrO_4 and MnO_4 exposed films.

In Figure 1, the Ar^{4+} spectra of molybdate and tungstate species incorporated into alumina films grown on ultrapure aluminum samples are shown. In both cases, the anionic species concentration is seen to decay as one moves from the oxide surface into the alumina film. This decay is not monotonic, but exhibits a periodic structure, which is slightly more pronounced for the tungstate than for the molybdate. In Figure 2, the alpha backscattering spectra are shown for tungstate, molybdate, manganate and chromate species incorporated into alumina films. The first three species again exhibit periodic concentration decay, as found in the Ar^{4+} backscattering spectra. Furthermore, a complementary periodic structure was evident in the aluminum oxide spectra (not shown), in that minimums in concentration were found for the aluminum which correspond to maximum concentrations for the anionic species. Even though the periodic structure is not seen on the chromium peak, the oscillatory alumina variation was seen, due to better counting statistics. This is additional evidence to support the presence of a layered concentration profile for the outer region of the alumina films. These spectra also show for the tung-

Key Words: alumina barrier films, anion incorporation, oscillatory phenomena

state and molybdate species that the anion-containing layer penetrates less than half the thickness of the alumina films. However, the chromate and manganate species appear to be more evenly distributed throughout the alumina. A reason for this difference may be linked to the ionic radii of the metal cations, the Cr^{+6} and Mn^{+7} being closer in size to Al^{3+} than the W^{+6} or Mo^{+6} but is more likely to be related to the anions' ease of charge removal.

As a result of this investigation, it appears that incorporation of anionic species into anodic barrier oxide films takes place by an oscillatory mechanism, resulting in characteristic growth patterns. Current work is investigating the mechanism of this incorporation, where it is believed that local space charge growth control is involved. This phenomenon, in addition to providing a means of dramatically altering the structure and properties of the anodic films, may provide a means of studying local space charge phenomena in these films.

Morphology of Defects in GaAs Revealed by Eutectic Etch

W. F. Tseng, H. Lessoff, and R. Gorman

Naval Research Laboratory, Washington, DC 20375-5000

Recently a new eutectic (KOH + NaOH) (1) has been developed to reveal defects in gallium arsenide (GaAs) for evaluating the wafer quality. The etched surface shows additional, distinct patterns other than the features formed by the commonly used molten KOH etchant(2). The purpose of this paper is to identify the defects which cause the formations of such different etched patterns.

The GaAs samples used in this study were semi-insulating 3-inch (100) wafers, grown by Liquid Encapsulated Czochralski method. The eutectic etchant with a melting point ($T_{m.p.}$) of 170°C was a mixture of KOH ($T_{m.p.} \approx 360^{\circ}\text{C}$) and NaOH ($T_{m.p.} \approx 318^{\circ}\text{C}$) in equal mole concentration. The etch procedure is described in ref 1. There is a modification to the procedure described in ref. 1 to insure an oxide free surface after removal of the wafer from the hot etchant. The wafers are immediately placed in ethylene glycol upon removal from the hot etchant. The residual hydroxides are soluble in the ethylene glycol and the surface of the etched wafer is left stain and oxide free. After the approximately 20 minutes in the ethylene glycol, the etched wafers are cleaned as described in ref. 1. To investigate the development of etched patterns, the GaAs samples were etched at 350°C for 15, 30, 45 and 60 min. individually. For comparison, another set of GaAs samples was etched in a molten KOH. The etched surfaces were then investigated by SEM, followed by TEM observation. TEM thin foils were prepared by a standard jet-polishing technique from the backside of GaAs samples using Br_2 -methanol solution.

Typical KOH etched surface is shown in Fig. 1. The etched patterns are in the shapes of hexagonal pyramid pits, and smaller-shallower dimples on the background. The side-walls of etched pits are smooth. On the other hand, for the

new eutectic (KOH + NaOH) etch, the side-walls of etched pits show stair-step structure as shown in Figs. 2a and 2b. The etched pyramids started with a square-shape, then, developed into hexagonal shape as the etch time increased. Most inverted pyramids have sharp pits, however, few of them have a flat bottom as shown in Fig. 2a. Another typical etched pattern is nearly rectangular in shape with its long edge perpendicular to the (110) cleavage edge. The depth is shallower than the depth of the pyramid pattern, as shown in Fig. 2b.

Fig. 1 SEM micrograph of GaAs surface etched by molten KOH etchant.

Fig. 2 SEM micrographs of GaAs surfaces etched eutectic (KOH + NaOH) etchant. (a) Pyramid pattern; (b) Rectangular pattern.

The etched pits in Fig. 2a, correlate to dislocations directly. The pyramid with a sharp pit has a dislocation connecting to the tip of etched pit, as shown in the TEM micrograph of Fig. 3. However, the pyramid with flat bottom, shown in Fig. 2a, does not have dislocations attached to it. This can be explained by the dislocation movement (3). The movement of the dislocation may be related to the residual stress in the wafers produced during the crystal growth. There is a large thermal differential at the solid-liquid interface during LEC growth, also the thermal conductivity of GaAs is such that large radial temperature differences will occur on cooling after growth. During the eutectic (KOH + NaOH at 350°C) etching, the dislocations can migrate at the speed of sound. A new pyramid pit with the dislocation attached to it was formed as a result of dislocation movement. The pyramid, now without the dislocation attached to it, was further etched. The (100) surface at the tip of the pyramid was flat in shape due to the slower etch rate on (100) surface than that on the side wall of pyramid. Reference 1 has shown that the rates of etching at 350°C for (100) and (111) GaAs are 0.09 and 0.22 $\mu\text{m}/\text{min}$, respectively.

Fig. 3 TEM micrograph of pyramid pattern attached with a single dislocation.

As for the rectangular shape etched pattern shown in Fig. 2b, TEM observation indicates that most shallow patterns are free of dislocations and the deep patterns contain tangled dislocations as shown in Fig. 4. Formation of these rectangular shape patterns may be explained in the following way: During 350°C etching, the residual stress from LEC GaAs growth caused the tangled dislocations to generate new dislocations, and the generated dislocations to glide (on (111) planes). As evidence, Fig. 4 shows an array of generat-

Manuscript submitted Nov. 8, 1984; revised manuscript received Aug. 9, 1985.

Fig. 4 TEM micrograph of rectangular pattern attached with tangled dislocations and generated dislocations.

ed dislocations aligned along a projected $\langle 110 \rangle$ direction. Regular pyramid shape etched patterns form when the generated dislocations reached the (100) sample surface. The array of these generated and aligned dislocations was revealed by etching. Due to this alignment of dislocation lines along the $\langle 110 \rangle$ projected direction and the slow etch rate on (100) GaAs (same argument as for Fig. 2a), a rectangular shape etched pattern was formed.

In conclusion, the defects, which result in the formation of pyramid and rectangular-shaped patterns as revealed by the eutectic (KOH + NaOH) etchant, have been identified. The pyramid pattern is caused by a single dislocation, whereas the rectangular pattern is caused by tangled dislocations.

Effect of Axial Ligand on the Catalytic Activity of Heat-Treated Tetraphenylporphyrinatoiron (III) Halides for the Cathodic Reduction of Oxygen

O. Ikeda, H. Fukuda, T. Kojima, and H. Tamura

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565, Japan

Metal complexes of the macrocycles such as porphyrin, phthalocyanine, and tetraazaannulene are promising electrocatalysts for the cathodic reduction of oxygen. It is worth noting that the heat treatment of metalloporphyrins in an inert atmosphere improves not only the stability, but also the catalytic activity (1-4). As the heat treatment gives polymeric products insoluble in any solvents, however, it is not easy to determine the true active site and the cause for the improvement of the catalytic activity. Thus far the active site for heat-treated metalloporphyrins has been ascribed to: (a) metal in the N_4 center (4,5), (b) carbonaceous structure formed by the degradation of the N_4 center (6), and (c) an intermediate structure between (a) and (b), namely, metal coordinated to a partially degraded N_4 center (7). However, these three types of active site may be differentiated by the heat-treatment temperature.

Recently, we found that heat-treated *meso*-tetraphenylporphyrinatoiron(III) chloride ($Fe^{III}(TPP)Cl$) showed an anomalously high magnetic moment for a Fe unit, consisting of one porphyrin unit per iron ion, and observed that the increase in the magnetic moment was closely correlated with the improvement of catalytic activity for the cathodic reduction of oxygen, especially, of the capability of reducing oxygen to water (4-electron reducibility) (8). We speculated a participation of chloride ion as an axial ligand in the above anomalous magnetic property of heat-treated $Fe^{III}(TPP)Cl$. In order to clarify such a participation of a ligand and the presumption that the active site is metal, *meso*-tetraphenylporphyrinatoiron(III) with different axial ligands ($Fe^{III}(TPP)X$, $X=F^-, Cl^-, Br^-, I^-$) was heat-treated, and the effect of axial ligand on the so-called 4-electron reducibility of oxygen was studied using the rotating ring-disc electrode technique.

The $Fe^{III}(TPP)X$ -coated disc electrode was prepared by loading 3×10^{-7} mol cm^{-2} of $Fe^{III}(TPP)X$ onto the top surface of a glassy carbon

rod (0.28 cm^2 , Tokai Carbon GC 20), and then heating it in an Ar atmosphere at 700°C for 10 min. After cooling in Ar, the rod was installed in the disc cavity of the ring-disc electrode. $Fe^{III}(TPP)X$ powder was also heat-treated and its molar magnetic susceptibility, χ_M , was measured as described before (8). The presence of halide ions was confirmed by ESCA, although the ratio of X to Fe was somewhat lower than unity.

Figure 1 shows voltammograms at the rotating ring(Pt)-disc(glassy carbon coated with the heat-treated $Fe^{III}(TPP)X$) electrode in O_2 -saturated 1 M KOH. The disc current at lower overpotentials decreases in the order $F^- > Cl^- > Br^- > I^-$, indicating the relative catalytic activity of heat-treated $Fe^{III}(TPP)X$ for the cathodic reduction of oxygen.

The apparent number of electrons consumed in the oxygen reduction n_{app} , which is a measure of the 4-electron reducibility, was evaluated at several potentials between the onset potential and the potential in the diffusion limiting region in Fig. 1. In the evaluation of n_{app} , it is assumed that the O_2 reduction at the disc consists of a mixed reaction of the 2-electron pathway ($O_2 + H_2O + 2e^- \rightarrow HO_2^- + OH^-$), and the 4-electron pathway ($O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$). Thus, n_{app} was estimated by the next relation: $n_{app} = 4I_{Disc} / (I_{Disc} + I_{Ring} / N_{corr})$, where I_{Disc} and I_{Ring} are the disc and ring currents at a potential, respectively, and N_{corr} is the collection efficiency for HO_2^- , corrected for a deviation from coplanarity between the Pt ring and the $Fe^{III}(TPP)X$ -coated disc. Figure 2 shows a correlation between the mean of n_{app} estimated in the above way and the effective magnetic moment μ_{eff} calculated from χ_M . It is obvious from Fig. 2 that n_{app} is closely correlated with μ_{eff} for a Fe unit.

The fact that the effect of axial ligand is clearly reflected in both the n_{app} and μ_{eff} values suggests that the active site for the electrocatalytic reduction of oxygen in $Fe^{III}(TPP)X$ heat-treated at 700°C is not the carbonaceous structure (b), but the metal (a) or (c). The magnetic moment of the Fe unit in all heat-treated $Fe^{III}(TPP)X$ was higher than

Key words: Porphyrin, Heat-treatment, Axial Ligand, Oxygen Reduction

Figure 1 - Voltammograms at the rotating ring (Pt)-disc(glassy carbon coated with $\text{Fe}^{\text{III}}(\text{TPP})\text{X}$ heat-treated at 700°C) electrode for the cathodic reduction of oxygen in O_2 -saturated 1 M KOH. $\text{Fe}^{\text{III}}(\text{TPP})\text{X}$: $\text{X}=\text{F}^-$ (—); Cl^- (---); Br^- (.....); I^- (-·-·-). Potential of the reference electrode: Hg/HgO in 1 M KOH, 0.098 V vs. normal hydrogen electrode (NHE). Ring potential, 0.25 V vs. Hg/HgO; sweep rate at the disc, 1 mV s^{-1} ; rotation rate, 1000 r.p.m.

that of unheated compound, about $5.9 \mu_B$ (Bohr Magnetron). This anomalously high magnetic moment of the Fe unit in the heat-treated $\text{Fe}^{\text{III}}(\text{TPP})\text{X}$, which varies depending on the axial ligand, might be due to a metal-metal interaction based on a structure of two Fe sites bridged by halide ion. This interaction seems to be a ferromagnetic superexchange interaction,

Figure 2 - Correlation between n_{app} and μ_{eff} .

because both the orders of the bond energy between Fe^{III} and X, and the electron donating strength of the axial ligands (9) are as follows: $\text{F}^- > \text{Cl}^- > \text{Br}^- > \text{I}^-$. Such a two-Fe site may act as an active center for the 4-electron pathway in the cathodic reduction of oxygen.

Acknowledgement: We thank Professor Dr. Jiro Shiokawa and his staffs for their helpful suggestions and discussions on the measurement and interpretation of the magnetic moment.

ized SO₂ electrolyte environment or the reduction process plays a role in the chemistry. The interrelationship among the electrolyte-dithionite-carbon matrix in an ever changing temperature and pressure environment of the cell is complex and warrants additional investigation.

ARC studies on cathodes depleted of electrolyte, taken from discharged Li/SO₂ cells, reveal that the major exothermic reactions arise solely from the thermal decomposition of lithium dithionite, regardless of the complexity of sulfur products present. This adiabatic decomposition is characterized by a rapid self-heating process, a sudden generation of SO₂ gas pressure, and is catalyzed by carbon black. Further studies are planned.

Hazards previously observed during overdischarge, especially at low temperature, occur primarily from a rapid and very exothermic reaction involving lithium with lithium dithionite. This triggers additional reactions involving carbon black producing additional gas pressure in the form of carbonaceous gases. This mechanism of almost synchronous reactions is capable of causing explosive venting in commercial Li/SO₂ cells.

Acknowledgments

I wish to express my appreciation to D. Oglesby for many informative discussions concerning dithionite chemistry. I am especially grateful to L. Van Rouckel for her contributions to the ARC study. This study was funded by the U.S. Navy High Energy Batteries for Weapons Block Program. Part of this paper was presented at the 2nd International Meeting on Lithium Batteries,

Paris, France, April 26, 1984. Travel expenses to the meeting were provided by the National Science Foundation.

The Oxide Film on Steel and Cathodic Disbondment of a Protective Organic Coating

E. L. Koehler*

Niles, Illinois 60648-2653

ABSTRACT

Cathodic disbondment of an oleoresinous organic coating on steel with an air-formed oxide film has been investigated in 0.1N sodium borate solution (pH 9.2) and in pH 7.6 borate buffer solution. This is compared with oxygen reduction and with oxide film reduction for uncoated steel surfaces. The rate of oxygen reduction on the steel surface is found to increase as Fe⁺³ in the oxide film is reduced. The rate of cathodic delamination of the organic coating is a function of the oxygen reduction rate as determined by the oxide film properties. Reduction of Fe⁺³ in the oxide film may result in either soluble Fe⁺² or in intermediate film compositions from Fe₂O₃ to Fe₃O₄, dependent upon pH and potential. At sufficiently negative potentials, once a portion of the Fe⁺³ in the oxide film is reduced, the steel substrate becomes active, yielding soluble or insoluble oxidation product, dependent upon pH and potential. This explains observed surface roughening and oxide film thickening beneath disbonded organic coatings.

Cathodic disbondment is caused by high pH at the coating/substrate interface, generally resulting from the reduction of atmospheric oxygen. Several hypotheses exist to explain the means by which the high pH condition causes the disbondment. These include: (i) cohesive failure within the polymeric material at the interface as the result of hydrolysis of bonding groups (1, 2), (ii) displacement of the coating by a film of high pH water at the interface (3), and (iii) disbondment by dissolution of the oxide film beneath the coating (4, 5). Whatever the mechanism, susceptibility to disbondment is markedly influenced by the oxide film, as indicated by differences displayed by different metals or by different surface treatments of the same metal. In this paper, we will consider the influence of an air-formed oxide film on untreated steel.

Primarily by ellipsometric measurements, Ritter has shown that disbondment is accompanied by roughening of the metal surface and by an increase in the thickness of the oxide film (6, 7). Simultaneous pH measurements be-

neath the coating indicated a change of from 6 to 13.5. Ease of the oxygen reduction process may be important for disbondment. For example, organic coatings on aluminum are not subject to disbondment under corrosion conditions (8). Leidheiser has related such differences between metal surfaces to relative ease of oxygen reduction (9).

Consideration is to be given here to the reduction of the ferric component of the oxide film on steel. Such reduction should occur during cathodic disbondment, but this has been given scant attention. Gonzalez *et al.* have investigated disbondment caused by autoreduction of ferric oxide beneath the coating and dissolution of the resulting ferrous iron (10). This requires a medium in which ferrous iron is appreciably soluble, i.e., a pH < 4 or presence of a complexing agent, unlike the disbondment at elevated pH being considered here. Castle and Watts (11) have indicated some reduction of oxide only at the disbondment front, but they did not consider subsequent oxide film thickening, as reported by Ritter (6, 7).

The effects of the oxide film during cathodic disbondment should be related to the behavior of the film on the

* Electrochemical Society Active Member.

uncoated metal when it is made a cathode. Electrochemical reduction/oxidation methods are used here on both bare steel and on organic-coated steel to tie together the oxide film influences on cathodic disbondment. Most work on cathodic disbondment uses a corrosive solution, usually NaCl. This medium is unsatisfactory in the present work, where effects at relatively positive potentials are investigated. Borate solutions appear ideal, especially in view of the experience with these solutions in oxide film investigations (12-14).

The aim here is to study the effects of the oxide film, its properties, and its cathodic reduction on cathodic disbondment.

Experimental

The steel base used was uncoated and untreated low carbon steel plate, such as used in the can industry. It was desired to work with a well-developed, air-formed oxide film. The material used had been in storage at least 10 yr. It was unruled. Prior to organic coating, it was vapor degreased. It was roll coated to an 8 μm thickness with an unpigmented oleoresinous enamel and baked for 8 min at 213°C.

Responses of the coated specimens were compared with those for the uncoated under conditions of applied cathodic potentials. Galvanostatic methods were unsatisfactory for such work. Both potentiostatic and potentiodynamic methods were used. A number of scanning rates were tried for the potentiodynamic experiments, and a scanning rate of 300 mV/h was selected. Borate solutions were used as test media. A pH 7.6 boric acid/sodium borate buffer was selected as a near-neutral solution. In this case, a soluble ferrous reduction product is expected. For a higher pH, a 0.1N $\text{Na}_2\text{B}_4\text{O}_7$ solution at pH 9.2 was used. While the solubility of ferrous iron is still not negligible at this pH, as a practical matter magnetite is produced. Considerable work was also done with a 0.1N Na_2HPO_4 solution at pH 9.1. Such results were found to be in substantial agreement with those for the sodium borate solution and will not be reported here. To avoid confusing the results for cathodic disbondment with possible simple diffusion effects, higher pH test media were not desired.

The cell shown in Fig. 1 was used for cathodic reduction on uncoated steel in pH 7.6 borate buffer solution. The counterelectrode was platinum. The specimen, 31.8 mm long by 6.4 mm wide (1.25 \times 0.25 in.), was masked with cellophane tape to give an exposure of 12.7 \times 6.4 mm (0.5 \times 0.25 in.), or 0.81 cm^2 on each side. Edges were not masked. The exposed edge area was only 0.05 cm^2 . Specimens

were cut about two weeks before use. Exposed edges had no significant effect on the results.

The solution was preflushed with purified nitrogen and flushed throughout testing. In operation, the specimen was held in the space above the solution. It was then dropped into the solution and instantly polarized to the desired potential. The current was recorded as a function of time. In preliminary work, using this test method, it was determined that vapor degreasing the plate had no evident effect on the response of the oxide.

Other testing was done in cells consisting of half of a spherical O-ring joint, sealed against the specimen by a buna N O-ring. A plastic back-up plate of suitable thickness was used, and the assembly was held together with a joint clamp. Two sizes of cells were used: the large cell had a test area of 22.1 cm^2 ; the small cell had a test area of 3.5 cm^2 . It was not possible to use the small cell in comparative tests requiring continuous nitrogen flushing. In tests on the organic coated plate, test cells were filled 24h before running the test. On uncoated specimens, testing started immediately after filling. For the air-free tests, cells were flushed with purified nitrogen before filling; they were filled with a preflushed solution; nitrogen flushing continued through the test.

In plotting the results, reduction currents are indicated as positive and oxidation currents are indicated as negative.

Results

pH 7.6 borate buffer solution.—Three specimens were potentiostatically treated at each potential, every 50 mV from -0.150 to -1.100V vs. SCE. Typical results are shown in Fig. 2. From -0.150 to -0.350V , the curves were of the form indicated for the -0.300 potential and leveled out at zero current. Coulombic equivalents were determined by measuring the areas under the curves with a planimeter and are shown in Table I.

For all potentials positive to the equilibrium potential for iron, iron would be oxidized except for the existence of the Fe_2O_3 film. At the positive potentials indicated in Table I, iron is completely passivated (15). Reducing the ferric oxide, or some significant part of it, permits oxidation of iron to proceed, as shown for the -0.550V curve (Fig. 2). The -0.750V curve again levels out at zero current and represents the reduction of all of the Fe_2O_3 to the ferrous state. Averaging the values obtained by integration gives a coulombic equivalent of 1.3 mC/cm^2 . At more negative potentials, hydrogen evolution commences and the curves do not level out at zero current. At still more negative potentials, Fe_3O_4 is reduced, resulting in a hump in the curve. The -1.000V curve is indicative of these last two features. Such potentials, negative to the equilibrium

potential for iron, have no relevance to cathodic disbondment produced in corrosion situations.

It was confirmed that even with this well-developed, air-formed oxide film, reduction of oxygen is necessary for cathodic disbondment, at least at potentials positive to hydrogen evolution. Figure 3 shows the response for the organic-coated plate, potentiodynamically polarized in the cathodic direction at 300 mV/h in the pH 7.6 borate buffer solution, with just a trace of air present. This illustrates that oxidation of iron takes place beneath the coating in the appropriate potential range. While this was going on, cathodic disbondment was occurring, starting from a number of cationic ingress points in the coating. For most purposes, potentiodynamic polarization is not ideal for studying cathodic disbondment of coated metal, as too many processes are happening simultaneously.

0.1N sodium borate solution.—The potentiodynamic method was selected to illustrate the response of the uncoated steel to cathodic polarization in 0.1N Na₂B₄O₇ solution. Typical results are shown in Fig. 4. The light curve represents the response under air-free conditions; the heavy curve indicates the response in the presence of air. For the air-free curve, a considerable amount of cathodic reduction takes place at potentials which the Pourbaix diagram for iron indicates should be well within the range of Fe₂O₃ stability (16). The transition to Fe₃O₄ would be expected at about -0.590V vs. SCE, which corresponds to the potential at which Fe oxidation commences according to Fig. 4. For the air-free curve, there is a small hump in the oxide reduction curve, centered at -0.400V. The equivalent of the reduction in this hump is only about 0.03 mC/cm². It is to be noted how closely the reduction of oxygen follows the oxide reduction curve. In particular, the oxygen reduction rate is very low until oxide reduction commences; after that, it increases dramatically.

Figure 5 shows the results of the potentiostatic polarization of the uncoated steel at -0.650V in the presence and in the absence of air. At this potential, oxidation of Fe occurs. In the absence of air, the oxidation rate is seen to decrease as the Fe₃O₄ layer builds up. This is in contrast to the -0.550V curve in Fig. 2, in the pH 7.6 borate buffer

Fig. 3. Test area 3.5 cm². Potentiodynamic current response for oleoresinous-coated steel in pH 7.6 borate buffer solution with trace of oxygen in cell.

solution, where Fe²⁺ is soluble. The oxide produced on the specimen in the air-free solution after 5h was barely visible. The oxide produced in the presence of air was much greater in amount and greenish-black in color. This should be considered a layer, rather than a film. It is evident that at this potential reduction of oxygen is occurring simultaneously with the oxidation of iron. At potentials positive to the peak potential in Fig. 4, potentiostatic reduction curves in the absence of oxygen level out at zero current.

In Fig. 6, are shown results for nine specimens of the oleoresinous-coated plate, potentiostatically polarized for 14h at 50 mV levels from -0.300 to -0.700V vs. SCE. The open-circuit potential of such specimens was usually around -0.125V vs. SCE. At -0.300V, there is only a very slight disbondment current, due to the restriction on the oxygen reduction process, as has been illustrated in Fig. 4. At -0.350 to -0.450V, the effects of the slight hump (Fig. 4) are noted. At -0.500 and -0.550V, there are greatly increased disbondment currents, as greatly increased oxygen reduction rates corresponding to the peak in the Fe₂O₃ reduction rate (Fig. 4) are attained. The disbondment currents increase further at -0.650V and more negative potentials, but slow down as disbonded areas start to run together.

Actual coating disbondment for these specimens is shown in Fig. 7. Immediately after the test, the specimens were quickly rinsed in distilled water, dried with a towel, and taped with a "super-stick" cellophane tape to remove the disbonded coating. It is noted that there was some disbondment for all of these potentials. There was even slight disbondment for the -0.300V polarization, which is not shown because it was too meager to photograph.

Discussion

As noted earlier, the high pH generated by the reduction process is instrumental in cathodic disbondment. For electrical neutrality, a cation must be transported to the site of OH^- production beneath the coating. The pH required for cathodic disbondment in any particular case is a function of both the coating and the substrate. In general, a strongly basic condition such as provided by KOH or NaOH is required. Other common cations, such as Ca^{+2} , provided only weak bases; therefore, the pH will not rise to the value required for disbondment (17). Cathodic disbondment is characterized by the establishment of an aqueous film or layer between the organic coating and the substrate. The water layer is visible on the surface of the substrate immediately after removal of the coating from the disbonded area by taping. From a comparison with the 8 μm organic coating thickness and the fact that the water layer evaporated in seconds, it is estimated that the water layer was less than 1 μm thick.

In a corrosive situation, such as in NaCl solution, metal exposed at a defect in the coating develops into an anode. Being freely exposed to the corrosive medium, such an area assumes a potential more negative, or active, than the coated areas, which, at least initially, maintain their oxide film. Disbondment starts from a cationic ingress point, which may be a thin spot in the coating, and spreads. It may also spread from the cathodic area around an exposed metal anode. In the disbonded area, the Fe_2O_3 originally existing in the oxide film is shown to be at least partially reduced. The fact that Ritter observed surface roughening of the metal and oxide film thickening indicates that the potential of the metal beneath the disbonded coating in his experiments was in the potential range where Fe oxidation to Fe_3O_4 should occur.

In spite of the fact that the disbonded coating remains intact, reduction of oxygen in the disbonded area is greatly increased. In fact, it is apparent from the results of Fig. 6, plus the results of supplementary experiments not reported here, that at any given potential the "disbondment current" is a direct function of the area disbonded. It follows that the oxide film or surface treatment film

Fig. 7. Test areas: 3.5 cm^2 . Cathodic disbondment for specimens of Fig. 6, polarized for 14h in air-saturated 0.1N $\text{Na}_2\text{B}_4\text{O}_7$ solution at potentials indicated. A: -0.350 . B: -0.400 . C: -0.450 . D: -0.500 . E: -0.550 . F: -0.650 .

beneath the organic coating is actually part of the protective coating system from the standpoint of limiting corrosion currents. Experiments involving a protective organic coating as a detached membrane can only be expected to tell part of the story.

The potentiodynamic curve for Fe_2O_3 reduction at pH 9.2, indicated in Fig. 4, suggests that Fe_2O_3 is not reduced directly to Fe_3O_4 , but that there is a continuous change between these two extremes. Hubbard and Anson have reported the reduction of Fe^{+3} to Fe^{+2} in thin layers of solution to yield a bell-shaped curve, obeying the Nernst equation, with the peak potential at E° . Oxide films represent a thin layer. The slow scan speed used in Fig. 4 should allow time for equilibrium conditions to be approached. Except for the early peak centered at about -0.400V vs. SCE, a bell-shaped curve is apparent for potentials positive to the current maximum. If a soluble reduction product were produced, it would diffuse away, and such a relationship would not be obtained. In conformity, the Pourbaix diagram for iron indicates that a soluble reduction product is not to be expected and that layerwise reduction of Fe_2O_3 to Fe_3O_4 should not occur at potentials positive to the current maximum (16). It would appear, therefore, that the results can be explained on the basis of a potential-dependent reduction of Fe_2O_3 to produce intermediate compositions between Fe_2O_3 and Fe_3O_4 , in a manner similar to the reduction of Fe^{+3} in thin films of solution. As closely as can be discerned, the potentiodynamic current maximum does occur at E° for $\text{Fe}_2\text{O}_3/\text{Fe}_3\text{O}_4$ at pH 9.2. This is also the potential below which the oxidation of iron to magnetite occurs.

The small peak at about -0.400V could represent a higher oxidation state than Fe^{+3} , as has been suggested for the outer layer on passivated iron (15, 19). However, since this is low carbon steel rather than pure iron, there could be other possibilities. The continuing influence of this portion of the curve on oxygen reduction would seem to favor its representing an oxidation state of iron. An increased resistance for such an outer layer on passivated iron has been indicated (20).

For pH 7.6, soluble Fe^{+2} should not be expected as the reduction product over the entire range of potentials considered. At the more positive potentials, the equilibrium solubility is too low (16). This is substantiated by the experimental results for the potential range covered in Table I. The potentiostatic reduction curves for this potential range, as indicated for the -0.300V curve in Fig. 2, all level out at zero current, which would not be expected if soluble Fe^{+2} were the reduction product. The potential-dependent reduction in this potential range is again indicative of reduction to a nonstoichiometric oxidation state in the film, tending to an equilibrium at the reduction potential. At reduction potentials more negative than those indicated in Table I, soluble Fe^{+2} is produced. This results

in a potentiostatic "reduction" curve of the type indicated at -0.550V in Fig. 2, where continuous oxidation of Fe to Fe^{+2} occurs after a preliminary partial reduction of Fe^{+3} .

There is much work in the literature concerning electrochemical formation and reduction of passive films on iron in borate buffer solution at pH 8.4. It has been demonstrated that, in the main, Fe_2O_3 is reduced directly to Fe^{+2} in galvanostatic reduction (21). The present work, however, is concerned with what happens in the limited range of potentials which might exist beneath the organic coating in a corrosion situation. The data presented in the literature at pH 8.4 are in agreement with the present indications at pH 7.6 in that at potentials representing the positive end of the galvanostatic reduction range, (i) there is an amount of cathodic reduction charge which does not result in soluble Fe^{+2} , (ii) Fe^{+2} in solution at the 10^{-4} level, and presumably at lower concentrations, is oxidized to ferric oxide, rather than the reverse reaction, and (iii) charge is passed at identical potentials when going either in the passivating direction or in the reverse direction (15, 22). Other investigations have indicated the existence of nonstoichiometric compositions between the Fe_2O_3 and the Fe_3O_4 layers in passive films and have indicated the high electronic resistance of Fe_2O_3 is decreased with increasing Fe^{+2} in the film (19, 23, 24).

Simultaneous Raman Spectroscopy and Electrochemical Studies of Corrosion Inhibiting Molecules on Copper

D. Thierry and C. Leygraf*

Swedish Corrosion Institute, S-114 86 Stockholm, Sweden

ABSTRACT

Surface-enhanced Raman scattering (SERS) has been used as a complementary *in situ* technique for electrochemical measurements in order to investigate five structurally related N-heterocyclic molecules on copper. Their different abilities to act as corrosion inhibitors are discussed in view of structural information obtained from SERS. It is concluded that the molecules investigated do not dissociate upon adsorption and that different functional groups result in different orientation of the adsorbed molecules on copper.

Since the early detection of anomalously intense Raman scattering from pyridine adsorbed on silver electrodes (1), surface-enhanced Raman scattering (SERS) has become a promising *in situ* tool for studies of reactions at metal/electrolyte interfaces.

The great enhancement of Raman scattering up to a factor of 10^6 for molecules adsorbed on rough Ag, Cu, or Au surfaces has resulted in successful efforts to use SERS as a surface-sensitive *in situ* method in corrosion science. Hence, during the last years, several investigations have been published on SERS experiments with corrosion inhibiting molecules, such as mercaptobenzothiazole ad-

sorbed on Ag (2), benzotriazole adsorbed on Cu (3-5), and thiourea on Cu (5). These results have shown that SERS is an extremely surface sensitive *in situ* technique for studies of inhibitor complexes formed on Ag and Cu surfaces under potentiostatic control.

N-heterocyclic compounds have been used as corrosion inhibitors on copper for several decades. Benzotriazole (BTA) is the most widely used corrosion inhibitor for copper and copper-based alloys and has been the subject of many investigations. Poling (6) attributed the inhibiting effect of BTA to a compact film of a Cu-benzotriazolate (Cu-BTA) complex polymer, which would act as a physical barrier against the corrosive media. Mansfeld *et al.* (7) suggested that the chemisorption of BTA^- on Cu pre-

* Electrochemical Society Active Member.

vents the adsorption of oxygen and the formation of a prenucleation layer, which is the essential condition for oxide formation. For these authors, the chemisorption of BTA^- plays the predominant role in the inhibition mechanisms.

Although BTA has been studied more extensively than other N-heterocyclic compounds, the structural nature of films formed upon adsorption on Cu is not well determined. In order to further examine the role played by BTA and other heterocyclic compounds as corrosion inhibitors for Cu, we report in this work SERS and electrochemical (polarization resistance and ac impedance) studies of BTA and, for the first time, of four other molecules structurally related to BTA.

Experimental

Electrochemical measurements.—The electrochemical measurements were performed using a potentiostat and a standard three-electrode electrochemical cell with a saturated calomel electrode as reference electrode and a platinum electrode as counterelectrode.

The working electrodes were cut from a 99.99% pure polycrystalline Cu rod, resulting in an exposed surface area of 1 cm^2 . The circular Cu samples were diamond polished down to a particle size of $1 \mu\text{m}$, rinsed with distilled water, and degreased with acetone before immersion under potentiostatic control in the electrochemical cell. The polarization resistance results were obtained by monitoring the current as a function of electrode potential in steps of 1 mV (5 mV/min) from -30 to $+30 \text{ mV}$ relative to the corrosion potential. All values of polarizing potentials are given relative to the saturated calomel electrode (SCE).

AC impedance experiments were performed using the same cell and electrodes as for the polarization resistance experiments. A frequency response analyzer (Solatron 1170) was used for measuring the impedance over the frequency range of 100 kHz – 10 mHz . Electrolytes were prepared by mixing 5 mM of inhibitors in 0.01 or 0.1 M NaCl . In all cases, triply distilled water and pure reagents were used as ingredients.

Surface Raman measurements.—The Raman Spectrometer, consisting of a Dilor RTI 30 triple monochromator and a photon counting system, has been described in more detail elsewhere (8). Oxidation-reduction cycling (ORC) in the electrolyte studied was performed in order to increase the amplitude of surface Raman signals. It consists of triangular sweeps from a cathodic potential where Raman spectra later were taken to some anodic potential in the range of 100 – 120 mV/SCE (corresponding to a total charge passed of 10 mC/cm^2). The ORC surface pretreatment was done under simultaneous laser illumination because this was found to increase the surface Raman signals further (8). An Ar laser (5140 \AA) was used for normal bulk Raman measurements, whereas a Kr laser (6470 \AA) operating at a power of 100 mW was necessary for obtaining detectable SERS signals (4, 5).

Results

Electrochemical measurements.—Tables I and II show the molecular structure of the investigated molecules, their polarization resistance, and their inhibiting efficiency in 0.01 and 0.1 M NaCl , respectively, obtained at the actual corrosion potentials. The inhibiting efficiency is defined as

$$I \% = \left(1 - \frac{i_i}{i_0}\right) \times 100$$

with i_i and i_0 the measured currents with and without inhibitor added. According to both electrochemical measurements and to separate weightless measurements, the molecules investigated exhibit the same order of inhibiting ability. In the less aggressive solution, the inhibiting efficiency varies from 75% for hydroxybenzimidazole to 99% for mercaptobenzimidazole (Table I). In the more aggressive solution, the inhibiting efficiency varies from no

inhibition at all for hydroxybenzimidazole to 83% for mercaptobenzimidazole (Table II). Hence, under present conditions, the inhibiting ability of mercaptobenzimidazole is significantly higher than that of benzotriazole in 0.01 as well as 0.1 M NaCl .

Surface Raman measurements.—The normal bulk Raman spectra of concentrated benzimidazole and benzotriazole solutions have been reported and discussed elsewhere (3, 9–11). Frequency shifts and tentative assignments of six main Raman lines taken from the literature are shown in Table III for benzotriazole and in Table IV for benzimidazole. The Raman lines shown for benzimidazole were found to be present for all benzimidazole derivatives. Hence, although no assignments of Raman lines have been published for mercapto-, methyl-, and hydroxybenzimidazole, the structural resemblance of these molecules suggests the same assignments for all benzimidazole derivatives.

Figure 1 illustrates the Raman lines of normal Raman spectra (lower part) of benzotriazole in ethanol (used as solvent) and of SERS spectra obtained at different applied potentials in 0.1 M NaCl . Figure 2 illustrates the same spectra for benzimidazole.

The surface-enhanced character of the SERS spectra was verified by a marked potential dependence of the Raman line intensities. This is illustrated in Fig. 1 and 2,

from which it is further concluded that normal Raman and SERS spectra exhibit approximately the same Raman peaks (except those originating from ethanol). This suggests that the benzotriazole and benzimidazole molecules, with exception of a possible loss of protons, are not dissociated upon adsorption on copper. This is in agreement with previous IR (6) and SERS (3) studies of the same system, suggesting that benzotriazole is adsorbed as an ion (BTA⁻) rather than as a neutral molecule (BTAH).

Furthermore, a comparison of Raman line intensities of normal Raman and SERS spectra reveals that peaks from vibrational modes of the triazole ring and the imidazole ring, respectively, increase in intensity more than peaks from vibrational modes of the benzene ring when going from normal Raman spectra to SERS spectra.

Figures 3-5 illustrate the same studies as in Fig. 1 and 2 for, respectively, mercaptobenzimidazole, methylbenzimidazole, and hydroxybenzimidazole. Again, normal Raman and SERS spectra exhibit similar features with Raman peaks at approximately the same positions. As for benzotriazole and benzimidazole, this suggests that the investigated molecules are not dissociated upon adsorption on Cu. For these molecules, however, no preferential enhancement of Raman intensities is observed, for neither the imidazole ring nor the benzene ring, when going from normal Raman to SERS spectra.

Figures 6 and 7 illustrate the potential dependence of the six Raman lines given in Tables III and IV for

Fig. 1. Normal Raman and SERS spectra of benzotriazole in ethanol and in 0.1M NaCl. SERS spectra were obtained at different electrode potentials. Arrows indicate normal Raman peaks of ethanol used as solvent.

Fig. 2. Normal Raman and SERS spectra of benzimidazole. See caption of Fig. 1 for further explanations.

benzotriazole and benzimidazole, respectively. Raman intensities of peaks originating from vibrational modes of the triazole or imidazole ring, on one hand, and peaks originating from vibrational modes of the benzene ring, on the other, change approximately uniformly in the potential interval from -700 to -100 mV/SCE. In agreement with (13), the maximum in Raman intensity is found at around -700 mV/SCE.

Discussion

General.—Following established procedures values of polarization resistance and inhibiting efficiency given in the previous section were obtained at the actual corrosion potential (around -150 mV/SCE). Raman spectra, on the other hand, were obtained at more cathodic potentials because of Raman line intensity problems at the corrosion

Fig. 3. Normal Raman and SERS spectra of mercaptobenzimidazole. See caption of Fig. 1 for further explanations.

Fig. 4. Normal Raman and SERS spectra of methylbenzimidazole. See caption of Fig. 1 for further explanations.

potential and an observed maximum in intensity at around -700 mV/SCE (Fig. 6 and 7). Hence, before combining results from electrochemical measurements with structural information from Raman measurements, it is first necessary to establish that no major structural changes occur in the interval from -700 to around -150 mV/SCE. Evidence for this is given in Fig. 1 for benzotriazole, which exhibits strong similarities in peak positions of the SERS spectra obtained in the interval between -700 and -100 mV/SCE. The same tendency is

Fig. 5. Normal Raman and SERS spectra of hydroxybenzimidazole. SERS spectra were obtained at different electrode potentials.

Fig. 6. Variation in amplitude of main Raman lines for benzotriazole with electrode potential.

found for the other molecules investigated, showing strong resemblance in peak positions between different potentials up to the most anodic potentials where surface Raman spectra could be obtained (Fig. 2-5). These results suggest that no major structural changes occur in the investigated potential region.

Further evidence is given by ac impedance measurements of the same components adsorbed on copper in 0.1M NaCl at different potentials. All ac impedance spectra exhibit characteristic hemicircles from which the total capacitance of the solid/liquid interface can be calculated (14). In Fig. 8, numerical values of capacitances are given at different potentials between -100 and -700 mV/SCE in 0.1M NaCl and with benzimidazole, benzotriazole, or mercaptobenzimidazole added. The curves exhibit a continuous decrease with applied potential. In qualitative agreement with ellipsometry measurements obtained elsewhere (7), this is consistent with a continuous growth in adsorbed film thickness when going from -700 mV/SCE to more anodic potentials. Any major change in adsorbed film structure would have resulted in more dramatic changes in capacitance in that particular potential region than those actually observed.

From Fig. 8 it is further concluded that the capacitance at any given potential decreases with inhibiting ability for the molecules investigated. This observation is in agreement with work reported elsewhere and interpreted as being due to the formation of a protective layer with adsorbed inhibitors (15).

To summarize, both Raman spectra and ac impedance measurements suggest that similar inhibition reactions occur at -700 mV/SCE (where the maximum of intensity in SERS is obtained) and around -100 to -200 mV/SCE where the polarization resistance measurements were performed.

Polarization resistance measurements.—Tables I and II clearly show that small variations in molecular structure

Fig. 7. Variation in amplitude of main Raman lines for benzimidazole with electrode potential.

Fig. 8. Capacitance values calculated from ac-impedance spectra of Cu in 0.1M NaCl at different potentials and with various inhibitors added.

can result in noteworthy differences in inhibiting efficiency. The replacement of the middle nitrogen atom in the triazole ring of benzotriazole by a hydrocarbon group leads to a significant decrease in inhibiting ability. This is consistent with observations reported elsewhere (16) that the inhibitive properties of benzimidazole and structurally related molecules such as indole and indazole are inferior to benzotriazole in near-neutral solutions. It suggests further that all three nitrogen atoms in the triazole ring may be involved in the adsorption process.

As further inferred from Tables I and II, the substitution of a proton or a methyl group in the imidazole ring by a mercapto group results in a notable increase in inhibiting efficiency, and mercaptobenzimidazole seems under present conditions to be a better corrosion inhibitor than benzotriazole. Functional groups such as the mercapto group are, for most organic corrosion inhibitors, reaction centers for adsorption processes, which becomes evident also from the present results.

The poor inhibiting ability shown by hydroxybenzimidazole is most likely due to the molecule being in equilibrium with its keto form according to the reaction scheme shown below

From this follows that adsorption on copper mainly occurs through one of the nitrogen atoms in the keto structure.

Considering all molecules investigated in this work, the inhibiting efficiency of various atoms in functional groups follows the generally observed order (16) sulfur > nitrogen > oxygen.

SERS results.—The enhancement of Raman scattering has been described as a contribution of short-range enhancement which applies to the first chemisorbed layer and long-range enhancement which includes many molecular layers away from the surface (18, 19). The short-range contribution is attributed to an increase in the molecule polarizability caused by changes in the electronic charge density distribution near the surface. This effect occurs only for the first adsorbed layer. The long-range contribution is attributed to the enhancement of electromagnetic fields which may arise from excitations of surface plasmon polaritons. The effect is very sensitive to

surface morphology. The exact contribution of these two effects remains uncertain (20, 21).

The difference in contribution of long-range electromagnetic and short-range chemical effects occurring at different distances from the metal surface can be used when interpreting the difference in Raman line intensities between normal and SERS spectra (Fig. 1-5). The increase in Raman line intensities of the triazole part in benzotriazole as compared to that of the benzene part (Fig. 1) may arise from short-range contributions of the total enhancement of Raman scattering. The same holds true for the corresponding increase in Raman line intensities of the imidazole part in benzimidazole as compared to that of the benzene part (Fig. 2). This, together with the appearance of the same peaks in SERS and normal Raman spectra, suggests that benzotriazole and benzimidazole are nondissociatively chemisorbed on Cu and that the triazole and the imidazole part, respectively, are more affected by the Cu surface than the benzene part of the molecules and therefore presumably bonded directly to Cu in the first adsorbed layer.

Further evidence is given by a comparison between frequency shifts from bulk and surface Raman spectra, respectively. This shows that there is a significantly larger difference in frequency shifts for vibrational modes originating from the triazole or imidazole part than for vibrational modes originating from the benzene part. Hence, SERS results suggest that adsorption of benzotriazole and benzimidazole occurs solely via the triazole and imidazole part, most likely through interaction of all three nitrogen or carbon atoms with the Cu substrate.

On the other hand, mercaptobenzimidazole, hydroxybenzimidazole, and methylbenzimidazole exhibit neither any preferential enhancement in Raman intensity nor any preferential shifts in Raman peak positions originating from the imidazole part (Fig. 3-5). Consequently, when adsorbed on copper, these molecules exhibit a different orientation than benzotriazole and benzimidazole as a result of other atoms or functional groups in the imidazole ring taking part in the adsorption process. Hence, the presence of two polar functions in mercaptobenzimidazole may result in adsorption on Cu via sulfur and one of the nitrogen atoms, which results in a different orientation of adsorbed mercaptobenzimidazole than of adsorbed benzotriazole or benzimidazole. Similarly, the presence of a methyl group in methylbenzimidazole and the keto form of hydroxybenzimidazole suggest that the different orientations of these molecules are caused basically via interaction of only one of the nitrogen atoms of the imidazole ring and the Cu surface.

Hence, the difference in inhibiting ability of all five molecules investigated can tentatively be explained by the number and type of functional groups or atoms in the triazole or imidazole ring that interact with Cu according to interpretations of SERS results.

However, even if structural information concerning the first adsorbed layer of inhibiting molecules as obtained by SERS suggests some explanations for their difference in inhibiting ability, it should be emphasized that, also, other parameters have to be considered in the design of an efficient corrosion inhibitor for Cu. Among such parameters should be mentioned possible polymerization of chemisorbed molecules, their acid strength, and surface film thickness. Their possible influence is the subject of further investigations of these and other corrosion inhibiting molecules structurally related to benzotriazole.

Conclusions

Polarization resistance studies of organic molecules on Cu, namely benzotriazole and four derivatives, show marked differences in their ability to act as corrosion inhibitors for Cu. These differences have been combined with structural information concerning chemisorbed films as obtained by SERS.

The results of polarization resistance have been obtained at the corrosion potential (ranging from -100 to -200 mV/SCE), while those of SERS have been obtained

at more cathodic potentials (ranging from -100 to -700 mV/SCE). SERS as well as ac impedance measurements, however, suggest a similar structure for each molecule in the whole investigated potential range from -700 to -100 mV/SCE. Consequently, results from present polarization resistance measurements can be directly combined with SERS measurements.

With the exception of possible losses of protons, SERS results show the molecules investigated not to be dissociated upon adsorption.

Bonding between the molecules investigated and the Cu surface is suggested to involve the N—N—N and N—C—N chain in the case of benzotriazole and benzimidazole, N and S from the N—H and S—H groups in the case of mercaptobenzimidazole, and only N from the N—H group in the case of hydroxy- and methylbenzimidazole.

The change in inhibiting ability of the molecules investigated is reflected in the number and type of functional groups or atoms that interact with the Cu surface.

Computation of Pourbaix Diagrams Using Virtual Species: Implementation on Personal Computers

John C. Angus*

ABSTRACT

Computation of the equilibrium composition in complex, multiphase redox systems is accomplished by treating the active element as a virtual species. For ideal solutions, the equation set may be solved sequentially, rather than simultaneously, for the concentrations of all species. For nonideal solutions, the method provides the basis for an efficient iterative solution. The procedure gives a simple test for phase stability and an algorithm for defining the boundaries of the regions of dominance of the dissolved species which is independent of concentration. Examples of Pourbaix diagrams generated on a small personal computer are given.

Since their introduction (1), Pourbaix diagrams have proven to be of great value in describing the complex phase chemistry of aqueous redox systems. Automated generation of Pourbaix diagrams by computer has been receiving increasing attention in recent years (2-7). Computational methods have been reviewed by Linkson (8).

In this paper, we describe a computational approach in which the active element undergoing redox transitions is treated as a virtual species. The resulting formalism is particularly simple and permits rapid solution on small desktop computers or even hand calculators.

The particular procedures described here are restricted to systems involving only one redox element, M, and to

pure solid phases containing only M, H, and O. No other solids, such as carbonates, or complexes, such as chlorides, are considered. The method is, however, completely general and can be extended to these cases.

Thermodynamic Analysis

Phase rule analysis.—Consider a system comprised of k species which contain the active element undergoing redox transitions. For example, for sulfur, these species could include among others: S^{-2} , HS^{-1} , H_2S , S^0 , SO_3^{-2} , HSO_3^{-1} , etc. In addition, there are the species H_2O , H^+ and the electrons, e^- , which are a virtual species. Among these species one can write $k - 1$ independent redox reactions.

The phase rule for reacting systems may be written as

*Electrochemical Society Active Member.

$$f = (s - r) - P + 2 \quad [1]$$

where s is the total number of species, r the number of independent reactions, and P the number of phases. Substituting $s = k + 3$, $r = k - 1$, and fixing both temperature and pressure, the phase rule reduces to

$$f = 4 - P \quad [2]$$

If OH^- ions appear in the reactions, there is an additional species; however, there is another equilibrium equation between the OH^- and H^+ . Furthermore, no provision was made to ensure electroneutrality. Again, adding an equation for electroneutrality and adding an inert counterion leaves the phase rule the same. Equation [2] indicates that a maximum of three independent intensive variables can be chosen, e.g., E , pH , and $[\text{M}]_T$, the total dissolved concentration of active element, M . Therefore, a three-dimensional space is required to truly represent the phase equilibria. It is customary, however, to construct a two-dimensional representation of the three-dimensional diagram by projection onto the E - pH plane.

The full three-dimensional diagram for the copper system is shown in Fig. 1. Figure 1 was obtained by solving the simultaneous equilibrium equations assuming ideal solutions ($\gamma_i = 1$) and pure, immiscible solid phases. In the three-dimensional E - pH - $\log_{10} [\text{Cu}]_T$ space, a two-phase region appears as a surface. The intersection of two two-phase surfaces is a line corresponding to a three-phase region (two solid phases plus the aqueous phase).

In Fig. 2, the three-dimensional diagram of Fig. 1 is plotted in conventional form as a projection onto the E - pH plane. The projections of the three-phase lines are shown as solid lines; lines of constant total dissolved concentration, $[\text{Cu}]_T$, are shown as dashed lines.

In the absence of any standardized nomenclature, we will call diagrams of the type shown in Fig. 2 "Pourbaix diagrams." These differ from so-called "predominance diagrams" in which the regions in which single species are dominant are also plotted on the E - pH field. The two types of diagrams are often superimposed on the same plot.

Calculation of equilibrium compositions: Virtual species.—There are very well-developed techniques for determining the minimum number of independent reactions required to describe the stoichiometry of a reacting system (9). For systems involving many chemical species, many different sets of mathematically independent reactions can be written. However, some sets may have great computational and conceptual advantages. We use the set obtained by writing the $k - 1$ formation reactions in the standard form

$$\text{M} = \nu_i \text{M}_i + h_i \text{H}^+ + w_i \text{H}_2\text{O} + z_i e^- \quad [3]$$

For example, for $\text{S}_2\text{O}_3^{2-}$, one has

$$\text{S} = 1/2 \text{S}_2\text{O}_3^{2-} + 3\text{H}^+ - 3/2 \text{H}_2\text{O} + 2e^- \quad [4]$$

Fig. 1. Three-dimensional Pourbaix diagram for the copper system

Fig. 2. Two-dimensional Pourbaix diagram for the copper system obtained by projection onto the E - pH plane.

where $\text{S} = \text{M}$, $\text{S}_2\text{O}_3^{2-} = \text{M}_i$, $\nu_i = 1/2$, $h_i = 3$, $w_i = -3/2$, and $z_i = 2$. Equation [3] can be shown to describe the equilibria even if the pure element, M , is not physically present in the equilibrium mixture.

From Eq. [3], one has the equilibrium equations

$$\mu_{\text{M}} = \nu_i \mu_i + h_i \mu_{\text{H}^+} + w_i \mu_{\text{H}_2\text{O}} + z_i \mu_e \quad [5]$$

The relationship between the chemical potential and concentration of species M_i is

$$\mu_i = \mu_i^0 + RT \ln \gamma_i [\text{M}_i] \quad [6]$$

We define a standard chemical potential per atom of active element by

$$\mu_i^{\Delta} \equiv \mu_i^0 / \alpha_i \equiv \mu_i^0 \nu_i \quad [7]$$

where α_i ($\equiv 1/\nu_i$) is the number of atoms of the active element per molecule of species i . Combining Eq. [5]-[7], one finds

$$[\text{M}_i] = \frac{1}{\gamma_i} \exp \frac{[\mu_{\text{M}} - \mu_i^{\Delta} - h_i \mu_{\text{H}^+} - w_i \mu_{\text{H}_2\text{O}} - z_i \mu_e]}{\nu_i RT} \quad [8]$$

The term μ_{M} is the chemical potential of the active element. If the pure element is not physically present in the reactive mixture, μ_{M} still has meaning. In this case, the element is a virtual species.

Virtual species have been used before to simplify equilibrium calculations (10). The most common example is, however, the separation of redox reactions into two half-cells. The electrons which appear in the half-cell reactions are not present as physically distinct species in the reaction mixture. It is nevertheless customary to treat them as virtual species and to use their chemical potential as one of the thermodynamic variables.

Further insight can be obtained by summing Eq. [8] over all dissolved species containing the active element and solving for μ_{M}

$$\mu_{\text{M}} = -RT \ln Q + RT \ln \sum_i (\gamma_i [\text{M}_i])^{\nu_i} \quad [9]$$

where

$$Q \equiv \sum_i \exp \left[\frac{-\mu_i^{\Delta} - h_i \mu_{\text{H}^+} - w_i \mu_{\text{H}_2\text{O}} - z_i \mu_e}{RT} \right] \quad [10]$$

Equations [9] and [10] are of considerable interest. First note the resemblance of the function Q to a partition function. The summation is over dissolved species rather than allowed quantum states. Further note that Eq. [9] can be cast into the standard form for the chemical potential

$$\mu_M = \mu_M^* + RT \ln a_M \quad [11]$$

with

$$a_M = \Sigma (\gamma_i [M_i])^{v_i} \quad [12]$$

and

$$\mu_M^* = -RT \ln Q \quad [13]$$

The sum $\Sigma(\gamma_i [M_i])^{v_i}$ can be interpreted as the overall activity of the active element in the solution. Note that this quantity is well defined even if the active element does not exist as the elemental form in the reaction mixture.

Stability criteria.—Consider any two species, *j* and *k*, which can either be dissolved species or solid phases. Assume the species coexist at some fixed pH and *E*, i.e., fixed values of μ_{H^+} and μ_{e^-} , but are not necessarily at thermodynamic equilibrium with each other. We examine the criterion which determines which is the stable species.

First write the formal expression for the stoichiometry of the transformation between *j* and *k* using Eq. [3]

The free energy change for this transition is just

$$\begin{aligned} \Delta G = v_k \mu_k - v_j \mu_j + (h_k - h_j) \mu_{H^+} \\ + (w_k - w_j) \mu_{H_2O} + (z_k - z_j) \mu_{e^-} \end{aligned} \quad [15]$$

But from Eq. [5]

$$(\mu_M)_k = v_k \mu_k + h_k \mu_{H^+} + w_k \mu_{H_2O} + z_k \mu_{e^-} \quad [16]$$

$$(\mu_M)_j = v_j \mu_j + h_j \mu_{H^+} + w_j \mu_{H_2O} + z_j \mu_{e^-} \quad [17]$$

Combining Eq. [15]-[17]

$$\Delta G = (\mu_M)_k - (\mu_M)_j \quad [18]$$

Equation [18] shows explicitly that the ΔG for a transformation between any species, dissolved or solid, is just equal to the difference in chemical potential of the active element in these two species. If $\Delta G < 0$, i.e., $(\mu_M)_k < (\mu_M)_j$, the transformation [14] proceeds to the right; if $\Delta G > 0$, to the left. In equilibrium $\Delta G = 0$ for all pairs, *j*, *k*

$$(\mu_M)_k = (\mu_M)_j \quad [19]$$

For any solid phase, one can obtain μ_M directly by writing Eq. [5] for the solid

$$(\mu_M)_s = v_s \mu_s + h_s \mu_{H^+} + w_s \mu_{H_2O} + z_s \mu_{e^-} \quad [20]$$

For the aqueous phase, μ_M can be computed from Eq. [9]. Therefore, Eq. [18] can be used to provide a simple algebraic test for stability. The stable phase will be the one with the lowest μ_M . A solid will dissolve in an aqueous solution if $(\mu_M)_s > (\mu_M)_{aq}$. Furthermore, since μ_M increases monotonically with a_M (see Eq. [11]), the solid phase with the lowest solubility is stable. This is in agreement with the well-known behavior of nonelectrolytes.

Predominance diagrams.—In addition to plotting the two- and three-phase boundaries, it is customary to divide the *E*-pH field into regions corresponding to the dominant dissolved species. The criterion used for determining the boundaries of these regions is usually

$$\gamma_j [M_j] = \gamma_k [M_k] \quad [21]$$

On the other hand, the criterion

$$(\gamma_j [M_j])^{v_j} = (\gamma_k [M_k])^{v_k} \quad [22]$$

may be easily shown to be independent of μ_M and hence concentration by using Eq. [8]. Since the boundaries determined by Eq. [22] are independent of concentration, they may be properly superimposed on the two-dimensional projection of a Pourbaix diagram.

Application of Theory

Conventions.—In this section, the working forms of the equations are developed. The equations are cast into the

form which is used when the free energy data are given as standard electrode potentials.

We assume that the electrode potentials are available for reactions [3] with all species in their standard states. If the standard potentials are not tabulated for all of the formation reactions, they can be obtained by making linear combinations of the tabulated reactions in the normal manner. There is, of course, no guarantee that a complete data set is available for each active element.

The relationship between the standard chemical potentials for the half-cell reaction given by Eq. [3] is

$$\mu_i^\Delta = \mu_M^\circ - h_i \mu_{H^+}^\circ - w_i \mu_{H_2O}^\circ - z_i \mu_{e^-}^\circ \quad [23]$$

Note that $\mu_{e^-}^\circ$ is the chemical potential of electrons in equilibrium with chemical species M_i , H^+ , and H_2O , all in their standard states. The standard-state free energy data for M_i , H^+ , and H_2O are encoded in tabulated values of $\mu_{e^-}^\circ$, which are reported as standard electrode potentials.

The following conventions are used to relate chemical potentials to the practical variables pH and *E*

$$\mu_{H^+} - \mu_{H^+}^\circ = -2.30259RT (\text{pH}) \quad [24]$$

$$(\mu_{e^-} - \mu_{e^-}^\circ) = -F(E - E_i^\circ) \quad [25]$$

Potentials only appear in the equations as the difference, $E - E_i^\circ$. Therefore, any consistent choice of reference electrode is permissible.

The chemical potential of H_2O in the solution, μ_{H_2O} , must be governed by the dictates of the Gibbs-Duhem equation and the chemical potentials of all other species. It appears customary, however, to ignore the influence of the other species and to replace the Gibbs-Duhem equation with the simple equality

$$\mu_{H_2O} = \mu_{H_2O}^\circ \quad [26]$$

It is assumed that all solid phases are pure and that

$$\mu_s = \mu_s^\circ \quad [27]$$

Equation [27] is an assumption about the nature of the system of interest and is not a convention for tabulating standard thermochemical data. If, for example, the pressure in the system of interest were not the standard-state pressure, then a Poynting-type correction would be necessary. Furthermore, if the solid phase were a solid solution, then one would have to introduce the properties of this solid solution.

General working equations.—The total dissolved concentration of active element, $[M]_T$, is used as the practical measure of concentration

$$[M]_T = \Sigma \alpha_i [M_i] \quad [28]$$

where the sum is over all dissolved species. The concentrations of the individual dissolved species are obtained by substitution of Eq. [23]-[27] into Eq. [8]

$$\begin{aligned} [M_i] = \frac{1}{\gamma_i} \exp \alpha_i \left\{ \frac{\mu_M - \mu_M^\circ}{RT} \right. \\ \left. + 2.30259 h_i (\text{pH}) + \frac{F}{RT} z_i (E - E_i^\circ) \right\} \end{aligned} \quad [29]$$

An expression for $\mu_M - \mu_M^\circ$ can be obtained by summing Eq. [29] over all dissolved species. One finds

$$\begin{aligned} \left[\frac{\mu_M - \mu_M^\circ}{RT} \right]_{aq} = - \ln \Sigma \exp \left\{ 2.30259 h_i (\text{pH}) \right. \\ \left. + \left(\frac{F}{RT} \right) z_i (E - E_i^\circ) \right\} + \ln \Sigma (\gamma_i [M_i])^{v_i} \end{aligned} \quad [30]$$

Equation [30] is the working form of Eq. [9].

The expression for the chemical potential of the active element in a pure solid phase, *s*, is obtained from Eq. [23]-[27] and Eq. [20]

$$\left[\frac{\mu_M - \mu_M^\circ}{RT} \right]_s = -2.30259 h_s (\text{pH}) - \left(\frac{F}{RT} \right) z_s (E - E_s^\circ) \quad [31]$$

Two-phase lines.—Eliminating $\mu_M - \mu_M^0$ between Eq. [31] and [29] one has

$$[M_i] = \frac{1}{\gamma_i} \exp \alpha_i \left[2.30259(h_i - h_s)(pH) + \left(\frac{F}{RT} \right) [z_i(E - E_i^0) - z_s(E - E_s^0)] \right] \quad [32]$$

Equation [32] gives the concentration of any dissolved species, M_i , in equilibrium with a pure solid phase, s . Using Eq. [32] in Eq. [28] one obtains the implicit algebraic relationship between E and pH along a two-phase line for any concentration $[M]_T$. These are the dashed lines in Fig. 2.

Three-phase lines.—The criterion of phase equilibrium for a pair of solids, u, v is

$$\left[\frac{\mu_M - \mu_M^0}{RT} \right]_u = \left[\frac{\mu_M - \mu_M^0}{RT} \right]_v \quad [33]$$

Using Eq. [33] and [31] gives the expression for the potential *vs.* pH along a three-phase line

$$E = \frac{z_v E_v^0 - z_u E_u^0}{(z_v - z_u)} - \frac{2.30259RT}{F} (pH) \quad [34]$$

In deriving Eq. [34], the general result that $h_s = z_s$ for all uncharged solids containing only H, O, and M was used.

Substituting Eq. [34] into Eq. [31], one obtains the chemical potential along a three-phase intersection

$$\left[\frac{\mu_M - \mu_M^0}{RT} \right]_{u,v} = - \left(\frac{F}{RT} \right) \left(\frac{z_u z_v}{z_u - z_v} \right) (E_u^0 - E_v^0) \quad [35]$$

Note that $(\mu_M - \mu_M^0)/RT$ is constant along the intersection.

The concentration of any species, M_i , in equilibrium with two solid phases, u and v , can be obtained from Eq. [34], [35], and [8]. One finds after some manipulation

$$[M_i] = \frac{1}{\gamma_i} \exp \left\{ \left(\frac{F}{RT} \right) \left(\frac{\alpha_i}{z_u - z_v} \right) [z_u(z_i - z_v) E_u^0 + z_v(z_u - z_i) E_v^0 + z_i(z_v - z_u) E_i^0] + 2.30259\alpha_i(h_i - z_i)(pH) \right\} \quad [36]$$

Another very useful result is obtained by differentiation of Eq. [31]. Using the fact that for uncharged solids, $h_s = z_s$, one finds

$$\left[\frac{\partial E}{\partial (pH)} \right]_{\mu_M} = -2.30259 \left(\frac{RT}{F} \right) \quad [37]$$

In other words, the chemical potential of any solid phase remains constant along a line of constant slope given by Eq. [37].

By comparison with Eq. [34], one sees that the chemical potential of any other solid, s , remains constant along a three-phase line where two solids, u and v , are in equilibrium.

Implementation

Pourbaix diagrams.—Computations were done on an Apple II+ computer. The stoichiometric coefficients, ν_i , h_i , z_i , and the standard electrode reduction potential, E_i^0 , were stored permanently on the program disk. No further computations of free energies or balancing chemical reactions are required. The sign convention for E_i^0 , embodied in Eq. [25], is consistent with previous published Pourbaix diagrams. The data used to construct the diagrams are given in Tables I and II. Data were obtained from standard sources (11, 12). No claim is made for these data sets, and they are included only as a reference for the diagrams.

The first step in constructing a Pourbaix diagram is to determine the relative stability of solid pairs. This is done

Table I. Copper data

Species	ν_i	h_i	z_i	E_i^0
Solid				
Cu	1	0	0	0
Cu ₂ O	0.5	1	1	0.470
CuO	1	2	2	0.570
Cu ₂ O ₃	0.5	3	3	0.929
Cu(OH)	1	1	1	0.568
Cu(OH) ₂	1	2	2	0.609
Dissolved				
Cu ⁺	1	0	1	0.520
Cu ⁺⁺	1	0	2	0.337
CuO ₂ ⁻⁻	1	4	2	1.515
HCuO ₂ ⁻	1	3	2	1.127
Cu ⁺⁺⁺	1	0	3	1.049
CuO ₂ ⁻	1	4	3	1.250

Table II. Sulfur data

Species	ν_i	h_i	z_i	E_i^0
Solid				
S	1	0	0	0
Dissolved				
S ⁻⁻	1	0	-2	-0.445
HS ⁻	1	-1	-2	-0.062
H ₂ S	1	-2	-2	0.144
S ₂ O ₃ ⁻⁻	0.5	3	2	0.465
HS ₂ O ₃ ⁻	0.5	5/2	2	0.440
H ₂ S ₂ O ₃	0.5	2	2	0.436
SO ₃ ⁻⁻	1	6	4	0.583
HSO ₃ ⁻	1	5	4	0.476
H ₂ SO ₃	1	4	4	0.450
SO ₄ ⁻⁻	1	8	6	0.353
HSO ₄ ⁻	1	7	6	0.333

by first computing $(\mu_M - \mu_M^0)/RT$ of a solid pair, u, v , from Eq. [35]. Next, compute E for this pair at any convenient pH , e.g., $pH = 0$, using Eq. [34]. Then, at this value of E and pH , compute $(\mu_M - \mu_M^0)/RT$ for all other solid phases, s , using Eq. [31]. The pair u, v is stable if for all other solids, s

$$\left[\frac{\mu_M - \mu_M^0}{RT} \right]_{u,v} < \left[\frac{\mu_M - \mu_M^0}{RT} \right]_s \quad [38]$$

Because the chemical potential of any uncharged solid is constant along a three-phase line, it is not necessary to repeat the test at any other pH . The above procedure is then repeated for all possible pairs of solids.

End points of the three-phase lines are found by using Eq. [36] in Eq. [28]. The resulting equation is solved, for fixed $[M]_T$, by the Newton-Raphson technique. Note that if $(\mu_M)_s > (\mu_M)_{aq}$ for all pH , no end points will be found. The two-phase boundaries are then traced out by a simple routine which follows the contour of constant $[M]_T$. The program displays the Pourbaix diagram on the video monitor. Labeling is accomplished by entering from the key board the coordinates of a point approximately in the center of each region. The program determines the stable phase at these coordinates and displays the name of the stable solid (or aqueous phase) at the point selected. Type fonts were obtained using Beagle Brothers software. The final plot is sent to a dot matrix printer using a commercial screen dump program (Advanced Grafpak, Smartware). Examples of several diagrams obtained in this way are shown in Fig. 3-6.

The program automatically handles the situation where a solid phase becomes unstable with respect to the aqueous phase, e.g., note the absence of Cu₂O₃ in Fig. 5. The case of a single stable phase is also covered; see Fig. 6 for sulfur.

The program was written in BASIC. Typical run times are 5 min, most of which is required to trace out the two phase boundaries. Use of a commercial BASIC compiler program could reduce this time by approximately a factor of three.

Predominance diagrams.—Consider any pair (j, m) of dissolved species. We are interested in determining the relationship between E and pH that guarantees

$$(\gamma_j[M_j])^{z_j} = (\gamma_m[M_m])^{z_m} \quad [39]$$

Using Eq. [29] in Eq. [39], one finds

$$E = -2.30259 \left(\frac{RT}{F} \right) \left[\frac{h_j - h_m}{z_j - z_m} \right] (pH) + \left[\frac{z_j E_j^0 - z_m E_m^0}{z_j - z_m} \right] \quad [40]$$

Fig. 7. Predominance diagram for dissolved copper species

Equation [40] is the equation of the lines that appear on predominance diagrams. Note that Eq. [40] is independent of concentration. Intersections of these lines determine the points where three species have equal values of $(\gamma_i[M_i])^{z_i}$. Writing Eq. [40] for the two pairs (j, m) and (k, m) and solving, one obtains the coordinates of the intersection

$$E = \frac{z_j E_j^0 (h_k - h_m) + z_k E_k^0 (h_m - h_j) + z_m E_m^0 (h_j - h_k)}{z_j (h_k - h_m) + z_k (h_m - h_j) + z_m (h_j - h_k)} \quad [41]$$

$$pH = \frac{[(z_j - z_m)z_k E_k^0 + (z_m - z_k)z_j E_j^0 + (z_k - z_j)z_m E_m^0] \left[\frac{F}{RT} \right]}{[h_k(z_j - z_m) + h_j(z_m - z_k) + h_m(z_k - z_j)]2.30259} \quad [42]$$

It can be shown from Eq. [40] that two lines are parallel if

$$h_j(z_m - z_k) + h_k(z_j - z_m) + h_m(z_k - z_j) = 0 \quad [43]$$

The above equations provide a very simple algorithm for construction of a predominance diagram. First, compute the coordinates of all possible intersections using Eq. [41] and [42]. Intersections falling outside the desired range, e.g., $-3 < E < +3$ or $-2 < pH < 16$, are discarded. At each remaining intersection, compute the value of $(\gamma_i[M_i])^{z_i}$ for all other dissolved species using Eq. [29]. The intersection (j, k, m) appears on the predominance diagram if for all other dissolved species, n, one has

$$(\gamma_j[M_j])^{z_j} > (\gamma_n[M_n])^{z_n} \quad [44]$$

This procedure is repeated for all possible intersections. The result is the coordinates of all intersections which should appear within the predominance diagram. Straight lines are drawn between all points which share a common pair of species.

The above procedure joins only those intersections (j, k, m) which are within the interior of the diagram. To complete the construction, one must connect some of these points to the boundaries of the diagram. Specifically, those interior points which are connected to only one or two other interior points must be connected to two or one boundaries, respectively. The appropriate boundary intersections are easily found using Eq. [40] and the equations for the boundaries, which in the present case were $E = -3V$, $E = +3V$, $pH = -2$, and $pH = 16$. All but one of the multiple intersections are discarded by demanding that the intersection be within the above ranges and by application of the criterion given by Eq. [44].

The predominance diagram for copper shown in Fig. 7 was obtained using this method.

Long-Term Atmospheric Oxidation of High Purity Iron

R. P. Frankenthal,* P. C. Milner,* and D. J. Siconolfi*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

High purity iron, cast and rolled more than 20 years ago and stored without special precautions in the laboratory, has largely maintained its bright surface finish over this period of time, showing that iron is stably passivated by air. Since long-term (>1 yr) oxidation studies of iron do not exist and since iron is usually thought to rust in air at moderate relative humidities, the thickness of the passivating oxide film was measured by Auger electron spectroscopy and depth profiling. After corrections for an adsorbed carbonaceous layer, the thickness was estimated to be 5-6 nm. This is in reasonable agreement with extrapolations of short-term (<24h) oxide film thickness data from gaseous and anodic oxidation studies in the literature.

There have been numerous investigations of the oxidation of iron at or near room temperature by air and by oxygen from low pressures to about 1 atm for times ranging from a few seconds to a maximum of several weeks (1-10). A summary of the results up to 1961 (7) indicates that the oxide film thickness lies in the range of 1-4 nm, depending on surface pretreatment, oxygen pressure, moisture content, and time of exposure. Later studies (8-10) agree with these findings. The various results imply that iron is stably passivated by oxygen and by air. However, there have been no reports of the passivation of iron when exposed to oxygen or air for long periods of time, i.e., for one or more years.

Andreeva (4) reported that after three years in a humid atmosphere rust centers developed at grain boundaries and spread radially over part of the surface. The surface not covered by rust retained its original brightness, and the thickness of the oxide film on those areas remained constant at the thickness it had after 30 days. Ali and Wood (10) reported that oxidation became rapid after about 60 days of exposure to laboratory air at room temperature at 44-46% relative humidity. After 120 days, the thickness of the oxide was greater than 50 nm, and it con-

sisted primarily of α - Fe_2O_3 . They attributed the increased oxidation rate to impurities in the atmosphere.

One of the present authors (RPF) has some strips of high purity (99.9+%), zone-refined iron (11) that was made in late 1963 or early 1964. These strips were stored in a glass bottle with a polyethylene stopper at the E. C. Bain Laboratory of the U.S. Steel Corporation in Monroeville, Pennsylvania, until 1972 and since then at AT&T Bell Laboratories in Murray Hill, New Jersey. No effort was made to protect these strips or to keep them from rusting, other than to keep the bottle stoppered. Recently (March 1984), we examined the strips and found most to be shiny and free from any visible tarnish or rust. A few pieces were partially discolored (gray), indicating that some tarnishing had occurred on them. Since we know of no really long-term (>1 yr) studies of the oxidation of iron in air and since it is generally assumed that iron will rust in air at moderate relative humidities, we thought it would be of scientific and technological interest and importance to measure the thickness of the oxide film that had formed on the surface of the iron strips that had remained shiny for a period of 20 years. We report here the results of that analysis and of calculations that extrapolate existing short-term gaseous and anodic oxidation data to 20 years.

Fig. 1. Auger electron spectrum of surface of high purity, zone-refined iron strip after 20 yr exposure to air at room temperature

Experimental

The preparation and typical analyses of the zone-refined iron are given in Ref. (11). The procedure used to roll the iron ingots is not known. However, the strips, which were not handled during the intervening 20 years, are shiny and free from any lubricant, rolling oil, or inhibitor, as evidenced by Auger electron analysis (see below).

The iron strips were introduced into the vacuum system of the Auger electron spectrometer without any cleaning or unnecessary handling. Surface analysis was performed with a Physical Electronics Industries Thin Film Analyzer system (TFA) using a single-pass cylindrical mirror analyzer. Spectra were recorded in the derivative mode. Operating conditions were 5 kV electron gun voltage, 10 μ A beam current, and 3 eV modulation amplitude. The spectral data were digitized with a TransEra 752 A/D converter that was the interface between a Tektronix 4052 microcomputer and the TFA. Depth profiles were obtained by argon ion sputter etching with a Perkin Elmer no. 04-303 differential ion gun. The ion gun voltage was 3 kV, and the beam was rastered over a 4 \times 4 mm area.

Results

The initial spectrum, before any sputtering, is shown in Fig. 1. The iron peaks between 550 and 720 eV are clearly visible, while the low energy peak at about 50 eV is barely visible above the noise. The oxygen peak is at 510 eV. All the peaks have been attenuated by a layer of adsorbed "dirt" from the atmosphere, as evidenced by the large carbon peak at 270 eV. Since all the iron peaks, including the one at low energy, are visible, the layer is probably no thicker than 1-2 nm, which indicates that no lubricant or rolling oil is present on the surface. The absence of a corrosion inhibitor is evidenced by the fact that the only extraneous peak in the spectrum is that from carbon. Most organic inhibitors contain nitrogen, whose peak at 380 eV is not evident. The most likely inorganic inhibitors are chromates and phosphates, and neither chromium nor phosphorus appears in the spectrum.

Sputter profiles through the 20 year oxide are shown in Fig. 2 for two strips. The initial rise in the oxygen signal,

I_{0s} , results from the sputter removal of the adsorbed carbonaceous layer. The carbon signal decreases rapidly as the oxygen signal increases.

To calibrate the sputter rate, a clean, sputtered area was exposed to air for 24h, after which a depth profile was obtained (Fig. 2). Since the thickness of a film grown for 24h in air or in O_2 containing a trace of water vapor is about 2 nm (4, 8) and the time to sputter through the film is 25s, the sputter rate is about 0.08 nm/s. The two 20 year oxide films, therefore, appear to be about 7-8 and 9-10 nm thick.

The apparent difference in film thickness between the two specimens is attributed to the thicker carbonaceous layer on c, as evidenced by the longer time needed to remove it, i.e., to reach the maximum in the curve. If the effect of this layer can be subtracted out, curves b and c should be the same, and the oxide thickness would be significantly less than the apparent thickness of 7-10 nm. The true thickness may be estimated as follows. We as-

Fig. 2. Sputter depth profiles (intensity of O 510 eV peak vs. sputter time) of oxide film on high purity, zone-refined iron. Curve a: After 24h exposure to air at room temperature. Curves b and c: After 20 year exposure to air at room temperature.

sume that the sputter time to reach the maximum of each curve in Fig. 2 is the time needed to remove the carbonaceous layer. Subtracting this time from the total time to sputter through the layers gives the time to sputter through the oxide. The oxide sputter rate calculated from the specimen exposed to air for 24h is 0.1 nm/s after this correction. Making the correction for the two 20 year specimens and using the corrected sputter rate, the films on these specimens are estimated to be about 5-6 nm thick.

Discussion

The results show that high purity iron is passivated by oxidation in air at or near room temperature and that it can maintain its passivity for more than 20 years. The thickness of the passivating film formed in 20 years (5-6 nm) is only two or three times that formed in 24h. Rusting or the formation of thicker films at long times (4, 10), as well as the tarnishing observed on bits of the iron used in the present study, is most likely caused by contamination from the atmosphere or from handling.

To determine whether the observed 20 year air oxidation of iron is consistent with short-term measurements, we sought studies in the literature that gave well-defined rate laws or sufficient tabulated data to allow extrapolation to 20 years. The data of Kruger and Yolken for the gaseous oxidation of iron yield the rate law (8)

$$d = 0.13 \ln t + C \quad [1]$$

in which d is the oxide film thickness in nanometers, t is the time, and C is a constant. The data of Sato and Cohen for the anodic oxidation of iron in pH 8.43 borate buffer yield the rate law (12)

$$i_t = k' \exp(\beta E - Q_T/B) \quad [2]$$

in which i_t is the faradaic current, E is the electrode potential, Q_T is the total faradaic charge accumulated in the oxide, and k' , β , and B are constants at a given temperature.

From the data in Fig. 6 of Ref. (8) for the oxidation of iron in 1 atm of O_2 at 27°C, one obtains $C = 2$ at time $t = 1$ min. Then, from Eq. [1], one calculates that the oxide film should grow to a thickness of 4.1 nm in 20 years.

To calculate the thickness of an anodically grown oxide film after 20 years from Eq. [2], it must be integrated to obtain the charge passed. Assuming that atmospheric exposure is equivalent to anodization at a constant potential E_2

$$\frac{dQ_T}{dt} = i_t = k' \exp(\beta E_2 - Q_T/B) \quad [3]$$

Rearranging

$$\int_{Q_{T,1}}^{Q_T} \exp(Q_T/B) dQ_T = k' \exp(\beta E_2) t \quad [4]$$

in which $Q_{T,1}$ is the initial amount of oxide. It follows that

$$Q_T = Q_{T,1} + B \ln \left[1 + \frac{k'}{B} \exp(\beta E_2 - Q_{T,1}/B) t \right] \quad [5]$$

The oxide film thickness, d , in nanometers, is obtained from Eq. [5], assuming that the film is $\gamma\text{-Fe}_2\text{O}_3$ with a density of 5 g/cm³ (13), by

$$d = 0.566 Q_T \quad [6]$$

when Q is given in millicoulombs per square centimeter. An analysis of the data of Sato and Cohen (12) and of Nagayama and Cohen (13) gives $k' = 17.0 \text{ A/cm}^2$, $B = 0.181 \text{ mC/cm}^2$, and $\beta = 1/2 \text{ F/RT}$ at 25°C. The oxide film thickness is then calculated from Eq. [5] and [6], assuming that $Q_{T,1}$ is 0 and that the potential is maintained at the reversi-

Table I. Calculated thicknesses as a function of time and temperature

Time	Anodic oxide thickness (nm)	
	20°C	25°C
1 min	2.52	2.54
1h	2.92	2.96
1 day	3.23	3.29
10 day	3.45	3.52
100 day	3.67	3.76
1 yr	3.79	3.89
5 yr	3.95	4.06
10 yr	4.02	4.13
20 yr	4.08	4.20
25 yr	4.10	4.22

ble oxygen potential in air, *i.e.*, at +477.1 mV *vs.* SCE at 25°C and at +486.5 mV *vs.* SCE at 20°C. The calculated thicknesses as a function of time and temperature are given in Table I.

The almost identical values calculated from Eq. [1] and from Eq. [5] and [6] for an oxidation time of 20 years are probably fortuitous, since the equations represent different rate laws and oxidation mechanisms (8, 12). However, this does strongly suggest that iron is passivated equivalently by either gaseous or anodic oxidation and that the passivating films prepared in these different manners grow at comparable rates.

The experimentally determined oxide film thickness, without correcting for the thickness of the adsorbed carbonaceous layer, is about twice that calculated from Eq. [1] or from Eq. [5] and [6]. The approximate correction yields an oxide thickness only about 1-2 nm greater than the extrapolated values. Differences between the experimental and calculated values may be attributed to one or more of several factors, including atmospheric impurities, residual surface impurities from rolling and handling, the many changes in relative humidity and temperature experienced by the iron over the 20 year period, and the length of the extrapolation.

Conclusions

The results show that high purity iron is passivated by air oxidation. The long-term stability of the passivating film has been demonstrated. Over a 20 year period, the film grew to a thickness of no more than 5-6 nm, in reasonable agreement with the values calculated by extrapolating short-term gaseous and anodic oxidation data to 20 years. Rusting of high purity iron apparently requires the presence of impurities and/or very high relative humidities or liquid water.

Modification of the Electrochemical and Corrosion Behavior of Stainless Steels with an Electroactive Coating

David W. DeBerry*

SumX Corporation, Austin, Texas 78758

ABSTRACT

Electroactive polyaniline coatings have been deposited on ferritic stainless steels. The coatings appear to be deposited over the passive metal oxide film but can undergo electron transfer with the metal. Polyaniline immobilized on the alloys imparts a form of anodic protection which stabilizes the materials in mineral acids. Electrochemical and SEM characterization results are presented, and effects of coating application techniques are discussed. Oscillations in the open-circuit voltage occur in solutions containing a high enough concentration of chloride ion to initiate pitting at potentials dictated by the coating. Inhibition of localized corrosion may also be obtainable for favorable systems.

There has been a great deal of interest for the past few years in electrodes chemically modified with electroactive materials (1-3). Most of these studies have been performed using nominally inert substrate materials such as Pt, Au, SnO₂, and various forms of carbon. Recently, interest has been shown in application of electroactive materials to relatively reactive substrates (4-6). Modification of active substrates appears to offer unique opportunities for investigation of the substrate itself, as well as any intervening "passive" films which may occur between the metal and electroactive material (4). The composite materials may also have practical applications in corrosion prevention. For example, a form of anodic protection may be obtained by coating an active/passive metal with a redox species capable of maintaining the native passive film on the metal.

This paper is concerned with electroactive coatings, which are shown to protect relatively low alloy 400 series stainless steels in corrosive acid media. The preparation techniques important to their effectiveness are discussed along with possible mechanisms for the observed behavior. Polyaniline (PA) was the primary electroactive material used in this study. Its use is advantageous in acidic environments since hydrogen ion is the preferred counterion for maintaining PA electroneutrality during electron transfer. Aqueous solutions of sulfuric acid have been the major corrosive media in this work, but results obtained in chloride-containing dilute acid are also present.

Experimental

Conventional electrochemical equipment was used for electrode modification and characterization. Solutions were prepared from analytical reagent-grade chemicals and type I water obtained from a Milli-Q (Continental Water Systems) water purifier equipped with an Organex cartridge for removal of trace organic compounds. The atmosphere in the airtight glass cells was maintained using either presaturated zero-grade air or prepurified nitrogen. All potentials were recorded and are reported *vs.* saturated calomel electrodes (SCE). Particularly during long-term experiments, the SCE was separated from the main cell solution by two frits, one being a porous Vycor frit. Platinum auxiliary electrodes were used.

Metal specimens were fabricated into 4-6 cm² "flag"-shaped samples with the integral "flagpole" or handle extending out of the solution and used to make electrical connection. This configuration was chosen to minimize anomalous effects at the metal/gas/solution interface without using insulating coatings, which can also cause irreproducible crevice effects, particularly on long exposure to solution. The electroactive coatings were generally applied to a portion of the flagpole as well as the main flag area, and the samples were then inserted in the corrosion test solution with 2-5 mm of the coated part of the pole extending out of solution. Except as noted,

samples were finished to 600 grit SiC on a Buehler polishing table and then degreased with methanol and thoroughly rinsed with water before use. The composition of the metals (obtained from Metal Samples, Incorporated, Munford, Alabama) are given in Table I.

In general, electroactive polyaniline coatings were obtained on the metals of interest by electrochemical treatment in a 1.0M aniline, pH 1.0 perchloric acid solution (7). The coating was usually applied by cycling the working electrode potential between *ca.* -0.2 and +1.1V at a scan rate of 50 mV/s. Detailed descriptions of the deposition variables and results are given in the next section.

The quantity of charge in the electrode coating was obtained by integration of the appropriate portion of the linear scan or cyclic voltammogram. Slow (0.5 mV/s) linear potential scans were used for determining the corrosion properties of the bare metals in the various environments, particularly the chloride containing solutions. These runs were generally done in deaerated solution with a 1h immersion of the sample prior to starting the scan. No solution agitation was used in the electrochemical treatments or tests unless otherwise specified.

Samples were routinely inspected with a stereomicroscope up to a magnification of 45 times. The scanning electron microscope work was done with a JEOL-JSM 35C operated at 25 kV and equipped with a KEVX elemental detection system.

Results and Discussion

Deposition and characterization of PA films.—Electroactive polyaniline coatings were obtained on types 410 (11.6% Cr) and 430 (16.2% Cr) stainless steels (SS) by electrochemical treatment in a 1.0M aniline, pH 1.0 perchloric acid solution. Typical voltammograms observed during cycling of type 430 SS in the deposition solution are shown in Fig. 1. If the electrode is allowed to become active in the pH 1.0 deposition solution, an active-to-passive current peak is observed at about -0.27V on the first anodic scan from open circuit. Note that this peak is not observed again on repeated scanning through the same potential region. The current decreases rather slowly past this peak on the first scan, with some indication of a postpassivation maximum at +0.12V, until a sharp increase begins at *ca.* +1.0V, signaling the start of polyaniline deposition. The anodic current on the second scan is much lower than the first until +1.0V is reached once again and more PA is deposited. The cathodic current does not show a clear increase until the third cycle. On the fifth cycle, the oxidation peak for deposited polyaniline at +0.12V starts to become significant, and it ultimately becomes the dominant peak. Also on the fifth cycle, three separate oxidation and three corresponding reduction peaks become discernable. These peaks then increase rather uniformly with continued cycling as more PA is deposited.

The effect of this treatment is the apparent buildup of PA film which increases in thickness with each cycle.

Table I. Nominal compositions of metals

Metal	Fe	Cr	Ni	C	Mo	Composition (w/o)						
						Mn	S	Si	P	Cu	N	Other
Type 410 SS	Bal.	11.62	0.19	0.122	0.06	0.54	0.002	0.50	—	—	0.048	0.005 Sn
Type 430 SS	Bal.	16.20	0.41	0.05	0.08	0.50	<0.01	0.46	0.02	0.09	—	—

Following the initial passivation peak, the deposition behavior on the active/passive alloys studied is similar to that for deposition of polyaniline on platinum or other "inert" metals (7-9). The redox reactions occurring in polyaniline on cycling are most likely quite complex. The results obtained on the first few scans seem to indicate that a passive metal oxide film is formed first on the stainless steel surface, with deposition of polyaniline occurring on top of it. Even a small amount of polyaniline appears to stabilize the passive film to some degree against dissolution and/or reduction. Once the surface is passivated and the initial layer of polyaniline is deposited, the cyclic voltammetric response is quite similar to an inert metal. However, the actual situation may be more complicated than indicated by these experiments, and the possibility of polyaniline being incorporated into the metal oxide passive film when initially formed cannot be ruled out.

The initial peak passivation current in the PA deposition solution is higher for type 410 stainless steel than for type 430. Following this, the major part of the scan response for PA deposition on type 410 is very similar to that for type 430.

The reversible electroactivity of the PA-coated stainless steel electrodes is demonstrated by cyclic voltammetric results in sulfuric acid solutions free of added redox couples. A typical response is shown in Fig. 2 for a PA-coated type 410 specimen in 0.2M H₂SO₄. This electrode had been exposed to this solution for 19h on open circuit and was still passive at the time it was potentiostatically reduced then cycled once before recording the cycle shown. A similar response is observed for PA-coated type 430 electrodes, and for both materials in 1.0M H₂SO₄. The cyclic voltammetric results show little change with time of exposure on open circuit, but do change somewhat with repeated cycling. The responses observed are quite similar to those seen for platinum coated with PA. This is noteworthy in view of the likelihood that electron transfer between the stainless steel metal phase and polyaniline is being mediated by a metal oxide passive film (4). This

facile electron-transfer exchange with the metal may be partially responsible for the ability of polyaniline to maintain the passivity of the specimen. It is quite likely that a high repassivation rate is important in "healing" the cracks and ruptures (which continually occur in the passive film) before the damage spreads and the metal becomes active.

Scanning electron microscope (SEM) examination of polyaniline-modified type 410 SS was done to further characterize the material. Typical photomicrographs for samples with no conductive overcoat are shown in Fig. 3a and 3b. As observed for PA on Pt, the coating is continuous and fairly smooth (7), although a number of small nodules can be observed extending out of the surface. A 400Å gold overcoat and somewhat higher magnification reveals more of the porous structure of the film, as shown in Fig. 4a. Both samples which had received a final cycle in sulfuric acid and those which had not were examined. They had practically the same appearance except at the highest magnification, where the cycled sample appeared somewhat "sharper" than the sample which had not been cycled. One edge of the electrode was abraded and then examined, as shown in Fig. 4b. Starting from the metal on the left-hand side of the photograph, the base of the polyaniline appears practically continuous, but then a layered structure becomes apparent, which is topped by the nodular growth. Although speculative, it seems possible that the layers are a result of the cyclic deposition procedure. From this photograph the polyaniline film appears to be about 3-4 μm thick, exclusive of the nodules. The nodules may be a residue from the nonadherent, inactive material described below. Many dark patchy areas can often be observed optically in ordinary light on the polyaniline surface, but these were not differentiated in the SEM photographs. These areas may be locally thicker than the rest of the film, or belong to portions of the film trapped in a higher oxidation state.

Effect of PA film on corrosion in chloride-free solutions.—Weight-loss corrosion measurements for bare type 410 flag samples showed an average equivalent penetration rate of $3.1 \times 10^4 \mu\text{m/yr}$ for a 64h exposure in 1.0M

H_2SO_4 at 25°C. This rate corresponds to the active corrosion state at ca. -0.5V . Similar weight-loss measurements for PA-coated type 410 in the same environment showed rates of less than $25\ \mu\text{m}/\text{yr}$ as long as the coating maintained the open-circuit voltage more positive than ca. $+0.0\ \text{V}$. Therefore, the open-circuit voltage measurement provides an adequate measure of the corrosion rate in this system. Continuous open-circuit voltage monitoring was accompanied by post-test sample examination for judging the effectiveness of a given coating technique.

Visual examination of the PA-coated samples *in situ* provides information on their corrosion status. Samples are ordinarily removed from the deposition bath in their most oxidized state and are then dark blue/black in color. Some extraneous loosely adherent black material is generally present on the electrode and is removed by a stream of wash water. Tests show that this material does not contribute to the electroactivity of the electrode. On placing in the acidic corrosion test solution, the OCV generally decreases fairly rapidly from about $+0.6\text{V}$. This is accompanied by a change in color to a dark green. On further exposure, a lighter, more metallic appearing green color is seen at a potential of ca. $+0.2\text{V}$, and this is usually the most stable state of the electrode. If the electrode begins to fail, this color becomes a lighter green, and finally becomes transparent in the fully reduced state and the electrode becomes active. The coating will persist on the electrode for some time after that, but extended exposure in the active state leads to disbonding, probably because of undermining of the coating by vigorous hydrogen evolution.

Bare or anodically passivated type 410 or 430 stainless steel specimens become active within minutes of being placed on open circuit in either of the dilute sulfuric acid solutions employed. Polyaniline-coated type 410 or 430 samples remained passive from several hours to at least 1200h after immersion. The breakdown time (time of exposure before passive-to-active transition occurs on open circuit) appears to be a function of metal pretreatment and coating application techniques, acid concentration in the corrosion medium, metal substrate properties, and solution aeration. Postapplication treatment affects the protectiveness of the film. With no further pretreatment, PA-coated ($28\ \text{mC}/\text{cm}^2$) type 430 stainless steel begins to fail after about 60 min in deaerated $0.2\text{M}\ \text{H}_2\text{SO}_4$. If the same electrode is cycled several times in the sulfuric solution, and then put on open circuit, there is no sign of breakdown after almost 17h.

Application techniques become more critical when $1.0\text{M}\ \text{H}_2\text{SO}_4$ is used at the test solution and the lower alloy type 410 as substrate. Results obtained for three different PA coating procedures are shown in Fig. 5, and the application methods are summarized in the caption. Similar to the type 430 results, cycling PA-coated type 410 in the dilute acid test solution appears to increase stability. Trials with various treatment techniques indicated that the three most important steps are: (i) an initial active-state open-circuit exposure to the PA deposition solution (5 min), (ii) cycling the potential during deposition, and (iii) cycling in sulfuric acid solution (three cycles) following deposition. A type 410 SS electrode treated in this way alone (and initially degreased) was found to be stable in

Fig. 5. Open-circuit voltage vs. exposure time in 1.0M H_2SO_4 for polyaniline-coated type 410 SS electrodes prepared in following ways. Dashed line: active for 5 min in PA deposition solution, then cycled seven times and taken out at +0.82V. Dotted line: active for 3 min in PA deposition solution, then passivated and held at +0.96V for 3 min, then cycled six times between -0.2 and 1.15V, then removed at 1.02V. Solid line: etched in 1.0M H_2SO_4 for 8 min, then passivated and cycled in same solution before cycling in PA deposition solution eight times (always positive of 0.0 V) then removed at +0.84V.

aerated 1.0M H_2SO_4 for at least 50 days without breakdown. Part of this exposure run is shown in Fig. 6. The initial cycling in 1.0M H_2SO_4 indicated that the polyaniline on this electrode had a total charge capacity of 25.1 mC/cm². The electroactive form of polyaniline appears to be continuously regenerated by oxygen, producing the observed long term stability.

A quantitative description of the corrosion protection offered by the coatings is difficult due to the interactions of the variables involved and the complexity of the passivation process itself. A major complication is that the properties of the passive film vary with exposure time. In particular, the anodic passive current density is often found to gradually decrease at a given potential in the passive region, presumably due at first to an increase in thickness of the passive metal oxide film and then to repair of defects in its structure. These processes probably explain the increased breakdown time with passivation time recently reported for type 440C SS (10). The second complicating factor is that coating coverage is a somewhat nebulous quantity, difficult to determine experimentally, which may depend on the coating technique in rather subtle ways. Thus the postdeposition cycling in H_2SO_4 solutions which was found to be advantageous for PA-coated electrodes could be explained by a

Fig. 6. Open-circuit voltage vs. initial exposure time for polyaniline modified type 410 SS in 1.0M H_2SO_4 . Application method described in text. Note that the time scale is in hours for this run.

restructuring of the film which decreases the effective exposed area.

Polyaniline-modified metals in chloride containing solutions.—Performance of the coated stainless steels in the presence of chloride ion is of interest since it is well known that application of ordinary anodic protection measures to such metals must be done with caution when chloride is present because of the possibility of localized corrosion. Results obtained for the initial part of an exposure of PA-coated 430 to a solution of 0.2M NaCl + 0.2M H_2SO_4 (pH = 0.8) are shown in Fig. 7. The unusual oscillations in the open-circuit voltage continued in a similar manner for over 30h. At this time the solution was changed to 0.2M H_2SO_4 without chloride ion, and the oscillations abruptly ceased. No pits were apparent at up to 45 times magnification on this particular electrode after the run. However, an 18 day exposure of a fresh specimen to the same conditions did result in the formation of about ten small (0.1 mm diam) pits on each side of the electrode. The solution was continuously aerated during this test. Oscillations occurred throughout the test, until the electrode finally became active about 7h before the run was terminated. A weight loss was observed, but, since it was the same as would be expected for the 7h active period, it is quite likely that there was practically no uniform corrosion during the 18 day period preceding breakdown.

These results can be interpreted in part by considering the localized corrosion properties of the bare electrode. A potentiodynamic scan obtained for bare type 430 stainless steel in the same 0.2M NaCl/0.2M H_2SO_4 solution is shown in Fig. 8. It can be seen that the oscillations occur primarily in the potential region between the pit initiation potential (+0.24V) and the so-called protection potential (+0.01V) below which pits are repassivated (11, 12). For the coated electrode, it appears that the passive film is periodically undergoing partial breakdown in the acid chloride solution and is then being reformed with the aid of the polyaniline. The polyaniline is partially reduced during the more negative part of the cycle before the electrode is completely repassivated. This can be observed visually as the electrode becomes clear to pale green. Once the electrode is repassivated, the polyaniline is reoxidized by the oxygen in the system, as evidenced by a return to a green to dark green color and positive open-circuit voltage. However, even though the polyaniline maintains the majority of the surface passive, since the oxidized state of the polyaniline is positive of the pitting potential, pits can be initiated and grow during the positive part of the cycle.

In a somewhat less aggressive environment, polyaniline was able to both maintain a type 430 SS electrode in the passive state and stabilize the open-circuit voltage at a value where pitting did not occur. The test solution contained 0.15M Na_2SO_4 /0.05M H_2SO_4 + 0.1M NaCl (pH = 1.5)

Fig. 7. Initial period of open-circuit exposure for polyaniline modified type 430 SS in 0.2M H_2SO_4 + 0.2M NaCl (initially deaerated); C1, solution aerated; C2, solution deaerated; C3, solution aerated.

Fig. 8. Potentiodynamic response for type 430 SS in 0.2M H_2SO_4 + 0.2M NaCl at 0.5 mV/s. Electrode area: 3.9 cm^2 .

and was aerated. The pitting potential for a bare type 430 SS sample in this solution is 1.18V. The coating was applied following a 5 min active stand in the polyaniline deposition solution. The electrode was cycled ten times to apply the polyaniline, then removed at a potential of +0.30V, rinsed, and placed in the test solution. No oscillations as such were noted, but the open-circuit voltage did undergo two rather abrupt drops during the first 20h period. After that, the electrode stabilized and the open-circuit voltage remained near +0.14V until the run was terminated after a 30 day exposure. No pits were visible on the electrode at 45 times magnification after the run. The electrode was still quite electroactive at the end of this run, as the remaining charge was 5.9 mC/cm^2 and the cyclic voltammograms were quite similar to those of a freshly immersed sample.

During the run described above, the sample was removed after 310h immersion and a deep scratch was administered with the point of a sharp knife. On reinserting the electrode in the test solution after this scratch, the potential decreased about 15 mV but the remainder of the 30 day run was completed with very little additional decrease. In contrast, a bare type 430 SS electrode was held passive potentiostatically in a similar test solution for 9 days to obtain a passive film stable enough to maintain open-circuit passivity for 2 days. It was then removed and scratched in the same fashion as the PA-coated sample. This specimen became active immediately upon re-immersion in the test solution. These results emphasize

the effect of the electroactive coating as far as preventing the breakdown of passivity and acting as an active adjunct to the passive oxide film.

Conclusions

Stainless steel electrodes coated with thin films of polyaniline remain passive for long periods of time in acid solutions in which they are normally active and subject to high rates of corrosion. The polyaniline-modified steels assume many of the electrochemical characteristics of inert metals coated with polyaniline. The stability of the coated materials is strongly dependent on the treatment method, but scratching has little effect once a favorable coating is deposited. Initiation of pitting of the coated substrate materials in chloride solutions is predictable from the pitting characteristics of the uncoated metal. Pronounced oscillations of the open-circuit voltage of the modified electrode are noted in solutions in which pitting can occur.

The Critical Geometry for Initiation of Crevice Corrosion

Richard Alkire,* Thor Tomasson, and Kurt Hebert

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The critical crevice dimensions for which initiation of crevice corrosion occurs spontaneously was determined experimentally for Al in 0.05M NaCl. An artificial crevice at room temperature and pressure was employed to permit controlled variation of the crevice length and crevice gap over the ranges 5-15 and 0.1-0.6 mm, respectively. The range of conditions which led to corrosion initiation was compared with theoretical predictions based on a mathematical model of the concentration and the potential distribution within the crevice. It was found that the critical condition for initiation of crevice corrosion could be predicted in this system.

The onset of crevice corrosion occurs when the metal oxide film protecting the metal from general corrosion breaks down as a result of transport restrictions between the crevice and the external solution. These restrictions lead to concentration of aggressive species within the crevice, to eventual breakdown of protective surface films, and to accelerated rates of corrosion attack. Once crevice corrosion has initiated, it is often difficult to stop.

Because crevices are invariably present in engineering structures, it is of interest to develop the ability to predict which geometries will, or will not, lead to crevice corrosion. The purpose of this investigation was to determine by both experimental and theoretical methods the critical crevice geometry which separates the regions between those where crevice corrosion initiates and those where corrosion initiation does not occur (1).

The study of crevice corrosion is commonly divided into two main areas, the preinitiation period prior to breakdown, and the postinitiation period when accelerated attack occurs. During the preinitiation period, the metal surface is passive and corrodes at the low rates associated with such conditions. Owing to transport restrictions, the products of the corrosion process accumulate and cause modification of the crevice solution composition in comparison to that external to the crevice. These changes may include depletion of oxygen, lowering of pH, buildup by migration of species such as chloride ions, and accumulation of dissolved metal species. If these changes cause any of these components to exceed some critical condition, then the passive metal oxide may be caused to break down, leading to rapid dissolution of the unprotected metal. In general, the detailed mechanism of breakdown remains unknown for most structural alloys.

Because the behavior of structural alloys is complex, fundamental studies have emphasized use of model systems which consist of pure metals and simple electrolytes. Thus, Siitari and Alkire (2, 3) investigated crevice corrosion of pure Al in 0.05M NaCl. By assuming tentatively that breakdown occurred as a result of acidification in the crevice, they developed theoretical calculations which, when compared with experimental data, gave agreement with some but not all observations. They emphasized that their theoretical model was highly sensitive to the events associated with breakdown.

Hebert and Alkire (4, 5), therefore, investigated in further detail the three mechanisms commonly accepted as causes of breakdown of passivity: differential aeration, localized acidification, and accumulation of chloride ions. They found that none of these was operative in the model Al system. Rather, accumulation of dissolved aluminum species within the crevice to above a critical value was operative. This conclusion is supported by the recent work of Foley *et al.* (6) which indicated that the weight loss of Al in AlCl₃ solutions was substantially higher than that in NaCl solutions.

While the classic studies of Rosenfeld (7, 8) were influential, more recent studies have emphasized more quantitative treatment of both experimental and theoretical aspects. Artificial crevice assemblies have been

widely exploited (8-15) since these offer controlled and reproducible geometries from which local samples of solution composition may be obtained. Theoretical analysis of alloy systems is complicated by uncertainty about the dissolution kinetics involved as well as by complex multi-component transport processes in the solution phase. Thus, Oldfield and Sutton (13) adopted semiempirical methods for estimating transport processes, while Turnbull (14) emphasized the limiting approximation of differential aeration as well as the steady-state active condition (15). These analyses represent substantial contributions which provide benchmarks for advanced theoretical developments.

From a practical point of view, it is straightforward to distinguish between a crevice which breaks down and corrodes and a crevice which does not. In this investigation, theoretical and experimental methods are directed toward identifying the critical zone between these two types of behavior based on the model system of Al in 0.05M NaCl.

Experimental

The equipment used in this study was described previously by Siitari (2) and Hebert (4) and is only summarized briefly here. A sectioned flat aluminum electrode surface was prepared by machining a set of concentric cylinders from an Al rod (99.9%, 4.45 cm diam, Research Organic/Inorganic) and assembling them with epoxy resin as illustrated in Fig. 1. There are eight sections numbered sequentially from the innermost, no. 1, to the outermost,

Fig. 1. Sectioned electrode, showing concentric sections separated by insulating rings. Diameters of the sections are: 7.19, 10.2, 14.4, 17.7, 20.4, 22.9, 25.1, and 41.9.

*Electrochemical Society Active Member.

Fig. 2. Experimental crevice corrosion cell described in detail in Ref. (2).

no. 8. Electrical connections were made to each section on the back side. The electrode was mounted in the corrosion cell, illustrated in Fig. 2, in which optically flat quartz disk could be positioned precisely to form a crevice of a preset geometry. The quartz disk shielded only the inner sections of the Al electrode; the outer sections became cathodes during crevice corrosion. As the corrosion proceeded, electrical currents between the sections were measured with a multichannel zero-resistance operational amplifier circuit (based on Analog Devices amplifiers no. 233 K). The output from the current followers was recorded on strip chart recorders.

The 0.05M NaCl solution was prepared by combining analytical reagent-grade NaCl with deionized distilled water. The metal surface was prepared by wet sanding to 600 grade silicon carbide on a flat granite block (DO-ALL Rockford Company, no. 501045967), and then polishing with an 0.3 μm alumina suspension (Buehler, Alpha Polishing Alumina).

The corrosion experiments were conducted by first pouring approximately 80 ml of electrolyte into the cell while the quartz disk was in a raised position. After about 20 min, the quartz disk was lowered to its preset position, thus creating the crevice.

Theoretical

Since the present investigation was based upon the theoretical model of Hebert and Alkire (5), the interested reader is advised to consult that reference for background to the following discussion.

The sequence of events leading to initiation of crevice corrosion begins with the formation of the crevice, which is shown schematically in Fig. 3. Prior to the formation of the crevice, the Al surface corrodes uniformly at a low rate associated with passivity; the corresponding cathodic reactions are oxygen reduction and/or hydrogen evolution. Once the crevice is formed, these corrosion processes continue except that transport restrictions within the crevice set in to an extent determined by the crevice geometry. Thus, deaeration occurs, the pH and chloride concentration become altered from the bulk values, and the concentration of dissolved Al builds up. Eventually, if the Al concentration exceeds the critical level of concentration needed for activation, breakdown occurs and crevice corrosion initiates.

In modeling the foregoing sequence of events, Hebert and Alkire used a one-dimensional transport analysis of the crevice region based upon dilute solution theory. They further assumed that the dissolved aluminum ions

Fig. 3. Schematic of model system showing geometry and coordinate system.

underwent hydrolysis to the first step only, and that the breakdown of the Al passivity led to a step change in the dissolution kinetics.

In predicting the critical crevice geometry for initiation, it is important to realize that it is only the steady-state transport problem that is significant. That is, the critical geometry corresponds to that geometry for which the maximum value of the total concentration of dissolved aluminum in the crevice solution, at steady state, equals the critical value. Thus, the transient part of the analysis of Hebert and Alkire was not included in the treatment which follows. Moreover, these authors also showed that the crevice became deaerated well before attaining the critical condition for initiation. That is, any effect that oxygen has would run its course long before initiation occurs; it is thus appropriate to neglect the presence of oxygen when evaluating the steady state. Also, they showed that both migration of chloride ions and reaction of hydrogen ions within the crevice play a minor role in the initiation phenomenon on Al. For these reasons, the analysis of Hebert and Alkire can be substantially simplified when used to predict the critical geometric conditions for initiation.

In the steady state, the concentration of dissolved aluminum species builds up owing to metal dissolution at the wall, and dissipates by diffusion along the crevice, so that the one-dimensional species balance is

$$D \left(\frac{d^2c}{dr^2} + \frac{1}{r} \frac{dc}{dr} \right) + \frac{\nu}{nFh} j = 0 \quad [1]$$

The dissolution rate of aluminum in the passive state j is assumed to have the linear form

$$j = \begin{cases} A(\phi - \phi_{R1}); & \phi \geq \phi_{R1} \\ 0 & ; \phi < \phi_{R1} \end{cases} \quad [2]$$

where ϕ_{R1} is the pitting potential, and the parameter A is

Table I. Summary of experiments

found from experimental polarization curves. The current flowing through the solution between the interior anode and the exterior cathode, obeys Ohm's law

$$i = -\kappa \frac{d\phi}{dr} \quad [3]$$

and the one-dimensional conservation of charge

$$\frac{1}{r} \frac{d}{dr} (ri) = -\frac{1}{h} j \quad [4]$$

so that the potential distribution within the crevice is

$$\frac{d^2\phi}{dr^2} + \frac{1}{r} \frac{d\phi}{dr} = \frac{1}{\kappa h} j \quad [5]$$

Equations [1], [2], and [5] constitute the steady-state model equations to be solved subject to boundary conditions. At the center of the cylindrical crevice, the potential and concentration fields are symmetric

$$\left. \begin{array}{l} \frac{d\phi}{dr} = 0 \\ \frac{dc}{dr} = 0 \end{array} \right\} \text{ at } r = 0 \quad [6]$$

and at the edge of the crevice, adjacent to the bulk solution, the concentration and the potential have values which are characteristic of the bulk solution outside the crevice

$$\left. \begin{array}{l} \phi = \phi_0 \\ c = c_0 \end{array} \right\} \text{ at } r = r_0 \quad [7]$$

The bulk potential ϕ_0 corresponds to the mixed potential of aluminum in the passive state, while the bulk concentration of Al species would be obtained from the equilibrium solubility product.

The foregoing equations are made dimensionless by introducing the following variables

$$\Phi = \frac{\phi - \phi_{li}}{\phi_0 - \phi_{li}} \quad C = \frac{c - c_0}{c_0} \quad R = \frac{r}{r_0} \quad [8]$$

Upon elimination of the local reaction rate j , the dimensionless model equations become

$$\frac{d^2\Phi}{dR^2} + \frac{1}{R} \frac{d\Phi}{dR} - \sigma_1\Phi = 0 \quad [9]$$

$$\frac{d^2C}{dR^2} + \frac{1}{R} \frac{dC}{dR} + \sigma_2\Phi = 0 \quad [10]$$

where

$$\sigma_1 = \frac{r_0^2 A}{\kappa h} \quad [11]$$

$$\sigma_2 = \frac{\nu A r_0^2}{n F h c_0 D} (\phi_0 - \phi_{li}) \quad [12]$$

The parameter σ_1 contains the ratio A/k and thereby denotes the ratio of the electrolyte solution resistance along the crevice to the charge transfer resistance associated with the anodic dissolution process. A value of σ_1 greater than unity would indicate that the electrolyte resistance is the dominant factor, so that anodic dissolution would tend to occur near the outer edge of the crevice. The parameter σ_1 is analogous to the polarization parameter or the Wagner number, which appears in electrochemical engineering analyses of current and potential distribution phenomena.

The parameter σ_2 contains the ratio A/D and thereby denotes the relative importance of the diffusion resistance along the crevice and the charge transfer resistance associated with the anodic dissolution process. A value of σ_2 greater than unity would indicate that diffusion resistance dominates so that substantial buildup of dissolution products would be expected to occur within the crevice.

The solution of Eq. [9] is

$$\Phi = \frac{I_0(\sigma_1^{1/2} R)}{I_0(\sigma_1^{1/2})} \quad [13]$$

where I_0 is a modified Bessel function of the first kind of order zero. By substituting Eq. [13] into Eq. [10] and integrating, one finds

$$C = \frac{\sigma_2}{\sigma_1} \left[1 - \frac{I_0(R\sigma_1^{1/2})}{I_0(\sigma_1^{1/2})} \right] \quad [14]$$

To obtain the maximum value of concentration, this expression is differentiated with respect to distance and set equal to zero

$$\frac{dC}{dR} = -\frac{\sigma_2}{\sigma_1^{1/2}} \frac{I_1(R\sigma_1^{1/2})}{I_0(\sigma_1^{1/2})} = 0 \quad [15]$$

Since I_1 has no real zeroes except at $R = 0$, the maximum steady-state concentration always occurs at the center of the crevice; by setting the maximum concentration equal to the critical concentration required for crevice initiation, one has

$$C_{cr} = \frac{\sigma_2}{\sigma_1} \left[1 - \frac{1}{I_0(\sigma_1^{1/2})} \right] \quad [16]$$

which may be rearranged to the form

$$I_0(\sigma_1^{1/2}) = \frac{1}{1 - \frac{\sigma_1}{\sigma_2} C_{cr}} \quad [17]$$

The right-hand side of Eq. [17] is independent of geometry, and contains only parameters which can be found by experimental measurement. The left-hand side of Eq. [17] contains a function of σ_1 in which the ratio r^2/h appears for the critical conditions associated with crevice corrosion initiation.

Results and Discussion

Table I summarizes conditions for 19 experiments carried out with crevices ranging in height from 0.1 to 0.7 mm, and in radius from 6.35 to 12.70 mm. Table I also indicates that about half of the crevices experienced breakdown within 2-8h, while the remainder did not.

Figure 4 illustrates typical results on an 11.1 mm radius crevice upon variation in the crevice height from 0.1 to 0.5 mm. For this geometry, the quartz disk shielded all of the five interior electrode sections and about half of section 6. The anodic currents flowing from typical interior sections are seen to depend strongly upon the crevice width. For the narrowest crevice (0.1 mm), the current in section 5 increases by more than an order of magnitude within 4-5h, for the widest crevice (0.5 mm), no appreciable in-

Fig. 4. Typical current vs. time behavior for crevice radius of 11.1 mm for four different crevice heights: 0.1, 0.3, 0.4, and 0.5 mm.

Table II. Value of model parameters

Parameter	Value
A	$1.0 \times 10^{-3} \text{ A/V-cm}^2$
ϕ_{M}	-0.440 V NHE
ϕ_0	-0.437 V NHE
n	3
ν	1
D	$1.0 \times 10^{-5} \text{ cm}^2/\text{s}$
C_0	$1.0 \times 10^{-7} \text{ M}$
κ	$5 \times 10^{-3} \text{ mho/cm}$

crease occurred in over 70h of observation. These data indicate clearly that there is a critical crevice geometry associated with this model system which separates regions where initiation of crevice corrosion occurs from regions where it does not occur.

Figure 5 provides a summary of the experiments carried out. The filled points indicate that for those crevice radius crevice height combination crevice corrosion did initiate, whereas the open points indicate that no breakdown of passivity occurred. As expected, breakdown occurred where crevice radius was larger and the crevice height smaller.

Theoretical calculations were carried out by setting the system equal to values reported in the literature, as summarized in Table II, except for the critical concentration. The three lines in Fig. 5 represent the predicted geometry required for crevice corrosion initiation by Eq. [17] for three different values of the concentration of aluminum required for breakdown. These values are in the lower half of the range which had been identified for the critical aluminum concentration by Hebert and Alkire (4), namely, 2-8 mM. These results show that a value of about 3 mM can now be used for the critical crevice concentration of aluminum. Based on this value, the general criterion for determining whether crevice corrosion will occur in this system is, following Eq. [17]

$$I_0(\sigma_1^{1/2}) = \frac{1}{1 - \frac{\sigma_1}{\sigma_2} (3 \times 10^4)} \quad [18]$$

These theoretical predictions indicate that the geometry required for corrosion initiation is sensitive to the values used for the physical parameters of the system, especially the critical device concentration.

Fig. 5. Summary of experimental data and theoretical comparisons for three values of the critical aluminum concentration: $C_{\text{cr}} = 2 \text{ mM}$; $C_{\text{cr}} = 3 \text{ mM}$; $C_{\text{cr}} = 4 \text{ mM}$.

Fig. 6. Effect of bulk conductivity on the critical crevice dimensions

Figure 6 summarizes theoretical calculations of the influence of bulk conductivity upon the critical crevice dimensions for the Al system. The figure contains three curves corresponding to a particular value of the crevice radius. These curves identify the critical conditions; for crevice height above the curve, breakdown will not occur. The region below the curves corresponds to that crevice height that corrosion initiation will occur. These results show that for conductivity above 5 mmho/cm, the critical crevice geometry is relatively insensitive to the value of the conductivity. Below that value, the dependency is strong. It should be noted, however, that the assumption of supporting electrolyte may not be valid for very low conductivity, as the increase in the ionic strength owing to the dissolution of aluminum may cause significant changes in the crevice conductivity.

Conclusions

This investigation demonstrated that understanding of certain features of the mechanism of initiation permits prediction of the geometries under which crevice corrosion will initiate on Al in 0.05N NaCl. The prediction is made by analysis of transport processes which occur during the preinitiation period during which crevice composition becomes altered by comparison with solution external to the crevice. The analysis identified groupings of the system variables, Eq. [11] and [12], which can be used to evaluate the most important physical processes which controlled a given situation. For the model system under study, a criterion was identified, Eq. [18], which describes the boundary between the region of parameter space where initiation occurs and the region where it does not.

Experimental investigations were carried on the Al/0.05 NaCl system over a region of operation which straddled the boundary. By comparison with the foregoing theory, it was found that agreement was excellent when the critical concentration was set at a value of 0.003M. This value falls within the range (0.002-0.008M) previously suggested by Hebert and Alkire (5), and serves, therefore, to improve their estimate.

Even for the model system under study, there remain questions of mechanism about the phenomena which establish the value of critical concentration at which initiation occurs. Even in the presence of such unresolved scientific understanding, however, it is possible to make fundamentally sound engineering predictions by limited use of empirical knowledge combined with a mathematical model of the corrosion process.

Film Formation and Current Oscillations in the Electrodeposition of Cu in Acidic Chloride Media

I. Experimental Studies

ABSTRACT

Oscillatory behavior of Cu electrodeposition in various acidic chloride solutions was studied with rotating disk electrodes. Oscillations were not observed in the apparent Tafel region. However, for 0.5 and 1M Cl⁻, nonsustained oscillations were found in the peak-current, current-minimum, and current-plateau regions. At potentials above the current-plateau region, apparent sustained oscillations were observed. Oscillatory behavior disappeared at sufficiently high rotation rates. Film dissolution studies indicate that the CuCl film begins to form at potentials near the peak current and suggest that oscillations only occur with the formation of a sufficiently thick film. A model based on the diffusion of chloride ions through the porous CuCl film to account for oscillatory behavior is proposed.

Observations of periodic electrochemical phenomena have been reported for over a century (1, 2). There have been numerous reports of oscillatory behavior of metals such as iron, chromium, copper, etc., in different aqueous media [e.g., see Ref. (3-6)]. Although oscillatory behavior occurs in both anodic and cathodic processes, most of the reported cases are directly associated with anodic polarization of metals and the instability of the anodic films formed.

Bonhoeffer and Gerischer (7) apparently were the first to develop a mathematical model to describe the periodic behavior of Cu dissolution in chloride solutions. Their explanation of the periodicity involved the formation and dissolution of CuCl and Cu₂O films. Cooper and Bartlett (8) studied Cu dissolution in 2N HCl under natural convection conditions and interpreted the observed oscillations in terms of the formation and instability of the CuCl film.

¹ Present address: IBM General Products Division, San Jose, California 95193.

In chloride media, Cu electro-oxidizes to cuprous chloride complexes and the rate is dependent on the chloride concentration but independent of pH (9); the electrodeposition rate has also been shown to be strongly affected by the rate of mass transfer (8-12). The mechanism of Cu dissolution in Cl⁻ media (< 1M) is generally expressed as

At chloride concentrations > 1M, concentrations of higher cuprous chloride complexes, such as CuCl₃⁻², become significant.

In the present study, the dependence of oscillatory anodic behavior of Cu on chloride concentration, potential, and hydrodynamic conditions is examined with rotating ring-disk electrodes.

Experimental

Electrodes were made from a 1.270 cm (0.5 in.) rod of pure Cu (99.9%). The rod was first turned down and pol-

Fig. 1. Anodic polarization of Cu in 0.1M NaCl + 1N H₂SO₄, 0.2M NaCl + 1N H₂SO₄, 0.5M NaCl + 1N H₂SO₄, and 1M HCl. Sweep rate: 0.5 mV/s.

ished on a lathe to a diameter of 1.128 cm, which provided a surface area of approximately 1 cm². The rod was then cut into 1 cm lengths. Smaller surface area electrodes were also prepared from the same Cu rod. The disk electrode surfaces were polished with waterproof alumina paper of various grit sizes (240, 400, and 600), washed thoroughly with distilled water, degreased with hot benzene in a Soxhlet column for 4h, annealed under vacuum ($\approx 10^{-5}$ torr) at 560°C for 4h, and allowed to cool slowly to room temperature. The counterelectrode was a platinum sheet (surface area ≈ 14 cm²). The reference electrode was a saturated calomel electrode.

The hydrochloric acid, sulfuric acid, and sodium chloride were reagent grade. The water was deionized and then distilled from permanganate solutions. Solutions were deoxygenated with prepurified nitrogen before (for 10h) and during each run.

The rotating ring-disk electrode assembly used in this work has been described elsewhere (13). The polarization experiments were carried out with a PAR potentiostat (Model 173) and a universal programmer (Model 175).

Fig. 2. Oscillations during Cu dissolution in 0.1M NaCl + 1N H₂SO₄. E_D : 250 mV

Fig. 3. Typical oscillations during Cu dissolution in 0.1M NaCl + 1N H₂SO₄. E_D : +400 mV.

Potential-current and current-time measurements were made with an H.P. (Model 7040A) X-Y recorder.

Potentiostatic experiments were performed to determine the current-time behavior of Cu in deoxygenated acidic chloride solutions. Unless otherwise noted, the electrode was first lightly polished with fine alumina paper followed by a rinse in distilled water before immersion in the acidic chloride solution; the electrode was then set at a rotation rate of 300 rpm. After steady-state rest potential was achieved (≈ 0.5 h), the anodic potential step was imposed, and the current-time behavior at 300 rpm recorded for several minutes before the potential step was terminated; occasionally, the time duration of the potential step ranged from a low of 1 min to a high of 2-3h. Then, while at open circuit, the electrode was set to a higher rotation rate. When steady-state rest potential was again attained, the potential step was reimposed. This same procedure was followed for each rotation rate run.

Fig. 4. Oscillations during Cu dissolution in 0.2M NaCl + 1N H₂SO₄, E_D: +300 mV

Results

Oscillatory behavior of Cu was observed during anodic potential sweeps, as shown in Fig. 1. The general polarization characteristics of Cu in acidic chloride solutions show a peak current and a current minimum at potentials above an apparent Tafel region (linear E -log i relationships are obtained when IR drop corrections are made). There is a small current plateau directly above the current minimum. The polarization results in Fig. 1 were obtained at a sweep rate of 0.5 mV/s; lower sweep rates provided essentially the same polarization behavior in the apparent Tafel region.

Figure 1 shows that for low concentrations (0.1 and 0.2M), the oscillatory behavior started at potentials greater than about 200 mV. At 0.5M Cl⁻, oscillations were not observed, but at 1M Cl⁻, oscillations were seen in the peak-current, current-minimum, and current-plateau regions. These potentiodynamic experiments show that oscillations occur in different potential regions at different chloride concentrations.

The dependence of oscillatory behavior on rotation rate, potential, and chloride concentration was examined further by a series of potentiostatic experiments. In these experiments, the current-time behavior of Cu in acidic solutions containing Cl⁻ ranging from 0.1 to 1.0M was recorded at various rotation rates and fixed potentials.

For 0.1M Cl⁻, oscillations were not observed at potentials less than +150 mV. However, at +150 mV, oscillatory behavior was recorded at a rotation rate of 300 rpm but not at 3000 rpm. The oscillations appear to be sustained and periodic with a frequency of 5.4 Hz and amplitude of about 1 mA/cm² [see Appendix of Ref. (13)]. Figure 2 shows that chaotic and apparently sustained oscillations occurred at +250 mV with an induction period that increased as the rotation rate increased from 300 to 2000 rpm. However, at the higher rotation rate of 3000 rpm, oscillations were not observed during a 760s recording period. Sustained and chaotic oscillations were observed at +400 mV for all rotation rates between 300 and 5000 rpm;

Fig. 5. Typical oscillations during Cu dissolution in 0.2M NaCl + 1N H₂SO₄, E_D: +400 mV.

Fig. 3 shows the oscillating behavior for 300 and 5000 rpm.

For 0.2M Cl⁻, oscillations occurred at +200 mV and higher potentials. At +200 mV and 300 rpm, nonsustained oscillations were recorded for about 30s beginning about 60s after the potential step was imposed (13); the frequency and amplitude were about the same as 0.1M Cl⁻ at +150 mV and 300 rpm. Oscillations were not observed at rotation rates of 600 rpm and above. At an anodic potential of +300 mV, sustained oscillations were found for rotation rates from 300 to 2500 rpm but not at 3000 and 4000 rpm. Figure 4 shows the rotation rate runs for 1000, 2500, and 3000 rpm. At +400 and +500 mV, sustained oscillations were observed for rotation rates from 300 to 4000 rpm. Typical runs at these potentials are shown in Fig. 5 and 6, respectively. For 0.1 and 0.2M Cl⁻, the amplitude of the oscillations increased with increase in potential.

For 0.5M Cl⁻, oscillations were not obtained below 0 mV. However, at 0 mV, nonsustained oscillations were observed at rotation rates from 1000 to 5000 rpm, but not below rotation rates of 1000 rpm (Fig. 7). When the electrode was removed from the cell after each rotation rate run and the electrode surface repolished and then reimmersed in the solution, oscillations were not obtained during any of the nine rotation rate runs between 300 and 5000 rpm (13). This experiment provides a tentative indication of a relationship between oscillatory behavior and the thickness of the CuCl film. At higher potentials of +200 and +400 mV, sustained oscillations were obtained for all rotation rates between 300 and 4000 rpm regardless of whether or not the electrode was removed and repolished after each rotation rate run. Figure 8 shows typical current-time behavior at these two potentials.

For 1M HCl, oscillations were not found below potentials of -40 mV. However, at -40 mV, sustained oscillations were observed for rotation rates of 300, 600, and 800 rpm but not for 1000 rpm and higher rotation rates (13). At -20 mV, nonsustained oscillations were recorded for rotation rates between 300 and 3000 rpm but not for 4000 rpm (Fig. 9); these oscillations were obtained even when the electrode was removed and repolished after each rotation rate run. At +100 mV, nonsustained oscillations were found at all rotation rates between 300 and 4000 rpm; a typical run is shown in Fig. 10. However, at 200 mV and higher potentials, no oscillations were observed for any of the 12 rotation rate runs between 300 and 7000 rpm (13).

For potentials of +300 mV and above, a white film was clearly visible at the end of each rotation rate run; others have also observed the presence of the film and reported it to be CuCl (8, 14-18). With termination of the potential step, the open-circuit potential abruptly dropped to a potential arrest region, the time duration of which decreased as the rotation rate increased as shown in Fig. 11 for 0.1M Cl⁻; the arrest potential was dependent on the Cl⁻ concentration, e.g., -55 mV (0.1M Cl⁻) and -72 mV (0.2M Cl⁻). After the potential arrest, the open-circuit potentials

Fig. 6. Typical oscillations during Cu dissolution in 0.2M NaCl + 1N H₂SO₄. E_D : +500 mV

decreased fairly rapidly to a steady-state value, which was approximately the initial rest potential.

The potential arrest approximates the equilibrium potential of Eq. [1], *i.e.*

where

$$E^e = -0.105 - 0.059 \log [\text{Cl}^-] \quad (\text{V vs. SCE})$$

For 0.1M Cl⁻, $E^e = -46$ mV, and for 0.2M Cl⁻, $E^e = -63$ mV. These calculated equilibrium potentials are fairly close to the experimental arrest potentials. These results and the observed dependence of the potential decay profile on the rotation rate (Fig. 11) indicate that the dissolution rate of the CuCl film (Eq. [2]) is affected by the mass-transfer rate.

Fig. 7. Oscillations during Cu dissolution in 0.5M NaCl + 1N H₂SO₄. E_D : 0 mV.

Experiments were performed to obtain a measure of the thickness of the CuCl film and its dependence on the potential and rotation rate. The Cu disk electrode was first set at a specific potential for a fixed time to allow the CuCl film to form and grow. The ring electrode was set at +600 mV to measure the dissolution rate of cuprous species from the disk [the collection efficiency of the ring, N_o , was determined to be 0.58, see Ref. (13)]. During the potential step, the formation (Eq. [1]) and dissolution (Eq. [2]) of the CuCl film occur simultaneously. However, when anodic polarization is cut off at the end of the po-

Fig. 8. Typical oscillations during Cu dissolution in 0.5M NaCl + 1N H₂SO₄.

Fig. 9. Oscillations during Cu dissolution in 1M HCl. E_D : -20 mV.

Fig. 10. Typical oscillations during Cu dissolution in 1M HCl. E_D : +100 mV

tential step, film dissolution (Eq. [2]) is essentially the sole process since the Cu disk is at open circuit. At this point, the ring current is recorded as a function of time to determine the amount of film dissolved. Thus, the area under the ring current-time plot to the background ring current provides a relative measure of the film thickness at the end of the potential step.

Figure 12 shows that there is essentially no film buildup in the apparent Tafel region since the ring current rapidly falls back to the background current when the disk polarization is shut off. However, at a potential step of -50 mV, which is just below the peak current (Fig. 1), formation of a thin but finite film is evident, as shown in Fig. 12. Significantly thicker films are formed at potentials above the current-plateau region (Fig. 13); the thicknesses of the films are shown to increase with increasing anodic potential. Since the rate of film growth (Eq. [1]) increases with anodic potential while the rate of film dissolution (Eq. [2]) remains constant at fixed rotation rates, higher anodic potentials should lead to thicker films as indicated by the experimental results shown in Fig. 13. The buildup of the CuCl film is also dependent on the rotation rate. Comparison of the areas under the ring current-time curves for each rotation rate (correcting for the background current) indicates that the film thickness decreases with increase in rotation rate (Fig. 14).

Higher rotation rates should lead to thinner films because the dissolution rate increases with increasing rotation rate.

The kinetics of the film dissolution reaction (Eq. [2]) were investigated by measuring film dissolution rates (ring current) at various chloride concentrations and rotation rates. In this series of experiments, the Cu disk was polarized at $+200$ mV for 1 min. Then, the ring current was recorded at the end of the potential step when the disk was at open circuit. The ring currents plotted in Fig. 15 are corrected for the collection efficiency and based on disk surface area (a different Cu disk electrode was used for each experiment). Figure 15 shows that the rate of the film dissolution reaction (Eq. [2]) is first order with respect to Cl^- (Fig. 15a) and is completely mass-transfer controlled, as indicated by the dependence of the dissolution rate on the square root of the rotation rate (Fig. 15b).

Discussion

The experimental rotating ring-disk results indicate the following: (i) the presence of a sufficiently thick CuCl film on the Cu surface is required for oscillatory behavior, (ii) oscillations are not observed in the apparent Tafel region where there is either no film or it is too thin, (iii) an increase in chloride concentration decreases the poten-

Fig. 11. Open-circuit potential-time behavior after polarization ($+300$ mV for 1 min) of Cu in 0.1M NaCl + 1N H_2SO_4

Fig. 12. Dissolution of the CuCl film formed after anodic polarization (1 min) of Cu in the apparent Tafel region.

tial at which oscillatory behavior begins, (iv) oscillations do not occur at sufficiently high rotation rates, and (v) the dissolution rate of the CuCl film is mass-transfer controlled.

A model to explain oscillatory behavior is proposed based on a formation-dissolution mechanism of the porous CuCl film

Fig. 14. Dissolution of the CuCl film formed after anodic polarization (+600 mV for 1 min). Effect of rotation rate.

Fig. 13. Dissolution of the CuCl film formed after anodic polarization (1 min) of Cu at potentials above the current-plateau region.

At low potentials (apparent Tafel region), the rate of formation of CuCl (Eq. [1]) is slow compared to the rate of film dissolution (Eq. [2]). Therefore, CuCl will be dissolved (Eq. [2]) as fast as it is formed by Eq. [1], and buildup of film will not occur. As the potential is increased further, the rate of film formation, which is potential dependent, will increase until a CuCl film begins to build up on the surface of the Cu electrode. As the film thickens, it is increasingly difficult for Cl^- to reach the Cu metal surface; thus, the rate of film formation (Eq. [1]) decreases, while film dissolution (Eq. [2]) occurs at a rate that is independent of film thickness. Oscillations are not observed when there is a stable, steady balance between the rates of film formation and film dissolution. The film thickness, the dissolution and formation rates, and the current are then constant and do not vary with time.

The observed oscillations, however, are surmised to correspond to situations for which this steady balance is unstable. In these cases, it is proposed that, when the nominally steady balance just described gives rise to a film that is too thick, a time-periodic balance between the rates of film formation and film dissolution is observed in which the film periodically thickens when the film formation reaction is faster than the dissolution reaction, and thins when the dissolution rate exceeds the film formation rate.

The stability of this periodic balance in preference to the steady balance can be explained as follows. Normally, small changes in film thickness are promptly corrected for by small changes in the chloride ion concentration at the film-metal interface as a result of increased (or decreased) resistance of the porous film to the diffusion of chloride ions from the electrolyte to the metal surface. For instance, an increased diffusion resistance results in a lower chloride ion concentration at the film-metal interface, which in turn gives rise to a decrease in the film formation rate, and hence to a thinning of the film until a

Fig. 15. a(left): The Cl^- reaction order for CuCl film dissolution. b(right): Mass-transfer effects during CuCl film dissolution

steady balance between the film formation and dissolution rates is achieved.

When the film thickness exceeds some critical value, however, there is a large time lag associated with diffusive communication between the electrolyte and the metal. This diffusive communication is so slow that the corrective decrease in the film formation rate continues past the nominally steady value. Eventually, the film has thinned so much that diffusion through the film increases the chloride ion concentration at the film-metal interface to the point that the film formation rate (temporarily) balances the dissolution rate, and the film thickness reaches a minimum. The chloride ion concentration elsewhere in the porous film is now higher than that in the nominal steady state, so that as chloride diffuses to the metal surface the film thickens. Again, diffusive communication is very slow, so that the film thickness overshoots its nominal value, returning to the original condition (an overly thick film). Thus a cycle is completed, and it is readily apparent how an initially infinitesimal disturbance can grow and result in oscillations of finite amplitude. This loss of stability by the steady state is known as "overstability" because it involves an overshoot by a mechanism that normally serves to restore (or stabilize) the steady state when it is disturbed from its nominal value.

This model predicts that oscillations can occur only for those combinations of rotation rate, potential, and chloride ion concentration for which a film of sufficient thickness exists on the Cu surface. Furthermore, the model predicts that oscillations can be suppressed by increasing the rotation rate sufficiently so that the film dissolution rate increases to the point where there is either no film or a very thin film. These predictions of the model are in accord with the experimental findings.

The mathematical development of the model will be presented in a subsequent paper.

The Mechanism of Aluminum Electrodeposition from Solutions of AlCl_3 and LiAlH_4 in THF

M. W. M. Graef

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

ABSTRACT

Aluminum coatings on metallic substrates can be made by electrodeposition from a nonaqueous solution such as LiAlH_4 and AlCl_3 dissolved in tetrahydrofuran. Raman spectroscopy has been used to identify the chemical constituents of the plating bath. A quantitative analysis of the equilibrium composition is given. The electrode reactions have been studied by means of chronoamperometry. The catalytic behavior of hydride and the role of neutral and ionic aluminum containing species in the faradaic and chemical processes are elucidated. The influence of variations in the composition of the solution on the properties of the plating bath is explained in terms of the mechanism of the electrodeposition process.

Aluminum has a wide range of applicability, due to a combination of three outstanding properties: it is inexpensive, it has a low density, and it is resistant towards corrosion because it is always covered with a passivating native oxide film. Only in recent years, however, has it become possible to coat metallic objects with aluminum by means of a galvanic process. The difficulties encountered in the electrodeposition of aluminum are related to its being a base metal, with a standard electrode potential of -1.71V vs. NHE in aqueous solutions. This fact precludes the use of aqueous solutions for aluminum plating.

Bulk aluminum can be produced by electrowinning from molten salts at high temperature. The deposition of thin films on metallic substrates can be performed by the use of aluminum complexes in organic solvents. The choice of a suitable plating bath is governed by the following conditions.

1. The solvent has to be electrochemically stable in order to permit the reduction of an Al(III) compound without electrolysis of the solvent. This requires in the first place that the Nernst potential which characterizes the electrochemical equilibrium between metallic Al and the solution lie within the existence regime of the solvent. Second, the electrode reaction has to be kinetically feasible (low overpotential), and mass-transport phenomena have to be in favor of a controllable surface morphology.

2. The solute which is used as an aluminum source should exhibit a high solubility in this solvent. A stable metal complex has to be formed in the plating solution.

3. For some applications, it is desirable that the composition of the bath not change during operation. This implies that the electrode process has to be chemically reversible. In this case, aluminum consumption at the cathode can be compensated by the dissolution of an aluminum anode. This permits long-term operation of the bath without changes of the electrodeposition characteristics.

4. The ionic conductivity of the solution should be sufficient to permit the electrodeposition of aluminum at a considerable rate. A cathode current density of 1 A/dm^2 should be possible without excessive heat evolution.

The first successful aluminum plating bath based on organic solvents was reported by Couch and Brenner in 1952 (1). These authors dissolved lithium aluminum hydride (LiAlH_4) and aluminum trichloride (AlCl_3) in diethylether (Et_2O). The technological application of this bath was hindered by its instability and extreme flammability. Later, improvements were made with the choice of a less volatile solvent such as tetrahydrofuran (THF) (2, 3). By adjustment of the bath composition, an electrode efficiency of 100% was attained by Daenen *et al.* (4). It was found that the conductivity and the stability of the THF-type plating bath could be enhanced by the addition of lithium aluminum tetrachloride (LiAlCl_4) (5). The $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ bath is presently known as the REAL (room temperature electroplated aluminum) process (6), and has been developed into a technical process. Other investigators studied organometallic aluminum com-

pounds (7) or used aromatic solvents (8). At present, a considerable amount of work is being conducted on the development of aluminum plating solutions (9-11).

In the present study, the hydride-type THF plating bath is analyzed with respect to several phenomena that are relevant for the electrodeposition process. The quantities of interest are the chemical composition, the electrochemical potential, the electrode process and its kinetic characteristics, the conductivity of the solution, and the morphology of the electroplated metal.

Experimental

All reagents used for the preparation of the solutions were purified by distillation or recrystallization. The adducts $\text{AlH}_3 \cdot 2\text{THF}$ (12), $\text{AlH}_2\text{Cl} \cdot 2\text{THF}$ (13), $\text{AlHCl}_2 \cdot 2\text{THF}$ (13), and $\text{AlCl}_3 \cdot 2\text{THF}$ (14) were prepared by methods reported in the literature. The hydride content of the compounds was determined by means of iodometry (15). Solutions of LiAlH_3Cl , $\text{LiAlH}_2\text{Cl}_2$, LiAlHCl_3 , and LiAlCl_4 were prepared by the addition of a stoichiometric amount of anhydrous LiCl to the corresponding solutions of the aforementioned compounds. All manipulations and all measurements were performed in an argon atmosphere.

Raman spectra were recorded for 1M solutions of these compounds, using a $19,436\text{ cm}^{-1}$ and a $20,489\text{ cm}^{-1}$ laser beam. The positions of the vibrational lines were calibrated with respect to the $\nu_{(\text{CC})}$ band (A_1) of THF at 1029 cm^{-1} .

For the EMF measurements, the electrochemical couple ferrocene/ferricenium picrate ($\text{FeCp}_2/\text{FeCp}_2^+$) (16) in contact with a platinum wire served as a reference electrode. The configuration of the measuring cell was

$\text{Al}/\text{LiAlH}_4, \text{AlCl}_3(\text{THF})/0.5\text{M LiAlCl}_4(\text{THF})/1\text{ mM FeCp}_2,$

$1\text{ mM FeCp}_2\text{pic}, 0.5\text{M LiClO}_4(\text{THF})/\text{Pt}$

The presence of buffer vessels and the separation of the solutions by glass frits prevented reaction between the test solution (left) and the reference solution (right). The working electrode consisted of freshly deposited Al on Pt wire. Polarization curves were recorded using a solid Al counterelectrode in the left vessel. A Luggin capillary was used in order to minimize the ohmic drop between the working electrode and the reference electrode.

Chronoamperograms were recorded with the aid of a PAR 173 potentiostat, a 175 function generator, and a 4101 scan recorder. For these measurements, a different electrochemical cell was used. The working electrode was a 1 cm^2 polished platinum disk plated with aluminum prior to each measurement. An Al-plated platinum wire was situated behind the working electrode (17) and served as a quasi-reference electrode (QRE). The QRE compartment was electrically connected with the bulk solution by way of a Teflon tube fitted in the working electrode. The uncompensated resistance of this construction was determined by measurement of the ohmic drop by means of current interruption, for which a Clare PRME 15005 B

Reed relay was used. The uncompensated resistance R_u amounted typically to 1.5Ω . The iR_u drop was compensated by the positive feedback method (18).

The specific conductivities of the solutions were determined with a Philips PW9501 conductivity meter and a PW9510 conductivity cell.

Thermodynamics of the Plating Solution

The chemical composition of a plating bath prepared by the reaction of LiAlH_4 and AlCl_3 in THF is of importance for an understanding of the electrochemical properties of the solution. Recently, the results were published of a ^{27}Al NMR study which showed the presence of a number of Al containing species in this plating bath (19). In the present study, a detailed analysis is given of the chemical composition of $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ solutions for different hydride/chloride ratios. The preparation of these solutions is based essentially on the Schlesinger reaction (20), i.e., the reaction of LiAlH_4 with AlCl_3 in diethylether, which is used for the synthesis of alane (AlH_3)

Lithium chloride is insoluble in diethylether. The conductivity of the diethylether-type plating bath is determined by the presence of alanate ions, AlH_4^- . Although "mixed hydrides," or chloroalanes (AlX_3 , with $X = \text{H}, \text{Cl}$), have been observed in diethylether solutions (20), chloroalanes (AlX_4^-) do not appear to be stable in this ambience. The situation is more complicated if THF is used as a solvent. In order to identify the chemical species that may be present in THF-type plating solutions, a set of solutions was prepared, each of which contained the stoichiometric composition of a hypothetical compound. Raman spectra of these solutions were recorded and interpreted. The results are shown in Table I. The spectra of $\text{AlH}_3 \cdot 2\text{THF}$ (21, 22), $\text{AlCl}_3 \cdot 2\text{THF}$ (23), AlH_4^- (24), and AlCl_4^- (25) were compared with the Raman and IR data reported in the literature. The vibrational spectra for the other solutions were found to be consistent with the postulation of two series of species with homologous configurations, viz., $\text{AlX}_3 \cdot 2\text{THF}$ and AlX_4^- with $X = \text{Cl}, \text{H}$. The presence of a shoulder on the CO stretching band (A_1) of THF (C_{2v} symmetry) indicates solvation of the aluminum compound via the oxygen atom. The magnitude of the shift with respect to the position of this band in the uncoordinated THF molecule at 912 cm^{-1} allows a classification of the relative strength of the Al-O bond (cf. Table II). The largest shift indicates the strongest Al-O bond. This order reflects the Lewis acidity of the mixed

alanes (20); the nucleophilic character is enhanced by the presence of chloride and decreases if a chloride group is substituted with hydride. The negative ions did not exhibit a CO shift of the solvent, which means that there is no significant solvent addition in this case. This is consistent with the fact that Cl^- is a stronger Lewis base than THF (25).

The absence of dimers of the type Al_2X_6 may be inferred from the fact that no peaks have been observed in the region for $\mu\text{-H}$ bonds around 1550 cm^{-1} (21); neither have Cl bridges been observed for AlCl_3 in THF (23). The formation of solvent-separated aggregates may occur at higher concentrations, but this does not alter the principal symmetries and will cause only minor shifts in the vibrational spectra (26). Ions of the type $\text{AlX}_3 \cdot \text{AlX}_2^+$, formed by association (27), were not detected. Raman spectra gave no positive evidence for the presence of ions such as AlX_2^+ , but concentrations of these species may have been below the detection limit. The existence of the species $\text{AlCl}_2^+ \cdot 4\text{THF}$ could be inferred from the ^{27}Al -NMR spectrum, recorded for solutions of AlCl_3 in THF. This is in agreement with observations reported by Derouault *et al.* (23). The existence of $\text{AlH}_2^+ \cdot 4\text{THF}$ seems to be implied by the fact that solutions of AlH_3 in THF exhibit a notable conductivity.

These considerations lead to the conclusion that three classes of aluminum containing compounds can be discerned in THF (cf. Fig. 1): tetrahedral univalent negative ions, bipyramidal neutral molecules, and octahedral univalent positive ions. This makes up 12 species in total. Lithium is present in the form of tetrahedral $\text{Li}^+ \cdot 4\text{THF}$ (26). Finally, the possible presence of LiH and undissociated LiAlH_4 should also be taken into account.

In commercial plating baths, an excess of AlCl_3 with respect to LiAlH_4 is used (3, 4). The most important features of a Raman spectrum recorded for such a bath are summarized in Table III. A comparison with the data in Table I makes it clear that the bath contains the species $\text{AlHCl}_2 \cdot 2\text{THF}$ and AlCl_4^- ; this is consistent with the preparative

reaction

Characterization of the solutions with Raman spectroscopy does not allow an accurate quantitative and qualitative description of the plating bath. In the remainder of this section, the chemical properties of the bath constituents will be discussed in the light of experimental data derived from EMF measurements.

The chemical equilibrium in a solution prepared by dissolving AlCl_3 and LiAlH_4 in THF may be represented by a set of eight arbitrary individual reactions [a]-[h]

The reactions describe the transfer of a chloride or hydride ligand between two particles. For the sake of clarity, THF as a ligand has been omitted (*cf.* Fig. 1). Furthermore, AlH_3^+ , AlHCl^+ , and LiAlH_4 have been ignored, since their respective concentrations are presumably negligible

Table III. Raman spectrum for aluminum hydride plating bath. Composition: 0.32M LiAlH_4 and 1.20M AlCl_3 in THF.

Assignment	ν (cm^{-1})	$\Delta\nu_{1/2}$ (cm^{-1})
$\nu_{(\text{Al-H})}$	1844	75
$\nu_{(\text{CO})}$	871	sh
$\nu_{(\text{Al-Cl})}$	341	10

and do not affect the final result. In the set [a]-[h], 13 species participate; consequently, 13 equations are required to describe the equilibrium. These are supplied by the definition of eight equilibrium constants K_a, \dots, K_h , associated with the equilibria [a]-[h]; four mass balances, for aluminum, hydride, chloride, and lithium, respectively, and one "input condition." If the input concentrations of aluminum trichloride and lithium aluminum tetrahydride are denoted by $[\text{AlCl}_3^0]$ and $[\text{LiAlH}_4^0]$, respectively, the input condition may be defined as a single parameter, *viz.* the molar fraction of LiAlH_4 , denoted by x

$$x = [\text{LiAlH}_4^0]/([\text{LiAlH}_4^0] + [\text{AlCl}_3^0]) \quad [1]$$

The total aluminum concentration in the solutions prepared for the EMF measurements was kept constant (C). Thus, the mass balances can be written as

$$[\text{Al}] = C \quad [2]$$

$$[\text{H}] = 4xC \quad [3]$$

$$[\text{Cl}] = C(3 - 3x) \quad [4]$$

$$[\text{Li}] = Cx \quad [5]$$

For the determination of the equilibrium constants, the equilibrium potentials for a series of solutions were measured against the ferrocene-ferrocenium reference couple (*cf.* experimental section). If a solution is brought into contact with metallic aluminum, an equilibrium potential is established. The measured equilibrium potential E as a function of the composition parameter x (*cf.* Fig. 2) can be used to generate a set of equilibrium constants, with the aid of the Nernst equation. The results are presented in Table IV. With these constants the composition of a solution, prepared by dissolving LiAlH_4 and AlCl_3 in THF, can be calculated as a function of x . This is shown in Fig. 3. It is seen that the initial ratio of AlCl_3 and LiAlH_4 has a great influence on the chemical composition. In chloride-rich solutions, chemical species such as AlCl_3 , AlHCl_2 , and AlCl_4^- are stable, whereas in hydride-rich solutions the more important species are AlH_4^- , AlH_3Cl^- , and AlH_3 . The cation AlCl_2^+ and LiH are relatively unstable and are present only in very low concentrations.

The most typical feature of the E vs. x diagram is the fact that the Nernst potential shifts to more negative

Fig. 2. Equilibrium electrode potential of Al in $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ solutions as a function of the initial composition. The total aluminum (III) concentration is kept constant.

Fig. 3. Calculated equilibrium composition of $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ solutions as a function of the initial composition. The mole fraction of each species, defined as $x_i = [i]/[A]$, is plotted on the ordinate.

values as the hydride content of the solution increases. This is equivalent to the consideration that the hydride group has a tendency to reside on neutral molecules or that the chloride group has a tendency to reside on univalent negative ions. This fact is also illustrated, implicitly, by the relative magnitudes of the equilibrium constants. Consider, for instance, the chloride transfer process described by reaction [f]. The mechanism of this reaction may be envisaged as the interaction between a chloride acceptor (*i.e.*, a Lewis acid) and a chloride donor (a Lewis base). Another way of representing the results of the equilibrium analysis is to arrange a list of species according to their electrophilic or nucleophilic character, respectively.

The Lewis acidity decreases in the order

The Lewis basicity decreases in the order

It should be remarked that this result is consistent with the relative strength of the Al-H and Al-Cl bonds in the respective complexes, which can be deduced from the Raman spectra. The replacement of a hydride group by the more electronegative chloride group results in an increased strength of the remaining covalent Al-H bonds. This, again, causes a shift of the Al-H stretching vibration to larger wave numbers.

Table IV. Equilibrium constants for the $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ system at 25°C

$\log K_a = 1.02$	$\log K_c = 4.21$
$\log K_b = 0.41$	$\log K_f = 0.76$
$\log K_e = 2.18$	$\log K_g = 5.25$
$\log K_d = 0.82$	$\log K_h = 13.45$

These results can be used to elucidate the observed solvent effect. The apolar diethylether molecule is insufficiently nucleophilic for the creation of a stable $\text{Li}^+ \cdot 4\text{Et}_2\text{O}$ complex. Therefore, the attempted reaction of LiCl with AlCl_3 in diethylether results in precipitation of the former, whereas in THF the stable AlCl_4^- is formed. This explains why the conductivity of solutions of AlCl_3 and LiAlH_4 in Et_2O is relatively low compared to analogous THF solutions (28).

Kinetics of the Electrode Process

Figure 4 depicts a cyclic voltammogram for a platinum disk coated with freshly deposited aluminum in contact with a $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ plating solution. The diagram shows that the cathodic/anodic peak/peak separation is 620 mV (corrected for the iR_u drop) at a scan rate of 100 mV/s. Thus, kinetic measurements are meaningful on a time scale of less than 10s. Also, only a single (though possibly complicated) electrode process takes place for cathodic or anodic overvoltages less than 500 mV. These observations permit an interpretation of potential-step experiments in terms of redox processes involving the aluminum electrode and the solution.

The chronoamperometric technique can be used for obtaining information on the mechanism of the electrode process by means of analysis of the extrapolated time-zero current. Mass transport phenomena can be studied by observation of the transient behavior of the current. The method consists of recording the faradaic current response caused by the implementation of a potential step by means of a potentiostat (29).

The charge-transfer mechanism.—The rate-determining step (rds) of the electrode process may be either mass transport towards the surface, surface diffusion, nucleation, or electron transfer, depending on experimental conditions and transient time. In the case where the rds is contained within the overall charge-transfer reaction, the relationship between current and overpotential is gov-

Fig. 4. Cyclic voltammogram of Al immersed in a solution containing 0.52M AlCl_3 and 0.29M LiAlH_4 in THF. The electrode area was 1.0 cm^2 . The potential was measured vs. a quasi-reference electrode.

erned by the general Butler-Volmer equation (30)

$$i = i_0 \{ \exp(\alpha_a F \eta / RT) - \exp(-\alpha_c F \eta / RT) \} \quad [6]$$

where i is the current as measured by a current follower, i_0 is the exchange current, and η is the overpotential. The notation has been chosen in agreement with the IUPAC recommendations (31). By convention, the anodic current has a positive sign and the cathodic current has a negative sign. The transfer coefficients α_a for the anodic and α_c for the cathodic reaction are defined by

$$\alpha_a = \bar{\gamma} / \nu + (1 - \beta)r \quad [7]$$

$$\alpha_c = \bar{\gamma} / \nu + \beta r \quad [8]$$

Here, $\bar{\gamma}$ is the number of electrons transferred in the steps preceding the rds, γ is the number of electrons transferred in the steps after the rds, and r is the number of electrons transferred in the rds. ν is the stoichiometric number of the rds, and β is the symmetry factor in the rds. The total number of transferred electrons n is given by

$$n = \bar{\gamma} + \nu r + \gamma \quad [9]$$

In Fig. 5, examples are given of chronoamperograms for reductive and oxidative processes occurring at an aluminum electrode immersed in a solution of 0.29M LiAlH_4 and 0.52M AlCl_3 in THF at 25°C. Qualitatively, both processes are comparable. An accurate analysis of the chronoamperometric transients may be rather complicated (32), but an extrapolation of the current to $t = 0$ for a series of values of η can be used to study Eq. [6], which is clearly time independent. The effects of mass transfer and nucleation are excluded in this way, and the overall charge-transfer reaction can be studied. The extrapolation is carried out graphically (Fig. 6), using the approximated linear relationship between i and $t^{1/2}$ for short times. The cathodic branch, for instance, is described by

Fig. 5. Chronoamperograms for the cathodic deposition (negative overpotential) and for the anodic dissolution (positive overpotential) of aluminum.

$$\frac{i(t)}{i(t=0)} = 1 - \frac{2i_0 t^{1/2} \exp(-\alpha_c F \eta / RT)}{\pi^{1/2} \eta F A C_0^* D_0^{1/2}} \quad [10]$$

(C_0^* is the concentration at the electrode surface of the species that is consumed by reduction; D_0 is its diffusion coefficient; A is the electrode area.) Graphs showing the relationship between the time-independent part of the current and the overpotential are presented in Fig. 7 for the reductive and for the oxidative process. The exchange current density is found by extrapolation of these Tafel lines to $\eta = 0$. This gives $i_0/A = 20 \text{ mA/cm}^2$ for both the cathodic and the anodic data. The transfer coefficients are determined from the slopes of the Tafel lines. They are roughly equal: $\alpha_c = \alpha_a = 0.3$. Since the sum of α_c and α_a should be equal to or larger than unity, the experimental values are obviously too low. This may be due to an error in the extrapolation caused by the decrease of the slope

Fig. 6. Linearization of cathodic chronoamperograms for short times

Fig. 7. Tafel lines for Al in a solution of 0.52M AlCl_3 and 0.29M LiAlH_4 in THF

for large overpotentials. This deviation cannot be accounted for completely by the possible influence of uncompensated resistance on the applied voltage. A tentative explanation may run as follows. Since no nonelectroactive supporting electrolyte was available, the conductivity of a solution is largely determined by the presence of aluminum containing anions which participate in the electrode process. A relatively large concentration is required in order to obtain a conducting solution. This implies that relatively high currents and potentials are encountered in the measurements. At large overpotentials the symmetry factor is affected, and this will cause nonlinearity of the i vs. η relationship (33). If allowance is made for this, the only physically meaningful solution in agreement with the experimental data requires that the values for the transfer coefficients are corrected to $\alpha_a = \alpha_c = 0.5$. With $\beta = 0.5$, Eq. [7], [8], and [9] give $r = 1$ and $\nu = 3$, which means that the rds is executed thrice during the reaction sequence. This is consistent with the following model for the charge-transfer mechanism. The cathodic process is described by

Since the process is symmetrical, the anodic process is a mirror image of the cathodic process

The influence of the bath composition on the electrode kinetics was studied qualitatively by measuring the polarization curves for different solutions (Fig. 8). These curves make it clear that the electrode process is facilitated by the presence of hydride, which lowers the polarization resistance. The observation that the reaction mechanism is influenced by the $\text{LiAlH}_4/\text{AlCl}_3$ molar ratio has been reported by Eckert and Galova, who studied the

$\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ system using a rotating disk electrode (34).

The overall reaction.—On a relatively long time-scale the electrochemical reaction rate becomes limited by mass transport to and from the electrode surface. The limiting case is described by the Cottrell equation

$$i_d = nFAD_0^{1/2}C_0\pi^{-1/2}t^{-1/2} \quad [11]$$

where i_d denotes the diffusion-limited current. Theoretically, i vs. $t^{-1/2}$ yields a straight line. In practice, the current is limited by the kinetics of the electrode process for short times, and is influenced by the onset of natural convection at longer times. In the intermediate region, Eq. [11] is more or less valid. Figure 9 shows the experimental data for the cathodic process. The slope of the asymptote (Eq. [11]) is determined by C_0^* . If the value $10^{-5} \text{ cm}^2\text{s}^{-1}$ is taken for D_0 , the experimental results appear to be in agreement with line b in Fig. 9, where C_0^* is equal to 1/4 times the concentration of AlX_3 (with $X = \text{H}, \text{Cl}$). Apparently, only a fraction of the Al containing species arriving at the electrode surface is actually reduced: four AlX_3 molecules are consumed for the creation of only one aluminum atom. The reason for this is the fact that, together with the Al atom, three unstable ligands of the type X^- are created. These are bonded to other AlX_3 molecules. This observation leads to the following general scheme for the electrode process

Charge transfer

Ligand transfer

Regeneration

The overall reaction is

It should be noted that the hydride group does not occur

Fig. 9. Cathodic current measured as a function of $t^{-1/2}$, for several overpotentials. The straight lines represent the diffusion-limited transients for the case in which aluminum containing species are reduced at the working electrode (a) and for the case where ligand transfers are taken into account (b).

explicitly in the overall reaction. However, the participation of H^- in the electrode process has been established by Daenen (35), who concluded correctly that the reaction is characterized by a cyclic pattern. It is seen that the hydride group is not consumed in the electrode reaction and serves as a catalyst for the charge-transfer step. For the electrode reaction, it is not important whether the active species is AlHCl_2 , AlH_2Cl , or AlH_3 , as long as at least one hydride group is present.

The functions of the bath constituents in the plating process are summarized in Table V.

Physicochemical Properties of the Plating Bath

The conductivity κ of the $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ solutions as a function of the composition parameter x is shown in Fig. 10. It is seen that the conductivity increases with increasing lithium alanate content. This result should be compared with Fig. 8, from which it can be deduced that the polarization resistance decreases with increasing lithium alanate content. These results can be combined to obtain the polarization parameter k (36), defined as

$$k = \kappa |d\eta/d(i/A)| \quad [12]$$

The polarization parameter is plotted as a function of the composition in Fig. 11. This current distribution function is of importance for the throwing power of the plating bath (37). A sharp maximum is visible near the point

Table V. Aluminum hydride plating bath

Constituent	Function
$\text{AlHCl}_2 \cdot 2\text{THF}$	H^- : Catalyst
$\text{AlCl}_3 \cdot 2\text{THF}$	AlX_3^- : Acceptor for X^-
$\text{LiAlCl}_4 \cdot 4\text{THF}$	AlX_4^- : Donor for X^-
	Charge carrier
	Li^+ : Charge carrier.

Fig. 10. Conductivity of $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ solutions vs. the bath composition.

where the molar ratio of $[\text{AlCl}_3^0]$ to $[\text{LiAlH}_4^0]$ is about 5. If a plating bath is prepared in this way, a very homogeneous Al deposit can be obtained on complicated structures (38).

The kinetic results can also be used for a consideration of the influence of the bath composition on the average grain size of the electrodeposit. Bockris and Razumney (39) defined the following relationship between the critical nucleus size r_c in the initial stage of electrodeposition and the overpotential η

$$r_c = a\gamma/nF\rho_s\eta \quad [13]$$

where a denotes atomic weight, γ is the edge free energy, and ρ_s denotes the surface density of a two-dimensional nucleus. Equation [13] is valid for the case of crystal growth governed by surface diffusion. This is expected to be the case for low overpotentials (40). If the bath is operated galvanostatically (as is usually the case in plating processes), the overpotential is only small during the nu-

Fig. 11. Current distribution function of $\text{AlCl}_3/\text{LiAlH}_4/\text{THF}$ solutions vs. the bath composition.

Fig. 12. Grain size parameter as a function of the bath composition under similar plating conditions.

cleation stage. Then, for a constant current, the critical nucleus size is proportional to the inverse of the polarization resistance. This model is rather unsophisticated for the present complicated case of heterogeneous nucleation, and the absolute value of r_c is without significance, but it may be assumed that the tendencies of this quantity under the influence of process conditions reflect the variations in the average grain size of galvanic layers produced in different baths. The relationship between the grain size and the initial concentration of nuclei is inferred from the columnar structure of the grains. Hence, the arbitrary quantity r_c/r_c^0 (where r_c^0 is defined as the theoretical critical nucleus size for a pure AlCl_3 solution under standard conditions) may be used as a grain-size parameter. The variation of r_c/r_c^0 with the bath composition is shown in Fig. 12. According to these data, the average grain size will increase as the hydride content of the plating bath increases. This can be understood by noticing that the presence of hydride enhances the rate of the plating process and also gives rise to a low density of large nuclei under similar plating conditions. This behavior is in fact observed, as Fig. 13 makes clear. Two baths, having comparable conductivities and operated at the same current density, produced different electrodeposited-aluminum layers. Indeed, the grain size was found to increase with increasing hydride concentration. If smooth layers are to be deposited, the plating bath should contain only a small amount of LiAlH_4 .

Concluding Remarks

The properties of the aluminum hydride plating solutions are determined by three parameters.

The first is the total hydride concentration $[\text{H}]$. Hydride is present as a catalyst for the electrode reaction. An excess of hydride gives rise to instability of the plating bath. In this case, reactions of the type

occur slowly if the solution is left to stand. Also, ether cleavage is possible in hydride-rich solutions (41), according to the reaction

The second is the total concentration of ligand acceptors $[\text{AlX}_3]$. If an insufficient amount of acceptors is present, the ligand X^- , created in the cathodic process, cannot be stabilized via addition towards AlX_3 . The lithium complex $\text{Li}^+ \cdot 4\text{THF}$ is the only Lewis acid available. This leads to the reactions

These products precipitate at the cathode.

Fig. 13. Scanning electron micrographs of the surfaces of aluminum deposited in different plating baths under similar conditions.

The third is the total concentration of ligand donors [AlX₄⁻]. At the anode, the ligands X⁻ are necessary for the creation of stable AlX₃ · 2THF molecules. These ligands are supplied by AlX₄⁻ anions. If the latter are absent, the activation overpotential for dissolution of aluminum increases. This may cause oxidation of the solvent.

Effects of Thiourea and Guanidine Hydrochloride on Electroless Copper Plating

Aina Hung

Department of Chemical Engineering, Ming-Hsin Engineering College, Hsin-Feng, Hsin-Chu, Taiwan, China

ABSTRACT

The effects of thiourea and guanidine hydrochloride on electroless copper plating were studied by voltammetric and gravimetric methods. Thiourea stabilizes the plating bath and simultaneously decreases the plating rate. The effect of stabilization is attributed to the strong complexing ability of thiourea with Cu(I) and the surface adsorption of thiourea on copper. The surface adsorption is the main reason for the decrease in plating rate. In the case of guanidine hydrochloride, the plating rate is maximum when its concentration is approximately 5 mg/liter. The occurrence of the maximum is interpreted in terms of the interplay of the delocalized π electron effect of guanidine hydrochloride and its surface adsorption on copper.

Since ABS was plated with metals successfully in 1960 (1), the technology of plastics plating has been improving continuously (2, 3). Numerous parts for industrial and household products formerly made with metals were replaced by plated plastics (4-6). The demand for plated plastics has been increasing rapidly; hence, the technique of preparing more stable electroless plating baths with improved plating rates has become one of the main concerns in research. Reported improvements in this regard include optimizations in the nature and concentration of complexing (7) and reducing agents (8), bath temperature (9), pH (10), and, most interestingly, additives (11, 12). Certain additives, such as pyridine and cytosine, enhance the plating rate of electroless copper plating. Small amounts of other additives such as HIQSA (8-hydroxy-7-iodo-5 quinoline sulfonic acid) not only enhance the plating rate, but also stabilize the bath (13). However, high concentrations of some additives such as thiourea result in the undesirable effect of decreasing the plating rate (14, 15). The mechanism of the effect of additives in electroless copper bath was discussed by Schoenberg (13), Nuzzi (9), and Paunovic (16, 17). The correlation between the plating rate and the electronic structure of additives has been discussed. It has been speculated that the change in plating rate results from the surface adsorption of additives and its effect on polarization characteristics of anodic or cathodic partial reactions.

In this paper, the effects of thiourea and guanidine hydrochloride on electroless copper plating were studied using both voltammetric and gravimetric methods. The polarographic method was also used to investigate the complexing ability of the additives and sodium potassium tartrate with copper ions at pH 12.5, an optimized pH suggested for practical plating (9, 10).

Experimental

The voltammetric experiments were performed at room temperature with an electroless copper plating bath recommended by Pearlstein and Baudrand (18). The bath contained 13.8 g/liter $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 69.2 g/liter sodium potassium tartrate, 38 ml/liter formaline (37% by weight), and sodium hydroxide to give a pH of 12.50. Oxygen was removed by bubbling nitrogen through the solution for a few minutes. 50 ml of the solution was put in a glass cell equipped with three electrodes. The working electrode was a 99.5% pure copper wire 1.74 cm long and of 0.165 cm diam. The counterelectrode was a platinum wire 2.14 cm long and of 0.085 cm diam. A saturated calomel electrode (SCE) was used as a reference electrode. The cyclic voltammetric instrument was made by Sun-Light Corporation of Taiwan. It includes a 9028 programmer and a 9627 potentiostat. The scan rate was fixed at 0.1 V/s for all measurements. First, the voltammogram of static electroless copper plating solution without additive was taken in the range of -0.8 to 0 V. Then the voltammograms of the same bath with various amounts of additives were taken in the same potential range.

The same plating bath was used for the gravimetric experiment. 250 ml of the plating solution was used for each gravimetric plating rate measurement. Prior to immersion into the plating solution, a copper plate with specific dimensions was cleaned, weighed, and activated in PdCl_2 . Oxygen was removed by bubbling nitrogen through solution before plating. During plating, nitrogen gas was allowed to flow over the loosely sealed plating bath to keep oxygen away. After 30 min of deposition at room temperature, the copper plate was removed from the bath, dried, and weighed to determine the amount of copper deposited.

A Model 384 polarographic analyzer with Model 303 static mercury drop electrode from EG&G PAR was used for measuring the reduction half-wave potential of copper ion at room temperature. The blank solution contained 10 ml of sodium hydroxide solution at pH 12.5. The reduction half-wave potential of copper was first measured when only copper ions were present at $10^{-3}M$ in the blank. Various amounts of tartrate, thiourea, or guanidine hydrochloride were then added, and the reduction half-wave potentials of copper were recorded.

Results

The effect of thiourea on the anodic peak of the voltammogram is shown in Fig. 1. The peak in the range of -0.67 to -0.45V is due to the oxidation of HCHO. The current decreased gradually with the addition of thiourea. The zero current potential shifted to more positive values as the amount of thiourea was increased. The peak at -0.43V resulted from the oxidation of copper electrode. The peak shifted to more positive values (-0.35V) when the amount of thiourea was increased in the bath. In Fig. 2, the oxidation of HCHO can be considered separately in two ranges: the current in the range between zero current potential and -0.67V increased with the increase of guanidine hydrochloride; however, the current in the range between -0.67 and -0.45V decreased with the increase of guanidine hydrochloride. Figure 2 also shows that the zero current potential was shifted to more negative values when the amount of guanidine hydrochloride was increased. The peak current for the oxidation of copper electrode (-0.43V) decreased with the amount of guanidine hydrochloride added.

The gravimetric study showed that the addition of thiourea caused a decrease in the rate of electroless copper deposition (Fig. 3). On the other hand, the plating rate showed a maximum with the addition of guanidine hydrochloride at about 5 mg/liter (Fig. 4).

In the polarographic study using the procedure described by Lingane (19), it was found that Cu(II) and tartrate form a strong 1:2 complex. The stability constant calculated was 3.2×10^8 . In actual electroless copper solution, there are various other possible strong complex ions of Cu(II)-tartrate (20). However, the complex between Cu(I) and tartrate was found to be relatively weak. On the

Fig. 1. Effects of thiourea on the anodic oxidation of formaldehyde shown on voltammograms of copper electrode in electroless copper solution. The numbers indicate the concentration of thiourea added in milligrams per liter. The I-V curves were shifted along the current (I) axis for clarification. Each curve was started to draw from zero current potential.

other hand, thiourea was found to form a very strong 1:4 complex with Cu(I). The stability constant calculated was 2.7×10^{11} , whereas the complex formed between thiourea and Cu(II) was relatively weak. For guanidine hydrochloride, there was no evidence of complex formation with copper ions from the polarographic study carried out at pH 12.5.

Fig. 3. Effect of thiourea on electroless copper plating rate, determined by gravimetric method.

Discussion

The disappearance of the peak for the oxidation of HCHO in Fig. 1 on addition of thiourea can be explained by the adsorption of thiourea to copper surface. This interpretation is supported by the gravimetric result that the plating rate decreases with the increase of the addition of thiourea. Suppose that the adsorption of thiourea on copper follows the Langmuir isotherm; then, the fractional surface coverage of thiourea is given by

$$\theta = \frac{KC_t}{1 + KC_t} \quad [1]$$

where C_t denotes the concentration of thiourea and K is the adsorption constant.

If the copper deposition is inhibited by the adsorption of thiourea on the copper surface, the fractional surface coverage of the adsorbed species should be reflected in the measured rates of deposition. Thus, if the plating rates measured in the presence and absence of thiourea are r_t and r_o , respectively, then the fractional surface coverage may be computed by

$$\theta = 1 - \frac{r_t}{r_o} \quad [2]$$

Equations [1] and [2] can be combined and rearranged to give

$$\frac{1}{r_t} = \frac{1}{r_o} + \frac{K}{r_o} C_t \quad [3]$$

Fig. 4. Effect of guanidine hydrochloride on electroless copper plating rate, determined by gravimetric method.

Fig. 5. Test of Eq. [3] for thiourea

The plot of reciprocal plating rate vs. concentration of additive (Fig. 5) was linear, as expected from Eq. [3]. However, the scattering of data should not be neglected. It implies that there are some other factors influencing the plating rate. Nevertheless, from the straight line drawn in Fig. 5, the adsorption equilibrium constant was estimated to be $3.14 \times 10^6 M$. The large K value shows that thiourea strongly adsorbs on copper surface. Hence, it is clear that the plating rate is controlled predominantly by the adsorption of thiourea on copper surface.

Small amounts of Cu(I) present in the plating bath may exist as Cu_2O precipitate. It tends to disproportionate readily to form Cu(O). The Cu_2O particles or Cu(O) particles randomly dispersed in solution can act as nuclei for uncontrolled deposition of copper, leading to bath decomposition (22). From the stability constant, it is evident that thiourea forms a strong complex with Cu(I). The voltammograms in Fig. 1 show that the peak for the oxidation of copper electrode shifted from -0.43 to $-0.35V$ with the addition of thiourea from 0 to 2.0 mg. It is speculated that a new slow reaction pathway was introduced because of the adsorption of thiourea on copper (17, 21). The adsorption of thiourea on copper and the formation of a strong complex between thiourea and Cu(I) explain why a small amount of thiourea stabilizes the electroless copper plating bath.

Voltammograms of plating solutions with various amounts of guanidine hydrochloride are shown in Fig. 2. Four phenomena were observed: (i) the zero current potential shifted to more negative values as the concentration of guanidine hydrochloride was increased; (ii) the current for the oxidation of HCHO in the range between zero current potential and $-0.67V$ increased concomitantly; (iii) the current for the oxidation of HCHO in the range between -0.67 and $-0.45V$ decreased as the amount of guanidine hydrochloride was increased; and (iv) the peak current for the oxidation of copper electrode decreased with the increase of guanidine hydrochloride. The first and the second phenomena are interpreted as a consequence of rate enhancement by the delocalized π electron of guanidine hydrochloride (17). The third is believed to result from the decrease in the number of active sites for the oxidation of HCHO caused by the adsorption of guanidine hydrochloride to the copper surface. The peak for the oxidation of copper electrode does not shift with the addition of guanidine hydrochloride. It shows that there is no new pathway for the oxidation of copper electrode with the addition of guanidine hydrochloride. However, the peak current did decrease as the amount of guanidine hydrochloride was increased. This result con-

firms the decrease of free copper surface by the adsorption of guanidine hydrochloride. The effect of delocalized π electron and surface adsorption work simultaneously at the copper surface, resulting in the appearance of a maximum plating rate at about 5 mg/liter of added guanidine hydrochloride.

With further additions of guanidine hydrochloride up to 40 mg/liter, the plating rate decreased only slowly. This indicates that the surface adsorption of this compound is not as strong as that of thiourea. Instead, the effect of delocalized π electron plays a much more important role in determining the plating rate in the presence of guanidine hydrochloride.

Another additive, urea, whose molecular structure is similar to thiourea and guanidine hydrochloride, was studied for comparison. The addition of urea had no observable effect on voltammogram and plating rate. The result implies that neither surface adsorption nor complex formation with Cu(I) had any significant effect on the rate of electroless copper plating.

In conclusion, it has been discussed that there are three different effects of additives in electroless copper plating: (i) the surface adsorption of additive on copper surface decreases the plating rate; (ii) delocalized π electron of additive enhances the plating rate; and (iii) the stronger complexing ability of additive with Cu(I) than with Cu(II) stabilizes the solution. Besides the three additives studied, the effects of other additives reported in the literature, such as 2-mercaptobenzothiazole, pyridine, adenine, 2,2'-biquinoline, and cystine, may also be explained in terms of the same arguments.

Factors That Affect Uniformity of Plating of Through-Holes in Printed Circuit Boards

I. Stagnant Fluid in the Through-Holes

Timothy Sullivan and Stanley Middleman

Department of AMES/Chemical Engineering, University of California, San Diego, La Jolla, California 92093

ABSTRACT

Solutions are presented to a mathematical model that accounts for mass-transfer effects on the rate of plating of through-holes in circuit boards. The assumption is made that the liquid in the through-hole is stationary. Results indicate that even for aspect ratios as low as 3:1, very nonuniform plating occurs along the axis of the through-hole, unless flow within the through-hole can be induced.

Printed circuit board design is moving in a direction leading to increased aspect ratios for plated through-holes that connect parallel layers of circuits. A plating process must be designed to achieve deposition rates that are high enough to yield acceptable productivity in a plating line while maintaining uniformity of deposition consistent with quality considerations. These criteria will be increasingly difficult to achieve as aspect ratios increase for through-holes.

Figure 1 suggests the nature of the physical problems that must be dealt with. We consider a cylindrical through-hole of diameter D , connecting a pair of plane layers separated by a distance L . We define L/D as the aspect ratio of the through-holes. Aspect ratios of 5:1 are common today, and ratios of 20:1 are in the prototype stage in many board shops. Under most industrial circumstances, the rate of plating is controlled by mass-transfer resistances between the plating bath and the board surface. Bath agitation can promote the delivery of electrolyte to the board, but ultimately it is diffusion that controls the delivery of the metal ions or compounds to the sites of deposition. The fundamental question of concern here is this: to what degree can control of the external hydrodynamics in the bath be used to promote diffusion into the relatively stagnant through-holes?

In this paper, we examine the nature of the problem at hand by developing a mathematical model for the non-uniformity to be expected in the plating of through-holes that are filled with stagnant liquid. Part II of this series will present the effect of flow through the through-holes on deposition rate and uniformity.

Mathematical Model

We consider, as in Fig. 2, the region that includes a representative through-hole and the surrounding bath. A diffusion boundary layer, of thickness δ , separates the

Fig. 1. Phenomena that affect plating within and near the surfaces of a through-hole.

well-agitated bath from the board surface. Fluid within this region is not necessarily stagnant. There could be flow parallel to the board surface, for example. However, we assume that such a flow cannot contribute to the transport of any dissolved species in the direction normal to the board. In other words, external hydrodynamics in the bath, due to agitation, can control the magnitude of the diffusion boundary layer, but ultimately it is diffusion across this layer that delivers a chemical species to the site of plating. In this model, we do assume that fluid in the through-hole is stagnant.

A metallic species is in solution at a concentration C_b in the bath. This species must diffuse through the stagnant solution until, upon achieving contact with the solid surface of the board or through-hole, a reaction occurs which leaves a metal film on the solid.

Within the diffusion layer and through-hole, the concentration of the metallic species, C , is a function of time and position, governed by the diffusion equation

$$\frac{\partial C}{\partial t} = \mathcal{D} \left(\frac{\partial^2 C}{\partial r^2} + \frac{1}{r} \frac{\partial C}{\partial r} + \frac{\partial^2 C}{\partial z^2} \right) \quad [1]$$

For simplification of the mathematics, it is assumed here that the concentration field has angular symmetry about the axis of the hole.

Boundary conditions express the following physical elements of the model

$$C = C_0 \text{ for } t \leq 0 \quad [2]$$

The board has entered the plating bath from a prior clean-

Fig. 2. Definition sketch for the mathematical analysis

ing bath, and the through-holes and the board have entrained a liquid film whose concentration in the metallic species is C_o , different from the concentration C_b in the plating bath. This is an initial condition on the solution of Eq. [1]

$$C = C_b \text{ at } z = -\delta \tag{3}$$

This reflects our assumption that the bath is of uniform concentration to within a distance δ of the board.

$$\frac{\partial C}{\partial z} = 0 \text{ at } z = \frac{1}{2}L \tag{4}$$

We assume symmetry of agitation on both sides of the board. Hence, at the midpoint along the axis of the hole, the concentration gradient vanishes.

$$\frac{\partial C}{\partial r} = 0 \text{ at } r = R, -\delta \leq z < 0 \tag{5}$$

We assume that at some distance R from the axis of the hole, in the diffusion layer above the board, the influence of the hole vanishes and C is no longer a function of r

$$\frac{\partial C}{\partial r} = 0 \text{ at } r = 0 \tag{6}$$

This expresses angular symmetry about the axis of the hole.

The final boundary conditions require some assumptions regarding the rate of deposition of the metallic species on the surface. Whatever factors control the deposition process, we know that the deposition rate (per unit of surface area), \mathcal{R} , must be balanced by the diffusion flux to the surface. In general, then, the boundary conditions take the form

$$\mathcal{R} = -\mathcal{D} \frac{\partial c}{\partial r} \text{ at } r = a, 0 \leq z \leq L/2 \tag{7}$$

$$\mathcal{R} = -\mathcal{D} \frac{\partial c}{\partial z} \text{ at } z = 0, a \leq r \leq R$$

These conditions require that we have kinetic data sufficient to permit a relationship to be written between \mathcal{R} and C . For example, if the reaction is first order

$$\mathcal{R} = kC \tag{8}$$

where k is the rate coefficient. Of course, more complex reaction schemes could be envisioned. In this study, we will adopt Eq. [8].

It is convenient to nondimensionalize Eq. [1] in the following manner. Define a dimensionless time and a radial and axial variable as

$$\theta \equiv \frac{\mathcal{D}t}{a^2} \quad s \equiv \frac{r}{a} \quad x \equiv \frac{z}{a}$$

Define a dimensionless concentration as

$$\phi \equiv \frac{C}{C_b}$$

Then, Eq. [1] takes the form

$$\frac{\partial \phi}{\partial \theta} = \frac{\partial^2 \phi}{\partial s^2} + \frac{1}{s} \frac{\partial \phi}{\partial s} + \frac{\partial^2 \phi}{\partial x^2} \tag{9}$$

Initial and boundary conditions take the forms

$$\phi = \phi_o \equiv \frac{C_o}{C_b} \text{ for } \theta \leq 0 \tag{10}$$

$$\phi = 1 \text{ at } x = -\Delta = -\delta/a \tag{11}$$

$$\frac{\partial \phi}{\partial x} = 0 \text{ at } x = A = \frac{1}{2} \frac{L}{a} \tag{12}$$

$$\frac{\partial \phi}{\partial s} = 0 \text{ at } s = B = \frac{R}{a}, -\Delta \leq x \leq 0 \tag{13}$$

$$\frac{\partial \phi}{\partial s} = 0 \text{ at } s = 0 \tag{14}$$

$$-\frac{\partial \phi}{\partial s} = K_D \phi \text{ at } s = 1, 0 \leq x \leq \frac{1}{2}A \tag{15}$$

$$-\frac{\partial \phi}{\partial x} = K_D \phi \text{ at } x = 0, 1 \leq s \leq B \tag{16}$$

where $K_D = ka/\mathcal{D}$.

We note that this nondimensionalization removes all parameters from the diffusion equation, and introduces, into the boundary and initial conditions, the dimensionless parameters Δ, A, B, K_D , and ϕ_o .

Solution Method

Equation [9] is solved by a finite difference method, using the alternating direction implicit (ADI) procedure (1). The spatial (s, x) discretization is refined until the solution becomes insensitive to mesh size. The advantage of the ADI method is that it is convergent and stable for any time step, although too large a time step gives inaccurate results. A few numerical "experiments" using various time steps and mesh resolution lead to determination of a solution method that represents a good compromise between accuracy, memory requirements, and machine time.

Two test problems, for which analytical solutions are available, were used as an aid to assessing the accuracy of the computational procedure. In each case, Eq. [9] was solved under a set of simplified boundary and initial conditions.

Test Case 1.—Transient diffusion into a through-hole in the absence of reaction.—We solve Eq. [9] with the following conditions

$$\phi_o = 0 \text{ at } \theta \leq 0 \tag{10'}$$

$$\phi = 1 \text{ at } x = -\Delta = 0 \tag{11'}$$

$$\frac{\partial \phi}{\partial x} = 0 \text{ at } x = A = 3 \tag{12'}$$

$$\frac{\partial \phi}{\partial s} = 0 \text{ at } s = 0 \tag{14'}$$

$$\frac{\partial \phi}{\partial s} = 0 \text{ at } s = 1 \tag{15'}$$

From the exact analytical solution (2), we may write

$$1 - \phi = \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{m} \cos \left[\frac{m\pi(A-x)}{2A} \right] \exp \left(-\frac{m^2\pi^2}{4A^2} \theta \right) \tag{17}$$

where $m = 2n + 1$.

Test Case 2.—Reaction on the walls of a through-hole isolated from the external bath.—We solve Eq. [9] with the following conditions

$$\phi_o = 1 \text{ at } \theta \leq 0 \tag{10''}$$

$$\frac{\partial \phi}{\partial x} = 0 \text{ at } x = -\Delta = 0 \tag{11''}$$

$$\frac{\partial \phi}{\partial x} = 0 \text{ at } x = A = 3 \tag{12''}$$

$$\frac{\partial \phi}{\partial s} = 0 \text{ at } s = 0 \tag{14''}$$

$$-\frac{\partial \phi}{\partial s} = K_D \phi \text{ at } s = 1 \tag{15''}$$

The exact analytical solution (2) may be written

$$\phi = \sum_{n=1}^{\infty} e^{-\lambda^2 \theta} \frac{2K_D J_0(\lambda_n s)}{(\lambda_n^2 + K_D^2) J_0(\lambda_n)} \tag{18}$$

where the λ_n are the roots of

$$K_D J_0(\lambda_n) = \lambda_n J_1(\lambda_n)$$

Figure 3 shows the transient approach to equilibrium of the concentration at a point on the axis of the hole ($s = 0$), midway between the top and middle of the hole (i.e., at $x = 1/2 A = 3/2$). The spatial mesh and the time step used in the numerical solution are shown in the figure as well.

It is apparent that the mesh and time step used give accurate solutions over most of the approach to equilibrium. It is also apparent that the time scales characteristic of the approach to equilibrium differ markedly depending upon whether radial or axial diffusion dominates, for an aspect ratio of $A = 3$. This observation suggests that it does not matter much if the through-hole has plating solution in it initially (Eq. [10']), or whether it is free of plating solution (Eq. [10'']). Any initially available metal ion will quickly diffuse to the wall, and subsequent plating will depend upon supply of metal ion from the external bath.

Results

Figure 4 shows isoconcentration lines for a given set of geometric parameters, at two different times. The times are selected to be at steady state, and at the half-time. Some remarks on the definition of steady state are necessary.

Figure 5 shows the approach to equilibrium (steady state) for several cases. An arbitrary definition of steady state is always necessary in diffusion problems. Since the approach to equilibrium is asymptotic, an infinite time is required to achieve steady state, and, of course, this does not yield a useful time scale for the process. We have used the concentration at the position $s = 0$, $x = 1/2 A$, as a "tracer" for the approach to steady state. Thus, in Fig. 5, we plot $1 - \phi(0, 1/2 A, \theta) / \phi(0, 1/2 A, \infty)$ against θ . By $\theta = \infty$, we mean a time long enough that $\phi(0, 1/2 A)$ no longer changes. As Fig. 5 shows, for the specific parameter values illustrated, half-times are of order $\theta = 1$, but depend on K_D and Δ .

Figure 6 gives an indication of the reduction in the plating rate to be expected within the through-hole. The results of the numerical simulation are normalized to the plating rate on the plane-exposed surface of the board, far from the hole (i.e., at $s = B$). Results are shown for times beyond that required for achievement of steady plating. In effect, Fig. 6 displays the plating thickness at various positions, relative to the thickness that would be achieved

Fig. 3. Transient approach to equilibrium for two test cases. Comparison of exact solutions (—) and numerical results (○). Values of A , K_D , Δ appended to the upper curve. A uniform mesh is used, with $\Delta x = \Delta s = 0.125$. A time step of $\Delta \theta = 0.1$ is used.

Fig. 4. Concentration profiles at steady state (—) and at the half-time (---), for the case $A = 3$, $\Delta = 0.25$, $\phi_0 = 0$, $K_D = 10$, $R = 1.25$.

on the board if the through-hole were absent. Note that the uniformity of plating is improved at smaller values of K_D . Under no circumstances, for the range of parameters examined, is the plating rate uniform. In the cases studied, the plating rate falls below half of the exposed-surface rate at a depth of less than one diameter of the hole. Thus one can anticipate highly nonuniform plating in through-holes of aspect ratios of 3 or greater, unless one operates at very low plating rates ($K_D \ll 1$), under conditions consistent with the assumptions of this simulation. In particular, of course, these results hold on the assumption that the liquid in the through-hole is stag-

Fig. 5. The approach to steady state, under various conditions. Values of A , K_D , Δ appended to each curve. In all cases, $\phi_0 = 0$.

Fig. 6. Plating rate as a function of position, for various parameters, at steady state, normalized to the rate on the exposed surface far from the hole.

nant. (Flow within the through-hole will be addressed in part II of this series.)

In addition to the nonuniformity of plating, our results also illustrate the effect of diffusion resistance on the magnitude of the plating rate, relative to what one would achieve in the absence of any mass-transfer resistance. The nonuniformity is a consequence of the mass-transfer resistance of the stagnant fluid in the through-hole. The magnitude of the plating rate is further reduced by a finite external mass-transfer resistance, controlled by the value of Δ and K_D .

In the absence of a through-hole, plating occurs via one-dimensional diffusion to the planar surface of the board. In this case, the diffusion equations simplify to the form (at steady state)

$$\frac{d^2\phi}{dx^2} = 0 \quad [19]$$

$$\phi = 1 \text{ at } x = -\Delta$$

$$-\frac{d\phi}{dx} = K_D\phi \text{ at } x = 0$$

One easily finds $\phi(x)$, and from the surface value, $\phi(0)$, the plating rate is found to be

$$\mathcal{R}_\Delta = K_D\phi(0) = \frac{K_D}{1 + \Delta K_D} \quad [20]$$

Under conditions of efficient agitation, where the surface of the board is at the bath concentration ($\phi = 1$), that is, at $\Delta = 0$, the maximum plating rate is

$$\mathcal{R}_{\max} = K_D \quad [21]$$

Hence, the reduction in rate, due to the presence of Δ alone, is given by

$$\frac{\mathcal{R}_\Delta}{\mathcal{R}_{\max}} = (1 + \Delta K_D)^{-1} \quad [22]$$

As a typical example, we find that for $\Delta = 0.25$ (efficient agitation) and $K_D = 10$ (rapid reaction, relative to the diffusion rate), Eq. [22] predicts that the plating rate is only 30% of the value that would be achieved in the limiting case of $\Delta = 0$, despite the fact that Δ is so small. This reflects the strong interplay of reaction with diffusion. A large K_D value can lead to significant mass-transfer inhibition, even though Δ itself may be quite small. This is because the factor ΔK_D may be written as

$$\Delta K_D = \frac{k\delta}{\mathcal{D}} \quad [23]$$

and it is the magnitude of this particular combination of parameters, rather than Δ and K_D individually, that controls the importance of external mass-transfer effects on plating rate.

Some comments on the time required to achieve steady plating are in order. As Fig. 5 shows, half-times are of order one for the $\Delta = 1$ cases examined, and about half that magnitude for the $\Delta = 0$ cases. Half-times will be longer or shorter for larger or smaller aspect ratios, respectively. Since dimensionless variables are used, it is worthwhile to examine what these results mean in terms of real times.

From the definition of θ , the real half-time is

$$t_{1/2} = \frac{a^2}{\mathcal{D}}\theta_{1/2} \quad [24]$$

Under typical conditions (3), we might have a board of thickness $L = 0.092$ in. with a through-hole of diameter $2a = 0.031$ in. ($A = 3$). The diffusivity of copper ion in aqueous solution is of order 10^{-5} cm²/s. Converting a to centimeters, we find

$$t_{1/2} = 123 \theta_{1/2} \text{ (s)} \quad [25]$$

Hence, for half-times of order one (in θ), we anticipate that the transient period of plating is only of a duration of a few minutes. Since plating times are typically of the order of tens of minutes, we expect that the steady-state results for plating rate are of most interest to us.

Since these simulations, and the conclusions drawn from them, are strongly dependent upon the magnitude of K_D , it is important to estimate the range of K_D to be expected in commercial plating operations. Plating baths are often "rated" in terms of microinches of copper deposited over a specific time interval. A plating rate of 30 microinches in 10 min is regarded as a fast rate in an electroless process in a bubble-agitated bath (4).

Unfortunately, it is rarely possible to estimate the magnitude of the diffusion layer thickness, δ , in commercial systems. An upper limit can be estimated on the assumption that the deposition is completely mass-transfer controlled. [In electrolytic plating, this is just the condition of plating at the limiting current (6).] We assume, then, that the flux of metal ions, which is just the deposition rate per unit area, may be written as

$$\dot{H} \rho_m / MW = \mathcal{D} C_b / \delta_{\max} \quad [26]$$

where \dot{H} is the rate of growth of the metallic layer, and ρ_m / MW is the molar density of the metal. Under the conditions that

$$\begin{aligned} \dot{H} &= 3 \mu\text{in./min} = 1.27 \times 10^{-7} \text{ cm/s} \\ C_b &= 18.7 \text{ g Cu/liter (3)} \\ \mathcal{D} &= 10^{-5} \text{ cm}^2/\text{s} \\ \rho_m / MW &= 6.9/63.5 \end{aligned}$$

we find $\delta_{\max} = 0.2$ cm.

In a bath operating such that δ is smaller, so that there is a finite resistance associated with the reaction at the surface, we may calculate k from an assumed value of $\delta < \delta_{\max}$. We begin with

$$k = \mathcal{R}/C = \frac{\dot{H}(\rho_m / MW)(1 + \Delta K_D)}{C_b} \quad [27]$$

Note that we use Eq. [22] to correct the bath concentration C_b to the value C that is actually in contact with the board surface.

Using Eq. [26], we may write

$$\frac{k\delta}{\mathcal{D}} = \frac{\delta/\delta_{\max}}{1 - \delta/\delta_{\max}} \quad [28]$$

Obviously, any value of $k\delta/\mathcal{D}$ in the range $(0, \infty)$ follows from a guess of δ/δ_{\max} in the range $(0, 1)$, respectively. Sonin (5) presents a discussion of a plating system which

utilizes liquid jets which impinge on the board surface and provide very efficient agitation. From the information which he presents, we have calculated a value of $\delta = 5 \times 10^{-4}$ cm for his "B-1 manifold." Clearly, this leads to a very small value for $k\delta/\mathcal{D}$. However, it is K_p which controls nonuniformity of plating in the hole, and for this case we find

$$K_p = \frac{ka}{\mathcal{D}} = \frac{k\delta}{\mathcal{D}} \frac{a}{\delta} \approx \frac{a}{\delta_{\max}} = 0.19 \quad [29]$$

Based on this value of K_p , and our simulations, one would expect uniform plating of through-holes in Sonin's laboratory system. However, one could easily imagine, in a bubble-agitated bath, a value of δ considerably greater than that in Sonin's jet-agitated system. Hence, one would expect difficulty in achieving uniformity of through-hole plating under such conditions, unless the bath were agitated in such a way as to induce the flow of plating fluid directly through the holes. A discussion of the effect of such flow is the topic of the next paper in this series.

Electrode Materials for Hydrobromic Acid Electrolysis in Texas Instruments' Solar Chemical Converter

J. D. Luttmer,* D. Konrad,* and I. Trachtenberg*

Texas Instruments Incorporated, Dallas, Texas 75265

ABSTRACT

Texas Instruments has developed a solar chemical converter (SCC) which converts solar energy into chemical energy via the electrolysis of hydrobromic acid. Various materials were evaluated as anodes and cathodes for the electrolysis of the acid. Emphasis was placed on obtaining low overvoltage electrodes with good long-term stability. Sputtered platinum-iridium thin films were identified as the best choice as the cathode material, and sputtered iridium and iridium oxide thin films were identified as the best choice as anode materials. Electrochemical measurements indicate that low overvoltage losses are encountered on these materials at operating current densities in the SCC. Accelerated corrosion tests of the materials predict acceptable electrode stability for 20 years in an environment representative of on-the-roof service.

The solar chemical converter (SCC) in Texas Instruments' solar energy conversion system converts solar energy into chemical energy via the electrolysis of hydrobromic acid into hydrogen and bromine (1-6). The choice of this electrolyte was dictated by several considerations, including electrolysis product separability, ionic conductivity, electrode kinetics, optical transmission, and reasonable load matching to the silicon solar cells. Selection of the hydrobromic acid electrolyte system required identification, characterization, and selection of appropriate materials to use as anodes and cathodes for HBr electrolysis in the SCC.

The primary requirements for SCC electrode materials are that they have low overvoltage for HBr electrolysis and sufficient stability to achieve 20 years of service in an on-the-roof environment. Additionally, the electrode should be low in cost and be readily manufacturable. For optimum SCC performance, the electrodes should also be transparent, although the SCC electrode structure can be designed to minimize light losses associated with the electrodes (3, 5, 6).

* Electrochemical Society Active Member.

The electrodes on the individual solar cells of the SCC experience a wide range of operating conditions over their 20 year service life. Wide variations in operating temperature, electrolyte composition, and electrochemical current density are anticipated. The investigations reported here were designed to encompass these variations and predict SCC operating characteristics.

The electrochemical and corrosion behavior of numerous materials were investigated as candidates for SCC electrodes. The most promising electrode candidates included platinum and iridium and their alloys and oxides. The results of the investigations with the most promising candidates are given here.

Experimental

Thin film electrodes and corrosion samples were prepared by sputter deposition using a MRC 822 sputter system incorporating 8 in. diam targets of iridium and platinum/iridium (7:3) alloys. Silicon wafer (n^+ and p^+) and quartz substrates were cleaned in boiling nitric acid, dried, and sputter etched at 500W for 30s with the sputter chamber containing 6 μm argon. Platinum/iridium and

iridium thin films were sputtered at 500W and 6 μm argon. Iridium oxide thin films were prepared by reactive sputter deposition at 500W using the iridium target with the chamber containing 100 μm oxygen. Iridium oxide thin film electrodes on silicon substrates included a thin (3 nm) barrier layer of iridium to prevent formation of a passivating layer (silicon dioxide) between the silicon and the iridium oxide. A 0.1 μm iridium film was deposited on the back side of the thin film/silicon electrodes to facilitate formation of an electrical contact to the electrode.

Tafel plots of the thin film electrodes were obtained with a single-compartment three-electrode cell. The thin film/silicon test electrode was spaced 1 in. from a parallel thin film iridium counterelectrode. A bromine/HBr (1.0M/6.9M) reference electrode was used with a Luggin capillary positioned approximately 1 mm from the test electrode. Tafel plots were obtained with PAR 173/175 potentiostat/waveform generator and HP 7004B X-Y recorder at a scan rate of 2 mV/s. The plots were corrected for test cell resistance, which was determined by current interruption.

Corrosion studies of the thin films were completed to evaluate electrode stability under SCC array operating conditions (light) and nonoperating conditions (dark). The corrosion rates of the electrode materials were measured both with and without an applied potential bias. Accelerated testing was performed in 48% HBr and in various HBr/bromine solutions containing 8.9 eq/liter bromine + bromide. Tests were made at electrolyte temperatures ranging from 20° to 100°C. Arrhenius plots were made of log corrosion rate as a function of (temperature)⁻¹ to obtain the activation energy of the corrosion reaction.

Corrosion rates and materials losses for nonoperating electrode materials were determined by optical transmission measurements and by electrolyte analysis. The optical transmission of thin films on quartz substrates was measured at 600 nm using a Varian SuperScan 1BE spectrophotometer with 4 nm bandwidth. The corrosion rate of the electrode materials on silicon substrates was determined by measuring the buildup of corrosion products in the electrolyte. Electrolyte analysis for platinum and iridium was done with an ARL 35000 ICP spectrometer. The resolution of the transmission measurements is 0.2% T. The sensitivity is indicated in Fig. 5. The detection limits for Pt and Ir by ICP was 50 ppb.

Operating thin film electrode corrosion rates were determined by monitoring the overvoltage losses as a function of time at fixed current densities and operating temperatures. Cathode tests were accomplished with a single-compartment cell with 48% HBr, a HBr/bromine (6.9M/1.0M) reference electrode, and a Pt/hydrogen (HBr saturated, 1 atm) counterelectrode. Anode tests were also made with a single-compartment cell which contained 1M bromine + 6.9M HBr, a HBr/bromine reference electrode,

SOLAR CHEMICAL CONVERTOR

and a large iridium foil counterelectrode. The electrolytes are comparable to those encountered in the SCC during peak outdoor operation. The overvoltage-time behavior was continuously monitored with a Fluke 1720/2400 data acquisition system. Disassembly of the test cell structures after observation of large sudden increases in overvoltage revealed total loss of the thin electrode films. The corrosion rates are calculated from the initial film thickness and the electrolysis time to total loss of the film.

Results and Discussion

The electrochemical activity of thin sputtered films of iridium and platinum/iridium (7:3) alloy on silicon substrates in 48% HBr is shown in Fig. 2. The overvoltage losses encountered on the platinum/iridium alloy cathodes are comparable to those found with bulk platinum electrodes, as shown in Table I. The activity of pure thin film iridium cathodes is considerably lower than that of platinum or platinum/iridium alloy. At the average current density, overvoltage losses on iridium and platinum/iridium cathodes are typically -200 and -95 mV, respectively.

Overvoltage losses encountered on thin film anodes of iridium, platinum/iridium alloy, and iridium oxide at the average SCC operating current density are given in Table I. The average current density anticipated for operational SCC electrodes is 150 mA/cm² (6). The platinum/iridium alloy and iridium oxide electrodes have comparably high electrochemical activity as anodes for HBr oxidation relative to the iridium anodes.

Some improvement in the performance of iridium electrodes was observed when the electrodes were electrochemically activated. Cycling the electrode potential of iridium film electrodes between hydrogen evolution and

bromine generation in 48% HBr at 2 Hz for 10s momentarily increased the activity of the electrodes. The iridium activity for both HBr oxidation and HBr reduction was increased by this technique. However the electrodes resumed their initial activity after several hours of operation at 150 mA/cm². Cycling the electrode potential had no apparent effect on the activity of platinum/iridium electrodes. Total loss of iridium oxide thin films was observed upon identical potential cycling in 48% HBr.

The variation in electrochemical activity of very thin (<10 nm) electrode films with film thickness was examined to determine SCC electrode thickness requirements. Films in excess of 6 nm were found to have electrochemical activity equivalent to thick films or bulk metal, but the activity of films less than 6 nm decreased with film thickness.

The stability of the thin films was determined by measuring the corrosion rates of the films in various HBr/bromine mixtures encountered in the SCC. Measurements were made at various elevated temperatures representative of and in excess of the average operating temperatures anticipated for the SCC. Arrhenius plots of the corrosion rate-temperature data were used with a knowledge of the operating temperature anticipated for the SCC to predict the total corrosion for 20 years of on-the-roof service under operating or nonoperating conditions.

Typical Arrhenius plots of the corrosion data under nonoperating conditions are given in Fig. 3 and 4. The corrosion rates of all the films examined increase both with the temperature and with the bromine concentration in the electrolyte. Iridium and iridium oxide thin films have comparable, very low corrosion rates in HBr/bromine mixtures. The corrosion rate of platinum/iridium alloy films was considerably larger than the rates of iridium or iridium oxide films and was found to increase with the platinum content in the alloy. The corrosion rate of pure Pt was found to be more than 100 times larger than that of Pt/Ir (7:3) alloy for the HBr/bromine mixtures evaluated. The corrosion rate of pure platinum is unacceptable for its use as an SCC electrode material.

The corrosion rates measured for iridium and iridium oxide thin films on quartz substrates were larger than the rates measured on silicon substrates. For these samples, the corrosion rate appeared to be determined by the stability of the metal film/quartz interface or by the stability of the quartz itself. The films evaluated by optical transmission were sufficiently thin (<20 nm) to allow corrosion of the quartz substrate through pinholes in the electrode material. In these cases, small metallic particles were often visible in the electrolyte after several days or weeks at elevated temperature. The optical transmission of platinum/iridium, iridium, and iridium oxide thin films on quartz as a function of film thickness is shown in Fig. 5. All but the iridium oxide film is essentially opaque for film thickness greater than 20 nm.

In the case of platinum/iridium alloy films, the corrosion rate measured by optical transmission on quartz or

Fig. 3. Platinum/iridium (7:3) film corrosion in HBr/bromine mixtures. Total bromine + bromide content is 8.9 eq/liter.

Fig. 5. Optical transmission of platinum/iridium (7:3), iridium, and iridium oxide films on quartz at 600 nm.

by electrolyte analysis on silicon substrates were identical. The corrosion of the platinum/iridium films was limited by the stability of the electrode material rather than by the stability of the substrate or electrode film/substrate interface in this case.

A knowledge of the SCC electrolyte operating temperatures is required to determine the corrosion of SCC system components. The electrolyte temperatures anticipated for the SCC were obtained with a SCC thermal management computer model and hourly weather data obtained from a SOLMET typical meteorological year (7). The simulated 20 year time/temperature histogram for the SCC electrolyte in the Dallas/Fort Worth region was used in predicting the corrosion stability of the thin electrode films. The histogram is given in Fig. 6. The operating temperature of the SCC varies between 0° and 60°C, the cooler temperatures during the nonoperating hours and warmer temperatures during the operating hours.

Table II. Projected corrosion for 20 years on-the-roof service under nonoperating conditions^a

Material ^b	Electrode	Corrosion (μm)	Conditions
Pt/Ir (7:3)	Cathode	0.14	0.05M Br ₂ /8.8M HBr
Pt/Ir (7:3)	Anode	2.4	1M Br ₂ /6.9M HBr
Ir	Anode	0.0015	1M Br ₂ /6.9M HBr
Ir oxide	Anode	0.0003	1M Br ₂ /6.9M HBr

^a Current density = 0 mA/cm².

^b Electrode films on n⁺ and p⁺ silicon substrates, 6-25 nm.

The projected total corrosion of the electrode films for 20 years on-the-roof service under nonoperating conditions is given in Table II. The worst-case predictions assume that the anodes are immersed in a 1M bromine + 6.9M HBr anolyte and the cathodes are immersed in 0.05M bromine + 8.8M HBr catholyte for the entire 20 year period. Bromine at low concentration may occur in the catholyte during nonoperating periods in the SCC.

The potential bias imposed on the electrodes during operation of the SCC has a significant effect on the stability of those materials. An anodic bias imposed on the anode materials in HBr/bromine electrolytes results in decreased stability, whereas a cathodic bias imposed on the cathode materials results in increased stability. Consequently, it was necessary to determine the stability of the materials under both operating (biased) and nonoperating (nonbiased) conditions.

The corrosion rates of the electrode materials under operating conditions were determined by biasing the electrodes to the average current density anticipated for SCC electrodes, 150 mA/cm², and monitoring the electrochemical overvoltage. The overvoltage observed with the electrodes reflected the integrity of the thin films.

A typical overvoltage-time plot observed for a corrosion test which models active SCC electrode operation is given in Fig. 7. A marked increase in the electrochemical voltage on the iridium anode after 5400h of anodic bias at 150 mA/cm² signaled the loss of the electrode film. The observed corrosion rate for this material under anodic bias was five times larger than that observed for the material in the nonoperating mode without bias. A similar increase in corrosion rate was observed for other anode materials under anodic bias.

Iridium and platinum/iridium materials under cathodic bias in HBr/bromine electrolytes displayed enhanced corrosion stability relative to the nonoperating tests. No dissolution of these materials was observed at temperatures to 80°C for test times in excess of 4500h. However, iridium oxide electrodes rapidly decomposed under cathodic bias in these electrolytes.

The total projected corrosion for the electrode materials after 20 years of on-the-roof operation is given in Table

Fig. 7. Overvoltage vs. hours of operation for 9 nm iridium film on p⁺ silicon at 80°C. Anodic current density is 150 mA/cm² in 1M Br₂/6.9M HBr.

Table III. Projected corrosion for 20 years on-the-roof service under operating conditions^a

Material ^b	Electrode	Corrosion (μm)	Conditions
Pt/Ir (7:3)	Cathode	0.0048	48% HBr
Pt/Ir (7:3)	Anode	8.3	1M Br ₂ /6.9M HBr
Ir	Anode	0.0066	1M Br ₂ /6.9M HBr
Ir oxide	Anode	0.0042	1M Br ₂ /6.9M HBr

^a Current density = 150 mA/cm².

^b Electrode films on n⁺ silicon substrates, 6-25 nm.

III. The projected corrosion rates assume continuous electrolysis at 150 mA/cm². The corrosion rates reported for the platinum/iridium cathode under operating conditions is considerably less than that reported for the material under nonoperating conditions and represents the platinum/iridium corrosion detection limit in the former case. The corrosion rates for the iridium and iridium oxide anodes under operating conditions are larger than observed under nonoperating conditions.

The total corrosion predicted for iridium and iridium oxide anodes and for platinum/iridium cathodes is small for both operating and nonoperating conditions. The total anode material lost for 20 years of on-the-roof service is less than 0.15 and 0.02 mg for each square meter of array anode area for iridium and iridium oxide, respectively. Likewise, the projected loss for platinum/iridium is less than 3.2 mg from each square meter of array cathode area.

Conclusions

Electrochemical and corrosion investigations of thin film iridium, platinum/iridium, and iridium oxide materials in HBr/bromine electrolytes reveal that the materials have adequate activity and stability as SCC electrodes for 20 years of on-the-roof service. Overvoltage losses less than 95 and 65 mV are predicted for platinum/iridium cathodes and iridium oxide anodes, respectively, at the average SCC operating current density. Iridium and iridium oxide anodes and platinum/iridium cathodes have shown excellent stability for simulated 20 year on-the-roof service conditions. Currently the performance of the Texas Instruments SCC which incorporates the hydrogen/HBr/bromine system is limited by electrical characteristics of the individual solar cells and not by the electrochemical behavior of the anodes or cathodes.

In the final analysis, the electrode materials selected are the result of many trade-offs, such as cost, manufacturability, activity, and total expected corrosion. Electrodes can be constructed which ensure adequate activity and continued operation for the entire lifetime of the SCC system.

Chemical and Electrochemical Behavior of the Cr(III)/Cr(II) Half-Cell in the Iron-Chromium Redox Energy Storage System

ABSTRACT

The Cr(III) complexes present in the acidified chromium solutions used in the iron-chromium redox energy storage system have been isolated and identified as $\text{Cr}(\text{H}_2\text{O})_6^{+3}$ and $\text{Cr}(\text{H}_2\text{O})_5\text{Cl}^{+2}$ by ion-exchange chromatography and visible spectrophotometry. The cell reactions during charge-discharge cycles have been followed by means of visible spectrophotometry. The spectral bands were resolved into component peaks and concentrations of the Cr(III) species calculated using Beer's law. During the charge mode, $\text{Cr}(\text{H}_2\text{O})_5\text{Cl}^{+2}$ is reduced to $\text{Cr}(\text{H}_2\text{O})_6^{+3}$, and during the discharge mode $\text{Cr}(\text{H}_2\text{O})_6^{+3}$ is oxidized back to $\text{Cr}(\text{H}_2\text{O})_5\text{Cl}^{+2}$. Electrode potential measurements also support this interpretation. Hysteresis effects in the charge-discharge curves can be explained by the slow attainment of equilibrium between $\text{Cr}(\text{H}_2\text{O})_6^{+3}$ and $\text{Cr}(\text{H}_2\text{O})_5\text{Cl}^{+2}$.

Redox flow cells are electrochemical storage devices that utilize the oxidation and reduction of two soluble redox couples for charging and discharging. The active electrode materials, separated by a highly selective ion-exchange membrane, are pumped through a stack of redox flow cells, where the electrochemical reactions take place at porous carbon felt electrodes. Since the redox flow cell concept was first proposed by Thaller in 1974 (1), a number of redox couples have been investigated. More recently, acidified solutions of chromium [Cr(III)/Cr(II)] and iron [Fe(III)/Fe(II)] have been successfully used as redox couples, both as unmixed reactants (2) and as premixed solutions (3), i.e., both the anolyte and catholyte contain both iron and chromium. This study, however, was performed on a system containing unmixed reactants.

A schematic diagram of a single iron-chromium redox cell and the associated electrode reactions is shown in Fig. 1. An ion-exchange membrane separates the compartments and prevents the cross-mixing of the reactive cations. Electrodes consist of carbon felt catalyzed on the chromium side by trace amounts of gold and lead. The catalyst is required on the chromium side because the rate of reduction of Cr(III) to Cr(II) is slow on most surfaces (4, 5). The catalyst must also have a high overvoltage for hydrogen, since, from a thermodynamic standpoint, hydrogen is evolved before chromium is reduced. Trace amounts of gold (12-25 $\mu\text{g}/\text{cm}^2$) and lead (100-200 $\mu\text{g}/\text{cm}^2$) deposited on the carbon felt meet the requirements for an effective catalyst (6). Trace amounts of gold seem to be necessary to produce a surface on which lead deposits uniformly during the charging cycle. The catalyst also improves the cell discharge rate (7). No catalyst is required on the iron side.

During discharge, chloride ions move from the cathode compartment to the anode compartment, and hydrogen ions move in the opposite direction. On charge, all reactions are reversed. Since all species are fully soluble, there are no life limiting factors such as shape changes, inactive forms of reactants, and dendrite formation. There are also many advantages in system sizing and control (2, 8).

Semipermeable membranes have been developed that are sufficiently conductive and selective for use for photovoltaic and wind energy storage applications (9). Methods of keeping the iron-chromium redox system in balance have been developed. Flow characterization and analysis of shunt currents have been carried out, and hardware has been scaled up with little difficulty (10).

The open-circuit voltage behavior of a typical iron-chromium redox cell is shown in Fig. 2, wherein the open-circuit voltages during charge and discharge modes are plotted as a function of state of charge for a complete cycle. There is a distinct difference in the open-circuit voltage of the system at the same state of charge, depending on whether the cell is in the charge or discharge mode. In addition, when charging the cell, a much greater polarization is observed after the open-circuit voltage

risers. Charging must then be done at either a higher voltage or at a much lower charging rate.

Since these effects contribute to lower energy storage efficiency, it seemed critical to undertake a thorough study of the processes occurring at the chromium electrode during the charging and discharging of the system.

It was observed that, during charging, the color of the chromium solution changes from a deep blue-green to a blue color at about 50% state of charge, about the same time that the open-circuit voltage rises and the rate of charging falls. During discharge, the color of the chromium solution changes back to the blue-green color at around 90% state of charge.

It has been demonstrated conclusively (11) that in aqueous solutions containing Cr(III) and chloride ion three inner-sphere complex ions are present: Cr(H₂O)₄Cl₂⁺¹ (green), Cr(H₂O)₅Cl⁺² (blue-green), and Cr(H₂O)₆⁺³ (blue). These ions are relatively "inert", i.e., they are very slow to exchange ligands in their coordination sphere. The electrochemical effects are apparently related to the concentrations of these ions and to the fact that equilibrium between them is reached very slowly.

This paper describes the results of spectrophotometric studies and measurements of electrode potential of the chromium solutions during complete charge-discharge cycles of a single subscale redox cell.

Experimental

A laboratory subscale flow cell with an active electrode area of 14.5 cm² was used for all studies. A schematic diagram of the cell is shown in Fig. 3. An ion-exchange membrane (CD1L series) supplied by Ionics Incorporated, Watertown, Massachusetts, was used in the cell. Electrodes were made from nominally 1/8 in. thick carbon felt. The electrode on the iron side was uncatalyzed, while the electrode on the chromium side was catalyzed with 12.5 μg/cm² of gold (6, 12). Lead was electrochemically deposited at 0.3 mA/cm² onto the electrode from the chromium solution which contained 6 × 10⁻⁵M Pb²⁺. One set of experiments was carried out using 1M CrCl₃ and FeCl₂ solutions in 2M HCl. Because of the high absorbancies of the Cr⁺³ ions, it was difficult to make accurate measurements at low states of charge. Another set of experiments was run with 0.45M CrCl₃ and 0.55M FeCl₂, so that the absorbancies would be less than 1.0 for all states of charge.

A 1 mm quartz flow cell was connected in parallel with the chromium side of the redox cell and placed in a Beckman DK-2A spectrophotometer. The spectrum was then recorded at selected states of charge from 350 to 1000 nm. Chromium half-cell potentials were measured at the same states of charge using a wax-filled graphite rod and a Ag/AgCl (4M KCl) reference electrode placed in the chromium reservoir.

In order to analyze the spectra of the redox solutions, the complexes Cr(H₂O)₆⁺³, Cr(H₂O)₅Cl⁺² and Cr(H₂O)₄Cl₂⁺¹ were prepared by established procedures (13) and the spectra recorded. Solutions of Cr(H₂O)₆⁺³ and Cr(H₂O)₅Cl⁺² in 1M HClO₄ follow Beer's law up to at least 0.70 and 0.40M, respectively, which were the highest concentra-

Fig. 3. Laboratory redox cell. Wax-impregnated graphite end plates with bolts for current collection, polyethylene gaskets, carbon felt electrodes catalyzed on chromium side, ion-exchange membrane.

tions studied and are in agreement with literature values (14) (Fig. 4). Maxima for the Cr(H₂O)₅Cl⁺² ion are at 430 and 650 nm and maxima for Cr(H₂O)₆⁺³ are at 407 and 575 nm.

Cr(II) species were generated by reduction with amalgamated zinc in a nitrogen atmosphere (15). Cr(H₂O)₆⁺² was prepared by reducing Cr(ClO₄)₃ in 1.0M HClO₄. The spectrum was then recorded from 350 to 1000 nm using a 1 mm quartz flow cell which was filled directly from the reaction flask. The use of a flow cell was necessary because of the rapid oxidation of Cr(II) in air. The absorption maxima was at 714 nm, identical to that reported in the literature (16). Cr(II) was also prepared by reducing CrCl₃ by ZnO in 6.0M HCl. The absorption maxima was at 750 nm. Reduction of CrCl₃ · 6H₂O in lower concentrations of HCl gave maximum absorption peaks between 714 and 750 nm.

The spectra measured during the charge and discharge cycles were analyzed using a du Pont 310 Curve Resolver. The spectra of the highest charged solution was examined first. The solution consisted mainly of Cr(H₂O)₆⁺³ and Cr(II) as indicated by absorption maxima. Once the curves due to Cr(H₂O)₆⁺³ and Cr(II) were established, the curves for other states of charge were resolved by reducing the curves for these species and adding the contribution of Cr(H₂O)₅Cl⁺². The relative absorbancies of the two peaks of the Cr(III) species were always kept in the ratio of the molar absorptivities (14). The concentrations of the Cr(III) species were then calculated from the resolved curves using Beer's law.

The Cr(III) species present in the uncharged cell solution were also separated by ion-exchange chromatography and the fractions were identified by spectrophotometry. Approximately 10 ml of cell solution were placed on

Fig. 4. Spectra of chromium complex ions likely to be present in the acidified chromium solutions of the iron-chromium redox cells. 1 mm path length of cell, 0.3M concentration.

a column of Dowex 50X8-100 cation exchange resin (50-100 mesh H^+ form). The sample was eluted with 0.1, 1.0, and 3.0M $HClO_4$, respectively, and spectra of the resulting fractions recorded (13, 14, 17).

Results and Discussion

The spectra of the chromium solutions of the redox cell were characterized by two broad absorption bands with maxima of 408-430 nm and 575-610 nm. In the highly charged state, a band with a maximum at 750 nm was also observed. Figure 5 is a typical spectrum.

The cell solution was analyzed prior to and immediately after taking it through two complete charge-discharge cycles using ion-exchange chromatography and spectrophotometry. The results indicated that only $Cr(H_2O)_6^{+3}$ and $Cr(H_2O)_5Cl^{+2}$ were present in completely discharged solutions in detectable amounts under normal operating conditions of the cell. This is in agreement with equilibrium constants reported in the literature, which indicate that $Cr(H_2O)_5Cl^{+2}$ and $Cr(H_2O)_6^{+3}$ should be the dominant existing species once equilibrium has been achieved (18, 19). It was also found that the spectra of the solution during charge and discharge could be resolved satisfactorily without assuming the presence of $Cr(H_2O)_4Cl_2^+$.

The band with a maximum at 750 nm is obviously due to the presence of Cr(II). Since $Cr(H_2O)_6^{+3}$ has a maximum at 714 nm (16), other Cr(II) species must be present. Preparation of Cr(II) in environments containing chloride ion at increasing concentrations shows a shift in the maximum to longer wavelengths reaching a maximum at 750 nm. The species identified with this peak are obviously chloride containing Cr(II) complexes. Since there is rapid equilibration among Cr(II) ions, it is not possible to identify the peak with an individual Cr(II) complex. The shift to longer wavelengths is in agreement with the decreased ligand field strength of chloride as compared to water (20).

The results of the second set of experiments with 0.55M $FeCl_2$ and 0.45M $CrCl_3$ in 2.0M HCl are presented in Fig 6 and 7. (The results from the first experiments in which the solutions were 1.0M $FeCl_2$ and 1.0M $CrCl_3$ in 2.0M HCl are similar.) These figures show the concentrations of $Cr(H_2O)_6^{+3}$ and $Cr(H_2O)_5Cl^{+2}$ at selected states of charge and discharge.¹ Differences between the two cycles are due to the different ratios of the species in the initial solutions and the different modes of cycling. The important features of both figures are the large decrease in $Cr(H_2O)_5Cl^{+2}$ concentration and a rather small change in

¹ The error in the spectrophotometric measurements is believed to be less than 1%, and the maximum error in resolving the curves is about 1%.

Fig. 5. Spectrum of 1M chromium chloride solution during discharge of iron-chromium redox cell (42.0% charged, 58.0% discharge).

Fig. 6. Concentration of Cr(III) species in iron-chromium redox cell, first cycle, taper current charge (0.45M $CrCl_3$ and 0.55M $FeCl_2$ in 2.0M HCl).

$Cr(H_2O)_6^{+3}$ concentration with increasing state of charge. The decrease of $Cr(H_2O)_5Cl^{+2}$ concentration to a minimal value at high states of charge coupled with the constancy of the $Cr(H_2O)_6^{+3}$ concentration suggests that $Cr(H_2O)_5Cl^{+2}$ is the predominant species involved in the reduction reaction at the electrode surface.

A similar argument applied to the discharge cycle indicates that the oxidation process involves the production of $Cr(H_2O)_5Cl^{+2}$ rather than $Cr(H_2O)_6^{+3}$. In addition, the fact that the $Cr(H_2O)_6^{+3}$ concentration changes only after the $Cr(H_2O)_5Cl^{+2}$ concentration has reached an appreciable level indicates a slow equilibrium step involving $Cr(H_2O)_6Cl^{+3}$ and $Cr(H_2O)_5Cl^{+2}$. This is in agreement with Gates and King, who have found the equilibrium quotient for the reaction $Cr(H_2O)_6^{+3} + Cl^- = Cr(H_2O)_5Cl^{+2} + H_2O$ to be 0.27 at 30°C (11). (Concentrations are used in the equilibrium quotient instead of activities.) The equilibrium state is achieved very slowly in the absence of Cr(II) ion, but the hydration of the $Cr(H_2O)_5Cl^{+2}$ to $Cr(H_2O)_6^{+3}$ is catalyzed by Cr(II) (21, 22).

The electrode potentials in the chromium solution with respect to a Ag/AgCl reference are plotted in Fig. 8 against the log of the ratio of concentration of Cr(II) to the concentrations of the different Cr(III) species. It can be seen that the curve for $Cr(H_2O)_5Cl^{+2}$ is linear and has a slope close to the Nernst slope, in contrast to the

Fig. 7. Concentrations of Cr(III) species in iron-chromium redox cell, second cycle, constant current density, 0.22 A/cm² (0.45M $CrCl_3$ and 0.55M $FeCl_2$ in 2.0M HCl).

Fig. 8. Plot of EMF of chromium solution during charge against ratios of Cr(II) to Cr(III) concentrations. Reference electrode Ag/AgCl. First charge, taper current (0.45M CrCl₃ and 0.55M FeCl₂ in 2.0M HCl).

curves for the total Cr(III) concentration and Cr(H₂O)₆⁺³. This Nernstian behavior, together with the formation of Cr(H₂O)₅Cl⁺² in the discharge mode and the disappearance of Cr(H₂O)₅Cl⁺² in the charge mode, indicates that the reaction pathway will most likely involve Cr(H₂O)₅Cl⁺². The electroactive species of Cr(II) is presumably Cr(H₂O)₅Cl⁺, since the Frank-Condon principle predicts that the geometry of the reacting species will be retained upon both oxidation and reduction, and since the spectra of the Cr(II) species show the presence of chloride complexes as shown by the shift in the absorption maxima in these solutions from the spectra of Cr(H₂O)₆⁺³.

Weaver and Anson (5) have carried out extensive studies of the electrode reactions of Cr(H₂O)₅X⁺² complexes at mercury electrodes. The formal potential for the Cr(H₂O)₆⁺³/Cr(H₂O)₅X⁺² couple was found to be -0.413 vs. H₂, while that for the Cr(H₂O)₅Cl⁺²/Cr(H₂O)₅Cl⁺ couple was -0.347V. They found electrode reaction rate constants of 2.2 × 10⁻⁵ and 5.60 × 10⁻³ for Cr(H₂O)₆⁺³ and Cr(H₂O)₅Cl⁺², respectively, evaluated at -700 mV vs. SCE (-452 mV vs. H₂). If we assume that the rate constants on the redox catalyst are in the same relative order as on the mercury electrode, the electrochemical behavior of the cell as shown in Fig. 2 can be explained by assuming that when the more electroactive pentahydrate is depleted, the equilibrium potential rises, since the standard potential of the hexahydrate couple is more negative than that of the pentahydrate couple. The greater difficulty in charging the redox cell after the pentahydrate is depleted is due to the slower kinetics of the hexahydrate reduction. Upon discharge the pentahydrate is rapidly regenerated and the equilibrium potential falls.

Weaver and Anson have also found that the oxidation of Cr(II) takes place by means of a chloride-bridged inner-sphere pathway at a mercury electrode, and they suggest that a more efficient reaction pathway is provided by the presence of chloride ion (5). It is likely that a similar mechanism is involved on the Pb/Au on carbon felt electrodes, since all the results here are in qualitative agreement with the results of Weaver and Anson on mercury electrodes.

Conclusions

The complex ions Cr(H₂O)₆⁺³ and Cr(H₂O)₅Cl⁺² have been isolated and identified by ion-exchange chromatog-

raphy and visible spectrophotometry in acidified chromium solutions of the discharged iron-chromium redox energy storage system. The reactions at the catalyzed carbon felt electrode can be followed spectrophotometrically during charge-discharge cycles. The spectra can be resolved and used to determine the concentrations of Cr(H₂O)₆⁺³ and Cr(H₂O)₅Cl⁺², which have been demonstrated to follow Beer's law up to at least 0.7 and 0.4M, respectively.

The spectral data indicate that the concentration of Cr(H₂O)₅Cl⁺² decreases much more rapidly with increasing state of charge than does the concentration of Cr(H₂O)₆⁺³, indicating that Cr(H₂O)₅Cl⁺² is the predominant species being reduced during the charging cycle. There is a rapid rise in Cr(H₂O)₅Cl⁺² concentration as discharge takes place, and the concentration of Cr(H₂O)₆⁺³ rises only after appreciable Cr(H₂O)₅Cl⁺² is produced. This is in agreement with other studies that show that equilibration between Cr(H₂O)₆⁺³ and Cr(H₂O)₅Cl⁺² takes place slowly. The predominant electroactive species in the discharge cycle is probably Cr(H₂O)₅Cl⁺. The electrode potentials also indicate that the main electroactive species in the charging mode is Cr(H₂O)₅Cl⁺². The electrochemical behavior of the redox cell can be explained on the basis of the different equilibrium potentials for the hexahydrate and pentahydrate couples and the different rates of reduction of the hexahydrate and pentahydrate species. The conclusions are consistent with other studies at mercury electrodes.

ABSTRACT

The photoelectrochemistry of n-CuInS₂ and CuInSe₂ in polysulfide electrolyte is studied with particular emphasis on the pretreatments of the electrodes and on their output stability. The use of Cd doping, (photoelectro)chemical etching, and mild air oxidation all were found to improve electrode performance. The effect of air oxidation was reproducible only for the diselenide, where it improved the fill factor and, because of a negative shift of the flatband potential, the open-circuit voltage. Optimized cells showed, at elevated temperatures, conversion efficiencies around 5 and 7.5% for the sulfide and selenide, respectively. The positive temperature dependence of the photo-I-V characteristics at both low and high illumination intensities, the existence of optimal polysulfide solution compositions, the linear dependence of the photocurrent on the light intensity, and the effects of temperature, solution composition, and initial current density on the photocurrent decrease during the first minute of operation of the cells, are ascribed to limitations of the charge-transfer process across the solid/liquid interface. Thermally activated rates of ad- and desorption of sulfur containing solution species on the semiconductor surface and/or the presence of adsorption-induced electronic states in the bandgap are postulated as causes for this behavior. Notwithstanding these limitations the cells are resistant to photocorrosion, after the initial decrease is arrested, in contrast to what is known for similar Cd-chalcogenide-based systems. We suggest that this stability, which persists under load and at high light intensities, is due to the strength and character of the bonds in CuIn-dichalcogenides, or to the presence of a top layer of indium oxide in which recombination will take place, or to both.

Ternary chalcogenides (and pnictides) with tetrahedral coordination and the general formula ABC₂ can be derived from the corresponding II-VI, e.g., CdSe, (and III-V) binary compounds by cation substitution. They can be thought of as resulting from proton exchange between two cations in the corresponding binary compound (1). Most of these materials are semiconductors and several of them exhibit interesting optoelectronic behavior (2). The partial Cu d character of the top of the valence band in these compounds, which gives bandgap excitation less of a bond breaking character, has been noted (2). To date, CuInSe₂ is probably the most studied of these compounds, by virtue of the very promising photovoltaic activity of thin film solar cells containing this semiconductor as the photoactive material (3). Both n-CuInS₂ (4, 5) and n-CuInSe₂ (6) can be used as photoanodes in a polysulfide containing photoelectrochemical cell (PEC). Such cells show respectable photovoltaic activity and very good output stability, as reported previously (4-6). Here we present results of our characterization of these cells. They show the importance of surface treatments to optimize photovoltaic conversion efficiency of these PEC's, and the occurrence of charge-transfer limitations in them, whose causes we attempt to assess. The time de-

pendence of the output of the cells is studied under a variety of conditions, and possible reasons for their stability are given. Some of the results described here and the conclusions drawn from them aided in the recent development of improved PEC's with a polyiodide electrolyte (7).

Experimental

CuInS₂ crystals were prepared by chemical vapor transport, using halogen transport agents, as described before (2). CuInSe₂ crystals were obtained by melt growth from the purified elements (8). As-grown crystals were generally semi-insulating, p-type, with 10⁵-10⁶ Ω-cm resistivities. They did not exhibit any photoelectrochemical activity. Hence, they were doped to obtain useful n-type material. Cd was found to be a suitable dopant. From various experiments, optimum doping conditions were found (Fig. 1). The dopant and the crystals were sealed in evacuated (10⁻⁶ torr) silica ampuls and heated for several days. For both compounds, In doping was found to be less satisfactory than Cd doping. The doping mechanism probably involves the introduction of Cd on Cu sites, Cd_{Cu}, where it acts primarily as a donor (9, 10).

The crystals were analyzed by electron beam-induced energy or wavelength dispersive x-ray fluorescence. In one case, the incorporation of Cd was verified by secondary ion mass spectroscopy. In addition, some samples were analyzed by Auger and/or x-ray photoelectron spec-

troscopy. Electrodes were prepared as described previously (5). The etching procedure was as follows: a sequence of 2-3 times 60s immersion in aqua regia, H_2O rinse, 60s immersion in 10% (w/v) KCN at 50°C and H_2O rinse. In some cases, a $\text{HNO}_3\text{:H}_2\text{O}$ mixture (55:100, v/v) was used instead of aqua regia. Photoelectrochemical etching was done in a 1:10 (v/v) diluted solution of 3% NH_3 in HCl (v/v) at reverse bias voltages (*vs.* the potential of the etching solution) between 0.3 and 1.0V. For CuInS_2 , optimum electrode improvement was obtained when this procedure was done at +1.0V. Air heating of electrodes (in addition to heating at 50°C to cure the silver epoxy, used as part of the ohmic back contact) was carried out in conventional laboratory furnaces.

Electrochemical measurements, including spectral response and output stability experiments, were done as described previously (5, 11). Capacitance measurements were carried out as outlined elsewhere (12), using frequencies up to 5 kHz. Concentrations of polysulfide solutions are expressed as follows: $X/Y/Z$, where X, Y, and Z give the molar concentrations for OH^- , S^- , and S, as added. Na and K were used as cations for S^- and OH^- , respectively, except where noted otherwise.

Results and Discussion

Surface treatments.—Previously, photoelectrochemical etching has been found to improve the photoelectrochem-

ical performances of Cd chalcogenides (13), as well as that of $n\text{-CuIn}_3\text{S}_8$ photoanodes (14). We found that this treatment improves the I-V characteristics of $n\text{-CuInX}_2$ PEC's, although it is less effective if the electrode performs well already before photoetching (after dark etching). Figure 2 shows the photocurrent-photovoltage plot for one of the better, as-etched electrodes. Table I compares the performance of two chemically and photoelectrochemically etched CuInS_2 and CuInSe_2 photoanodes, for which the latter treatment was effective.

Figure 3 shows the surface of a CuInS_2 photoanode, that was photoelectrochemically etched and, subsequently, chemically etched. On the surface of the photoelectrochemically etched electrode, we see the etch pit pattern, familiar from photoetched surfaces of other chalcogenide semiconductors (13). The rather irregular shape of the etch pits can be explained by the fact that a randomly oriented surface was used. Parts of the surface of photoelectrochemically etched CuInSe_2 electrodes showed similar etch pits, while other parts were less affected by the treatment.

The differences between the two compounds are also expressed in their behavior after air-heating. While this treatment was invariably found to improve the performance of CuInSe_2 PEC's (Fig. 4) this was not the case for CuInS_2 ones, where it mostly led to a poorer performance.

In the following paper (15), we present results of detailed surface analyses, on the basis of which we can attribute the effect of the air heating step to the formation of an indium oxide layer on the surface of these semiconductors, or, rather, to the increased homogeneity of a partially existing layer. [In_2O_3 is the native oxide on these materials; *cf.* Ref. (16).] The difference between CuInS_2 and CuInSe_2 may be due to the larger thermodynamic

driving force for oxide formation on the disulfide, compared to the diselenide.

We also measured the flatband potential (fbp) of the electrodes as function of surface treatment. Capacitance-voltage measurements were, in many cases, complicated by the relatively narrow potential range over which the C⁻²-V plots were linear, by large frequency dispersion that was encountered, and by hysteresis in the curves. After an etched electrode was either left standing in air overnight, or used for some time in polysulfide solution (*i.e.*, some photocharge was passed), better behavior was observed, suggesting the occurrence of chemical changes in the near-surface region and/or at the surface. Although the dark forward currents for several samples were high in the region of the fbp, measurements of the potential of onset of photocurrent is often an alternative way to obtain a lower limit (in terms of absolute potential) for the fbp. Table II summarizes the results. From it we see that, for most cases where both types of measurements were done on CuInSe₂, the agreement is reasonable. The situation for CuInS₂ electrodes is not so satisfactory; there, the onset potential appears to be the more reliable measurement. We note that these values for the n-CuInS₂ fbp in

polysulfide, even though they are quite approximate ones, are between 1 and 1.5V more negative than those found for p-CuInS₂ in polysulfide (5), or in 1M NaOH as reported by McCann and Pezy (17), suggesting that this semiconductor/electrolyte interface behaves reasonably ideally.

The effect of pH of a nonsulfide solution and of polysulfide concentration on the fbp of n-CuInS₂ was briefly investigated. The importance of such an investigation stems from the expectation that if CuInSe₂ behaves as CdS or CdSe, there will be little shift of the fbp as a function of pH over most of the pH range, while if an In-oxide layer on the surface of the CuInSe₂ is in equilibrium with the electrolyte, there would be a 59 mV/pH unit fbp dependence.

The results (obtained by C⁻²-V measurements) show an irregular dependence of the fbp on pH, which is, on the average, less than the 59 mV/pH expected from a simple oxide-electrolyte junction. Still, it is considerably greater than that shown by CdS or CdSe. This indicates that the In-oxide/electrolyte interface is electronically active, and that in sulfide-free electrolyte this oxide layer is involved in charge transfer between CuInSe₂ and the electrolyte, rather than serving merely as a porous interlayer.

Because this result in itself does not prove that a similar situation holds in polysulfide, fbp measurement as function of nominal polysulfide concentration were done as well. Solutions of equimolar concentrations of added hydroxide, sulfide, and sulfur, between 10⁻² and 1M (pH 12-14) were used, and a change of nearly 100 mV/decade of concentration was found. Of this, some 50 mV can be ascribed to the effect of pH. The remainder of the change must be due to sulfur containing species.

After optimization of the surface treatments, it was possible to study the photoelectrochemistry further. Before presenting the results of these measurements, the results of the photoelectrochemical characterization of the CuInS₂ samples, which differed considerably from those of crystals used earlier (5), are given.

Photoelectrochemical characterization of CuInS₂ crystals.—Wavelength dependence of the photocurrent.—Previously, we reported spectral response data for n-CuInS₂ (5), in arbitrary units, and for CuInSe₂ (6), in terms of absolute quantum efficiencies. Therefore, we will show here only the wavelength dependence of the absolute, external, quantum efficiency for n-CuInS₂ (Fig. 5). These results are similar to those obtained previously for single crystals (5), for polycrystalline films (18), and for p-CuInS₂ polycrystalline samples (19), in that they show optimal response at higher wavelengths. The quantum efficiencies are less than those obtained for CuInSe₂ (6).

Monochromatic current-voltage behavior.—As discussed in Ref. (5), we can obtain the fbp from the voltage depen-

Fig. 5. Wavelength dependence of the absolute external quantum efficiency for a n-CuInS₂/(1/1/0.1) polysulfide cell.

dence of the monochromatic photocurrent (at reverse bias). In the sulfur-poor solution of Fig. 5, we find a value of -750 mV vs. the solution potential, which is similar to that reported earlier, for samples with poorer performance [cf. Fig. 3 with the I-V curve in Ref. (5)]. This difference is expressed mainly in the effective minority carrier diffusion length obtained from these data [cf., Ref. (5)], which is ca. $0.65 \mu\text{m}$ vs. $0.2 \mu\text{m}$ for the inferior crystals. The effective net doping density, obtained from monochromatic I-V plots in the range of strong depletion [cf. Ref. (5)], is similar for both cases: $2.1 \times 10^{16} \text{ cm}^{-3}$ vs. $2.8 \times 10^{16} \text{ cm}^{-3}$ for the inferior crystals.

Photoelectrochemical performance of $\text{CuInX}_2/\text{polysulfide}$ PEC's.—Light-intensity dependence of I-V characteristics.—For both CuInS_2 and CuInSe_2 , plots of the logarithm of the short-circuit currents vs. the open-circuit potential were quite linear from ca. 10 mW/cm^2 up to 100 mW/cm^2 . Saturation sets in only well above this (normal insolation) level. From the slope of these plots values for n , the diode quality factor for the illuminated semiconductor-electrolyte interface could be calculated. Values around 2.4 for CuInS_2 and 1.7 for CuInSe_2 were found, indicating the nonideality of the Schottky barrier. A similar situation was found for Cd-chalcogenides (20). Both types of electrodes show a linear dependence of the short-circuit current on the incident white light intensity between 5 and 100 mW/cm^2 . This suggests the absence of kinetic limitations due to simple solution or interfacial charge transfer processes up to ca. AM1 illumination at least. To investigate this point, which has obvious implications for PEC performance, we studied the effects of solution composition and temperature on the photocurrent-photovoltage characteristics.

Effect of polysulfide composition on I-V characteristics.—The actual composition of aqueous polysulfide solutions is a strong function of the relative and absolute concentrations of the added components (21). Therefore, we investigated the effect of nominal polysulfide composition on the I-V characteristics of $n\text{-CuInS}_2/\text{polysulfide}$ cells. Figure 9 illustrates the marked differences for CuInS_2 in two solutions. From systematic studies, we found that optimal power conversion efficiencies are obtained for solutions with $[\text{S}]/[\text{S}^-]$ between ca. 1.5 and 3. For CuInSe_2 , the optimum value for this ratio was found to be around 1. The solution redox potential decreases with increasing $[\text{S}]/[\text{S}^-]$ ratio, but no systematic correlation between open-circuit voltages and redox potentials was seen, for either of the two types of photoanodes. Because no significant variations in dark currents were measured in different polysulfide solutions, it is likely that the solution composition dependence of the I-V characteristics is attributable to changes in relative concentrations of the oligosulfide species in the solutions, and especially their availability near the surface and their adsorption-desorption equilibria.

Temperature dependence of I-V characteristics.—Robbins *et al.* (4) first noted the strong positive temperature dependence of the $n\text{-CuInS}_2/\text{polysulfide}$ system. Their results were confirmed by us (5), and a similar behavior was found for the diselenide system (16). Figures 6 and 7 and Table III show for CuInS_2 that the temperature dependence is less pronounced if an electrode with better room temperature I-V characteristics is used. The same situation exists for CuInSe_2 , as shown in Fig. 8 and Table IV. This behavior is quite different from that found for solid-state photovoltaic cells, where the increase in short-circuit current is generally more than offset by decreases in open-circuit voltage and fill factor. It is also different from the temperature dependence of single-crystal and thin film $\text{CdSe}/\text{polysulfide}$ cells (22-24), where the power output goes through a maximum at temperatures slightly above room temperature. There the initial strong increase in short-circuit current was attributed to the temperature dependence of sulfur dissolution from the photoanode. Such an effect should depend on the current densities involved, as sulfur is the product of the oxidation reaction

Table III. Temperature dependence of $n\text{-CuInS}_2$ photoanodes

Sample A					
In 1/1/1 polysulfide; 98 mW/cm^2 illumination intensity

23	9.6	617	0.39	2.31	2.36
30	12.0	588	0.42	2.96	3.02
40	13.3	583	0.44	3.41	3.48
50	14.1	555	0.45	3.52	3.59
60	15.0	524	0.46	3.62	3.69
Increase (%)	56	-15	18	57	57
Sample B					
In 3/3/4 polysulfide; 89 mW/cm^2 illumination intensity					
19	14.2	540	0.41	3.14	3.53
29	14.8	550	0.44	3.58	4.02
39	15.3	550	0.47	3.95	4.44
49	15.9	540	0.50	4.29	4.82
59	16.1	535	0.50	4.30	4.83
69	16.3	530	0.51	4.40	4.95
Increase (%)	15	-2	24	40	40

occurring at the photoanode. Therefore, we checked the temperature dependence of the short-circuit current at low light levels. For CuInS_2 , experiments at 0.75 mW/cm^2 gave results similar to those obtained at 85 mW/cm^2 . At 55°C , the photocurrent was 0.11 mA/cm^2 ; at 23°C , it was 0.072 mA/cm^2 . Experiments on a number of CuInS_2 electrodes gave comparable results. The same holds for CuInSe_2 electrodes, where, for example, the same 40% increase in short-circuit current was found between 15° and 52°C , at 1, 5, 12, 36, and 100 mW/cm^2 light intensities. For polycrystalline CdSe electrodes, however, the temperature dependence of the short-circuit current decreases when lower light intensities are used.

It is interesting to note that a slightly negative temperature dependence is found for the $n\text{-CuIn}_3\text{S}_7/\text{polysulfide}$ (14) and the $n\text{-CuInSe}_2/\text{polyiodide}$ systems (7). A possible explanation may be the temperature dependence of specific adsorption processes involving oligosulfides or HS^- (21) occurring on the chalcopyrite surface in polysulfide electrolyte, but to a much smaller extent on spinel (CuIn_3S_7) surfaces, which are predominantly oxide free (14). With iodide solutions, completely different adsorption processes are expected. The very occurrence of a

Fig. 6. Temperature dependence of the photo-I-V curves of 2.4% efficient (at room temperature) $n\text{-CuInS}_2$ electrode in 1/1/1 polysulfide solution. The temperatures used are, in order of increasing short-circuit current: 23° , 30° , 40° , 50° , and 60°C . Illumination intensity is 98 mW/cm^2 (cf. Table III).

Fig. 7. Temperature dependence of 3.5% efficient (at room temperature) $n\text{-CuInS}_2$ electrode in 3/3/4 polysulfide solution. The temperatures are, in order of increasing short-circuit current, 19°, 29°, 39°, 49°, 59° and 69°C. The light intensity is 89 mW/cm^2 (cf. Table IIIb).

positive temperature dependence of the short-circuit photocurrent indicates that not all photogenerated holes are used for oxidation of sulfide. In the case of Cd chalcogenides, it was argued that such a mismatch between hole flux and electrochemical reaction flux will lead to self-oxidation of the semiconductor and thus to instability (25, 26). As we will see in the following section, this is not so for the $\text{CuInX}_2/\text{polysulfide}$ systems.

Output stability.—One of the most remarkable features of the $\text{CuInX}_2/\text{polysulfide}$ systems is their stability (4, 5). Previously, we reported results of initial experiments for both semiconductors. Further work showed the CuInS_2 system to be stable, even in a poorly stabilizing solution [cf. Ref. (5)] at various initial current densities (Fig. 10). The initial photocurrent density was regulated by changing the incident light intensity. While there is some decrease, which increases with increasing initial current density, the cell stabilizes after a short time rather than exhibiting the catastrophic decreases known for Cd-chalcogenide systems. The initial decrease is also a function of the efficiency of the electrode used (Fig. 12). Here, we compare two electrodes with optimal quantum yields, at 750 nm, of 0.7 and 0.4. Again, the situation is quite different from that known for CdSe, for example, where low efficiency electrodes will corrode more readily. Here only an initial decrease is found. Longer-term experiments, comparing an optimally prepared CdSe single-crystal electrode (27) with CuInS_2 bear out the differences clearly

Fig. 8. a(top): Temperature dependence of photo-I-V characteristic of $n\text{-CuInS}_2$ in polysulfide (3/3/4) solution. (Fig. 13). From detailed surface analyses, described elsewhere (15), we find that the CuInS_2 surface is at least partially covered with an indium oxide layer. This layer may well prevent direct contact between sulfide ions and the semiconductor, which could lead to further photocurrent deterioration. The initial decreases, observed here, might then be due to chemical changes of the surface or to the relative inability of the electrolyte to dissolve off S, the product of the photo-oxidation (28) (*vide infra*). Surface analyses show that for CuInS_2 in polysulfide solution no Se/S exchange is found (15). While at first sight this may not seem surprising, it should be remembered that this type of exchange takes place on CdSe, where it indicates the occurrence of semiconductor self-oxidation, *i.e.*, breaking of Cd—Se bonds. Also, the CuInS_2 initial decreases in photocurrent output are found at high light intensities (Fig. 14b) and in dilute solutions (Fig. 14c). For comparison, results for CdSe are shown as well (Fig. 14a), indicating apparent total stability at low photocurrent densities, but steady decreases at higher photocurrent densities, even for photoetched samples, *i.e.*, the most stable types of electrodes (27). In this case, the quantum efficiency of the CuInS_2 electrodes was deliberately kept low (0.4) by using electrodes whose surfaces were only partly optimized. This provided photocurrents of 16-18 mA/cm^2 at 100 mW/cm^2 , thereby allowing comparison with the structurally similar CdSe electrodes, which gave 13-15 mA/cm^2 under the same illumination. Here, as in the case of CuInS_2 , the photocurrent will return to its initial

Fig. 9. Photo-I-V characteristics of n-CuInS₂ in 3/3/4 (solid line) and 0.8/0.8/0.8 (dashed line) polysulfide solutions under ca. 80 mW/cm² white light illumination.

value if illumination is interrupted. The initial periods of decreasing photocurrents lasted from a few seconds, in solutions poor in S, to ca. 60s in S-rich solutions. Licht has shown (21) that the main difference between such solutions is the higher concentration of free hydroxide in the S-poor ones. For very dilute solutions (e.g., 0.8/0.8/0.8),

Fig. 12. Short-circuit photocurrent density as function of photocharge passed for two different n-CuInS₂ photoanodes in 1/1/1 polysulfide solution at 34°C. The solid line gives results for the less efficient electrode. The dashed line for the more efficient one.

this initial decline was followed by a much smaller decrease, lasting from 0.5 to 1h, after which the output current stabilized.

The initial output decrease was investigated in a systematic fashion, as it was found to be influenced by initial current density, solution temperature, solution composition, and initial quantum efficiency of the CuInSe₂ electrode. We can define a ratio J_s/J_i where J_s stands for the steady-state value of the photocurrent, reached after 1 min or less, and J_i stands for the initial photocurrent. Figure 15 shows the dependence of this ratio and of J_s on J_i . A linear decrease of J_s/J_i with increasing J_i is found for both electrodes, but the initial photocurrent at which the decrease (from 1.0) starts is higher for the more efficient electrode. The value of J_s/J_i increases with increasing temperature and with increased concentration of the solution. By varying only the concentration of added sulfur, a maximum value for J_s/J_i around $[S] = 1-1.5M$ was found for 1/1/[S] solutions. This value was still somewhat lower than that obtained for solutions containing higher concentrations of added OH⁻ and S⁻, e.g., 3/3/4. This behavior is reminiscent of that found for CdSe (28), where it was explained by the varying dissolving power, for sulfur, of the polysulfide solutions, as S could form a blocking layer on the electrode. It was shown, there, that this phenomenon occurs also at metal/polysulfide interfaces. It is likely that, at the high photocurrent densities encountered with CuInSe₂, a similar explanation holds. For some of the experiments at CuInS₂, the current densities would seem to be sufficiently low to minimize this effect. It is likely that there, and possibly also at CuInSe₂, the above explanation is too simplistic and the previously mentioned processes, i.e., surface adaptation to the solution, for example by forma-

Fig. 13. Short-circuit photocurrent density as function of photocharge passed for n-CuInS₂, (112) face exposed, and for n-CdSe, (1120) face exposed to the 3/3/4 polysulfide solution at 50°C. The CdSe crystal was photoetched to obtain the best possible output stability characteristics (24). The (1120) face of CdSe is more stable than the (0001) or (1000) faces.

tion of hydrated indium oxide (In(OH)₃, for example), and varying ad- and desorption of sulfides, need to be considered as well.

All the output stability tests described up to this point were carried out under short-circuit conditions, *i.e.*, no electrical power was extracted from the system. In the case of CdSe, it was shown that PEC is less stable at maximum power than at short-circuit, under identical illumination intensity (29). Therefore, it was imperative to check the output stabilities of n-CuInS₂ and n-CuInSe₂ under load conditions, and compare them to that of CdSe from which a comparable amount of electrical power was obtained. Table V summarizes these experiments. Except for the CuInSe₂ entry explained in footnote e, no systematic decrease in performance was found for CuInX₂ photoanodes. Whenever a lower final than initial photocurrent density is shown, the decrease occurred during the initial stages of the experiments (*cf.* Fig. 10-12, 14). In two cases, a higher final than initial photocurrent is indicated. Then an increase occurred during the initial stages of the experiments, and could be due to some "auto-etching" of the electrodes which were, apparently,

not treated optimally before starting the experiments. A similar phenomenon is, at times observed for Cd-chalcogenide photoanodes (27). The results shown in Table V indicate that the CuInX₂ photoanodes are stable against photocorrosion, even when they are used at potentials corresponding to their optimal power points, and when they are subjected to high light intensities. For example, the third entry for CuInSe₂ was run under an illumination intensity that corresponded roughly to 2-2.5× AM1 solar intensity.

General Discussion and Conclusions

The salient features of the work reported here are the apparent crucial role of the electrode surface in determining cell behavior, the involvement of the surface in the occurrence of kinetic limitations on the charge-transfer process, and the stability of these PEC's, notwithstanding those limitations.

To elucidate the role of the electrodes' surface, we carried out detailed surface analyses (15), which show that the top layer of electrodes, used in polysulfide, is composed mainly of indium oxide and is depleted in Cu. They also show that no Se/S exchange takes place for CuInSe₂. The effect of air oxidation can then be connected with the formation of a more complete, more stoichiometric indium oxide layer. Our fbp measurements show this layer to be an active participant in the charge-transfer process.

A central question concerns the nature of the processes that give rise to kinetic limitations on the charge transfer, as expressed in the positive temperature dependence. The effect of solution composition on PEC I-V characteristics and on the initial decrease in photocurrent suggests the involvement of the HS⁻ and/or oligosulfide species [S₃⁻ and S₄⁻ are those present in the highest concentrations in most of our polysulfide solutions; *cf.* Ref. (21)]. Because the optimal concentration ratios are similar to those found for CdSe (28), these effects can be interpreted in terms of the dissolving power (for the oxidized oligosulfide) of the polysulfide solution. Still, the different temperature dependences of CdSe and CuInX₂/polysulfide PEC's indicate that other factors are involved as well. The linear dependence of the photocurrent on the light intensity and the persistence of the positive temperature dependence of the I-V characteristics at low light levels show that the problem is not the availability of the oligosulfides near the surface. We suggest that the main additional factor is, rather, the thermally activated ad- and/or desorption of sulfides, as fbp measurements are consistent with adsorption of such species. The occurrence of chemisorption implies creation or annihilation of electronic states or changes in the population of existing ones, of the solid state. Thus, when we discuss (de)sorption processes, this includes such electronic effects in the solid itself.

^a Negative of the solution redox potential.

^b Initial and final photocurrent densities.

^c All CuInS₂ experiments were done in 1/1/1 solutions. All CuInSe₂ experiments and that with CdSe were done in 3/3/4 solutions.

^d Experiment was stopped because a leak in the protective epoxy occurred.

^e Auger analyses showed the presence of Cd on the surface, after the experiment. From scanning Auger microprobe maps, it appears that the presence of Cd is connected with that of S and O, i.e., it may occur as CdS and CdO. This phenomenon probably explains the steady, very small decrease in photocurrent shown by this electrode.

The initial, reversible decrease in photocurrent could be due to a diffusion-limited process in the electrolyte (including slow dissolution and/or desorption of the oxidized sulfide species, as for CdSe). Another possibility which can explain the slow shift in fbp of etched electrodes is that a solution-induced chemical change of the surface, e.g., to a hydrated oxide, In(OH)₃, takes place. The faster initial change in S-poor solutions can then be connected with the higher concentration of free hydroxide in them, as compared to S-rich solutions. The absence of S on surfaces of CuInX₂ electrodes, used in polysulfide, argues against the formation of mixed oxysulfides. The adsorption and desorption process will occur on this modified surface. The lack of a positive temperature effect for CuIn₃S₉/polysulfide PEC's can be understood from the absence of an indium oxide layer on CuIn₃S₉ electrodes.

The fact that the positive temperature dependence is less pronounced for more efficient electrodes indicates that other processes play a role, too. For example, the normal solid-state photovoltaic effect may have a negative temperature dependence that is stronger for more efficient systems, although no strong temperature dependence is encountered with the CdS/CuInSe₂ solar cell. Another possibility which might explain the positive temperature dependence is that the charge transport through the top indium oxide (hydroxide) layer is thermally activated; however, the fact that no positive temperature dependence is found with the CuInSe₂/polyiodide cell argues against this.

Summarizing, we can list three probable reasons for the kinetic limitations on the CuInX₂/polysulfide cells: (i) the S-dissolving power of the polysulfide solutions (as for CdSe); (ii) (near) surface adaptation, to In(OH)₃, for example; and (iii) thermally activated adsorption of HS⁻ and/or oligosulfides (S₃⁻, S₄⁻) and/or thermally activated desorption of their oxidized forms from the adapted surface.

Notwithstanding these limiting factors, both systems showed reasonable photovoltaic performances with 5 and 7.5% efficiencies at elevated temperatures for the disulfide and the diselenide, respectively.

We can ask now how the remarkable stability of these ternary chalcopyrite PEC's can be understood. On the basis of thermodynamic calculations, we expect less susceptibility to photoanodic corrosion for them than for CdSe, because of the position of their decomposition potentials with respect to the solution redox potential. Another factor may be the presence of the native indium oxide layer on the electrode surface. Such a film was found to provide improved performance and improved resistance against photocorrosion also for the n-CuInSe₂/polyiodide system (7). The role of the oxide layer can be to provide a phase where those photogenerated holes that are not transferred to the solution can recombine without causing decomposition. It is unlikely that all these photo-

generated holes will recombine in the oxide layer, which is rather thin [50-100Å, cf. Ref. (15)]. The bond strengths of the Cu—X and In—X bonds and the Cu d orbital character of the top of the valence band can be additional factors. Another aspect of the oxide layer is that it can stop field-assisted migration of positive ions from the bulk. The possibility exists, furthermore, that a photovoltaic solid-state junction forms at the oxide/chalcogenide interface; however, preliminary experiments have not yielded conclusive evidence for this, as yet.

Finally, we note the sensitivity of the performance of these photoelectrodes to surface treatment. It should be stressed that no complete reproducibility has yet been achieved and the effect of the various treatments described here becomes less pronounced the better the initial performance of the electrode. This is usually the case because any such surface treatment will be most effective for an electrode with a severely damaged surface, where there is much room for improvement.

It is obvious from our results that improved PEC's can be obtained with these materials, if solution-related limitations can be overcome. However, when attempting use of alternative or modified solutions, thought should be given to possible causes for photocorrosion. Such a line of action has recently proved effective for the iodide system, and, with increased knowledge of these materials and related ones, other systems should be achievable.

ABSTRACT

$n\text{-CuInS}_2$ and $n\text{-CuInSe}_2$ were subjected to surface analyses by x-ray photoelectron and Auger electron spectroscopy, after their use as photoanodes in polysulfide solutions. For CuInS_2 samples that had a poor (ca. 2%) conversion efficiency, a rather heterogeneous surface was found, with patches rich in In, which is probably present mainly as oxide. Some CuO was found as well, although the top layer was depleted in Cu, compared to a reference sample. More efficient (ca. 5%) samples showed a more homogeneous surface and even stronger Cu depletion. These changes are ascribed to additional surface treatments, viz., dipping in hot KCN solution and thermal oxidation of the resultant etched surface. For CuInSe_2 samples, no significant exchange of lattice Se by S from the polysulfide solution is seen, in sharp contrast to what is observed for CdSe or CdIn_2Se_4 . If sulfur is found, its presence could be correlated with the spurious occurrence of Cd (used as dopant) or Ag (used for the ohmic back contact). Cu depletion also occurs near the surface of the diselenide after use in polysulfide solution. Most of the remaining In seems to occur in indium oxide and/or indium selenide. Cu^{2+} was found neither here nor on the surface of the more efficient disulfide sample. It is suggested that the occurrence of an indium oxide top layer, aided by thermal oxidation of the electrode in the case of CuInSe_2 , has a beneficial effect on electrode performance.

One of the most remarkable aspects of photoelectrochemical cells (PEC's) of the type $\text{CuInX}_2/\text{aqueous polysulfide}$ ($X = \text{S}$ or Se) is their excellent output stability, even under high light intensities and near their maximum power point (1-4). In this, they defy the often accepted rule of thumb that only high bandgap semiconductors can be stable under the conditions of an operating PEC. Indeed, we can compare the CuInX_2 -based PEC's to those using CuIn_5S_8 (5), CdIn_2Se_4 (6), CdS (7), or CdSe (7) as photoanodes. For all of these systems, instability has been observed, either with simulated solar illumination or

in accelerated tests (cf. Fig. 1). For CdSe and CdIn_2Se_4 , this instability could be connected with the occurrence of Se/S exchange at the semiconductor surface (7). For CuIn_5S_8 , it was found to correlate to some extent with both Cu depletion from the surface and the presence of Cu-S-like phases at the surface, while for CdS (and CdSe) it could be connected with the formation of a rather disordered, microcrystalline, top layer. In all of these cases, these phenomena can be explained by breaking of chemical bonds (between Cd, Cu, or In and X) by photogenerated holes that reach the surface of the photoanode and which prefer to attack the semiconductor itself, rather than to oxidize the sulfide species present at the surface.

¹Present address: Israel Aircraft Industries, Ben Gurion International Airport, Lod, Israel.

Fig. 1. Comparison of the output stability of CuInS_2 and CdSe photoanodes in polysulfide electrolyte (1M KOH, 1M Na_2S , and 1M S^0 added reagents).

In the case of Cd chalcogenides, it was found that improved sulfur dissolution from the surface of the electrode (where S is formed as the product of sulfide oxidation), improves output stability of this system (7). The reason for this is probably that in such a case the probability of the hole attack on the semiconductor itself is decreased because of the increased probability of hole transfer to the solution species. For n- CuInSe_2 , transient photocurrent measurements indicated the existence of some imbalance between hole flux to the surface and hole transfer to the solution (8), which is exactly the criterion for instability of Cd-chalcogenides. With CuInSe_2 , however, no output deterioration could be observed.

This would seem to imply that hole attack on the bonds in CuInSe_2 is not successful under the normal conditions of operation for a photoelectrochemical cell. Indeed, the argument has been forwarded that participation of d orbitals of Cu in the top of the valence band of CuInSe_2 and CuInS_2 and of anion s and/or p orbitals in the bottom of the conduction band leads to some degree of localization of the bandgap photoexcitation on the Cu site and the anion sublattice (9). This implies that it weakens the chemical bonds less than in, for example, CdSe . This would explain the ineffectiveness of hole attack, as such a localization of the photogenerated electron-hole pairs would increase the probability that those that are not transferred to the solution will simply undergo recombination. However, it is well known from the studies of Kazmerski and co-workers that CuInSe_2 , at least, has an indium oxide film as the native oxide on its surface (10). It could thus be argued that this oxide layer fulfills some protective role, for example, by serving as a region with high probability for recombination which could decrease the quantum efficiency. The very high (0.9)-quantum efficiencies observed for CuInSe_2 (3), argue against this explanation. Another possibility is that the oxide film spatially prevents solution species from reaching the semiconductor proper, thus preventing them from stabilizing possible products of hole attack (e.g., Cu_2S or In_2S_3 , analogous to the formation of CdS on CdSe). The fact that in sulfide-less aqueous electrolyte some pH dependence of the flatband potential is seen (8) indicates that the oxide is not a completely passive element. A third explanation could be that the oxide serves to passivate defects, which would serve as centers for corrosion. At present, insufficient evidence is available to decide between these or other functions of this oxide film.

Notwithstanding the excellent output stability of the CuInX_2 photoanodes, scanning electron micrographs reveal that some surface restructuring occurs during their use in polysulfide electrolyte (Fig. 2). Therefore, we felt that analyses of the surfaces of CuInX_2 photoelectrodes that had been used in polysulfide solutions was needed to try to reach some understanding of the causes for their resistance to photocorrosion. Here we report on our results of such analyses, mainly by x-ray photoelectron spectroscopy. In future reports, we will deal with more detailed surface analyses of clean and etched CuInSe_2 , with analyses of the surface of electrodes used in polyo-

Fig. 2. Scanning electron microscopy pictures of the surface of n- CuInSe_2 . The increase in photocurrent density occurred during the initial stages of the experiment and is not uncommon in this system (8). Right: after subsequent acid etching of the surface, i.e., restoration to its initial state.

dide solutions, and with thermodynamic analyses of possible decomposition pathways.

Experimental

CuInS_2 and CuInSe_2 electrodes were prepared from Cd-doped crystals, as described previously (4, 8). They were etched in aqua regia, and, after rinsing with water, dipped in KCN solution to remove oxidation products. The CuInSe_2 electrodes were subsequently heated in air for 1 h at ca. 100°C . Polysulfide solutions were prepared from analytical-grade reagents: KOH, $\text{Na}_2\text{S}_2\text{H}_2\text{O}$, and S. Large area brass gauze counterelectrodes were used for two-electrode experiments. Some experiments were done under potentiostatic control, using a Pt wire as the reference electrode. All solutions were prepared and kept under inert atmosphere. X-ray photoelectron spectroscopy (XPS) spectra were obtained mostly on an AEI ES 200 B spectrometer, using Mg K_α (1253.6 eV) radiation, with $\sim 0.7 \text{ eV}$ linewidth. The samples were handled in a glove box attached to the spectrometer, which was made free of oxygen and water by cooling a Cu coil, situated in the glove box, with liquid N_2 , until condensation stopped. Both wide scans (1-1000 eV binding energy [BE]) and narrow scans (20-40 eV) were made. Ar ion sputter etching was done using an ion beam, situated at 60° with respect to the sample surface, operating with a beam current of 3-6 μA and 1 kV.

Some XPS and Auger (including scanning Auger microscope) analyses on less efficient samples, were performed on a PHI 549 spectrometer, using Mg K_α radiation for the XPS experiments and a 15 μm focused electron beam operated at 3 kV for the AES experiments. Some of the results on other samples, mentioned here for comparison, were obtained using PHI 550 or 590 (XPS or Auger) spectrometers.

Generally, the C_{1s} peak at 284.6 eV was used as an internal reference. From time to time, the calibration of the spectrometer was checked using the 4f lines of a Au sample.

Results

CuInS_2 .—Low efficiency electrodes.—The photoelectrochemical characteristics of these electrodes resembled those reported earlier by us (1). A typical sample yielded a photovoltage of 550 mV, a short-circuit photocurrent of 9 mA/cm^2 , and a fill factor of 0.36 under 86 mW/cm^2 white light illumination, corresponding to a 2.2% conversion efficiency. A sample was used for several hours as a photoelectrode under short-circuit conditions, in polysulfide electrolyte, and after it was rinsed in aqueous sulfide and water was inserted in the sample chamber (of a PHI 549 spectrometer). After measurement, the sample was sputter etched using an Ar ion beam. For comparison, a clean sample that had not been in contact with polysulfide so-

lution was measured as a reference. In Table I, we present the In and Cu Auger parameters for these samples, as well as for some binary In and Cu compounds. The Auger parameter, α , defined as the difference between a photoelectron energy and the corresponding Auger electron energy, is given here, because in this way uncertainty about the C_{1s} photoelectron energy for some samples is avoided. When both energies are measured in a normal XPS scan, where they will be expressed as "binding energies," $\alpha = \text{BE}(\text{photoelectron}) - \text{BE}(\text{Auger electron})$. It is customary to use $\alpha + h\nu$ (the x-ray photon energy), which equals the sum of the kinetic energy of the Auger electron (KE_A) and the binding energy of the photoelectron (BE_p) (11, 12).

In addition to the data presented in Table I, Auger microprobe analyses were done to obtain information on the spatial distribution of the constituent elements on the electrode surface. For the nonsputtered electrode, a heterogeneous surface was found, with oxygen-rich and sulfur-deficient regions a few tenths of a millimeter wide. These regions contained both Cu and In. Some correlation was found also between In and S. Thus it appears that the surface of this electrode had undergone some rearrangement, resulting in patches of Cu + In + O and In + S. This large-scale decomposition resembles the effect induced by 3 kV electron bombardment of a CuInS₂ surface, where residual oxygen was found to substitute for S in the areas exposed to the electron beam, yielding a composition formulated as Cu₂O · In₂O₃ (13). In our experiments, the surface heterogeneity was limited to the outer atomic layers only as the surface presented a much less varied composition after only ca. 40s Ar ion sputtering. After ca. 200s, it became essentially homogeneous, without any oxygen being present.

The XPS results given in Table I provide additional evidence for the difference in composition between the surface of a used electrode and its bulk. The In Auger parameter of the surface corresponds closely to that of oxidized In metal, i.e., a native oxide, while the Cu Auger parameter indicates the presence of Cu¹⁺ and Cu²⁺. The presence of divalent copper was verified by observing the Cu 2p spectral region, which contained the shake-up satellite lines, characteristic for this paramagnetic species (11, 12). In binary copper sulfides and selenides, the formal valence of copper remains fixed at +1 and that of the chalcogen varies (14). Therefore, we can conclude that the divalent Cu species is associated with an oxygen environment such as CuO or possibly Cu₂In₂O₅ (2CuO · In₂O₃). The Auger parameters and relative peak intensities after 200s Ar ion sputter etching agree with the values expected for CuInS₂. Thus only a very thin surface layer (estimated at some 20Å) has been affected, in contrast to what is the situation for CdS and CdSe electrodes that un-

derwent similar treatment (7). There, no appreciable deviation from stoichiometry or significant amount of oxides could be detected (7). Further clues to what might be happening at the surface of this latter type of electrode are found in results obtained from combined reflection electron diffraction, low angle x-ray diffraction, and scanning electron microscopy analyses on electrodes that had passed between 100 and 2500 C/cm² of photocharge. They show the formation of a highly polycrystalline top layer, surface roughening, and some charging in the electron beam. This behavior is consistent with the formation of an insulating polycrystalline phase on the electrode surface [cf. Ref. (1, 15)].

These results provide a ready explanation for the poor performance of these electrodes as they indicate a highly defect surface, which is expected to lead to low currents and fill factors, because of the presence of intra-bandgap states that will enhance recombination.

More efficient electrodes.—Surface analyses by XPS on these electrodes essentially bear out the conclusions obtained from the less efficient ones. The improved performance was the result of better control over the doping process and optimized surface treatments, which involved, after acid etching, dipping in hot (ca. 50°C) KCN solution (10% w/v) and mild heating in air at 70°-100°C for 1h. Such electrodes, when used in 3/3/4 polysulfide solution, gave the following "best" characteristics: 15.9 mA/cm² short-circuit current, 550 mV open-circuit voltage, and 0.5 fill factor at 49°C under 89 mW/cm² simulated solar illumination. This translates into a 4.9% conversion efficiency, i.e., a more than two-fold improvement over the samples described above. Table II summarizes XPS results for this type of electrode. Again, we include, for comparison, data on binary Cu and In chalcogenides. In addition, Table II contains some data on related ternary sulfides. Because data obtained on more than one instrument are included, and the In MNN Auger line was not always resolved well enough to allow a proper determination of the Auger parameter, we have chosen here to present the data mainly as the differences in binding en-

Fig. 3. XPS spectra of Cu 2p, In 3d, and S 2p in CuInS_2 . I: Reference. II: After etching in aqua regia, dipping in hot KCN solution, and heating in air at 100°C . III: after passage of 1340 C/cm^2 of photocharge at short circuit in polysulfide solution. The poorly resolved Cu 2p_{1/2} lines in traces II and III are a result of the low (II) to very low (III) Cu concentration on the surfaces of these samples.

ergies. For completeness' sake, the Cu 2p 3/2 and In 3d 5/2 BE's, referred to C_{15} at 284.6 eV, are given also. For CuInS_2 , these peaks and the S 2p ones are shown in Fig. 3.

Etched as well as polysulfide-used CuInS_2 electrodes differ from the clean CuInS_2 mainly in their In 3d 5/2 BE's, something that can be seen also from their values for $\Delta(\text{In-S})$. The rather small In 3d peak widths (cf. Tables I and II) suggest that for all these CuInS_2 samples only one type of In is present on the surface, although the similarity between In_2S_3 and CuInS_2 in terms of In and S BE's is such that the presence of In_2S_3 cannot be excluded. Because some broadening of peaks would be expected if both CuInS_2 and In_2S_3 were present, due to the occurrence of both tetrahedral and octahedral In coordination in In_2S_3 and only tetrahedral coordination in CuInS_2 , the presence of more than ~5% In_2S_3 is unlikely. In a way similar to the less efficient material, In_2O_3 or some type of oxidized In seems to be the dominant In containing species on the surface of etched or polysulfide-used samples.

The results for copper show that this element is now present in mainly one valence state only, namely Cu^+ , albeit at very low concentrations after etching and especially after use, in polysulfide, of the electrode (cf. Fig. 1). The widths of the peaks of used and of etched samples show more than one type of Cu^{2+} species on or near the surface. The presence of Cu_xS and/or Cu_2O can cause this peak broadening. For all etched samples that were studied, a high BE peak some 7 eV from the main S peak was observed. It is attributed to a SO_4^{2-} species, present only on the very surface as it disappeared after a short time of sputter etching. On samples that had been used in polysulfide, this peak could be discerned as well, though at lower relative intensity. Not only as regards the formation of sulfate does CuInS_2 resemble CuIn_3S_8 (5). Also, the Cu environment, with respect to sulfur, is similar in these two materials, as well as in CuFeS_2 and Cu_2S , and remains fairly constant for the different CuInS_2 surfaces.

Thus, while the two types of CuInS_2 electrodes studied (Tables I and II) behave similarly with respect to use in polysulfide solution, the higher efficiency ones are characterized by a better surface homogeneity, especially as far as Cu species are concerned. The absence of Cu^{2+} on this latter type of electrode may well be due to the action of the hot KCN solution, which will dissolve Cu^{2+} com-

pounds. Indeed, the overall amount of Cu on the surface was found to be less for the more efficient electrodes. Interestingly, this seems to boost electrode performance, or at least, to be connected with it. The decrease in Cu content, which is found also for other CuIn -chalcogenide photoanodes [cf. Ref. (5)] can be understood from the solubility of Cu sulfides in polysulfide solutions with the formation of CuS_4^{2-} salts (17, 19). This ability of Cu to dissolve as copper sulfide in polysulfide solutions was noted also by Hodes *et al.*, who found CuS , originating from the brass counterelectrode, on the CdSe photoanode in a PEC (19).

CuInSe_2 .—In view of the well-documented Se/S exchange on CdSe in polysulfide, especially when they are used as photoelectrodes (7), it was obvious to check if a similar process occurs on CuInSe_2 electrodes. Figure 4 shows the Se 3s and 3p peak regions for a clean CuInSe_2 electrode and for one that passed over 13 kC/cm^2 at ca. 35 mA/cm^2 short-circuit current after washing off the solution and of the same electrode after 10 min of Ar ion sputter etching. For comparison, the S 2s and S 2p peak regions from a clean sample of CuInS_2 are included as well. Clearly, no evidence for Se/S exchange is found. The very small amount of S that may be present on the surface (ca. 5%) is probably due to adsorbed species that were not removed by washing the electrode in sulfide (to dissolve off any sulfur) and in water. It is much smaller than that found for the "clean" reference sample, which probably contained some adsorbed sulfur as well. Thus no bond breaking appears to take place during operation of CuInSe_2 in polysulfide solution, in contrast to what is found for Cd-chalcogenides and for $n\text{-CdIn}_2\text{Se}_4$ (6). A short sputter-etch treatment (10 min) produces sharp Se 2s and Se 2p peaks, confirming our suggestion that only

Fig. 4. XPS spectra of Se 3s and Se 3p regions of CuInSe_2 samples. Ref.: clean sample. 0 min: After passage of 13 kC/cm^2 of photocharge at short circuit in polysulfide solution. 10 min: After 10 min of Ar ion sputter etching. The bottom spectra are the S 2s and S 2p regions of clean CuInS_2 .

a slight amount of adsorbed sulfur species is present on the surface of the used electrode. Some experiments on additional samples did show more S on the surface, but this was always accompanied by a foreign metal, Cd or Ag. In one case, the Cd used to dope the crystal appeared to have migrated to and segregated on the surface, where it, obviously, reacted with sulfide from the solution. Indeed, for that electrode some decrease in photocurrent (at -150 mV vs. the sulfide solution potential) was observed, while 42 kC/cm² of photocharge passed. On another sample which showed S on the surface, Ag was found as well. This comes from the Ag paint used in the back contact, and creeping of the Ag through defects in the epoxy/crystal contact is a problem that is, unfortunately, not uncommon during long-term experiments of this type. In that case, it is likely that the sulfur on the surface came from Ag₂S. In both these instances, sputter etching removed the Cd (or Ag) at a rate similar to the disappearance rate of S.

Figure 3 shows the Cu 2p and In 3d regions for the reference sample and the one that passed 13 kC/cm². In Table III, we summarize results for two samples of CuInS₂ and compare them to those of the related binary chalcogenides. The results for Cu indicate that it exists only in the +1 valence state, i.e., that CuO is absent. After use in sulfide, the results for the first sample show Cu depletion, which disappears after sputter etching. The shift in the indium peak may correspond to the presence of indium oxide, although the very small full width at half maximum (FWHM) shows that, if such oxide is present, it covers the surface completely and homogeneously. Sputter etching then restores the normal CuInSe₂ surface. Because of the similarity in $\Delta(\text{In-Se})$ between In₂Se₃ and cleaned CuInSe₂, it is not possible to exclude the presence of this binary selenide, after use of the electrode in polysulfide. This situation is different from that described for the disulfide, because the common form of In₂Se₃ contains tetrahedrally coordinated In, as in CuInSe₂. They differ only in the stacking arrangement of the Se layers, which is hexagonal, rather than cubic, for In₂Se₃.

On the second sample, for which results are given in Table III, some S was found on the surface. This was correlated with the presence of Ag (see above). However, the data for $\Delta(\text{In-O})$, $\Delta(\text{Cu-O})$, and $\Delta(\text{Se-O})$ (not shown) as well as the In 3d 5/2 BE values also suggest the presence of indium oxide here. After prolonged sputter etching, only adsorbed oxygen seems to occur on the surface and the CuInSe₂ surface is restored. The differences between the

$\Delta(\text{Cu-Se})$ values of the clean samples are due to the fact that the first, the reference, sample had been exposed to air for some days before measuring, and they indicate the presence of a fully formed native oxide (23). The values of $\Delta(\text{Cu-Se})$ and $\Delta(\text{In-Se})$ for the used, the second, sample are given for completeness' sake only, as they are influenced by the presence of S (cf. Se FWHM).

These analyses thus indicate that the (near) surface of used CuInSe₂ electrodes do not have the bulk stoichiometric composition; rather, there is a Cu-deficiency and probably some indium oxide.

General Discussion

The observed changes in the (near) surface region of the Cu-In dichalcogenides, after etching, after use in polysulfide solution, or even after prolonged exposure to the ambient at room temperature may be understood from the fact that three constituent elements are involved. All of the treatments described here are oxidizing ones, and, therefore, we have to consider what may happen to CuInX₂ in such oxidizing environments. While it is true that the acid etching, for example, will remove recombination centers, which did affect cell performance adversely, such a treatment will also lead to chemical changes on the surface, and these can lead to heterogeneity. We then can ask the question: what are the factors controlling the formation of the oxidation products, such as In₂O₃, CuO, Cu₂O, SeO₂, S, Se and Cu₂S, Cu₂Se, In₂Se₃, In₂S₃? The final composition of the top layer will be dictated not only by the chemical thermodynamics and kinetics of the preferred oxidation reactions, but also by the mutual solid solubility of oxidation products and ternary compound, the diffusion constants of the different elements in these compounds, evaporation rates and solubility of products in the acid etching, and basic polysulfide environments. Obviously, not enough information is available to allow a firm prediction as to what we can expect to happen. However, we can get some idea from known data, such as the enthalpies of formation, solubility in acid and in basic polysulfide, and ease of evaporation at low temperatures. Some of these are given in Table IV. The possible oxidation products of the chalcogen constituents, S or Se, and SO₂ or SeO₂ were not observed. The latter ones are quite volatile, while the former

ones would dissolve in polysulfide and would be further oxidized in acid or dissolved in hot KCN. The only chalcogen oxidation product that was observed was SO_4^{2-} , which could have precipitated as a basic sulfate.

Recently, Wager *et al.* (20) have considered the oxidation of CuInS_2 from a thermodynamic point of view, using the heats of reaction per gram-atom of the reagents or products as their guideline. They concluded that, when no kinetic limitations exist, the oxides or other oxidation products with the most negative heat of formation per gram-atom are indeed the most likely products. These are CuSeO_4 , In_2O_3 , and SeO_2 , with the formation of CuO and Cu_2O being only slightly less likely. They also noted that the very formation of oxidation products should impose kinetic limitations on the process, particularly with respect to Cu out-diffusion. [A recent study by Becker and Wagner shows Cu^+ to be the major diffusing species in CuInX_2 (21).] If this is taken into account, the likely products become Cu, In_2O_3 , and SeO_2 , with the probability of Cu_2Se or CuSe formation being somewhat lower. The formation of Cu_2Se has been reported (10) for CuInS_2 crystals and films that were thermally oxidized at temperatures between 150° and 300°C , but only in a thin interfacial layer between the surface film (of several hundreds of angstroms, composed mainly of indium oxide) and the bulk, *i.e.*, not in the surface film itself.

Under the conditions prevalent in a polysulfide PEC, CuSeO_4 should dissolve, Cu should react to give Cu sulfides (which can dissolve as alkali thiocuprates), and SeO_2 will dissolve. This leaves In_2O_3 as the oxidation product that is most likely to remain on the surface. Similar conclusions can be drawn for CuInS_2 , by repeating the calculations of Wager *et al.*, using S rather than Se oxidation products. Table V shows the six most probable reactions for the disulfide and the free energy changes per gram-atom in them. Thus, it is likely that during the oxidative etch, the mild air heating step, or during use of the electrode as photoanode, oxidation products of In will be formed. This is consistent with results from our surface analyses, and also with results obtained by Kazmerski *et al.* (10). It can explain the heterogeneity of the top layer and the high In/Cu ratios found for all samples, except those that were cleaned by sputter etching. Of all the possible In containing products, In_2O_3 is the only one that, at least in crystalline form, will not dissolve in acid. While the formation of Cu-oxides cannot be excluded, and evidence for CuO was actually seen for the low efficiency CuInS_2 electrodes, even if they are formed, they are likely to be removed from the surface during the acid etching step. As we noted in the Results section, the presence of binary sulfides or selenides [cf. Ref. (10)] cannot be excluded. If they would form during operation of the photo-

anode, they too could dissolve off as thiocuprates (17, 18). Finally, we cannot exclude the formation of mixed oxo-chalcogenides. If a heterogeneous top layer forms on the surface of these electrodes, either during etching or during their use in polysulfide solution, how will the presence of such a layer affect the performance of the photoelectrochemical cell containing these electrodes? A comparison of the surface analyses for the two types of CuInS_2 electrodes studied indicates that increased homogeneity, as expressed mainly by a lower Cu content, is related to increased efficiency. This increase is affected primarily through an increase in fill factor and short-circuit current. Thus, it is likely that heterogeneity introduced traps that led to recombination of photogenerated charge carriers. Clearly, the mere presence of a top layer different from the bulk material is not sufficient to cause a degradation in performance. Indeed, if this layer is thin enough and insulating, it may even increase the device performance (22). Apparently, in the case of the Cu-In-dichalcogenides, an air oxidation step or another type of mild oxidation affecting the whole surface is needed to create some kind of order in the mixture of possible initial oxidation products. The high quantum yields at short circuit, obtained for $\text{CuInS}_2/\text{S}_n^-$ and for $\text{CuInSe}_2/\text{S}_n^-$ (0.7 and 0.9, respectively) indicate that, when a sufficiently strong electric field is present, the charge carriers can pass the top layer. An additional or alternative explanation for the effect of the air oxidation step can be that a barrier forms between indium oxide and the bulk, and that this has a beneficial effect on the cell performance. Preliminary results on indium oxide/n- CuInS_2 structures (24) suggest that the magnitude of such a barrier is insufficient to account for the total photovoltaic effect observed here.

Summary

CuInS_2 .—XPS and Auger analyses on CuInS_2 photoelectrodes revealed heterogeneous patches, rich in In, on

Table V. Possible oxidation reactions of CuInS_2 and the corresponding free energy changes [after Ref. (20); data from Table IV (Ref. 29)]

Fig. 5. XPS spectra of the Cu 2p and In 3d regions of CuInSe_2 . Ref.: clean CuInSe_2 . 0 min: After passage of 13 kC/cm^2 of photocharge at short circuit in polysulfide solution. 10 min: After 10 min Ar ion sputter etching.

the surface of low efficiency photoanodes. These patches probably contain mainly oxidized In. Some Cu compounds, such as Cu_2S , Cu_2O , and CuO , may be present as well. On the surface of higher efficiency electrodes, a decrease in Cu content is found together with a better homogeneity of the top layer.

CuInSe₂.—No significant Se/S exchange is found in CuInS_2 photoanodes operated in polysulfide solution. If S is present, it can be correlated with Cd or Ag, the former a dopant, the latter one from the back contact.

The surface of CuInSe_2 electrodes used in polysulfide is depleted in Cu, and the remaining In may be present mainly as an indium oxide.

Acknowledgments

We thank the U.S.-Israel Binational Science Foundation, Jerusalem, Israel, for support of this research. We thank P. J. Ireland, J. R. Pitts (Solar Energy Research Institute, Golden, Colorado), for some of the XPS and Auger analyses on CuInSe_2 samples. We are grateful to W. Giritat (I.V.I.C., Caracas, Venezuela) for providing crystals of CuInS_2 and CuInSe_2 . Part of this work was carried out under the auspices of the Dutch-Israeli Cultural Exchange agreement.

Manuscript submitted May 18, 1984; revised manuscript received Jan. 16, 1985.

The Effect of Hydroxide Ion on Cd-Chalcogenide/Aqueous Polysulfide Photoelectrochemical Cells

Stuart Licht and Joost Manassen

Department of Materials Research, The Weizmann Institute of Science, Rehovot 76100, Israel

ABSTRACT

Alkali hydroxide, added to the aqueous polysulfide electrolyte in n-Cd chalcogenide/ S_x^{2-} photoelectrochemical solar cells (PEC's), is shown to be detrimental to cell performance. It is demonstrated that the added hydroxide increases visible light absorption in the polysulfide solution and decreases the solution lifetime. Even after compensation for the decrease in light transmission by the electrolyte, added hydroxide is shown to decrease the PEC photocurrent, photovoltage, and optical-to-electrical conversion efficiency. In a cell of 1 cm path length, the transmittance at 580 nm, for solutions containing 2*m* K_2S , 3*m* sulfur, and 0, 2, 6, or 12*m* KOH, was, respectively, 66, 55, 44, and 37.5%. Analysis of the distribution of ionic species reveals a shift from S_4^{2-} to S_3^{2-} with increasing hydroxide. Compared to S_4^{2-} , the peak absorbance of S_3^{2-} is shifted 50 nm toward the visible, causing the variation in solution spectral response with hydroxide. K^+ activity measurements were interpreted as indicative of increasing ion pairing with increased added hydroxide which may adversely effect charge-transfer kinetics. A measured negative shift in polysulfide redox potential with increasing hydroxide is evidently not paralleled by a comparable shift in Cd(SeTe) flatband potential, resulting in the observed decrease in open-circuit voltage. Relative conversion efficiency for an electroplated thin film $\text{CdSe}_{0.65}\text{Te}_{0.35}$ electrode was 36% less in polysulfide with 12*m* KOH compared to the PEC without added KOH. The electrode immersed in 2/2/2, 2/2/3, 0/2/3, or 0/1.3/2 (molality KOH/ $\text{K}_2\text{S}/\text{S}$) exhibited conversion efficiencies of 4.72, 4.80, 5.24, and 5.44, respectively, at 100 mW/cm² tungsten-halogen lamp illumination.

Cadmium-chalcogenide/aqueous polysulfide photoelectrochemical solar cells ($\text{CdX}/\text{S}_x^{2-}$ PEC's) were introduced as a potentially inexpensive method for solar-to-

electrical energy conversion. Yet, since their early inception, neither single-crystal (1) nor polycrystalline thin film (2) $\text{CdX}/\text{S}_x^{2-}$ PEC's have achieved solar-to-

electrical conversion efficiencies higher than 7-8%. Furthermore, CdX/S_x⁻ PEC operating lifetimes of greater than one year have yet to be proven. Little attention has been paid to the solution chemistry aspect of these cells, possibly due to the complexity of the aqueous polysulfide system. The aqueous alkali polysulfide system is known to contain, in addition to H₂O and alkali cations, OH⁻, H⁺, H₂S, HS⁻, S⁼, S₂⁼, S₃⁼, S₄⁼, and S₅⁼ (and perhaps HS_x⁻, x = 2-5). Nevertheless, the equilibria relationships for many of these species are known (3, 4). Recently, a computer model which incorporated these equilibria constants was developed to predict the distribution of ionic species in polysulfide solution upon input of the nominal sulfur, sulfide, and hydroxide concentrations in solution (5). The model provides simultaneous solution of the 11 equations which relate the species in solution. As exemplified in this paper, knowledge of the various species in solution allows for a systematic modification of the polysulfide electrolyte, and significant PEC improvements can result.

In addition to sulfide and sulfur, alkali hydroxide had been added, in molar quantities, to the aqueous polysulfide electrolyte preparation for CdX/S_x⁻ PEC's. This had been done in order to maintain a large concentration of sulfide in the solution according to the equilibrium

which has the equilibrium constant

$$K' = (a_{\text{S}^{=}} a_{\text{H}_2\text{O}}) / (a_{\text{HS}^-} a_{\text{OH}^-}) = K_2 / K_w \quad [2]$$

where K_2 is the aqueous second acid dissociation constant for H₂S and K_w is the water dissociation constant. Spectroscopic (6, 7) and potentiometric (8) studies indicate that K_2 is less than 10⁻¹⁷, which is many orders of magnitude smaller than previously thought. Therefore, little divalent sulfide will exist in solution, even upon sufficient hydroxide addition to increase the solution pH from 14 to 15.

Recently, we reported on the effect of alkali cations on CdX/S_x⁻ PEC performance (9, 10). This cation effect, combined with an optimization of the polysulfide electrolyte sulfur-to-sulfide ratio (11) and the effect of added alkali hydroxide reported here, has led us to the one of the highest sustained solar-to-electrical conversion efficiencies reported to date for a photoelectrochemical solar cell—12.7% (12).

Experimental

Electrolyte preparation.—Analytical-grade potassium hydrosulfide and sulfide are not available. Potassium hydrosulfide solutions were prepared by saturation of aqueous potassium hydroxide solution with H₂S

The reaction is exothermic and results in an increase in volume, a proportional mass increase, and a pH decrease, all consistent with Eq. [3]. Saturation with H₂S was monitored by mass change yielding 98.5 (±1)% reaction. Potassium sulfide is then nominally formed upon addition of equimolar hydroxide

Polysulfide solutions were obtained by addition of sulfur. Solutions were prepared with analytical-grade reagents and deionized, doubly distilled water and were prepared, stored, and utilized under argon to prevent solution oxidation.

Bulk electrolyte measurements.—Potassium ion activities were determined by measuring the potential response in solution of a cation responsive electrode couple (pM). The electrode couple consisted of a Beckman 39137 cationic selective electrode and a Radiometer K401 saturated calomel electrode (SCE). The pM cell potential, E_{M^+} , exhibits a nernstian potential response to cationic activity, a_{M^+} . In alkaline solutions containing only potassium salts, the pM cell responds only to cationic potassium (13)

$$E_{\text{K}^+} = E_{\text{K}^+}^0 + (RT/F) \log (a_{\text{K}^+}) + E_j \quad [5]$$

E_j represents the liquid junction potential arising over the solution/SCE interface. The pM cell was thermostatically maintained at 25.0° ± 0.1°C. The mean solution activities of aqueous potassium chloride and potassium hydroxide solutions are known (14) and were used for calibration of the pM cell. These measurements are summarized in Fig. 1.

Spectroscopic measurements were made in a UVIKON 810 spectrometer using a cell of path length 1 cm. Thermostatically controlled specific conductivity measurements were made at 25.0° ± 0.1°C using a Radiometer CDC304 immersion conductivity cell and a Radiometer CDM 2d conductivity meter, as calibrated with solutions of known conductivity.

Electrode preparation.—Thin films of CdSe_{0.65}Te_{0.35} were prepared by electrodeposition. A previous method for the electrodeposition process (15) resulted in electrodes which occasionally evidenced good light conversion performance, although the results were irreproducible. A more reproducible method was obtained by optimization of the experimental parameters. This modified procedure, described here, has reproducibly produced 1-20 cm² electrodes of 4-5% conversion efficiency, as measured in a 2*m* KOH, 2*m* Na₂S, 2*m* S electrolyte. The electrodeposition bath, prepared with deionized, doubly distilled water using analytical-grade reagents, is 1*m* in sulfuric acid, 0.0654*m* in 3CdSO₄ · 8H₂O, 0.02*m* in SeO₂, and 0.0058*m* in TeO₂. Upon dissolution of the SeO₂ and TeO₂, which takes several hours with stirring at 40°C, 2 cm²/liter of 10% Triton X solution is added.

The deposition substrate is prepared from a section of 0.67 mm thick Ti sheet which has been cleaned and immersed in 5% aqueous HF, until the sheet is uniformly corroded. On the sheet, a gray layer can be observed which is not removed, but only scratched with 220 mesh sandpaper. A substrate thus treated turns clear blue when heated for 2 min in an argon stream containing 0.5% oxygen at 630°C.

The blue substrate is immersed into the plating solution between a Pt auxiliary electrode and the SCE. The solution is not stirred, and at 40°C the potential is switched on at -700 mV vs. SCE and brought down to -650 mV within 30s. Plating is continued at this voltage for 40 min at a current density of approximately 7.5 mA/cm².

Fig. 1. The voltage response, as a function of solution activity, of a Beckman 39137 cationic selective electrode, measured vs. a Radiometer K401 SCE, in aqueous potassium hydroxide and potassium chloride solutions at 25°C. Solution activities are calculated from Ref. (9).

Electrode treatments.—The plated CdSeTe electrode is immersed in polysulfide solution to dissolve excess Se or Te and then annealed for 10 min in an argon stream containing 0.5% oxygen at 630°C. The electrode is photoetched (16) under 80 mW/cm² illumination at -1V reverse bias in (i) 0.1N HCl and then in (ii) 10N HCl, until the measured photoetching current decreases slowly. The photoetching procedure increases the photocurrent, as measured in polysulfide electrolyte, by up to fivefold.

PEC measurements.—Standard electrochemical equipment was used for obtaining the photocurrent vs. applied potential (I-V) curves data and redox potentials. A constant distance (5 mm) from the front wall of the test cell to the photoelectrode, and also a constant distance from the stabilized tungsten/halogen lamp to the photoelectrode, was maintained during the experiments. To insure that the observed I-V changes were reproducible and reversible, each I-V curve measurement was both preceded and followed by an additional I-V curve measured using the same electrode but in a polysulfide solution set aside for this standardization. The I-V measurements reported here represent the average of repeated results on two or more photoelectrodes.

Results and Discussion

The cation electrode couple response in a variety of potassium sulfide and polysulfide solutions is presented in Fig. 2. Accurate theoretical calculation or experimental measurement of the variation of the liquid junction potential in concentrated aqueous solutions is not available, although Licht has indicated that it is small in concentrated KOH solutions (13). Using the calibration provided by Fig. 1, potassium ion activities were calculated from Eq. [1], using the data in Fig. 2 and assuming zero liquid junction potential variation. The results are presented in Fig. 3 along with several other bulk properties measured in these solutions.

Activity coefficients larger than one in concentrated aqueous solutions result from immobilization of water within the sphere of ionic hydration. This decrease in free solvent concentration acts to raise activities. This is evident for potassium hydroxide in Fig. 3, in which activity coefficients of up to 25 are measured. In this figure, it can be seen that the measured potassium activities in sulfide and polysulfide solutions are depressed compared to the potassium activities in the hydroxide solutions. We attribute this, in part, to considerable ion pair-

Fig. 2. The voltage response, as a function of potassium ion concentration, of a Beckman 39137 cationic selective electrode, measured vs. a Radiometer K401 SCE, in aqueous potassium sulfide and polysulfide solutions at 25°C. The polysulfide solutions contain 2m potassium sulfide, 3m sulfur, and either 0, 2, 6, or 12m potassium hydroxide.

Fig. 3. The specific conductivity, potassium ion activity, and transmittance at 580 nm for various aqueous potassium hydroxide, potassium sulfide, and potassium polysulfide solutions. The activity results are at 25°C and were determined from data in Fig. 1 and 2. Spectral data were measured at room temperature. The specific conductivity results for polysulfide were measured at 25°C; those for KHS and K₂S are at 18°C and are from Ref. (22) and (23); those for KOH are at 15°C and are from Ref. (22). The polysulfide solutions contain 2m potassium sulfide, 3m sulfur, and either 0, 2, 6, or 12m potassium hydroxide.

ing in solution, similar to that observed in Ref. (10). Hence, it appears that the addition of potassium hydroxide to solution, by increasing the cation concentration in solution, increases the probability of sulfide or polysulfide ion pairing.

The specific conductivities of a variety of potassium hydroxide, hydrosulfide, sulfide, and polysulfide solutions are presented in Fig. 3. The high conductivity of the KOH solutions reflects the known high mobility of the hydroxide species (17). In all solutions, a near maximum conductivity is found at a 10m concentration of ionic potassium. In a polysulfide solution containing 2m K₂S and 2m S, the maximum specific conductivity occurs upon the addition of 6m KOH.

Polysulfide solutions absorb light strongly at near-UV and visible wavelengths. Therefore, concentrated polysulfide solutions act as cutoff filters for shorter wavelength light. This will diminish the amount of solar irradiation incident on the photoelectrode in aqueous polysulfide-based PEC's and thereby reduce conversion efficiencies. Surprisingly, it is seen in Fig. 3 that the relative transpar-

Table I. The calculated distribution of species within a polysulfide solution containing 2*m* potassium sulfide, 3*m* sulfur, and various concentrations of potassium hydroxide. The calculation is based on equilibria constants in Ref. (3) and (4) according to the method presented in Ref. (5). The activity coefficient of all species in solution is considered unity except for *F*, the activity coefficient for OH⁻ and K⁺, and *A_w*, the activity coefficient of water. *F* and *A_w* are the values for potassium hydroxide solutions of the same ionic strength (18)

ency of polysulfide solutions is a strong function of the added potassium hydroxide in solution. The 580 nm light transmittance, through a 1 cm path-length cell containing 2*m* sulfide and 3*m* sulfur, drops by half when 12*m* KOH is added to the solution. Similarly, these polysulfide solutions containing 0, 2, 6, or 12*m* KOH, exhibited 90% light transmittance at 615, 620, 635, and 640 nm, respectively.

Known equilibria constants (3, 4) and the known variation of aqueous potassium hydroxide mean solution activity (18) were incorporated into an iterative computer model (5). This was used to calculate the distribution of species in polysulfide solutions, containing 2*m* K₂S and 3*m* S, as a function of added hydroxide in solution. The results of these calculations, presented in Table I for 25° and 60°C, show that the main ionic components of these solutions are K⁺, OH⁻, HS⁻, S₃⁼, and S₄⁼, and, additionally in the polysulfide solutions with concentrated KOH, S⁼ and S₂⁼. The distribution of species is not a strong function of temperature. It also is seen in the tables that a primary effect of the addition of hydroxide is an increase in the S₃⁼-to-S₄⁼ ratio with increasing hydroxide. The S₄⁼ species displays peak absorbance at 368 nm, the S₃⁼ species, at 417 nm (19). The transmission measurements in Fig. 3 reflect the long wavelength shoulders of these peaks. Hence, as an increasing hydroxide concentration is added to these polysulfide solutions, the concentration of S₃⁼ increases, which shifts the solution transmission spectra from the near-UV toward the visible and significantly decreases the transparency of the solution.

Thermodynamically, aqueous polysulfide solutions are unstable. Giggenbach observed that polysulfide spontaneously disproportionates in solution according to the reaction (20)

The half-life of a polysulfide solution may be defined as the time for half of the free sulfur (as polysulfide) to disproportionate. This time, *t_h* (s), is given by (20)

$$t_h = 0.173c_s(a_{HS^-})^2[(10.9 - 5600/T)a_{OH^-} - a_{S_5^{=}}]^{-1} \quad [7]$$

where *c_s* is the concentration of sulfur initially added to the solution and *a_{HS⁻}*, *a_{OH⁻}* are the activities of HS⁻ and OH⁻ in solution, and *T* is the temperature in degrees Kelvin. Temperatures over 60°C have been measured for CdX/S_x = PEC's operating under normal insolation (21). At these temperatures, the calculated useful half-life of polysulfide solutions is seen in Table II to be strongly limited by adding hydroxide, decreasing from 442 to 12 days in solutions with 0 and 12*m* KOH, respectively.

Potentiostatic current-voltage measurements were made for illuminated 1 cm² CdSe_{0.65}Te_{0.35} electroplated thin film electrodes immersed in a variety of polysulfide solutions. These results are presented in Fig. 4, in which a cutoff filter was used to eliminate light of wavelengths below 665 nm, and also in Fig. 5, in which the full spectral output of the lamp was incident on the cell. Use of the cutoff filter negated differences in light absorbance by the different polysulfide solutions.

Redox potentials of polysulfide electrolytes prepared with 2*m* K₂S and 2*m* S, as a function of added KOH concentration, are also included in Fig. 4 and 5. It is seen that the redox potential of the bulk electrolyte becomes increasingly negative with increasing hydroxide. If one makes the assumption that the flatband potential of the Cd(SeTe) photoelectrode remains approximately the same in each of these solutions, then this should be reflected in an open-circuit voltage, *V_{OC}*, which decreases with increasing concentration of added hydroxide. In Fig. 4, this is indeed seen to be the case.

In Fig. 4, the variation of short-circuit photocurrent, *I_{SC}*, is shown to decrease as a function of increasing added KOH in the potassium polysulfide solution. This depression of *I_{SC}* with increasing hydroxide may be attributed to one or more of the following effects. (i) The activity results presented indicate that ion pairing increases with hydroxide concentration. This will remove photo-oxidizable species from solution, and thereby diminish the rate of charge-transfer kinetics and the measured current. (ii) As we have shown, increasing hydroxide will decrease S₄⁼ concentration in solution. If we hypothesize that the kinetically preferred photo-oxidized species is S₄⁼, then suppression of this species will decrease the rate of adsorption and again diminish charge transfer and the cur-

Table II. The calculated time for half the free sulfur to disproportionate to thiosulfate and hydrosulfide in polysulfide solutions containing 2*m* potassium sulfide, 3*m* sulfur, and various concentrations of potassium hydroxide. The half-life, *t_h*, is calculated from Eq. [7] using data from Table I

KOH	Nominal concentration (mol/Kg H ₂ O)			
	0	2	6	12
Calculated time of 50% sulfur disproportionation (days)				
<i>t_h</i> (25°C)	37,800	14,500	4,640	235
<i>t_h</i> (60°C)	442	179	68.9	11.9

Fig. 4. The variation, with potassium hydroxide concentration, of polysulfide redox potential and of various current- and voltage-related properties of an illuminated 1 cm^2 electroplated thin film $\text{CdSe}_{0.65}\text{Te}_{0.35}$ electrode in aqueous polysulfide solution at room temperature. $E_{S/S^{2-}}$, V_{OC} , V_{MP} , and I_{SC} refer to the polysulfide redox potential, the open-circuit voltage, the voltage at the I-V point of maximum power, and the short-circuit current, respectively. The light source was a tungsten halogen lamp with a cutoff filter to eliminate radiation below 665 nm . Illumination intensity was approximately 60 mW/cm^2 .

rent. (iii) An increase in OH^- species in solution may have some direct negative effect on charge transfer.

As seen in Fig. 4, the fill factor, calculated as the ratio of the maximum measured photopower to the product $V_{OC}I_{SC}$, shows a slight increase from 0 to $2m$ added KOH in the polysulfide electrolyte and then exhibits a sharp decrease with increasing hydroxide. Hence, the measured variations in V_{OC} and I_{SC} with hydroxide are expected to be generally additionally enhanced by the fill factor. This is reflected in Fig. 4 by the sharp optical-to-electrical energy conversion efficiency gains, for the CdSeTe photoelectrode, when a diminishing amount of potassium hydroxide is added to the polysulfide electrolyte. Note that there is no correlation between the specific conductivity of the electrolyte, presented in Fig. 3, and the variation in efficiency in Fig. 4.

In order to roughly simulate real operating conditions for these PEC's, performance was tested under nonfiltered artificial illumination at an intensity approximating peak insolation. These measurements are compiled in Fig. 5. As expected, the increasing light transmittance by the polysulfide electrolyte, with decreasing added KOH, produces an additional increase in relative I_{SC} . It can be seen, upon comparison to Fig. 4, that the relative increase

Fig. 5. As in Fig. 4, but the light source was a tungsten halogen lamp (without cutoff filter) providing an illumination intensity of approximately 100 mW/cm^2 .

in efficiency, with decreasing hydroxide, is also additionally enhanced. We point out that the magnitude of this additional enhancement is dependent on the proximity of the photoelectrode to the cell wall. The I-V curves for a 1 cm^2 electroplated CdSeTe electrode, at approximately 100 mW tungsten halogen illumination, immersed in polysulfide electrolytes, containing $2m \text{ K}_2\text{S}$, $3m \text{ S}$, and either 0 or $12m \text{ KOH}$, are presented in Fig. 6. There is a 36% relative increase in efficiency upon comparing the electrode in the polysulfide electrolyte with and without the added hydroxide.

Initial tests indicate that by not adding alkali hydroxide to the polysulfide solution, not only are solution lifetimes improved and CdX/S_x PEC efficiencies increased (and electrolyte costs reduced), but also the operating lifetime of the photoelectrode is extended. These results will be presented in a future publication.

An aqueous solution containing $2m \text{ KOH}$, $2m \text{ K}_2\text{S}$, and $2m \text{ S}$ is typical of electrolytes previously used in CdX/S_x PEC's. Some of the measured improvements, gained upon modification of this polysulfide electrolyte, are presented in Table III. Increasing the sulfur-to-sulfide ratio to 1.5 increases charge-transfer kinetics but decreases solution transparency (11). The first effect is evidently dominant; a relative improvement in electrode conversion efficiency is measured. However, the extent of this

Fig. 6. Current/potential curves of an illuminated 1 cm² electroplated thin film CdSe_{0.65}Te_{0.35} electrode in solutions 2m in potassium sulfide, 3m in sulfur, and containing either 0 or 12m potassium hydroxide, at room temperature. Scan rate: 10 mV/s. Tungsten halogen lamp illumination intensity approximately 100 mW/cm².

improvement depends on the proximity of the electrode to the front wall of the cell. An additional 9.2% relative efficiency improvement is gained employing an electrolyte without added hydroxide. As has been shown, this is a result of a decrease in solution transparency and an increase in both current and voltage light response of the photoelectrode. In situations where higher current densities are to be maintained by the electrode, the relative importance of improved charge-transfer kinetics should increase. Therefore, if the PEC were to be illuminated under concentrated light, or if electrodes of higher conversion efficiencies were employed, the relative increase in efficiency by removal of hydroxide is expected to be even higher. As can be seen in Table III, an additional 3.8% relative efficiency improvement is gained by maintaining the sulfur-to-sulfide ratio but removing total sulfur from solution. It should be noted, however, that this final efficiency gain is accomplished by decreasing the concentration of oxidizable polysulfide in solution, which may decrease mass transport in the solution and diminish photoelectrode lifetime.

Conclusions

Removal of the alkali hydroxide, which had always been added in the preparation of the alkali polysulfide electrolyte for CdX/S_r PEC's, has been shown to (i) decrease the solution absorbance of light, (ii) positively shift the redox potential, and (iii) increase the calculated disproportionation-limited lifetime of the solution. If alkali hydroxide is not added to the polysulfide electrolyte, improvements in PEC current, voltage, and efficiency are observed. These improvements are shown to be related to the calculated change in distribution of the species in the solution and to apparent ion pairing in the solution.

Analysis of the Transient Response of a Semiconductor-Electrolyte Circuit to a Short Light Pulse: Application to CdSe Electrodes

R. H. Wilson,^{*,1} T. Sakata, T. Kawai, and K. Hashimoto

Institute for Molecular Science, Myodaiji, Okazaki 444, Japan

ABSTRACT

A model to describe the transient response to a short light pulse of a circuit containing a semiconductor-electrolyte interface is presented. It is applicable to the case where charge separation across the depletion layer is fast compared to other processes. Rate constants for charge transfer and carrier recombination at the interface are introduced in the model, and the conditions necessary for measuring these are discussed. Experimental results using 10 ns light pulses on n-CdSe electrodes are used to demonstrate the validity of the model for properly prepared electrodes and to illustrate the role of semiconductor defects in masking interface reactions in improperly prepared electrodes.

The phototransient response of a circuit with a semiconductor-electrolyte interface has been investigated in a number of previous reports (1-4). Attempts have been made to use the experimental observations to obtain information about the rate constants for various charge-transfer processes at the interface. There is a need to describe these processes with a quantitative model that can be used as a guide in the interpretation of the experimental results. In this report, such a model is developed and applied to experimental measurements using an n-type CdSe electrode.

The model treats the system as a RC circuit with rate constants for charge-transfer processes. A short light pulse creates minority carriers in the semiconductor which rapidly move across the depletion region to change the potential across the depletion capacitance in a process faster than other processes in the circuit. Charge transfer across the Helmholtz capacitance, recombination of the photoexcited carriers, or charge redistribution through the external circuit then occur with their own rates. Information available in the resulting external signal depends on the relative values of these rates and the relative size of the depletion and Helmholtz capacitance.

Measurements with n-CdSe electrodes are used to support the applicability of the model. With a properly prepared sample, the transient decay is dominated by the circuit RC time constant at potentials more than about 0.5V positive of the flatband potential. Some of the properties of poorly prepared electrodes that can interfere with the interpretation of the observations are illustrated. Nearer the flatband potential, the transient decay is dominated by an interface recombination process. Light pulses that cause fewer than 10^{11} hole/cm² to be transferred across the depletion region are used so that the small signal approximation used in the analysis is appropriate.

Analytical Model

The circuit used is shown in Fig. 1a. No potentiostat is used. The potential is applied to R_v through a power supply (a battery circuit is used to avoid noise pickup through the power line), and the potential between the semiconductor and the reference electrode is read with a voltmeter using an isolated dc power supply.

A simplified circuit with the essential elements used in the analysis is shown in Fig. 1b. C_s is the capacitance across the depletion region of the semiconductor, and C_H is the Helmholtz capacitance at the semiconductor-electrolyte interface. R_i is the total, unknown series resistance internal to the cell, and R_e is the total, known series resistance external to the cell. Current generators across the two capacitors are labeled with k_s and k_H which will be used as rate constants and defined in the equations describing the charge-transfer processes. This circuit differs from those in Ref. (3) by the inclusion of the Helmholtz capacitance and the use of rate constants in place of re-

sistances. This allows physical interpretation of the observed rates.

The assumption is that a fraction of the minority carriers generated by the photons from a short light pulse incident on the semiconductor are moved across the depletion region in a time short compared with other processes to be measured. The remaining minority carriers recombine within the semiconductor. The time for this transport process is the shorter of the minority carrier lifetime or $(\alpha^2 D)^{-1}$ where α is the absorption coefficient of the semiconductor for the wavelength of light used and D is the diffusion coefficient of the minority carriers. Field-driven transport across the depletion region of the semiconductor occurs in a time on the order of $2\epsilon\epsilon_0/N_d u$, where $\epsilon\epsilon_0$ is the permittivity of the semiconductor, N_d is its doping density, and u its minority carrier mobility. This is generally much faster than the diffusion times discussed above.

For purposes of the analysis only deviations from the steady-state condition that existed before the light pulse will be considered. Thus, the initial condition will be a charge, Q_{SO} , on the depletion capacitance caused by the motion of the minority carriers across the depletion layer. Q_{HO} is zero. Due to the resulting potential, Q_{SO}/C_s , a current will flow through the external circuit with a consequent buildup of Q_H so that the magnitude of the current is determined by

$$\frac{Q_s}{C_s} + \frac{Q_H}{C_H} = i(R_e + R_i) = iR \quad [1]$$

Simultaneously, the excess minority carriers at the semiconductor electrolyte interface will begin to react to produce charge transfer across the capacitors so that

$$\frac{dQ_s}{dt} = -i - k_s(Q_s - Q_H) \quad [2]$$

and

$$\frac{dQ_H}{dt} = -i + k_H(Q_s - Q_H) \quad [3]$$

To avoid conceptual difficulties, it should be pointed out that the charge on the right side of C_s in Fig. 1b may be indistinguishable from that on the left side of C_H ; it is the difference in these two charges that is related to the photoinduced minority carrier density at the interface. Equations [2] and [3] can be combined to give

$$\frac{d(Q_s - Q_H)}{dt} = -k_s(Q_s - Q_H) - k_H(Q_s - Q_H) \quad [4]$$

It should further be noted that the charge transfer processes may be more complex than shown in Eq. [2] and [3]. It may be necessary to distinguish between holes in the valence band and holes in localized surface states. Furthermore, the availability of conduction band electrons is an important consideration in the value of k_s , and the availability of reducing agents in solution is an impor-

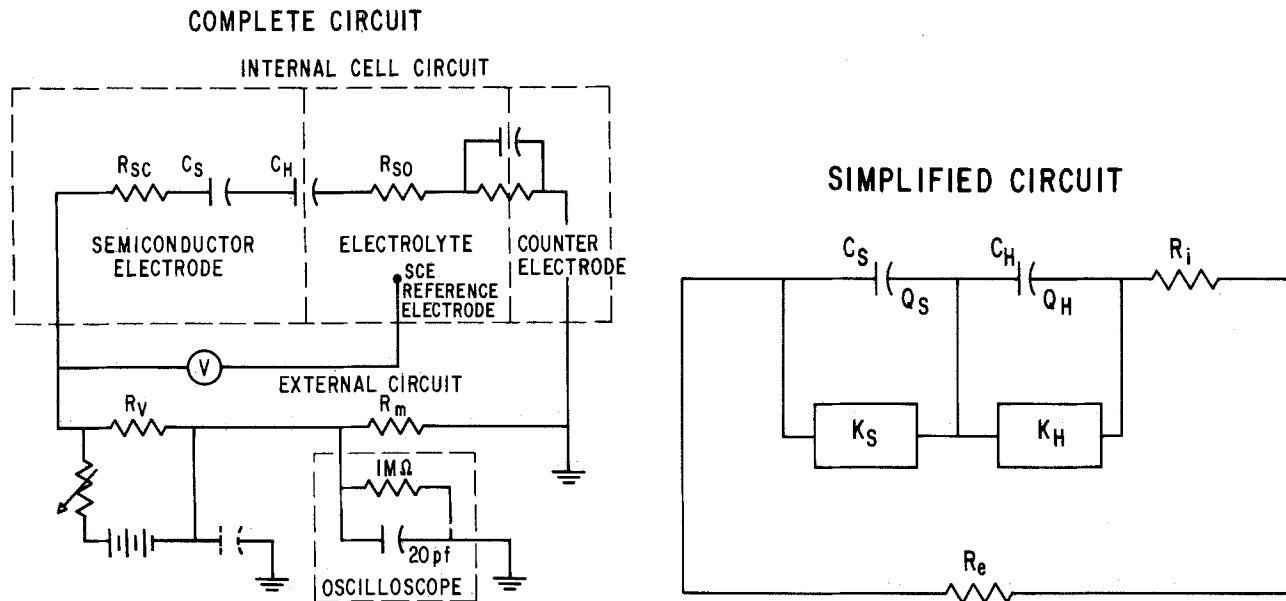

Fig. 1. a: Complete circuit for a semiconductor-electrolyte cell . b: Simplified circuit used in model

tant factor in k_H . Such refinements can be made as needed. The objective here is to illustrate the competition between the internal charge transfer rates and the external RC time constant for charge transfer through the external circuit.

Using Eq. [1]-[3], the initial conditions $Q_s = Q_{s0}$ and $Q_H = 0$, and the final conditions for large t of $Q_s = Q_H = 0$, the expression for the current in the external circuit becomes

$$i = Q_{s0} \left[\left(\frac{k_s}{RC_s} - \frac{k_H}{RC_H} \right) e^{-kt} + \left(\frac{k_H}{RC} - \frac{1}{R^2CC_s} \right) e^{-t/RC} \right] \quad [5]$$

where $k = k_s + k_H$ and $1/C = 1/C_s + 1/C_H$. The potential change across the depletion layer is assumed small enough so C_s can be considered a constant at a given applied voltage.

Equation [5] fulfills all of the intuitive expectations. In addition, it gives insights into the experimental conditions necessary to measure the rate constants. The initial value of the current is Q_{s0}/RC_s . For $kRC \gg 1$, i.e., a long time constant for relaxation through the external circuit (approximating a coulostatic condition), the internal charge transfer controls the current decay. If in that case $k_H \gg k_s$, the current will increase to $[1 + (C_s/C_H)]$ times its

original value, as the charge is now across a smaller capacitance, C , than it was originally. This can be seen in Fig. 2a for $C_s = C_H$. (For this change to be significant, C_s must be made comparable to C_H by low voltage across the depletion region, a high doping density, high dielectric constant, or a combination of these.) The current would eventually decrease through the external circuit with time constant RC. This case is also shown in Fig. 2a. As the RC time constant is decreased, it dominates the decay, leaving a small tail dominated by k_H .

If, however, $k_s \gg k_H$ and $kRC \ll 1$, the current would simply decay with time constant RC as shown in Fig. 2b. As k_s increases, however, the current decays to a negative value depending on the relative size of k_s and RC. This current then decays to zero with a time constant RC, as shown in Fig. 2b. This is the case that is addressed experimentally in this report.

Experimental Considerations

CdSe is a material widely studied for use in solar photoelectrochemical applications. Its transient response has been investigated previously (3) in the presence of sulfide ions. In the absence of sulfide or selenide ions in solution, the dominant photoelectrochemical reaction is a two or more electron process leading to cadmium ions in solution and a selenium layer on the surface of the electrode. An investigation of the kinetics of the corrosion process and the factors that affect it seemed appropriate. The CdSe crystals available (obtained from Cleveland

Fig. 2. Calculated response based on Eq. [5]. a: With $C_s = C_H$ for various values of RC. b: With $C_s \ll C_H$ and $k_s \gg k_H$ for various values of k_s

Crystals, Incorporated) were doped at about $10^{17}/\text{cm}^3$, making it difficult to achieve a C_j/C_H ratio large enough to study the charge-transfer process across the Helmholtz layer. Furthermore, the surface recombination process involved in the rate constant, k_s , can yield important information about intermediates of multielectron reactions (5). Therefore, the experimental conditions chosen approximated those of Fig. 2b.

The internal resistance of the cell is not readily measured directly. Assuming good ohmic contact, the electrode resistance for the samples used was expected to be about 2Ω . The electrolyte resistance was calculated to be few tens of ohms for the geometry used. As is discussed below, the total internal resistance was inferred experimentally to be about 10Ω .

Intensity of the light pulse is another important consideration. Pulses producing 10^{19} minority carriers per square centimeter have been shown to produce results that are not proportional to the number of photons. The model used here is not appropriate for that case. Light pulses of a few times 10^{11} photons per square centimeter were found to produce currents proportional to the number of photons. The size of the signal is 100 mV or less, so the change in sample bias is not excessive but the signal is still measurable. (At low band bending potentials, the signal was maintained even lower to avoid excessive perturbations of the applied potential.) Furthermore, by using a small number of photons, the minority carriers produce so few reaction intermediates at the surface that a second oxidation reaction can probably be neglected.

Finally, the importance of the quality of the semiconductor electrode should be mentioned. Several electrode related factors can affect the time response measurements.

Minority carrier traps.—If these are present at a density high enough, the risetime will be delayed by the rate of emptying of these traps. If this rate is very slow, it can also affect the decay time of the signal.

Recombination centers in the depletion region.—The photogenerated minority carriers are not all at the semiconductor surface. They are distributed some distance into the depletion region. A high rate of recombination in the depletion region can control the decay of the signal. An experimental example is presented later.

Nonuniform doping.—If the doping of the semiconductor is not uniform, then linear Mott-Schottky plots are not expected and it is difficult to separate surface and bulk effects.

High leakage current.—If a localized low resistance path exists in parallel to other parts of the semiconductor, both the chemical and potential distributions can be different than assumed in the model and thereby can change the observed effects. The point to be emphasized here is that these electrode characteristics must be evaluated by independent measurements to assure that they do not interfere with the surface reactions effects that are being investigated.

In the experiments reported here, single-crystal CdSe wafers about 0.1 cm thick had GaIn contacts mechanically applied to one side and a copper wire attached with silver cement. The wire was fed through a glass tube, and the wire, tube, and semiconductor were potted in epoxy to make a seal leaving one surface of the electrode exposed. The exposed area was about 0.25 cm^2 . This assembly was mounted in a quartz cuvette with a platinum counterelectrode and a saturated calomel reference electrode mounted in a separate holder connected by a plastic tube.

The electrodes were connected in the circuit in Fig. 1a or to a potentiostat system for steady-state dark and photocurrent measurements. For capacitance measurements, a phase sensitive detector at 1000 Hz was used.

Experimental Results

The samples were first checked for dark-current, capacitance, and quantum efficiency in the potentiostatic

systems. If a dark current of more than about $1\ \mu\text{A}$ was observed, the phototransient measurements were erratic. Most samples gave quantum efficiencies of about 10-40% at the dye laser wavelength of 520 nm. An exception was a sample that had been baked for 10 min at 300°C in air to improve the GaIn contact. This sample gave a much lower quantum efficiency, and capacitance measurements indicated a very lightly doped surface layer. After a 6 min etch in aqua regia, however, this sample showed a good quantum efficiency, a linear Mott-Schottky plot and well-behaved, consistent phototransient results. Figure 3 shows Mott-Schottky plots for this electrode in 1N KCl and 1N KI. There is a negative shift of 200 mV in the intercept of the KI data compared to the KCl results. The slope indicates a doping density of $7 \times 10^{16}\text{ cm}^{-3}$. Under some conditions with continuous illumination, the Mott-Schottky plots shifted to more positive potentials. During pulse illumination, however, no shift was observed, so it is presumed that Fig. 3 gives the capacitance for the phototransient measurements.

When the sample was illuminated with a light pulse from a nitrogen laser pumped dye laser at 520 nm [the system has been described previously (2)], the voltage developed across R_m in Fig. 1a showed a single exponential decay when the sample was biased at potentials more positive than 0 V vs. the SCE. The voltage decay constant, τ , determined from $\exp(-t/\tau)$ was measured for different values of R_e with the electrode biased at $1.2\text{ V}_{\text{SCE}}$ in 1N KCl. Results for several of the lower values of R_e are shown in Fig. 4. The linearity shown there continues up to $20,000\Omega$. [The nonlinearity reported in Ref. (3) suggests that their decay was affected by the semiconductor itself.] Assuming that τ is determined by the RC time constant of the circuit, the slope shown gives a value of $C = 0.017\ \mu\text{F}$ compared to the value determined from capacitance measurements of $0.016\ \mu\text{F}$. The negative intercept on the R axis indicates an internal cell resistance of 10Ω .

Values of τ were measured as a function of electrode potential with an external resistance of $20,000\Omega$. The results of 1N KCl and 1N KI are shown in Fig. 5, where $1/\tau^2$ is plotted in analogy with a Mott-Schottky plot. The solid curves are calculated for $\tau = RC$ using the slopes and intercepts of Fig. 3 and the $20,000\Omega$ external resistance. It

Fig. 3. Mott-Schottky plots for properly prepared n-CdSe electrode in 1N KI and 1N KCl. Capacitance measured at 1000 Hz.

Fig. 4. Measured decay constant, τ , as a function of external series resistance, R_e .

can be seen that after some deviation at high potentials the data points fall on the predicted curve within experimental error until the potential is about 0.6V positive of the flatband potential. Examples of the observed signals are shown in Fig. 6. At the lower potentials, there is a dramatic increase in the decay rate and an accompanying departure from a single exponential decay curve. Figure 6b shows the negative current obtained with some samples reminiscent of the calculated behavior in Fig. 2. The behavior of the decay at low potentials depends on the history of the electrode surface and the electrolyte used in the observation. The investigation of these effects is incomplete and will be reported in a later publication.

Another electrode was prepared in the same manner except it was not baked and not etched. It showed quite different behavior. Its internal resistance was estimated to be 40Ω possibly indicating some contact resistance in the back contact. A calculated $1/\tau^2$ plot based on measured capacitance is shown in Fig. 7. Under illumination, there is a change in slope of this curve to about one-third of the dark slope. A plot of measured $1/\tau^2$ is also shown in Fig. 7. Significant discrepancies are apparent. The τ values plotted are slopes taken from the longer time constant after an initial, faster decay. These effects are believed to be due to trapping and recombination in the depletion region, as suggested earlier and discussed below. This difference between samples that were baked and not baked was reproduced in other samples. If an unbaked sample is etched, it does not give a single exponential decay, but the longer decay constant is that predicted by the measured capacitance and known resistance.

Discussion

The good agreement between predicted and observed values of τ shown in Fig. 5 suggests that at potentials

Fig. 5. Reciprocal of the square of the measured decay constant, τ , plotted (in analogy to a Mott-Schottky plot) vs. voltage (referred to a saturated calomel electrode) applied to the same electrode as Fig. 3 for 1N KI (circles) and 1N KCl (squares). The solid lines are calculated from Fig. 3 and 20,000Ω external resistance.

more positive than 0 V SCE the decay is determined by the RC time constant of the circuit. This is not surprising since for our samples $C_H \gg C_s$, so that even for large k_{H1} no effect of charge transfer across the Helmholtz layer would be observed. Furthermore, at these potentials, the

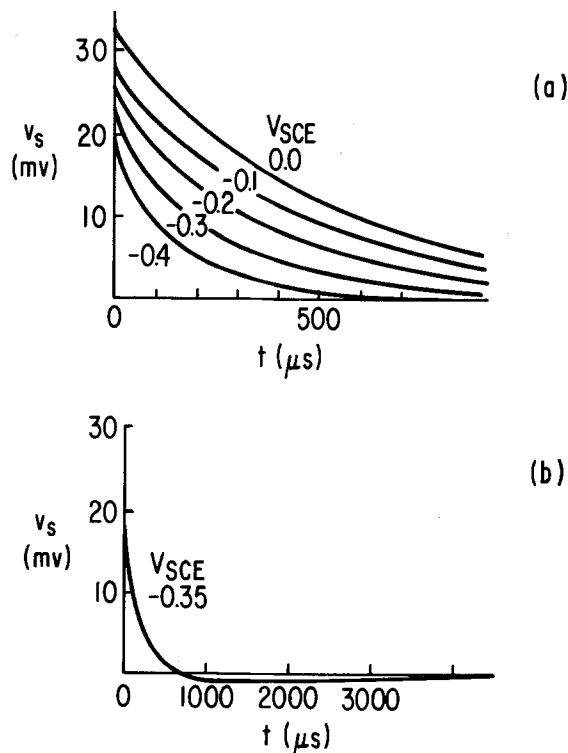

Fig. 6. Signal as a function of time after 10 ns light pulse as read on the oscilloscope of the circuit in Fig. 1a with $R_m = 20,000\Omega \gg R_v$.

Fig. 7. Plot similar to Fig. 5 for an n-CdSe electrode that was not adequately etched after polishing.

density of electrons in the conduction band at the interface, n_s , would be small so k_s would also be small, as will be discussed later. In addition, the lifetime of holes in CdSe is less than 10 ns, *i.e.*, less than the length of the light pulse. In other words, under these circumstances the model described earlier is applicable and predicts $\tau = RC$ as in Fig. 2b. As n_s increases at more negative potentials, however, k_s increases and the decay is no longer determined by RC. The model prediction of this is seen in Fig. 2b, and experimental observation of it shown in Fig. 6. Thus, in a properly prepared sample, transient measurements at low potentials can be used to obtain information about rate constants for reactions at the semiconductor-electrolyte interface through measurement of k_s . The relationship between k_s and rate constants is discussed in the Appendix.

If, however, the electrode is not properly prepared, substantial deviation from the model can occur. For our unbaked, unetched sample, not only is the decay faster than predicted, as seen in Fig. 7, but the decay is not a single exponential. At least two causes for these observations are possible. One is a nonohmic contact to the electrode which introduces another, unknown circuit element. Another possible cause is traps and/or recombination centers in a layer of the electrode near the electrolyte interface. Recombination at centers away from the interface can occur at potentials where the interface density of electrons is very small. Such recombination could cause a fast decay of the phototransient signal.

As mentioned before, the slope of the Mott-Schottky plot for the electrode of Fig. 7 changes slope under illumination. The change is consistent with a larger positive charge density in the depletion region. This could be due to photoexcited holes trapped in defects that could also give rise to recombination and consequently faster decay of the signal. While these measurements could be used to study defects in CdSe, they are included here to illustrate some of the effects that can interfere with using phototransient measurements to study surface reactions.

Appropriate criteria for samples to be used in phototransient measurements would be a single exponential decay and approximate agreement with predicted RC de-

cah times at potentials more than several tenths of a volt positive of the flatband potential for n-type electrode (or negative for p-type). Since this implies an independent measurement of the capacitance, a word of caution concerning frequency-dependent capacitance is needed. If a strong frequency dependence is observed, then the capacitance should be measured at a frequency on the order of reciprocal of the decay times being measured. (In some cases, such a frequency dependence itself could imply defects in the semiconductor.)

Conclusions

Within the constraints discussed, the model developed for the response of a semiconductor-electrolyte circuit to short light pulses correctly describes the observed photovoltage decay if the semiconductor itself is sufficiently free of defects. At low band bending, the majority carrier density at the surface is high enough so that a back reaction or recombination controls the decay. An approach to analyzing this process is developed in the Appendix, thus providing the basis for future use of these methods to study the kinetics of the process.

Manuscript submitted June 29, 1984; revised manuscript received Jan. 3, 1985.

APPENDIX

The general relationship between k_s and the physical parameters at the interface between the semiconductor and the electrolyte can be very complicated. A simplified relationship is developed here to illustrate the approach. The simplifying assumptions used may be appropriate for some experimental circumstances but must be evaluated before being used to interpret experimental results in detail.

Starting with Eq. [4], using $Q = Q_s - Q_H$ and assuming $k_H \ll k_s$ gives

$$\frac{dQ}{dt} = -k_s Q \quad [\text{A-1}]$$

Under these circumstances, however, the only mechanism for changing Q is the flux of electrons, F_n , in the conduction band of the semiconductor reacting at the interface, consequently

$$\frac{dQ}{dt} = -qAF_n \quad [\text{A-2}]$$

where q is the magnitude of the electronic charge and A is the area of the electrode.

Assume that there are interface states with an area density, N_0 , capable of capturing a hole from the valence band and that the area density of these states that have captured a hole is N_1 . The photogenerated charge is then distributed between holes in the valence band and holes in these interface states

$$\frac{Q}{qA} = Hp_s + N_1 \quad [\text{A-3}]$$

where p_s is the volume density of valence band holes at the semiconductor surface, and $H \approx WkT/2q$, where W is the width of the depletion region, k is Boltzmann's constant, and T is the absolute temperature. The value for H is obtained from

$$H = \int_0^\infty \frac{p dx}{\rho_s} = \int_0^\infty \exp\left(-\frac{qV(x)}{KT}\right) dx \quad [\text{A-4}]$$

Ignoring other possible electron reactions at the interface, F_n can be written

$$F_n = N_1 n_s \sigma_e v_e \quad [\text{A-5}]$$

where n_s is the volume density at the surface of electrons in the conduction band, σ_e is the cross section for capture of electrons by the interface states, and v_e is the thermal velocity of the electrons. Combining Eq. [A-1], [A-2], [A-3], and [A-5] gives

$$k_s = \frac{N_1 n_s \sigma_e v_e}{H \rho_s + N_1} \quad [\text{A-6}]$$

N_i is determined by kinetic expressions such as

$$\frac{dN_i}{dt} = (N_0 - N_i)p_s\sigma_h v_h - N_i n_s \sigma_e v_e - N_i p_s \sigma_p v_h - N_i k_r C_r \quad [A-7]$$

The first term of the right-hand side is the rate of hole capture by the unfilled interface states giving rise to the filled state; the second term is the rate of electron capture by these filled states; the third term is the rate of a second hole capture by the filled states, e.g., the second step in a corrosion process; and the fourth term is the rate of electron capture from a reducing species in the electrolyte with concentration, C_r .

These expressions can be used to interpret the transient decay measurements at low potentials.

ABSTRACT

The electrorefining of zirconium metal in alkali halide melts has been investigated. Variables affecting the electrodeposition process such as the composition of the electrolyte, the current density, and the configuration of the electrodes were studied. Two types of electrolytes were used: the alkali chloride-rich and the alkali fluoride-rich electrolytes. The various electrolytes are considered in terms of their ability to complex the soluble zirconium ions, a property which is important for the electrodeposition of coherent metal deposits from these melts. Crystalline zirconium metal of good quality has been obtained from fluoride melts containing NaF, LiF, and either ZrF₄ or K₂ZrCl₆ at about 750°C.

Nuclear-grade, hafnium-free zirconium metal is used in nuclear reactors for structural purposes and for containing the nuclear fuel. Zirconium is an irreplaceable component because of its very low neutron capture cross section.

With the expected depletion in the supplies of fossil fuels throughout the world, a shift toward nuclear energy seems inevitable and the demand for nuclear-grade zirconium is expected to increase dramatically. The metal is produced today exclusively by the reduction of zirconium tetrachloride with magnesium metal by the well-known Kroll process (1). In this method, the tetrachloride is reduced to zirconium sponge in closed reactors. Magnesium is particularly suitable, since it is readily available in an oxygen-free condition. The oxygen content is critical as 0.7% oxygen makes zirconium metal unworkable (2) and the specifications for reactor-grade zirconium call for a maximum oxygen content of 1000 ppm. In this sense, the closed reactor in the Kroll process ensures purity and the oxygen carried into the metal product depends on impurities present in the magnesium and the zirconium tetrachloride reagents. The latter must be anhydrous and freshly distilled.

High temperature electrolysis from molten salt baths containing ZrCl₄ has been proposed as an alternative to the Kroll process. For an electrolytic process to become truly competitive, however, it should be continuous, contamination from oxygen should be avoided at all cost, and the metal produced should be in the form of dense, coherent deposits with very low salt content. In this respect, electrolytic deposition of zirconium from aqueous solvents appears to be impossible (3), owing to the hydrolysis of all zirconium salts by water and to the high chemical reactivity of the finely divided zirconium metal.

* Electrochemical Society Active Member.

Electrodeposition from fused-salt baths is promising, although all efforts to date have yielded poorly defined dendritic or microcrystalline powdery deposits at low current efficiencies. A comprehensive review of the work prior to 1953 has been given by Steinberg and co-workers (4).

Mixtures of ZrCl₄ and ZrF₄ dissolved in alkali fluoride and alkali chloride melts were electrolyzed and produced a zirconium metal (5) deposit which was a nonadherent granular metal-salt agglomerate. Current efficiencies were about 50%. The granules in this deposit had a particle size of about 100 mesh and a large electrolyte "pull-out" factor—"one-third metal and two-thirds salt" (5). Thus, elaborate crushing and leaching procedures had to be adopted to remove the entrapped solidified electrolyte.

Tablets of zirconium oxide and carbon dissolved in a fluoride bath (6) upon electrolysis yielded a deposit that contained 2% oxygen.

Recently, Martinez *et al.* (7, 8) of the U.S. Bureau of Mines reported that ductile zirconium dendrites had been produced at 800°C from an electrolyte that contained NaCl-NaF-ZrCl₄. The current density used was about 3230 A/m², and 93% of the deposit granules had a particle size greater than 100 mesh. This deposit also contained salt and had to be leached. The average cathode efficiency was 76%. At such high current densities and high voltages (5.34V), it is likely that metallic sodium was also produced and that some of the sodium metal could have reacted with tetravalent zirconium to produce powdery zirconium metal.

Lebedeva and Baraboshkin (9-11) have also reported that Zr deposits could be obtained from chloride melts. Again, these deposits were in the form of coarse loose crystals.

In all of the preceding efforts, zirconium was deposited on a solid cathode. Attempts have also been made to deposit Zr on a liquid cathode, such as molten tin, copper, or zinc (12) from electrolyte containing fluorides. With the tin cathode, only a black amorphous powder was formed, which was dispersed throughout the electrolyte; also, a ZrSn alloy was produced. Similarly, powders and alloys were produced when a copper cathode was used. With a liquid zinc cathode, the deposit was an alloy of zirconium as well as unidentified lower-valency zirconium species.

A promising electrolytic process for the deposition of coherent zirconium metal was reported by Mellors and Senderoff (13, 14), who conducted the electrolysis in a melt of ZrF_4 dissolved in alkali fluorides. Most of the work was conducted in the NaF-KF-LiF ternary solvent, to which was added 10 weight percent (w/o) ZrF_4 . The most efficient plating conditions were at 750°C with the cathode current density at 100-300 A/m². However, the exact nature of the deposit has not been described.

In all-chloride melts, zirconium was electrodeposited as a powder mixed with a large amount of dark colored salt, and recoveries were very low (4, 7, 13). It was also noted that recoveries from fluoride melts were far from satisfactory.

In the case of electrodeposition from molten chloride baths that contain $ZrCl_4$, the entire electrolytic process is affected by the thermodynamic stability of the $ZrCl_4$ in solution and the related properties of solubility and volatility. Previous investigations (15-23) have established that the state of $ZrCl_4$ dissolved in alkali chloride melts is determined by the thermodynamic stability of complex compounds of the general formula A_2ZrCl_6 , where A is an alkali metal. These compounds melt congruently.

In the present study, an electrorefining cell was used to investigate the deposition characteristics of zirconium metal in molten alkali halide electrolytes. Electrorefining was chosen in preference to electrowinning mainly because the cathodic process, which is of primary interest in the deposition of the metal, is expected to be the same during electrorefining as during electrowinning. Also, electrorefining is becoming more important to industry, particularly in the treatment of the zirconium scrap metal. Finally, during electrorefining, complicating factors, such as depletion of the melt in zirconium, chlorine, or fluorine evolution at the anode, and technical problems

related to the separation of the anode from the cathode compartments are absent.

The research work was focused on two types of electrolytes: the alkali chloride-rich melts with small additions of alkali fluoride containing zirconium bearing compounds of the type A_2ZrCl_6 and the alkali fluoride-rich melts with small additions of alkali chlorides. By studying these two extreme cases, the behavior of the intermediate melts should be predictable.

Variables affecting the electrodeposition process, such as the composition of the electrolyte, current density, and electrode configuration were studied.

The structural characteristics of the deposits were determined by means of scanning electron microscopy and by optical methods. The purity and hardness of some deposits were also determined. Reducibility experiments in which zirconium metal is allowed to react with tetravalent zirconium in solution in a number of solvent electrolytes were also conducted.

Experimental

Zirconium tetrachloride used in this work was obtained from two sources: as spectrographic-grade $ZrCl_4$ available from Puratek MC/B Manufacturing Chemists and supplied in glass containers loaded under argon, and as reactor-grade $ZrCl_4$ purchased from the Teledyne Wah Chang Corporation. The later required further purification by the vacuum sublimation technique through molten tin, as described earlier (16).

Zirconium tetrafluoride of purity better than 99% was obtained from the Research Organic/Inorganic Chemical Corporation and was treated in a vacuum oven.

Cesium chloride of purity better than 99.9% was obtained from Cerac, Incorporated, and from the British Drug House Limited. All other alkali chlorides were of analytical grade and were dehydrated by heating under vacuum to 400°C. The alkali-metal fluorides were also of reagent grade and were treated in a similar way as the chlorides.

Zirconium metal rods of about 6 mm diam were of reactor-grade quality and, prior to use, were etched with a solution containing by volume 45% HNO_3 , 45% H_2O , and 10% HF (24).

Spectroscopic-grade graphite was used for electrodes. They were purified by heating in a silica glass tube under vacuum for about 12h at 900°C, followed by chlorination at 800°C, and then cooling under vacuum. A small amount of an oily impurity product was observed at the ends of the silica tube after completing the purification cycle.

Stoichiometric Cs_2ZrCl_6 and K_2ZrCl_6 were prepared by a method previously developed in this laboratory (15). K_2ZrF_6 and ZrF_4 were the commercially available compounds described earlier.

The furnace-cell assembly used in these experiments is shown in Fig. 1. The furnace was a resistance type with a Chromel wire element. The temperature was maintained constant with a Honeywell proportionating controller connected to a Chromel-Alumel thermocouple. The temperature in the furnace was constant to within $\pm 2^\circ C$, and a hot zone of about 15 cm could be established. This furnace could accommodate an electrolysis cell provided with a nickel crucible of about 10 cm diam having a capacity of 750 ml.

Special care was taken to exclude nitrogen and oxygen, for which zirconium metal is an excellent getter, from the environment of the cell, along with moisture which causes hydrolysis of the electrolyte components. Dehydrated and oxygen-free helium was used in all of the experiments for purging and as a blanket gas.

The cell assembly consisted of the following three main parts: the Inconel cell-crucible system, the upper quartz part, and the electrode cover assembly.

The cell-crucible system was made of an Inconel tube 60 cm long and 10 cm id. A brass fitting, furnished with an O-ring for vacuum-tight sealing, was attached to the top of the Inconel tube for connecting the two sections of the cell. The upper part of the cell was a quartz tube, both

Fig. 1. Furnace-cell assembly for the electrorefining of zirconium in alkali chloride-rich electrolytes.

ends of which were fitted with water-cooled brass plates and O-ring-type seals for vacuum-tight connections with the other parts of the cell. The cell was equipped with a sidearm feeding tube from which additions of solute to the cell could be made using a magnetically operated piston without opening the cell.

The electrode assembly consisted of the zirconium cathode surrounded symmetrically by three zirconium anodes. Electrical connections were provided by means of threaded 3 mm Inconel leads, onto which the electrodes could be attached. The cathode assembly was electrically insulated from the anode assembly by means of boron nitride spacers and it could be independently rotated to provide stirring of the melt. The electrode assembly could be lifted or lowered through sliding seals attached onto the cover plate. A spare plain cell cover plate bearing only an opening for loading the materials into the crucible was used during the initial stage of a run alternatively with the cover plate containing the electrode assembly.

The assembled cell was checked prior to use for leaks with a Veeco MS-9 mass spectrometer leak detector using helium as a tracer fluid.

Prior to a run, the assembled cell, except for the electrode-cover assembly, was heated under vacuum at about 400°C for approximately 12h and then cooled to room temperature under helium gas. The solid solvent salt mixture was loaded through the opening in the spare plain cover into the crucible, and the cell was quickly evacuated. The temperature was slowly increased over a 24h period to 450°C, when the salts were melted under vacuum and cooled to room temperature under flow of helium gas.

The electrode assembly was quickly positioned into the upper part of the cell, and the solute zirconium salt, which was either Cs_2ZrCl_6 , K_2ZrF_6 , or ZrF_4 , in the form of pellets was placed into the feeding tube. The cell was again evacuated with the electrode assembly raised into the upper cold section of the cell, and the temperature was increased until the salts were melted under vacuum. Purified helium was then introduced into the system, and the solute was introduced into the crucible. The addition of the zirconium bearing compound was done at this stage in order to avoid any thermal decomposition or losses of ZrCl_4 due to prolonged evacuation. The electrodes were then lowered to the desired depth and electrolysis was started.

At the end of the experiment, the electrodes were withdrawn from the melt, left for about 1h in the hot section of the cell in order to drain the entrapped salt, and then lifted to the upper part of the cell to cool.

A much simpler cell design was used for electrorefining zirconium metal in alkali fluoride-rich electrolytes. The cell assembly is shown in Fig. 2 and consists of a nickel tube closed at one end with a brass cover plate. This cell could accommodate a zirconium or nickel crucible of about 12 cm diam, having a capacity of about 250 ml.

The cell was checked for leaks prior to its use, and its ability to hold vacuum for extended periods of time was tested. The experimental procedure involved loading the crucible with the appropriate amounts of salts in the dry box and then lowering it into the electrolysis cell, which was immediately covered and evacuated. With the electrodes kept in the cold part of the cell, the salts were melted under vacuum. Purified helium was introduced into the cell, and the heating continued until the temperature of the melt reached the desired level. Then the electrodes were lowered to the desired depth and electrolysis was started.

At the end of the experiment, the electrodes were pulled over the melt level and left there to drain the entrapped salt. Then the electrodes were withdrawn to the cold part of the cell and the cell was cooled down to room temperature.

All experiments were performed using a constant current-constant voltage direct current power source,

Fig. 2. Electrorefining cell for zirconium in alkali fluoride-rich electrolytes.

having a voltage range of 0-15V and a corresponding current range of 0-10A.

At the end of a series of experiments the electrodes were cleaned in water and alcohol, air dried, and stored in stoppered test tubes. Sectioning of the electrodes was done by means of a low speed diamond saw using kerosene as lubricant. The specimens were mounted with "Koldmount" self-curing resin and polished in the conventional manner.

The microhardness of the polished samples was determined on the Krenton microhardness tester using a 100g load. Debye-Scherrer x-ray powder patterns were taken on electrodeposited zirconium using a copper target and a nickel filter. Energy dispersive analysis was also used to record the x-ray emission spectra of electrodeposited zirconium samples. A 20 kV accelerating voltage source and a current of 120 mA were applied.

The zirconium content of the deposits was determined by conventional wet chemical analysis. The metal was not analyzed for nitrogen or oxygen, but the content of the metal deposits in these elements could be deduced approximately from the microhardness measurements. The solubilities of zirconium metal in alkali chloride melts containing zirconium tetrachloride were investigated directly.

The experiments involved the measurement of the weight loss of zirconium metal which was reacted with alkali chloride melts as well as with alkali chloride melts containing known amounts of tetravalent zirconium added in the form of stable hexachlorozirconate compounds, A_2ZrCl_6 .

The cell used for the experiments is shown in Fig. 3; it consisted of a closed quartz tube separated into two compartments. A boron nitride, or an Inconel crucible, located in the lower compartment, constituted the reaction chamber. The two compartments were separated by a quartz porous fritted disk which allowed filtering of the melt and separation of any solid reaction product. Zirconium metal and the salt mixture containing Cs_2ZrCl_6 or K_2ZrCl_6 were loaded into the reaction cell in a dry box, the cell was evacuated, and its side arms were flame-sealed under vacuum. After heating for about 48h in a furnace at constant temperature, the cell was inverted inside the furnace and the melt was allowed to filter through the fritted disk. After solidification, the cell was opened in a dry box and the zirconium metal was weighed to

establish the solubility. In all cases, the reacted electrolyte was found to be reactive toward water and to evolve hydrogen.

Results

The results of the investigations on the electrorefining of zirconium in alkali chloride-rich electrolytes and in alkali fluoride-rich electrolytes are summarized in Tables I and II, respectively. The tables contain information on melt composition, temperature, cell voltage, current density, coulombic efficiency, and type of deposit.

The experiments were conducted using the following electrolytes: (i) CsCl-KF with soluble zirconium added in the form of the stable Cs_2ZrCl_6 compound; (ii) NaF-LiF in which the soluble zirconium was added as ZrF_4 ; (iii) NaF-LiF with addition of zirconium in the form of K_2ZrCl_6 or Cs_2ZrCl_6 ; (iv) NaF-LiF-KF eutectic, also called FLINAK, with additions of zirconium as K_2ZrF_6 ; and (v) NaF-LiF-KF (1:1:1 mole) and zirconium additions as K_2ZrF_6 .

The current densities shown were calculated on the basis of the initial geometric surface area of an immersed

electrode. However, as the deposit grows, the surface area increases substantially. Thus the current densities listed represent initial apparent current density values.

The evaluation of the quality of the deposits was based on external characteristics, as well as by the analytical techniques already mentioned. An excellent deposit would be smooth, shiny, and continuous, having a considerable thickness. This kind of deposit would be superior to the metal produced by the conventional Kroll process (25). Coherent, coarse dendritic deposits and the noncoherent fine crystalline portion of a deposit which could be collected separately on a diaphragm would also be acceptable (25).

The Table I summarizes the results obtained with solutions rich in CsCl. These melts also contained KF in amounts corresponding to KF/ Cs_2ZrCl_6 ratios from 4 to 12, respectively.

The zirconium metal obtained from run 2-a, shown in Fig. 4, is the best of this series and should be described as coarse dendritic, not too coherent, and rather reactive towards water. This deposit was similar to those obtained previously (26) from solutions of similar compositions. Contrary to expectations, the presence of fluoride ions appears to be detrimental to the quality of the deposited zirconium. As shown in Table I, higher KF/ Cs_2ZrCl_6 ratios in the electrolyte yielded powdery and noncoherent deposits. Previous investigators (10) attributed the adverse effect of the fluoride ions in mixed chloride-fluoride melts to their ability to inhibit the growth of large crystals.

Solidified electrolyte recovered at the end of electrolysis contained significant amounts of a black precipitate, which is indicative of the presence of zirconium species of lower valence. This electrolyte also reacted with water, and vigorous evolution of hydrogen was observed.

Reduced zirconium species may form either electrochemically or by the direct chemical reaction of tetravalent zirconium with the metal, following reactions of the type

where $4 > n > 1$. Anodic current efficiencies higher than 100% are clear indications of such chemical reactions.

The reducibility of tetravalent zirconium by zirconium metal and the presence of reduced zirconium species were confirmed in a separate series of experiments. These results are given in Fig. 5, as plots of moles of dissolved zirconium metal vs. the initial number of moles of $ZrCl_4$ present in a reaction cell. Some of our previous solubility measurements conducted in similar closed con-

tainers (26) are also included in Fig. 5. Dashed lines represent theoretical solubilities in accordance with various possible reaction mechanisms. The results indicate that the solubility of zirconium metal is related to the degree of reduction of the tetravalent zirconium in solution. The latter appears to be related to the size of the alkali chloride ion present in these melts. For example, solutions of ZrCl₄ in mixtures of NaCl-KCl, or in molten KCl, appear to have been reduced to monovalent zirconium, with a corresponding high solubility of zirconium metal.

Solutions of ZrCl₄ in molten CsCl are reduced approximately to divalent zirconium. The addition of KF or CsF further reduces the solubility of zirconium metal and the zirconium in solution appears to be in a trivalent state. It

should be noted that some of our previous solubility experiments (26) in the presence of either KF or KF and CsF were conducted in open-reaction cells for which equilibrium conditions could be doubtful.

The loss of metal due to the reducibility of tetravalent zirconium has also been observed elsewhere (27).

Alkali fluoride-rich electrolytes.—Table II shows the results obtained with the alkali fluoride-rich electrolytes. Deposits from this series of electrorefining experiments were of much better quality than those obtained from the alkali chloride-rich electrolytes. Metallic deposits were generally coherent and of nodular or dendritic morphologies. Dendrites, however, were quite large, and in some

Fig. 4. Dendritic zirconium deposit from run 2-a (Table I). The electrolyte was CsCl-KF-Cs₂ZrCl₆, the current density was 3.0 A/dm², and the temperature was 700°C.

cases "plates" or "flower"-like deposits of pure crystalline metal were obtained, indicating that the deposition of dense and coherent electrolytic zirconium is possible. It should be emphasized that this is the first time that such truly metallic large electrolytic deposits have been reported in the literature.

The observations from the experiments with the alkali fluoride-rich electrolytes with respect to the characteristics of the deposition process are summarized below.

Experiments 1-a to 1-e in Table II constitute a series in which the electrolyte was the eutectic NaF-LiF (40% mole NaF, melting temperature of 652°C) and zirconium tetrafluoride was the zirconium bearing solute. The container was a zirconium crucible, and no evolution of alkali metal during electrolysis was observed.

The applied potentials were in the range of only 140-420 mV, depending on the apparent cathode current density, which was in the range of 30-120 mA/cm or 3-12 A/dm². The solute concentration was the same for all the experiments, namely 5 w/o ZrF₄.

Each of the deposition experiments in the 1-a to 1-e series was conducted using new zirconium electrodes which were introduced into the same melt after the completion of a run. This was necessary, as it was observed that conditioning of the melt was a prerequisite for obtaining good deposits. Thus, in a series of experiments, the first two or three successive experiments yielded deposits of lower quality and low current efficiency.

However, after the melt had been conditioned, all subsequent deposition runs produced metal of higher quality. For example, in the 1-a to 1-e series, the quality of the deposits improved from coarse dendritic or nodular, for run 1-a to 1-c, to the type of deposit shown in Fig. 6 (for run 1-d). This deposit is continuous, appears to be dense and microcrystalline, and represents shiny metal of good quality.

Cathodic current efficiencies for these experiments were very low, and the anodic current efficiencies higher than 100%. Solidified salt samples after electrolysis reacted violently with acidified water and evolved hydrogen gas. The behavior indicates that reducibility reactions had taken place.

Runs in the 2-a to 2-d series in Table II corresponded to experiments having the same electrolyte as in series 1, except that the solute was the complex K₂ZrCl₆.

The deposits obtained from these experiments consisted of massive crystalline zirconium and of large plates of pure metal. These plates grew from the electrode surface as in experiment 2-d and are shown in Fig. 7a and 7b. In the case of experiments 2-b and 2-d, the plates originate from the dendrites which cover the parent electrode, as shown in Fig. 7a. The plates consisted of large crystals of zirconium metal and probably acted as a secondary surface for electrodeposition. The amount of entrapped salt in this part of the deposit was also insignificant. The formation of the plates may indicate field-oriented preferred electrodeposition, which is common in the electrodeposition of the refractory metals and has also been

observed recently by Schulze (28) during the electrorefining of niobium.

The well-defined crystalline nature of this deposit is seen in Fig. 8a and 8b, which include photographs of the cathodic deposit taken on the scanning electron microscope. The hexagonal zirconium crystals from experiment 2-d have well-defined faces and a columnar character which is characteristic for the unidirectional electrodeposition process. X-ray diffraction pattern obtained from a sample of this deposit were compared with patterns produced from a sample of reactor-grade zirconium metal and were identical.

Microhardness tests were also conducted. The mean Vickers hardness of the deposit (162 VHN) is comparable to the mean Vickers hardness of the parent electrode (160 VHN). This may indicate that the deposit contains acceptable levels of oxygen and nitrogen impurities.

From the viewpoint of melt conditioning, the following observations are pertinent.

The cathode current efficiencies vary from 0, as in experiment 2-a, which gave no deposit, to the highest value of about 92% for experiment 2-d. The anodic current efficiencies varied from 81 to 108%. The current densities were in the range 30-120 mA/cm² or 3-12 A/dm².

The calculation of metal recovery for individual runs may be misleading, since run 2-a gave no deposit while the anodic current efficiency was 81%. It appears that the dissolved metal was used either for the purification of the electrolyte from oxygen or for bringing the mean valence of zirconium in the melt to the proper value for electrodeposition. At the completion of the series of experiments, the metal recovery, calculated as the ratio of the amount of the electrodeposited metal to the amount of the metal dissolved, was of the order of 72%. Recoveries of zirconium metal in the range of 60-75% have also been reported recently (25) from an electrolyte consisting of NaCl-K₂ZrF₆.

In conclusion, the results of this series of experiments indicate that crystalline zirconium metal of acceptable purity may be obtained by electrolysis of fluoride solutions containing potassium hexachlorozirconate as solute. The potassium hexachlorozirconate can be easily prepared by reaction of zirconium tetrachloride vapors with solid or molten potassium chloride, thus making the electrorefining in these melts compatible with the presently employed zirconium extractive cycle. Furthermore, electrolysis in chloride-fluoride melts containing potassium ion is free of any alkali metal evolution as opposed to the all-fluoride melts to be discussed subsequently.

In experimental runs 3-a to 3-b, the electrolyte was again the NaF-LiF eutectic, but K₂ZrCl₆ was replaced with Cs₂ZrCl₆ as the zirconium bearing solute. The concentration of Cs₂ZrCl₆ in the melt was 5 w/o. As shown in Table II, no deposit was obtained. The applied current densities were 100 mA/cm² and 200 mA/cm², respectively. No alkali metal evolution was observed. In experiment 3-a, both electrodes lost weight.

It appears that melts containing Cs₂ZrCl₆ needed more time to be "conditioned" for successful electrodeposition to begin, although this was not understood at the time this system was investigated.

The final series of experiments were conducted in all-fluoride melts. For runs 4 and 5, the electrolyte was the eutectic of the ternary system KF-NaF-LiF, which is also called FLINAK. This electrolyte, containing 10% mole NaF, 45% mole KF, and 45% mole LiF, has a very low melting temperature of only 454°C. The zirconium bearing solute was potassium hexafluorozirconate.

The deposits obtained from run 4 were coarse dendritic with salt inclusions, as shown in Fig. 9, representing run 4-c. As shown in Fig. 10, representing run 5-a, the quality of the deposit improves as the concentration of the potassium hexafluorozirconate solute increases and the applied cathode current density decreases. The cathode current efficiency varied in the range of 18-97%, with the lower values associated with very high cathode current

Fig. 5. Solubility of zirconium metal in alkali halide melts containing Zr^{4+} as an alkali-hexachlorozirconate compound

densities. Again, cathodic deposition required the conditioning of the melt.

Potassium evolution was observed during these experiments. Potassium evolution during electroplating of zirconium in FLINAK has also been reported previously by Mellors and Senderoff (13) and was attributed to the exchange reaction

with the value of n close to 4. Their conclusion that the potassium evolution is not due to electrolysis is supported by the results in the present work. Thus in experiments where potassium fluoride is absent, as in runs 1-3, there was no evolution of an alkali metal. Also, in an at-

tempt to electrodeposit the metal from an electrolyte consisting of the KF-LiF eutectic, contained in a zirconium crucible, the evolution of potassium metal occurred as soon as the salt melted at 492°C with simultaneous total disintegration of the zirconium crucible.

The effect of the potassium metal evolution on an electrolytic process, as well as on the possibility of its industrial application, should not be underestimated. Apart from making the process difficult and dangerous to operate, it consumes valuable metal by eroding the anode and the cathodic deposit.

Excessive potassium evolution was also observed in runs 6 and 7, which utilized the equimolar ternary KF-NaF-LiF system having a melting temperature of about

Fig. 6. Dense, microcrystalline zirconium deposit from run 1-d (Table II). The electrolyte was NaF-LiF-ZrF and the current density was 9.0 A/dm². Temperature was 750°C.

670°C. Excessive dissolution of the anodes took place due to reaction [2], while the cathodic current efficiency was very low at the initial runs of this series. However, for run 6-d, the current efficiency had increased to its maximum value of 85% and the quality of the deposit improved following the same pattern. For this run, pre-electrolysis was also carried out with two graphite electrodes for 12h prior to the commencement of the actual electrolysis.

The scanning electron microscope photograph of a smaller "flower" type of deposit obtained in run 6-e is given in Fig. 11, and it indicates a columnar structure. With respect to purity, the results of the energy dispersive analysis on this deposit did not indicate the presence of

any other metal except zirconium. The mean Vicker hardness of the deposit was 156 VHN, which was even better than in the starting electrode materials, which had a mean Vicker hardness value of 163 VHN. This appears to indicate that by purifying the melt by pre-electrolysis, the oxygen level of the deposit is reduced.

Finally, run 7-a also gave an excellent, coarse, crystalline zirconium deposit which is shown in Fig. 12a, 12b, and 12c. The cross section of this deposit reveals the formation of a continuous coherent crystalline deposit of limited thickness. The smooth interface between the electrodeposited zirconium metal and the parent electrode is shown in Fig. 12c. The electrodeposition is interrupted, however, probably due to the evolution of potassium metal because of chemical reaction [2] between zirconium and potassium fluoride in the electrolyte. A well-grown large zirconium crystal from this deposit is shown in Fig. 12b. Unfortunately, because of the disintegration of the zirconium crucible, used as container in this experiment, it was not possible to determine current efficiencies. The present results can only be compared with the recent work at the U.S. Bureau of Mines (8) and with that on previous deposition work in this laboratory (26).

It should be noted that both studies were directed toward obtaining zirconium metal from all chloride salt baths. The deposits, however, were dendritic or powdery, loosely adhered to the cathode, and contained an excessive amount of salts. Deposits of better quality were obtained from cesium chloride-rich electrolytes. Small additions of fluoride have shown positive effect, although the quality of a deposit did not improve significantly (26). Additions of larger amounts of fluoride salt (up to 20 w/o) resulted (8) in the formation of flakes containing entrapped salt. Current efficiencies and metal recovery was of the same order as in the results obtained in this study.

Fig. 7. a: Large platelike zirconium deposit from run 2-b. Plates originate from dendrites in deposit. Current density was 5.0 A/dm². Electrolyte was a mixture of (NaF-LiF)_{eutectic} containing 10 w/a ZrF₄ at 750°C. b: Same melt as in a, except for current density, which was 12.0 A/dm². Massive platelike crystalline deposit from run 2-d (Table II).

Fig. 8. a: Microphotograph of zirconium deposit (X510) taken on the scanning electron microscope. This crystalline deposit from run 2-d is columnar and shows well-defined faces. b: The same as in a, except taken at a magnification of 3000. Well-defined hexagonal crystal growth is evident.

The results of the present study indicate that the fluoride-rich electrolytes are most promising as electrolytes for electrorefining of zirconium metal.

Discussion

With respect to electrodeposition from alkali chloride baths, the mechanism of the electrolytic process is affected by the solubility and the thermal stability of the solutions of $ZrCl_4$ in these melts, and particularly by the thermodynamic behavior of the complex compounds of the general formula A_2ZrCl_6 , where A is an alkali metal cation. The latter form when $ZrCl_4$ reacts with an alkali chloride in the bath.

The alkali metal hexachlorozirconates represent stable compounds in which the activities of the corresponding tetrachloride are particularly low. This is manifested by the dramatic reduction in the pressures of $ZrCl_4$ over the pure A_2ZrCl_6 compounds, shown in Fig. 13, which represents the temperature dependence of the partial pressure of $ZrCl_4$ in equilibrium with alkali hexachlorozirconates. As shown in Fig. 13, the vapor pressure of pure $ZrCl_4$, at $450^\circ C$, is about 25 atm (29), as compared to the partial

pressure of $ZrCl_4$ of 0.01 atm over the pure Cs_2ZrCl_6 at $450^\circ C$.

The thermodynamic stability of the A_2ZrCl_6 compounds, where A represents an alkali metal, may be related to the size of the alkali cation A^+ . In Fig. 13, the decomposition temperature of the alkali metal hexachlorozirconate compounds, which is defined as the temperature at which the partial vapor pressure of $ZrCl_4$ over the pure compound becomes 1 atm, increases as in the sequence $Li_2ZrCl_6 \rightarrow Na_2ZrCl_6 \rightarrow K_2ZrCl_6 \rightarrow Cs_2ZrCl_6$, i.e., as the size of the alkali metal cation increases.

The thermodynamic properties of these solutions were also investigated by vapor-pressure (15-23) measurements in the composition range that represented the subsystems $ACL-A_2ZrCl_6$. In this range, the equilibrium pressures of $ZrCl_4$ over the melts are determined by equilibria of the type

Any composition within an $ACL-A_2ZrCl_6$ subsystem may be realized if the applied tetrachloride pressure over the system is kept at the corresponding equilibrium value. It

Fig. 9. Condition of anode and cathode, respectively, after completion of run 4-c. Uniform wear of anode is indicated. Zirconium deposit on cathode is coarse dendritic with salt inclusions. Electrolyte was the $(KF-NaF-LiF)_{eutectic}$ containing K_2ZrF_6 (2.5 w/o). Current density was $21.7 A/dm^2$ at $750^\circ C$.

Fig. 10. Massive coarse dendritic deposit from run 5-a, at a high current density of $2.5 A/dm^2$. Electrolyte same as Fig. 9, except for K_2ZrF_6 content, which was 5.7 w/o.

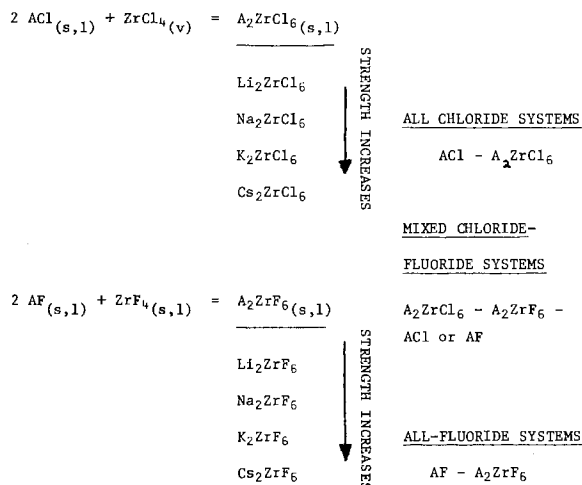

was also shown that solutions that contain $ZrCl_4$ in excess of the amount required to form A_2ZrCl_6 , i.e., in the composition range that represented the subsystem A_2ZrCl_6 - $ZrCl_4$, are extremely unstable and cannot be considered as potential electrolytes for zirconium electrolysis. The volatility of $ZrCl_4$ from such melts is excessively high.

The thermal stability of the pure A_2ZrCl_6 compounds and of the solutions of A_2ZrCl_6 and ACl at comparable concentrations increases with the size of the alkali-metal cation. In this sense, the solutions of $ZrCl_4$ in $LiCl$ are the least stable, and the solutions of $ZrCl_4$ in $CsCl$ are the most stable in this series. It should also be noted that the solutions of $ZrCl_4$ in alkaline-earth chlorides are even less stable than those in $LiCl$.

It is evident that in high temperature electrolytic cells in which the parts outside the furnace are at room temperature and act as a condenser, equilibrium conditions cannot be maintained, and industrially useful electrolytic solutions should have escaping pressures of $ZrCl_4$ of no more than 1-2 mm Hg. This requirement restricts the optimum bath compositions to those that contain less than 10 mole percent (m/o) A_2ZrCl_6 and to solvent melts that contain alkali-metal cations such as K^+ , Rb^+ , and Cs^+ .

The thermodynamic stability of the A_2ZrCl_6 complex compounds in solution also affects the solubility of zirconium metal. In consideration of the possible equilibria between Zr metal and Zr^{4+} species in solution, such as those given in reaction [1], it is reasonable to expect that the position of equilibrium for each reaction will be determined primarily by the state of the zirconium species having the highest valency. Melts that contain $ZrCl_4$ at low activity levels should also be expected to contain the least amounts of zirconium of lower valency. This is in agreement with the trends indicated by the reducibility results where solutions containing cesium chloride, in which the activity of $ZrCl_4$ is very low, were reduced to a lesser extent than those containing $NaCl$ or KCl .

With regard to melts containing fluoride salts, the latter introduce an additional element of stability. Again, within the alkali fluoride salt series, the thermodynamic stability of the compounds A_2ZrF_6 where A is an alkali metal cation should increase as in the order $Li^+ \rightarrow Cs^+$. From such considerations, the expected sequence of thermodynamic stability of Zr^{4+} ions in solution in alkali halide melts should be as follows

The probable anodic and cathodic reactions in an electrorefining cell may be written as follows.

1. For a chloride type electrolyte, the cathodic reaction is

and side reactions which could lower current efficiencies may be written schematically as

Fig. 11. Columnar structure of a zirconium deposit obtained from run 6-e. Microphotograph taken on the scanning electron microscope represents a magnification of 3300. Melt consisted of equimolar $KF-NaF-LiF$ and 5 w/o K_2ZrCl_6 . Current density was $20 A/dm^2$, at $750^\circ C$.

Redox electrode reaction causing lower current efficiencies could also be considered, such as

and so on. Disproportionation reactions of the type

which are thought to be responsible for producing metal powders, could also be part of the overall equilibration process.

The anodic reactions are the opposite of the cathodic processes. In the absence of diaphragms, mass transfer of reduced zirconium species should be taking place and could result in their oxidation to tetravalent zirconium at the anode. In this manner, electrons are consumed without gaining any useful metallic deposit, creating a "redox loop."

2. For a fluoride-type electrolyte, the main cathodic reaction may be written as

and the side reaction, in addition to possible Zr metal solubility and other redox schemes, should include the potassium evolution reaction [2].

All these equilibria depend upon the activity levels of the zirconium species in solution and could be controlled through choice of a solvent electrolyte having the appropriate salt components.

The potassium metal producing reaction is predominant in the all-fluoride electrolytes, containing potassium ions, as in runs 6-a and 6-d, because in such electrolytes Zr^{4+} are present at a very low activity state in the form of ZrF_6^{2-} .

To avoid potassium metal evolution, it is necessary to add some alkali chloride, which, in effect, increases the activity of Zr^+ ions, probably by an exchange reaction mechanism representing the equilibrium

which, however, introduces some zirconium metal reducibility side reactions. Thus, the conditioning of the electrolyte prior to electrodeposition is necessary for obtaining good zirconium metal deposits.

It appears that conditioning contributes to the purification of the melt and allows the formation of zirco-

Fig. 12. a: Coarse, crystalline, coherent and shiny deposit obtained from run 7-a. The electrolyte consisted of the equimolar mixture of KF-NaF-LiF containing 2.5 w/o K_2ZrF_6 . nium species having a mean valence, from which successful electrodeposition becomes possible.

The present results and, particularly, the chemical and electrochemical behavior of the molten salt electrolytes investigated in our laboratory appear to be consistent with these general comments.

Conclusions

The observations regarding the electrodeposition of zirconium metal from the alkali chloride and alkali fluoride melts used in the present study may be summarized as follows.

1. Zirconium deposits obtained from $CsCl$ - Cs_2ZrCl_6 melts, to which small additions of potassium fluoride were made, are dendritic in nature and highly oxidized.

The current efficiencies for the applied cathode current densities are very low. Although the melts contained potassium fluoride as a component, no potassium metal evolution occurred. The deposits, however, are of no commercial value. It is doubtful that crystalline zirconium metal can be obtained from these melts due to the formation of lower valence zirconium chlorides.

2. Truly crystalline zirconium deposits of very good quality were obtained from all-fluoride melts containing potassium ions. Unfortunately, the presence of potassium fluoride in the electrolyte, which is helpful to the electrodeposition process, is undesirable from the operation point of view, as it is thought to cause the evolution of potassium metal.

3. Crystalline zirconium may be obtained from fluoride melts to which potassium hexachlorozirconate

Fig. 13. Temperature dependence of the partial pressure of $ZrCl_4$ in equilibrium with the various alkali hexachlorozirconate compounds

has been added as a solute, such as those containing NaF-LiF-ZrF₄ or NaF-LiF-K₂ZrCl₆. Alkali metal is not generated from these melts, and the quality of the obtained deposits could be further improved.

It was found that the metal dissolves in significant amounts in melts that contain zirconium tetrachloride. In the presence of tetravalent zirconium, the degree of zirconium metal solubility depended on the type of the alkali chloride present, on temperature, and on the concentration of zirconium tetrachloride in the melt. The addition of fluoride salts generally reduced metal solubility, and appears to increase the average valence of zirconium in these melts.

Liquid-Line Corrosion of Nickel in Molten Sodium Carbonate

Venkatraman R. Iyer and Owen F. Devereux*

Department of Metallurgy and Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Liquid-line corrosion of nickel in molten sodium carbonate at 1000°C under reduced air pressures was measured as a function of time and of air pressure. The observed attack profile approached a circular arc whose depth increased parabolically with time. Attack depth increased with air pressure from zero under an inert environment, passed through a maximum, and decayed approximately hyperbolically at higher (subatmospheric) pressures. These observations are shown to be quantitatively consistent with rate control by the electron-transfer step of the cathodic process, reduction of peroxide.

During the course of a study of the polarization characteristics of the nickel electrode in molten sodium carbonate (1, 2), we observed marked liquid-line attack on a specimen that had been only partially immersed in the melt. The striking feature of this attack was the remarkably circular nature of the attack profile shown in Fig. 1. The study reported herein was initiated to determine whether such a profile was a reproducible feature characteristic of this process and to investigate the mechanism by which it was created.

Liquid-line corrosion is generally understood in aqueous systems in terms of an oxygen concentration, or differential aeration, cell in the meniscus region, in which ready access of oxygen to the electrode surface near the meniscus renders that region cathodic and, thereby, the electrode surface immediately below becomes anodic via reactions typified by

*Electrochemical Society Active Member.

and

The restricted geometry of the region of meniscus-electrode intersection, together with the close proximity of the anodic and cathodic regions, encourages hydrolysis of the reaction products

which may further isolate the anolyte, forming an "occluded cell" of low pH which continues to experience active anodic dissolution (3, 4). Similarly, the catholyte remains basic, allowing the cathodic region to be passive and enhancing the rate of dissolution in the anodic region (4). Pourbaix (5) has reviewed in detail the electrochemical features of such occluded cells in the general context of localized corrosion.

The partially immersed electrode has also served as a model for the gas diffusion electrodes of interest in fuel cell technology. Studies of hydrogen oxidation (6, 7) and

Fig. 1. Circular arc superposed on typical attack profile

of oxygen reduction (8) on platinum electrodes partially immersed in sulfuric acid have shown the electrode reactions to occur almost exclusively at a narrow region of the electrode surface just above the visible meniscus, presumed to be coated with a thin film of electrolyte. Similar results were found for oxygen reduction on silver and nickel electrodes partially immersed in aqueous potassium hydroxide (9). The rates of these electrode reactions were found to be dependent upon molecular and ionic transport processes in the thin film region and on charge transfer. Similar interfacial effects are seen in molten salts; Rahmel (10) observed enhanced dissolution of silver specimens partially immersed in neutral alkali sulfate melts, and attributed the effect to rapid oxygen transport through a thin electrolyte film coating the exposed portion of the specimens.

Experimental Program

All of our studies were conducted using nickel specimens partially immersed in reagent-grade sodium carbonate at 1000°C under partial vacuum (reduced air pressure). Specimens 1.5 cm long were prepared from Ni-200 (99% Ni) rod of nominal 1/4 in. diam (0.635 cm) and mounted to 1/4 in. (0.635 cm) od alumina support tubes with an alumina cement (Ultrabond 552, Aremco Products, Incorporated). Surface preparation consisted of grinding with 600 grit SiC paper, washing, and drying. The test cell was similar to that previously described for electrode polarization studies (1), consisting of a vertical 3 1/2 in. (8.9 cm) od closed-end mullite tube with a vacuum-tight closure from which the specimens were suspended. The melt was contained in a recrystallized alumina crucible also supported by the top flange. The cell was evacuated continuously by a mechanical pump; cell pressure was regulated by an air bleed valve and measured with a mercury manometer. Two sets of experiments were conducted: one to establish the effect of cell pressure, P , at a constant immersion time of 48h, and the other to establish the effect of immersion time at a constant cell pressure of 667 Pa (5 torr). At the end of each experiment, the melt was cooled and then dissolved in water to permit removal of the specimen. The specimen was then immersed in a saturated mercuric chloride solution for 48h to remove the oxide scale without further dissolution of metal. Following rinsing and drying, the profile of the attacked region was recorded as a scanning electron micrograph. Depth of attack as a function of position was measured directly on the scanning electron micrograph. In one exception to this procedure, the solidified carbonate was left intact, and the crucible containing the carbonate and specimen was sectioned vertically to establish the profile of the meniscus and its relationship to the region of corrosive attack. This specimen had been partially immersed for 24h at a cell pressure of 667 Pa.

Experimental Results

Specimens showed reasonably uniform attack around their circumference; however, there was significant variation in attack depth from specimen to specimen at the same pressure. Figure 2 shows typical profiles obtained at cell pressures of 667, 10,000, 20,000, and 40,000 Pa (5, 75, 150, and 300 torr), while Fig. 3-6 depict measured attack profiles for the several specimens tested at each pressure. The abscissa on these plots is a relative height, in that position relative to the melt meniscus could not be fixed with certainty save for the one test in which a section was made through the solidified carbonate. Several tests were performed in air at 1 atm and in nitrogen (Matheson Extra Dry, >99.9%) at 1 atm. Attack was slight in each case; a profile typical of the meniscus region of a specimen tested in nitrogen is shown in Fig. 7. The maximum depth of attack observed thus increases very rapidly from essentially nil in nitrogen to its maximum value at the lowest cell pressure tested, then decays to a small value in air at 1 atm. Attack profiles for specimens tested for various times at a cell pressure of 667 Pa are shown in Fig. 8-10, and Fig. 3, showing a somewhat less than linear increase in attack depth with time and the development of an approximately circular attack profile. The section prepared through the specimen and solidified melt is shown in Fig. 11, and Fig. 12 shows the measured meniscus profile superposed on the measured attack profile (the scale of the latter exaggerated) for that specimen. It is clear in this figure that anodic activity is confined to the upper portion of the meniscus, but that the anodic region does not extend to the top of the meniscus. There is no visual indication of a thin electrolyte film above the meniscus.¹

The tested specimens invariably displayed a black oxide scale, even in the region of anodic activity. The scale formed on the immersed portion of the specimen, however, was thinner than that on the portion not immersed. This thinning was found to be associated with dissolution of the oxide in the melt in the following experiment. Three specimens were oxidized in air at 1000°C for 6h. One of these specimens was subsequently immersed in a carbonate melt under vacuum for 24h at 1000°C, and a second immersed in a similar melt exposed to atmospheric air. Following this, all three specimens were cleaned, but not descaled, and then electroplated with nickel to provide mechanical support for the scale, sectioned, and polished. Average scale thicknesses, determined by SEM examination of the polished sections, were observed as follows: as-oxidized was 24 μm ; immersed in air-saturated melt, 4.4 μm ; and immersed in melt under vacuum, 0.5 μm . These observations indicate that the nickel oxide scale is dissolved to a limited extent by molten sodium carbonate, and that dissolution is enhanced by reduced air pressure. This is consistent with the existence of a nickelate species, e.g., NiO_2^- , soluble in the basic environment afforded by carbonate decomposition at low CO_2 pressures. A similar examination was made of a specimen that had been partially immersed in a melt under a reduced pressure for 24h without prior oxidation. On the nonimmersed portion of the specimen, the scale thickness was 14 μm ; on the fully immersed portion, it was 8.3 μm ; and at the site of maximum attack, 5.5 μm . This, together with the aforementioned observations on fully immersed oxidized specimens, suggests that scale thinning is enhanced at the liquid line by increased basicity

¹The line through the meniscus profile data is drawn according to the theoretical form (11)

$$\frac{x}{h} = \frac{1}{\sqrt{2}} \left[\cosh^{-1} \left(\frac{\sqrt{2}h}{z} \right) - \cosh^{-1}(\sqrt{2}) + 1 - \sqrt{2 - \left(\frac{z}{h} \right)^2} \right] + \delta$$

where x and z are the horizontal and vertical coordinates, respectively, $h^2 = 2\gamma/(\Delta\rho g)$ is the capillary constant, and δ is the thickness of a thin liquid film above the meniscus. The data in Fig. 12 correspond to $h = 3.756$ mm and $\delta = 0.08$ mm, whereas the expected value of h is 4.674 mm (12). The discrepancy is most obviously attributable to a lowering of the surface tension of the melt by adsorption of the various additional species present in the meniscus region, e.g., O^- , O_2^- , and Ni^{+2} .

Fig. 2. Pressure dependence of liquid line attack after 48h partial immersion. A: 667 Pa. B: 1×10^4 Pa. C: 2×10^4 Pa. D: 4×10^4 Pa

in that region due to cathodic production of oxide ion. The scale, as shown in Fig. 13, was observed to be bilayered; the outer layer was columnar and compact, while the inner layer was finer grained and porous. Wavelength

dispersive x-ray analysis (WDX) in the scanning electron microscope revealed that the scales contained nickel and oxygen; no sodium was detected. Similar observations

were made by Douglass on the structure of air-formed films on dilute alloys of chromium in nickel (13). The sectioned specimens also revealed considerable grain boundary attack; this is evident in Fig. 13 and also in Fig. 2.

Discussion

Three distinct forms of attack were seen in this study: a generalized attack above the liquid-line region (gaseous ambient), a generalized attack below the liquid-line region (liquid ambient), and a localized attack at the liquid-line region (liquid ambient). The first of these is mani-

Fig. 7. Specimen profile after 48h partial immersion under nitrogen atmosphere.

festes simply in a scale formation, but the latter two must, in general, be regarded in terms of both scale formation and scale dissolution in order to explain the occurrence of the thinnest scale at the site of the greatest metal loss. Such simultaneous scale formation and dissolution processes have been discussed previously (14, 15). The data reported in Fig. 3-6 and 8-10 represent the extent of localized liquid-line attack relative to general attack, the base line of these figures representing the postexperiment metal surface above and below the meniscus. Examination of the figures indicates that the extent of generalized attack is approximately the same in these two regions, the one immersed in the melt and the other in the gaseous ambient above the melt. The extent of scale formation above the melt is consistent with data reported by Philips (16) for gas phase oxidation of impure nickel. He reports a parabolic constant at 1000°C of $1.5 \text{ mg}^2\text{cm}^{-4}\text{h}^{-1} = 57 \text{ } \mu\text{m}^2\text{h}^{-1}$, which corresponds to the formation of an oxide layer $7.5 \text{ } \mu\text{m}$ thick after 1h and $52 \text{ } \mu\text{m}$ thick after 48h, and to a metal losses of 5 and $34 \text{ } \mu\text{m}$, respectively.

Fig. 8. Measured attack profiles for different specimens after 6h partial immersion at 667 Pa.

Fig. 9. Measured attack profiles for different specimens after 12h partial immersion at 667 Pa.

The observed $1/6$ power dependence of the parabolic constant on oxygen pressure (17) would cause only a variation of a factor of two over the cell pressures studied quantitatively in this investigation (667-101,325 Pa).

Given the p-type nature of NiO (18) and the ubiquity of scale formation in this system, it is likely that anodic oxidation in the liquid-line and subliquid-line regions is preceded by injection of cation vacancies at the oxide/melt interface

Fig. 10. Measured attack profiles for different specimens after 24h partial immersion at 667 Pa.

Fig. 11. Metallographic section through solidified interfacial region, showing region of maximum attack in relation to the line of three phase contact.

followed by their diffusion to the metal/oxide interface, where they are consumed in the anodic reaction

Scale dissolution in the basic melt may be represented by

again postulating the existence of NiO_2^{\ominus} in basic solutions, and may be presumed to be essentially independent of the anodic process. However, the rate and extent of such dissolution processes may, in general, be regarded as a function of the electric field at the scale/solution interface as well as of solution parameters such as basicity (14, 15).

The absence of significant attack under oxygen-free environments indicates that the cathodic reaction is reduction of dissolved oxygen, and the dependence of the extent of attack upon cell pressure further implies that the overall process is rate limited by the cathodic reaction. Dissolution of oxygen in carbonate melts has been observed to be non-Henrian, with formation of peroxide according to the reaction (19-23)

or

Fig. 13. Section through scale, showing two-layer structure and grain boundary attack in substrate.

if the equilibrium

is assumed, and superoxide according to the reaction (19, 21-23)

Reduction in carbonate cells is attributed to (20, 22)

or, assuming equilibrium [9]

and, at more negative potentials (22)

Although the dependence of the extent of liquid-line attack upon air pressure within the cell indicates control by the cathodic reaction on the overall process, it is difficult to argue that the localized nature of the attack is due to diffusion control by the cathodic reactants within the melt. We lack specific data concerning the diffusivities of peroxide or superoxide ions in molten carbonates; however, Turkdogan (24) notes that the diffusivities of foreign ions in molten salts are similar to the self-diffusivities, and that the latter fall in the range of 1×10^{-5} to 8×10^{-5} cm^2s^{-1} . These values correspond to a diffusion distance, $x = 2\sqrt{Dt}$, ranging from 1.6 to 7.4 cm, *i.e.*, a value of the order of the melt depth, for the maximum exposure time of 48h. However, significant corrosive attack is confined to a band of ~ 2 mm width in the vicinity of the meniscus, and a logical explanation is that the major part of the flux of cathodic reactants is through the thin electrolyte film just above that region postulated by Rahmel (10). In their careful potentiostatic investigation involving the gold electrode in carbonate melts, Appleby and Nicholson (22) found cathodic oxygen reduction to be rate limited by electron-transfer processes, *i.e.*, reactions [12] and [13] with the latter dominant at high $P_{\text{O}_2}/P_{\text{CO}_2}$ ratios.

The rate of the cathodic electron transfer process, J , is proportional to the corresponding exchange current density, expressed by Vetter as (25)

$$J \propto i_0 = k_- c_0 \exp\left(\frac{\alpha F}{RT} \epsilon_0\right) \quad [14]$$

where k_- is a rate constant incorporating the electronic charge, c_0 is the concentration (or, more properly, the activity) of the oxidized species at the reaction site, α is the transfer coefficient, and ϵ_0 is the equilibrium potential of the half-cell reaction. For peroxide reduction, assuming reaction [8] to be at equilibrium, c_0 may be expressed as

$$c_0' = a_{\text{O}_2^-} = \frac{K_1^{1/2} P_{\text{O}_2}^{1/2} a_{\text{CO}_3^{2-}}}{P_{\text{CO}_2}} \quad [15]$$

where K_1 is the equilibrium constant for reaction [8]. The equilibrium potential for reaction [12] may then be expressed

$$\epsilon_0' = \frac{RT}{nF} \ln K_2 = \frac{RT}{2F} \ln \frac{a_{\text{CO}_3^{2-}}}{P_{\text{CO}_2} P_{\text{O}_2}^{1/2} K_1^{1/2}} \quad [16]$$

where K_2 is the equilibrium constant for half-cell (12). Substituting

$$J' \propto i_0' = k_-' K_1^{(1/2-\alpha/4)} P_{\text{O}_2}^{(1/2-\alpha/4)} P_{\text{CO}_2}^{-(1-\alpha/2)} a_{\text{CO}_3^{2-}}^{(1+\alpha/2)} \quad [17]$$

If we assume that the partial pressures of oxygen and carbon dioxide are simply proportional to pressure (*i.e.*, their mole fractions in the cell environment remain constant), Eq. [17] becomes

$$J' \propto i_0' \propto P^{-(1/2+3\alpha/4)} a_{\text{CO}_3^{2-}}^{(1+\alpha/2)} \quad [18]$$

Comparable expressions for superoxide reduction are

$$c_0'' = a_{\text{O}_2^-} = \frac{K_1^{1/4} K_3^{1/2} P_{\text{O}_2}^{3/4} a_{\text{CO}_3^{2-}}^{1/2}}{P_{\text{CO}_2}^{1/2}} \quad [19]$$

where K_3 is the equilibrium constant for reaction [10]

$$\epsilon_0'' = \frac{RT}{nF} \ln K_4 = \frac{RT}{F} \ln \frac{K_1^{1/4} a_{\text{CO}_3^{2-}}^{1/2}}{K_3^{1/2} P_{\text{O}_2}^{1/4} P_{\text{CO}_2}^{1/2}} \quad [20]$$

where K_4 is the equilibrium constant for half-cell (13), and

$$J'' \propto i_0'' = k_-'' K_1^{(1+\alpha)/4} K_3^{(1-\alpha)/2} P_{\text{O}_2}^{(3-\alpha)/4} P_{\text{CO}_2}^{-(1+\alpha)/2} a_{\text{CO}_3^{2-}}^{(1+\alpha)/2} \quad [21]$$

which, on assuming constant cell gas composition, becomes

$$J'' \propto i_0'' \propto P^{(1-3\alpha)/4} a_{\text{CO}_3^{2-}}^{(1+\alpha)/2} \quad [22]$$

Note that in Eq. [15]-[22], the superscripts ' and '' refer to peroxide reduction and superoxide reduction, respectively. In developing expressions similar to Eq. [17] and [21], Appleby and Nicholson assumed $a_{\text{CO}_3^{2-}}$ to be constant (22).

The cathodic reaction rate is related to the depth of liquid-line attack by a simple model which is consistent with our observations. We presume that initial anodic action is quite localized, occurring only at a narrow band or line just below the intersection of the meniscus with the specimen surface. Once attack has started, the profile of the corroding surface recedes radially from the initial point of attack as seen in the time progression of Fig. 8-10 and Fig. 3, thus creating the circular attack profile of Fig. 1. Since the total rate of dissolution is determined by the rate of the cathodic reaction, which is constant with time, the depth of attack is described by a simple parabolic expression of the form

$$X^2 = \alpha v n J t \quad [23]$$

where α is a geometric factor, v is the molar volume of the metal ($v_{\text{Ni}} = 6.6 \text{ cm}^3/\text{mol}$), and n is a stoichiometric factor (2 mol Ni/mol O_2). If the rate of cathodic reaction is expressed per length of meniscus/specimen contact, the constant α is given by the ratio of the attack depth squared to the area of the sector representing metal loss in the specimen profile, approximately 0.12 as estimated from Fig. 3-6. Thus

$$J = 0.63 X^2/t \quad \text{mol O}_2 \text{ cm}^{-1} \text{h}^{-1} \quad [24]$$

or for constant J , attack depth is proportional to (exposure time)^{1/2}. This parabolic correlation is shown in Fig. 14 using data from Fig. 8-10 and 3.

Figure 15 is a log-log plot of the average cathodic reaction rate, calculated from average maximum attack depth by means of Eq. [24] vs. cell pressure. The plotted line

Fig. 14. Plot of attack depth at 667 Pa vs. $t^{1/2}$. Line is least squares fit through all points.

represents a least squares fit of the data for $P \geq 10^4$ Pa to the relation

$$\log J = \log b + m \log P \quad [25]$$

where b and m are constants with the values of 1.047×10^{-2} mol O_2 $cm^{-1}h^{-1}Pa^{-m}$ and -0.925 , respectively. The correlation factor, $R = 0.9992^2$ shows excellent correspondence of the higher pressure data to Eq. [25], which itself is consistent with either Eq. [18] or [22] for constant carbonate activity. Agreement with the latter, however, would require a transfer coefficient of 1.567, while assumption of the former, rate limitation by reduction of peroxide, leads to a transfer coefficient of 0.603, in agreement with Appleby and Nicholson, who noted values "close to 1/2" (20).

The equilibrium constant for reaction [9], assumed to be at equilibrium in the above argument, is 1.41×10^{-6} atm at 1000°C (26). Using the average CO_2 content of air, 0.033% (27), and assuming this to be representative of the cell environment independent of pressure, at a cell pressure of 10^4 Pa the equilibrium value of the ratio $a_{O_2}/a_{CO_3^{2-}}$ is 0.0433; i.e., at this and higher pressures very little dissociation of the carbonate occurs and $a_{CO_3^{2-}}$ is essentially independent of pressure. This is consistent with the simple power relationship between cathodic reaction rate and cell pressure observed in this pressure range. However, at the lowest controlled cell pressure, 667 Pa, the equilibrium value of the ratio $a_{O_2}/a_{CO_3^{2-}}$ is 0.649, indicating considerable decomposition of the melt and suggesting a substantial change in the value of $a_{CO_3^{2-}}$. In order for the cathodic reaction rate determined at this pressure to be consistent with Eq. [18], the value of the carbonate activity would have to be 0.17 (vs. a standard state of pure sodium carbonate), a value not inconsistent with the equilibrium activity ratio. At very low pressures, a simple proportionality between $a_{CO_3^{2-}}$ and pressure (or P_{CO_2}) is expected. For transfer coefficients less than 2, Eq. [18] predicts a cathodic reaction rate approaching zero, in accord with observation.

Conclusions

Liquid-line corrosion of nickel in molten sodium carbonate under reduced air pressures is rate limited by the cathodic reaction. Initial attack occurs just below the line of three-phase contact and appears to be quite localized. Subsequent metal loss occurs at a uniform rate along the surface of the attacked region; the attack profile thus approximates a circular arc whose radius increases with time. Inasmuch as the rate of the cathodic reaction is not affected by the progress of corrosive attack while the area of anodic activity (the attack profile) increases in propor-

$$^2R = \left[1 - \frac{\sum (J_{exp} - J_{calc})^2}{\sum (J_{exp} - \bar{J})^2} \right]^{1/2}$$

Fig. 15. Plot of cathodic reaction rate, calculated from attack depth, vs. pressure after 48h partial immersion. Points are average values for the several specimens tested at each pressure. Line is least squares fit of Eq. [25] to open points.

tion to attack depth, the attack depth displays a parabolic dependence upon time. Corrosive attack is nil in the absence of oxygen, increases very rapidly to a maximum value at the lowest controlled air pressure studied (667 Pa), and again decreases to approximately nil in atmospheric air. Higher (subatmospheric) pressure data follow a simple power relationship that is consistent with control by the electron-transfer step of peroxide reduction. Deviation from this behavior at low cell pressures is attributed to a decrease in carbonate activity.

Optimization of Electrolytic Cells

Richard Alkire,* See-Aun Soon,** and Mark Stadtherr

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A methodology was developed for optimizing electrolytic cells described by a potential field distribution along with material, voltage, and economic balance equations. In the present study, the cell consisted of two flow-through porous electrodes separated by a membrane. The model consisted of two nonlinear differential equations, 19 variables, eight equality constraints, and five inequality constraints. The optimum solutions were obtained for simple economic objectives with use of a successive quadratic programming method. The sensitivity of the optimum to operating variables and design constraints was found with the use of Lagrange multipliers. The method may be applied to any electrolytic cell which can be modeled by a combination of differential, algebraic, and polynomial (curve-fit) equations.

A central goal of engineering design practice is to predict the optimal configuration of a system on the basis of economic and scientific principles. Until recently, electrochemical cell and process design have depended largely on intuition, empirical relationships, and rules of thumb based on past experience. As a consequence, large margins of safety were required in design and optimization, especially of new systems.

The modeling of electrochemical systems based on fundamental principles has advanced to a high degree of sophistication in recent years. Rigorous electrochemical models based on current and potential distribution phenomena within the cell have been developed for the more common cell configurations (1). These models pave the way for the use of improved techniques for optimizing electrochemical processes. In the present study, a flexible and robust method is used to optimize an electrolytic cell modeled by a set of differential and nonlinear algebraic equations.

The literature on electrochemical optimization studies has recently been reviewed (2). Published works on optimization have generally used an analytical technique in which a cost equation is differentiated with respect to the variable of interest, the derivative set to zero, and the equation solved to obtain the optimum value. Another commonly reported approach is use of a graphical technique where the trade-off curves were plotted and the optimum determined by inspection.

With the advent of the digital computer, the field of optimization has been completely revolutionized. Within the past two decades, there has been a rapid growth in the literature on optimization. There are available several reviews of nonlinear optimization methods (3), applications (4, 5), as well as algorithms and software (6, 7). Lasdon (6) has identified the four most promising nonlinear optimization algorithms as the augmented lagrangian (AL), successive linear programming (SLP), generalized reduced gradient (GRG), and successive quadratic programming (SQP). Recent comparative studies (8, 9) have found that GRG and SQP seemed to be the most promising of the four methods. Schittkowski (9) ranked SQP methods first in efficiency and reliability, followed closely by GRG methods.

Modern techniques of optimization have not penetrated the electrochemical literature to any significant extent. To date, there have been few efforts directed towards incorporating state-of-the-art optimization techniques as an engineering design tool (10). Alkire *et al.* (10) implemented a state-of-the-art algorithm for the optimization of

an electrolytic cell. They used the GRG method of Lasdon (11) to optimize profit for a chlor-alkali cell based on a model of a diaphragm cell by MacMullin (12). The model consisted of a system of nonlinear algebraic constraint equations which included 42 variables, 37 equality constraints, and two inequality constraints. In addition, sensitivity to certain design and operating variables was also explored. Current and potential distribution phenomena in the cell, however, were not taken into account because the optimization method used in that study did not lend itself efficiently to applications which involve differential equations. This limitation is removed in the present study.

Models of current and potential distribution within cells have increasingly served as guides in the design, scale-up, and optimization of electrochemical cells (13). Models of electrolytic cells generally include both nonlinear algebraic and differential equations. In the present work, a general methodology was developed that incorporate state-of-the-art optimization techniques with a model of the current and potential distribution within an electrolytic cell (14). The goal was to optimize efficiently all cell parameters simultaneously. In this study, a divided cell containing two flow-through porous electrodes was chosen for investigation.

Theoretical

The following text is divided into three subsections that involve developing the porous electrode model, establishing the additional criteria necessary to identify the optimum, and carrying out the optimization.

Formulation of porous electrode model.—An electrolytic cell having two flow-through porous electrodes separated by a membrane and operated under steady, continuous conditions in a flow-by configuration was investigated. Figure 1 illustrates the cell configuration. The model of the reactor is an extension of that of Alkire and Ng (15, 16), and also includes multiple reaction terms following procedures established by Alkire and Gould (17-19). The porous electrodes were of uniform porosity, thickness, and specific surface area throughout, and were assumed to be made up of a packed bed of spheres. Dilute solution theory was used to describe the transport of species in solution. The kinetic behavior of the electrochemical reactions was represented by the Tafel form of the Butler-Volmer equation.

The main reaction at the anode represents a hypothetical oxidation reaction involving a two-electron transfer process

*Electrochemical Society Active Member.

**Electrochemical Society Student Member.

Fig. 1. Schematic diagram of electrolytic cell

The thermodynamic voltage for the above reaction is given by the following equation

$$E_1^+ = E_1^0 + \frac{RT}{n_1 F} \ln \frac{\alpha'_1}{(\alpha_1)^2} \quad [1]$$

The side reaction at the anode is oxygen evolution and is given by

The thermodynamic voltage for this half-cell reaction is given by

$$E_2^+ = E_2^0 + \frac{RT}{n_2 F} \ln \frac{\alpha'_2 (\alpha_{H^+})^4}{(\alpha_2)^2} \quad [2]$$

In this case, the activity of oxygen, α'_2 was taken to be the partial pressure of oxygen and the activity of water; α_2 was taken to be unity.

The main reaction at the cathode represents a hypothetical reduction reaction involving a two-electron transfer process

The thermodynamic voltage for the half-cell reaction is given by

$$E_3^- = E_3^0 + \frac{RT}{n_3 F} \ln \frac{(\alpha_3)^2}{\alpha'_3} \quad [3]$$

The side reaction on the cathode is hydrogen evolution and is given by

The thermodynamic voltage for the half-cell reaction above is given by

$$E_4^- = E_4^0 + \frac{RT}{n_4 F} \ln \frac{(\alpha_4)^2}{\alpha'_4} \quad [4]$$

In this case, the activity of hydrogen, α'_4 is the partial pressure of H_2 at the cathode and may be calculated from the total pressure of the system minus the cathode vapor pressure of water.

The equations representing the system were based on several assumptions: (i) the electrode phase was isopotential; (ii) the pores of the electrode were large with respect to the double layer; (iii) convection through the porous electrodes occurred by plug flow with no channeling effects; (iv) transport through axial diffusion and dispersion were negligible compared to axial convection; (v) conduction through bulk electrolyte obeys Ohm's law, and migration effects were negligible due to a large excess of supporting electrolyte; (vi) mass transfer from the bulk stream to the electrode surface may be characterized by an average mass transfer coefficient which was independent of position; (vii) the system was operated isothermally; and (viii) the conversion per pass was low.

The stoichiometry of the reaction to the porous electrode can be defined in the general form

$$\sum_i s_{ij} M_i^{z_i} = n_i e^- \quad [5]$$

The flux of species i due to migration, diffusion, and convection is given by

$$\underline{N}_i = -z_i u_i c_i F \nabla \Phi - D_i \nabla c_i + c_i \underline{v} \quad [6]$$

The current density in the solution is defined by

$$\underline{i} = F \sum_i z_i \underline{N}_i \quad [7]$$

A material balance on species i gives

$$\frac{\partial c_i}{\partial t} = -(\nabla \cdot \underline{N}_i) + R_i \quad [8]$$

The source term, R_i , for each species may be written as

$$R_i = -\sum_j \frac{\alpha_{sj}}{n_j F} f_j^e \quad [9]$$

The solution phase is electrically neutral

$$\sum_i z_i c_i = 0 \quad [10]$$

Combining Eq. [7]-[10] gives the current balance equation

$$\nabla \cdot \underline{i} = -a \sum_j f_j^e \quad [11]$$

The rate expression for the main anodic reaction is

$$f_1^e = i_{01} \frac{c_1^s}{c_1^0} \exp \{ \alpha n_1 F \Phi^+ / RT \} \quad [12]$$

For the side reaction at the anode, the reaction kinetics is given by

$$f_2^e = i_{02} \frac{c_2^s}{c_2^0} \exp \{ \alpha n_2 F (\Phi^+ + \phi_{r1}) / RT \} \quad [13]$$

In the above two equations, Φ^+ is the potential with respect to the thermodynamic rest potential of the main anodic reaction, while ϕ_{r1} is the thermodynamic rest potential of the main anodic reaction with respect to the thermodynamic rest potential of the side reaction at the anode. The reaction kinetics for the main cathodic reaction is given by

$$f_3^e = -i_{03} \frac{c_3^s}{c_3^0} \exp \{ -\beta n_3 F \Phi^- / RT \} \quad [14]$$

For the side reaction at the cathode, the reaction kinetics is given by

$$f_4^e = -i_{04} \frac{c_4^s}{c_4^0} \exp \{ -\beta n_4 F (\Phi^- + \phi_{r2}) / RT \} \quad [15]$$

In the above two equations, Φ^- is the potential with respect to the thermodynamic rest potential of the main cathodic reaction, while ϕ_{r2} is the thermodynamic rest potential of the main cathodic reaction with respect to the thermodynamic rest potential of the side reaction at the cathode.

The local concentration difference between the surface of the electrode and the concentration of the bulk electrolyte is related through the mass-transfer coefficient

$$f_j^e = \frac{n_j F k_{1j}}{s_{ij}} (c_i - c_i^0) \quad [16]$$

In the electrolyte phase, Ohm's law is obeyed

$$\underline{i} = -\kappa \nabla \Phi \quad [17]$$

Combining Eq. [11] and [17], the differential equation for the potential distribution in solution is obtained

$$\nabla^2 \Phi = \frac{a}{\kappa} \sum_j f_j^e \quad [18]$$

From the assumptions of the model, particularly in that it was a differential reactor, the differential equation

is one-dimensional and in Cartesian coordinates is given by

$$\frac{d^2\Phi}{dy^2} = \frac{a}{\kappa} \sum_j f_j^e \quad [19]$$

Equation [19] is applicable to both the anode and the cathode. By combining Eq. [12], [13], and [16], the differential equation for the anode is

$$\frac{d^2\Phi^+}{dy^2} = \frac{a}{\kappa_1} \left[\frac{i_{01} \exp\{\alpha n_1 F \Phi^+ / RT\}}{1 + \frac{i_{01} S_{11}}{n_1 F k_1 C_1^0} \exp\{\alpha n_1 F \Phi^+ / RT\}} + i_{02} \exp\{\alpha n_2 F (\Phi^+ + \phi_{r1}) / RT\} \right] \quad [20]$$

Similarly, combining Eq. [14]-[16] gives the following differential equation for the cathode

$$\frac{d^2\Phi^-}{dy^2} = \frac{a}{\kappa_2} \left[\frac{i_{03} \exp\{-\beta n_3 F \Phi^- / RT\}}{1 + \frac{i_{03} S_{33}}{n_3 F k_3 C_3^0} \exp\{-\beta n_3 F \Phi^- / RT\}} + \frac{i_{04} \exp\{-\beta n_4 F (\Phi^- + \phi_{r2}) / RT\}}{1 + \frac{i_{04} S_{44}}{n_4 F k_4 C_4^0} \exp\{-\beta n_4 F (\Phi^- + \phi_{r2}) / RT\}} \right] \quad [21]$$

The model for the porous electrode was completed by the following boundary conditions. For the anode

$$\text{at } y = O^+, \frac{d\Phi^+}{dy} = -\frac{i}{\kappa_1} \quad [22]$$

$$\text{at } y = H^+, \frac{d\Phi^+}{dy} = 0 \quad [23]$$

For the cathode

$$\text{at } y = O^-, \frac{d\Phi^-}{dy} = \frac{-i}{\kappa_2} \quad [24]$$

$$\text{at } y = H^-, \frac{d\Phi^-}{dy} = 0 \quad [25]$$

Formulation of objective function and constraints.—

The objective function represents the goal of the optimization. For example, return on investment, discounted cash flow rate of return on investment, and profit are frequently used as objective functions. Two objective functions were formulated in this study. The first objective was that of maximizing a profit function consisting of total revenue minus total cost on an annual basis. The profit function was chosen to demonstrate methodology because of its simplicity. More complex economic models may be incorporated, provided that investment cost data are available. The second objective function was that of maximizing current per unit volume. This is equivalent to maximizing the space-time yield. In order to relate these objectives to the behavior of the porous electrode modeled in the previous section, it is necessary to introduce additional equations in the form of material balances, energy balances, mass-transfer correlations, and voltage balances.

The applied current density is

$$i = I/xz \quad [26]$$

A material balance on the anode for species A is

$$C_1^0 Q_1 = C_1 Q_1 + \frac{2IU_1}{n_1 F} \quad (\text{mol/s}) \quad [27]$$

A material balance on the anode for water is

$$\frac{M_1^0}{m_1^0} Q_1 = \frac{M_1}{m_1} Q_1 + \frac{36I(1 - U_1)}{1000n_2 F} \quad (\text{kg/s}) \quad [28]$$

A material balance on the cathode for species C is

$$C_3^0 Q_2 = C_3 Q_2 + \frac{2IU_2}{n_3 F} \quad (\text{mol/s}) \quad [29]$$

A material balance on the cathode for H⁺ is

$$C_4^0 Q_2 = C_4 Q_2 + \frac{2I(1 - U_2)}{n_4 F} \quad (\text{mol/s}) \quad [30]$$

The anode volumetric flow rate is

$$Q_1 = v^+ yz \quad [31]$$

The cathode volumetric flow rate is

$$Q_2 = v^- yz \quad [32]$$

There are also a number of inequality constraints. Anode and cathode conversion are constrained to be less than or equal to 10%, because of the assumption of low conversion per pass. The membrane area is set not to exceed a maximum area of 4500 cm (45 × 100 cm). A cell with a maximum electrode size of 45 × 100 cm allows for maximum membrane interchangeability since availability of ion-exchange materials is a size limiting factor for various applications (20). Upper bounds on the anode and cathode pressure drops are also imposed. The pressure drop is correlated using the Ergun equation (21)

$$\frac{\Delta p}{L} = 4.2 \frac{\mu v a^2}{\epsilon^3} + 0.29 \frac{\rho v^2}{\epsilon^3} \quad (\text{g/cm}^2 \text{s}^2) \quad [33]$$

The vapor pressure of water in solution is calculated with an equation which fits the data (22)

$$\ln p_w = 0.01621 - 0.1380m + 0.1933m^{1/2} + 1.024 \ln p_w^0 \quad [34]$$

The pure vapor pressure may be estimated to within 1% by (22)

$$\ln p_w^0 = 37.04 - 6276/T - 3.416 \ln T \quad [35]$$

Equations [34] and [35] are valid for the temperature range 25°-300°C.

The mass-transfer correlation of Wilson and Geankoplis (23) is used in this study

$$k_i = 1.09 \left(\frac{\rho D_i}{d_p} \right)^{2/3} G^{1/3} \quad [36]$$

The spheres are assumed to be packed in a hexagonal close-packed (hcp) arrangement. For a hcp arrangement, $\epsilon = 0.26$ and the specific surface area is given by

$$a = \frac{6(1 - \epsilon)}{d_p} \quad [37]$$

The activity of species *i* is given by

$$a_i = f_i c_i \quad [38]$$

The activity coefficient, f_i , may be calculated using a Debye-Huckel equation

$$-\log_{10} f_i = 0.5 z_i^2 (\Lambda)^{0.5} \quad [39]$$

where

$$\Lambda = 0.5 \sum_i M_i z_i^2$$

The conductivity of the solution has to be corrected for the porous media. The effective conductivity for the porous media is given by (24)

$$\kappa = \left(\frac{2\epsilon}{3 - \epsilon} \right) \kappa_0 \quad [40]$$

The voltage drop across the membrane is calculated by taking into account the resistivity of the membrane, the conductivities of the anolyte and catholyte, as well as the thickness of the membrane. The voltage balance is given by

$$V = E_1^+ + \Phi^+|_{y=0^+} + V_M - E_3^- - \Phi^-|_{y=0^-} \quad [41]$$

Table I. Description of variables in optimization

Variables	Description
X(1)	Total cell current (A)
X(2)	Applied current density (A/cm ²)
X(3)	Thickness of porous electrode (cm)
X(4)	Length of porous electrode (cm)
X(5)	Width of porous electrode (cm)
X(6)	Anodic volumetric flow rate (cm ³ /s)
X(7)	Anodic superficial velocity (cm/s)
X(8)	Initial concentration of species 1 (mol/cm ³)
X(9)	Final concentration of species 1 (mol/cm ³)
X(10)	Cathodic volumetric flow rate (cm ³ /s)
X(11)	Cathodic superficial velocity (cm/s)
X(12)	Initial concentration of species 3 (mol/cm ³)
X(13)	Final concentration of species 3 (mol/cm ³)
X(14)	Initial concentration of species 4 (mol/cm ³)
X(15)	Final concentration of species 4 (mol/cm ³)
X(16)	Particle diameter (cm)
X(17)	Specific surface area (1/cm)

The final model consisted of two nonlinear differential equations, 19 variables, eight equality constraints, and five inequality constraints. The two differential equations were used to solve for the potential distributions Φ^+ and Φ^- . The remaining 17 variables used in the optimization are presented in Table I. Upper and lower bounds are imposed on all these 17 variables. The number of degrees of freedom was determined by the number of variables minus the number of equality constraints. In this study, the total number of degrees of freedom was nine.

Method of solution.—The nonlinear differential equations were solved with a finite difference numerical technique. The nonlinear differential equations were first linearized about a trial solution, and the equations were then written in finite difference form by employing central difference operators. The resulting tridiagonal matrix was then inverted by a modified Gauss-Jordan elimination method (25) with the use of CDC Cyber 175. Solutions of the equation were obtained when a convergence of 0.01% was achieved by the mesh points during successive iterations.

The optimization problem was solved using a successive quadratic programming method as implemented in the program SQPHP (26, 27). Successive quadratic programming was chosen because of its need for fewer function and gradient evaluations, efficiency, ease of use, and reliability. In general, the optimization problem can be written in the following standard form

Minimize $F(\mathbf{X})$

$$\text{Subject to: } \begin{array}{ll} h_i(\mathbf{X}) = 0 & i = 1, 2, \dots, P \\ h_i(\mathbf{X}) \geq 0 & i = P + 1, \dots, Q \end{array}$$

where \mathbf{X} is a vector of variables, $F(\mathbf{X})$ is a nonlinear objective function, and $h_i(\mathbf{X})$ are nonlinear equality and inequality constraints. This is the standard problem solved by SQPHP. Maximization problems can be easily transformed into standard minimization problems by multiplying by -1 ; hence, there is no loss in generality in considering maximization problems.

In SQPHP, the P equality constraints are used to eliminate some of the variables. This is tantamount to reducing the dimensionality of the problem from N to $N - P$. The code then solves the original problem by solving a sequence of reduced quadratic programming (QP) subproblems.

The code handles bounds on the variables directly in the QP subproblems. There are several options available in the code. There is an option to restrict the initial step size during the initial first three iterations, and there is an option providing for automatic scaling of the objective function as well as for user-selected scaling of the variables.

Reverse communication is used to provide SQPHP with values for $F(\mathbf{X})$, $h_i(\mathbf{X})$, $\partial F/\partial x_i$, and $\partial h_j/\partial x_j$, $i = 1, 2, \dots, Q$; $j = 1, 2, \dots, N$. This means that computer instructions for their calculation must be present in the user's pro-

gram that calls SQPHP initially. When the subroutine requires the values of these terms, it sets the appropriate values of the variables in the vector \mathbf{X} and it returns to the user's program with a flag variable, called INF, which is set to a negative value that indicates whether the evaluation of functions and derivatives is required. The user's program then sets the values of the required terms and, without altering any of the other arguments of SQPHP, calls SQPHP again with INF unchanged. The initial call of SQPHP is indicated by setting $\text{INF} = 0$, and the final return from SQPHP was indicated by $\text{INF} > 0$. Before the initial call, it is necessary to calculate $F(\mathbf{X})$, $h_i(\mathbf{X})$, $\partial F/\partial x_i$, and $\partial h_j/\partial x_j$, $i = 1, 2, \dots, Q$; $j = 1, 2, \dots, N$ for the initial value \mathbf{X} . Figure 2 is the flow diagram illustrating reverse communication.

In the execution of the optimization runs, a large number of different starting points were used, in an attempt to ensure that a global rather than local optimum was found. A total of 68 optimization runs were made for each objective function. The final program required 32.25K words of core on the CDC Cyber 175.

Results and Discussion

The methodology by which the following results were obtained was general enough for it to be applied to any electrolytic cell which can be modeled by a combination of differential and algebraic equations. Hence, the results below are presented to illustrate the types of considerations that can be made with the optimization method presented here. The particular results obtained with the model system were not intended to correspond to a particular application.

A series of case studies was carried out in order to evaluate optimization methodology as well as to explore electrochemical aspects of the problem. The 17 variables in the optimization problem are listed in Table I. Table II summarizes model parameters used, including physical property data, thermodynamic and kinetic rate constants, mass-transfer correlation, as well as economic data. For the case studies here, values of parameters were chosen to be representative of a paired synthesis from aqueous solution of two organic compounds, one valued at about \$4/kg and the other about \$5/kg.

The simple profit objective function took into consideration power costs as well as market prices of feedstocks and products. Table III shows the optimal values together with the initial guesses. These initial guesses represent the starting point in the search for the optimum and they are needed to initialize the program. A total of 68 starting points were tried, and several local maxima were found. The best of these local maxima has a maximum profit of \$63,419.45/yr with a production rate of 10.1 mol/h, and corresponds to the optimal values and starting point given in Table III. Since a large number of different starting points were tried, making it likely that all local maxima were found, one can be reasonably confident, though not absolutely certain, that this is the global maximum.

x	≤ 100 cm	
y	≤ 45 cm	
z	≤ 4 cm	
Δp	1×10^6 g/cm s ² (1 atm)	

It is seen from the optimal results in Table III that the dimensions x , y , and z of the porous electrode cell were forced to their upper bounds; this was expected since the objective function did not take into account capital costs. Increasing the dimensions of the cell would mean an increase in production rate and, hence, profit. However, as the dimensions of the cell increase, the capital costs associated with the cell also increase. To account for this trade-off between increasing production rate and capital cost, a capital cost term incorporating the costs of the material and the labor required for the fabrication of the cell needs to be taken into consideration. Provided estimated or actual cost data are available, this can be incorporated into the optimization scheme with modest effort.

The optimum anodic volumetric flow rate Q_1 was found to exist at the upper bound of the range, while the cathodic volumetric flow rate Q_2 was not. It was more profitable to increase the throughput of the anode since the anodic product was more valuable than the cathodic product.

With the simple profit objective function, the effect of an increase in energy costs was examined. Alkire *et al.* (10) had used a different optimization problem to explore how changes in the price of electricity impact on profit and on optimum production rate. As the price increases, the profit and the production rate were found to decline. In the present study, the major impact of increasing energy costs was decreasing profits. In the study of Alkire *et al.* (10), it was found that changes in market prices affect only the optimum value of the objective function and not the optimal operating conditions. The same effect was observed in the present study.

Table III. Optimal solution obtained with simple profit as objective

Variable	Initial guess	Optimal value	Unit

d_p	1.0×10^{-3}	2.0×10^{-2}	cm
α	220	222	cm ⁻¹

To test the consistency of the methodology further, an objective function was chosen which maximized the current per unit volume. Table IV shows the optimal values of the variables together with initial guesses. It was found that the optimum value was 0.5 A/cm³, or 14,000 A/ft³. Again, because a large number of starting points were tried, it is likely that this is the global maximum.

The major differences in the optimal results obtained from the two different objectives as shown in Tables III and IV are in the dimensions of the cell and in the applied current density. In the case of the current per unit volume as objective, the cell dimensions are smaller and the applied current density higher in comparison to the profit as objective case. This is because the energy cost in production is not taken into account in the current per unit volume case.

For the cases investigated, the total CPU time needed to arrive at the optimum depended on the starting point and ranged from 1.7 to 40s on a CDC Cyber 175. Of this, the time spent in the optimization code ranged from 0.5 to 1.5s, the remainder was spent in solving the differential equations. These results suggested that efficient numerical methods for the solution of the differential equations is critically important. These results also suggested that adroit selection of starting point is important, but that the computational costs of the present model are modest in all cases.

The results of the optimization runs may be reformulated into information such as current efficiency, selectivity, space-time yield, and energy consumption. Table V compiles optimal results for the two objectives investigated in this study.

It was found that a temperature rise of about 1.5°C occurred in both cases. Hence, heat transfer was not an important consideration.

The sensitivity of the operating variables was investigated by evaluation of the Lagrange multipliers associated with the optimal solution. The Lagrange multipliers are sensitivity coefficients and are therefore capable of giving an indication of sensitivity. The Lagrangian multipliers are determined as a byproduct of the optimization code. They provide a relative measure of the sensitivity of

Table V. Optimal electrochemical figures of merit

	Objective function	
	Profit	Current per unit volume
Current efficiency of anode	100%	100%

the objective function with respect to small changes in the constraints. If the objective function is in terms of dollars of profit, then the Lagrange multiplier λ_i may be interpreted as dollars of profit per unit of the i th constraints.

Tables VI and VII show the Lagrange multipliers for selected variables for the two objectives investigated in this study. The changes were based on a 1% perturbation of the variables at the optimum. The expected changes in optimal value were calculated by multiplying the Lagrange multipliers by the magnitudes of the change. By this method, it is possible to identify the more sensitive features of the cell from among the large list of input parameters and constraints. This capability should be particularly helpful in the early stages of engineering assessment and development. In the cases studied in this investigation, it was found that the sensitive variables were the anodic flow rate and the initial concentration of the anodic reactant, with the latter being the most sensitive.

Conclusions

In this study, a successive quadratic programming technique was used to optimize a model of a porous electrode cell that incorporated current and potential distribution phenomena. The model was prepared for optimization by formulating an objective function as well as a system of equality and inequality constraints that included material balances, charge balances, physical property, and physical limitations.

The model used in this study consisted of two nonlinear differential equations, 19 variables, eight equality constraints, and five inequality constraints. The methodology described here gave the optimal value of all the variables required for optimization of two different objectives: maximum profit based on the prices of chemicals and electrical energy and maximum current per unit volume. Lagrangian multipliers were used to determine the sensitivity of the constraints to the optimal solution.

The model required the use of certain physical property data such as mass-transfer coefficients, density, viscosity, conductivity, vapor pressure, activity, and pressure drop. Membrane transport properties were needed to calculate cell voltage. Physical property data correlations were incorporated wherever possible for determining pressure drop, vapor pressure of water, and correcting

conductivities for the effect of porosity. A lack of availability of such auxiliary data may limit the accuracy of any optimization model.

It is recognized that to optimize a process an entire flowsheet needs to be considered rather than a single cell. It is also recognized that in process optimization the objective function normally consists of maximizing a rate of return on investment or maximizing venture profit. While rate of return is the final criterion in the assessment of a process, it is sometimes convenient, especially in electrochemical processes, to develop a criterion which pertains more closely to the electrolytic process. Hence, for electrolytic processes in the preliminary design stages, high selectivity, space-time yield, chemical yield, or energy yield may be the desired objective. However, in a first-generation study such as this, the simple profit function served adequately to illustrate the usefulness and feasibility of the methodology.

Tremendous advances in the modeling of electrochemical systems have been made in recent years. Rigorous electrochemical models based on current and potential distribution phenomena within the cell have increasingly served as guides in the design, scale-up, and optimization of electrochemical cells. The development of digital computers and numerical methods for optimization, as well as the recent progress in the thermodynamics of electrolyte solutions, has paved the way for the use of improved optimization techniques for electrochemical processes. This study attempted to show how state-of-the-art optimization techniques can be applied to cell models to obtain optimal conditions and to provide an estimate of the sensitivity of operating variables. Optimization methods can assist in implementing wise technological changes in the electrochemical process industry.

Voltammetric Studies of Electrodes in Contact with Ionomeric Membranes

James McBreen*

Brookhaven National Laboratory, Department of Applied Science, Upton, New York 11973

ABSTRACT

Cyclic voltammetry studies were carried out on platinum and gold screen electrodes in contact with Nafion ionomeric membranes. In addition, experiments were carried out on multiple combinations of platinum screens with either graphite felt or gold screen electrodes, with only one of the electrodes in direct contact with the membrane. In the case of platinum and gold screens, it was found that the voltammograms were almost identical to that found for the same screens in acidic aqueous electrolytes. When two platinum screens were used, the adsorption charges on the platinum doubled. Obviously, adsorption can occur on sites remote from the membrane/electrode contact, provided the metal is wetted with water. In the case of platinum, a mechanism based on rapid mobility of adsorbed hydrogen and hydroxyl species is proposed. The implications of these findings regarding solid polymer electrolyte electrolyzers and fuel cells are discussed.

In the past 25 years, ionomeric membranes have been used in many electrochemical applications. These include water electrolyzers (1, 2) fuel cells (2-4), electrochemically regenerative energy storage systems (2), and various electrochemical reactors. The latter include brine electrolyzers (2), ozone generators (5), and reactors for organic synthesis (6-8). In the case of water electrolyzers and fuel cells, the electrodes are bonded to the membrane surface. This is accomplished by pressure bonding an electrocatalyst (e.g., Pt or RuO₂) on to the membrane surface (8) or by direct reduction of platinum on to the membrane (9). The structure (10, 11) and transport properties (12, 13) of these membranes have been characterized by most of the sophisticated techniques of materials science. However, there have been very few studies of electrodes in contact with ionomeric membranes.

In fuel cells with ionomeric membranes, it is well known that good performance can be obtained only with prehumidified reactants. This has been attributed to maintenance of water content and conductivity of the membrane (4). In the case of electrolyzers, corrosion problems have been observed on bipolar separator plates in regions that are remote from the membrane electrocatalyst interface. The mechanisms of this are not understood.

Stucki and Menth (14) reported the first cyclic voltammograms for a platinized platinum screen in contact with a Nafion ionomeric membrane. They found that the cyclic voltammograms for the same screens in 1N H₂SO₄ were almost identical. No explanation was given for this. More recently (15), investigations were made on chemically reduced platinum on Nafion membranes. Cyclic voltammograms were found to be the same irrespective of whether the working electrode was exposed to nitrogen or flooded with nitrogen purged 1M HClO₄.

The electrochemical oxidation of hydrogen on platinum in contact with an ion exchange membrane has been investigated (16). However, interpretation of the results is difficult because of residual H₂SO₄ in the membranes and the effects of organic materials from the membrane on hydrogen oxidation (17).

Chernyshov has examined the catalyst/solid polymer electrolyte both experimentally and in terms of porous electrode theory (18). He concluded that increases in electrode activity can be achieved by dispersing a powder of the finely divided ionomeric material in the catalyst (19).

At present, the current-generation mechanism and the factors controlling catalyst utilization at electrodes in contact with ionomeric membranes are poorly understood. This is the subject of the present investigation. Cyclic voltammetry results for platinum and gold screens in contact with Nafion membranes are presented. Initial studies with platinum screens confirmed the results of Stucki and Menth (14). The hydrogen adsorption charge was

identical for a platinum screen pressed against a Nafion membrane and for the same screen in 0.5M trifluoromethanesulfonic acid. Obviously, all of the screen was utilized for hydrogen adsorption even though only approximately one third of the screen was in contact with the membrane. Two hypotheses were advanced to explain this: one was fast mobility of adsorbed hydrogen on the platinum metal surface; the other was an ionic pathway through the water surrounding the Nafion membrane. To test these hypotheses, several experiments were carried out. These included use of multiple platinum screens one on top of the other and the interposition of graphite felt or a gold screen between the platinum and the membrane. It is known that hydrogen neither adsorbs nor is mobile on either of these materials. By means of these tests, it was possible to elucidate the relative contributions of fast surface mobility and ionic pathways in the water.

Experimental

The cell.—The cell used in these investigations is shown schematically in Fig. 1. The cell body was machined from two blocks of PTFE. The overall dimensions of the machined blocks were 6.5 × 6.5 × 2.0 cm. When the cell was assembled, the Nafion membrane and the electrodes were clamped between both PTFE blocks, which were bolted together. Provisions were made for having the electrodes and membrane under a slight compression during a run. A number of holes and grooves were machined in the PTFE to ensure ready access of water to the electrodes and membrane.

The reference electrode.—The reference electrode was a dynamic hydrogen electrode (DHE) and is shown in Fig. 1. The electrode was in a glass tube containing 0.5M trifluoromethanesulfonic acid (TFMSA). The salt bridge consisted of a 1.25 mm Nafion tubing (du Pont no. 815X) inside a PTFE tube. The tubing was wetted with triply distilled water prior to cell assembly. To prevent siphoning of the TFMSA, several knots were tied on the tubing. Electrolytic contact was made by pressing the tubing against the membrane.

Working and counterelectrodes.—The counterelectrode was a circular disk of 52 mesh platinum screen (2.4 cm diam) with a spotwelded platinum lead. The working electrodes were similar circular electrodes with wire leads. The graphite electrode was a 0.25 mm thick graphite felt (Fiber Materials, Incorporated, GH Graphite Felt).

Experimental procedures.—Particular care was given to cleaning the cell, the membrane, and the electrodes.

The cell was cleaned by immersion in concentrated HNO₃ for three days and then washed repeatedly in triply distilled water for an additional three days.

The membranes (du Pont Nafion 125) had a yellowish tinge which has been ascribed to some unknown impurity (20). The membranes were cut to size and boiled for

* Electrochemical Society Active Member.

Fig. 1. Schematic of cell for cyclic voltammetry studies. This shows the electrode arrangement when one platinum and two gold electrodes were used as the working electrode.

4h in triply distilled water. The water was changed four times during the boiling operation. After that the membranes were soaked for five days in triply distilled water. The water was changed twice each day. The washed membranes were clear.

The platinum electrodes were cleaned by a method described by Hoare (21). Gold electrodes were cleaned by soaking for three days in concentrated HNO_3 and were then subjected to repeated washings in triply distilled water for three days. The graphite felt was cleaned by repeated washings in triply distilled water.

Prior to a run, the Nafion membrane was placed in 300 ml of triply distilled water in a covered container. Nitrogen was bubbled through the water for 30 min to remove oxygen from the membrane. Meanwhile the beaker cell container (Fig. 1) was filled with triply distilled water, and the water was purged with nitrogen for 30 min. The cell was quickly assembled and transferred to the beaker cell. The cell was immediately evacuated to remove air bubbles, thus ensuring complete flooding of the electrodes with water. The bell jar was backfilled with nitrogen. The cell was then immediately connected to the potentiostat (Stonehart Associates BC 1200), and cyclic voltammetry measurements were started.

Results

Platinum screens on Nafion and in 0.5M TFMSA.—Figure 2 shows cyclic voltammograms for a platinum screen in contact with Nafion and in 0.5M TFMSA. The results are similar to those of Stucki and Mentz, in that the cyclic voltammograms are very similar. One salient aspect of the cyclic voltammograms on platinum in contact with Nafion is the reversibility of the peaks. Peak shifts with sweep rate (10-200 mV/s) were very similar to those reported for platinum in 1M H_2SO_4 (22).

Results with platinum electrodes that were not flooded with water were similar. However, it was necessary to carefully prehumidify the nitrogen gas to get reproducible results. Therefore, in the remainder of the experiments the simple expedient of flooded electrodes was used.

When two screens, one on top of the other, were placed against the Nafion membrane, the amount of charge in the hydrogen and oxide region was doubled (Fig. 3a). Even though only one screen was in direct contact with the Nafion, the surfaces of both screens were utilized for hydrogen and hydroxyl adsorption. Introduction of the second screen did not introduce any irreversibilities in the cyclic voltammogram.

When a graphite felt disk was interposed between the two platinum screens and the membrane, the cyclic voltammogram in Fig. 3b was obtained. This cyclic

Fig. 2. Cyclic voltammograms for a 2.4 cm diam, 52 mesh platinum screen electrode in contact with Nafion (solid line) and the same electrode in 0.5M TFMSA (broken line). Platinum wire diameter was 0.1 mm; sweep rate was 50 mV/s.

voltammogram differed from that for the graphite felt alone in contact with the membrane (Fig 3c). The results in Fig. 3b would indicate that there is double-layer charging of the platinum as well as some hydrogen adsorption and reduction of platinum oxide. The shape of the cyclic voltammogram is consistent with these processes occurring through a highly resistive electrolyte pathway (23, 24).

A gold screen on Nafion and in 1M H_2SO_4 .—Figure 4 shows cyclic voltammograms for a gold screen in contact with a Nafion membrane and for the same screen in 1M H_2SO_4 . Even though there was some shift in the peaks the cathodic oxide stripping charge was identical for both voltammograms. This indicates that, as with platinum, all of the screen is utilized for oxide formation. In the case of the screen in contact with the Nafion membrane, the

Sweep rate was 50 mV/s.

Fig. 4. Cyclic voltammograms for a 2.8 cm diam, 80 mesh gold screen electrode in contact with Nafion (solid line) and the same electrode in 1M H_2SO_4 ; the gold wire diameter was 0.1 mm. The sweep rate was 50 mV/s.

peak shifts with sweep rate (10-200 mV/s) were similar to that observed for gold in 1M $HClO_4$ (25). There was no evidence of hydrogen adsorption.

Combinations of gold and platinum screens on Nafion.—Figure 5 shows cyclic voltammograms for a combination of one gold and two platinum screens, with the gold screen in contact with the Nafion membrane. The reversible reduction peaks for the oxide on gold can be seen at ≈ 1.1 V. The peaks for hydrogen desorption and reduction of platinum oxide are distorted. However, they can be seen more clearly than in the case where graphite felt was interposed between the platinum and the membrane. Once again, processes occurring through a highly resistive electrolyte pathway are indicated. The results were reproducible. After minor changes in the cyclic voltammogram in the first few cycles, the pattern remained stable over a 6h period of cycling between 0.05 and 1.8V.

On increasing the sweep rate from 10 to 100 mV/s, the gold oxide reduction peak shifted from 1.14 to 1.09V. The corresponding potentials for the platinum oxide reduction peak were 0.6 and 0.32V.

Figure 6 shows a cyclic voltammogram for a combination of one platinum and two gold screens with the platinum screen in contact with the Nafion membrane. Also shown is a cyclic voltammogram for the two gold screens alone. All of the oxide reduction, hydrogen adsorption, and hydrogen desorption peaks are at the expected po-

tentials. There are no distortions in the cyclic voltammograms, other than those that can be ascribed to reduction of oxygen that is dissolved in the membrane. This shifts the current in a negative direction at potentials less than 0.9V.

Discussion

General features of the cyclic voltammograms.—The results in Fig. 2-4 indicate that the cyclic voltammograms on either platinum or gold screens in contact with Nafion are very similar to those found for the same screen in aqueous acid electrolyte. Slight negative shifts in the current in the hydrogen region can be ascribed to reduction of dissolved oxygen in the membrane. Differences in the oxide region can be explained in terms of anion adsorption (26). The doubling of the adsorption charges when a second screen is introduced (Fig. 3a) confirms the fact that parts of the electrode that are remote from the membrane surface are electrochemically active. The results indicate that, provided the nitrogen gas humidity is sufficiently high, flooding of the electrode with water is not necessary to achieve complete utilization of the electrode surface.

If either graphite felt (Fig 3b) or a gold screen (Fig. 5) is interposed between the platinum electrode and the membrane, there is considerable distortion of the platinum oxide reduction peaks and the peaks for hydrogen adsorption and desorption. The results are consistent with the effects of a resistive electrolyte path. However, interposition of a platinum screen between the gold electrodes and the membrane does not affect the oxidation or reduction behavior at the gold electrodes.

Mechanism of current generation.—Three possible mechanisms for current generation at sites remote from the membrane surface are (i) fast surface mobility of adsorbed species on the electrodes, (ii) conduction through the water because of dissolved Nafion fragments, or (iii) surface conductance effects.

If material leached from the Nafion into the water, one would expect a decrease in the water pH with time. No such pH change was observed. The stability of the cyclic

voltammogram in Fig. 5 over a 6h period would tend to exclude this mechanism.

The most likely mechanism for the highly reversible behavior with platinum and gold screens is rapid surface mobility of adsorbed hydrogen and hydroxyl species. Adsorbed hydrogen on platinum is undoubtedly a very mobile species (27), and recent studies show that adsorbed hydroxyl species on platinum are reactive, even at very low temperatures (28). This would imply a rapid surface mobility, so the mechanism appears reasonable.

Hydrogen does not adsorb on gold or graphite. This would explain the absence of reversible behavior in the hydrogen region (Fig. 3b and 5). Reduction of platinum oxides occurs in a potential region where oxide species are not adsorbed on gold or graphite. This would account for the irreversible behavior found for oxide reduction (Fig. 5). However, in the case where the platinum is interposed between the gold and the membrane, gold oxide formation and reduction occurs in a potential domain where hydroxyl groups are adsorbed on the platinum. Rapid migration of these on platinum yield the reversible behavior for reduction of the gold oxide species (Fig. 6).

Surface conductance effects are the most plausible explanation for the resistive conductance path which yields the irreversible behavior in the cyclic voltammograms in Fig. 3b and 5. It is well known that, when glass is immersed in water, ionization of the silicate groups will alter the water conductivity at the glass surface (29). Similar effects will occur when Nafion is immersed in water. These surface protons can provide a conductive pathway along the surface of the gold or graphite and transmit current to the platinum. In the hydrogen region, the gold will be negatively charged and the protons at the membrane surface can rearrange themselves over the gold surface to provide a conductive pathway. At more positive potentials, conduction can occur via adsorbed water and a Grotthus mechanism. A mechanism such as this would explain the reproducibility of the effects and the invariance of the cyclic voltammograms in Fig. 5 over several hours.

Implications regarding electrolyzers and fuel cells.—Solid polymer electrolyte electrolyzers use platinum black hydrogen electrodes and noble metal oxides (e.g., IrRuO₂) as oxygen electrodes (30, 31). The adsorbed intermediates for both reactions are mobile on their respective electrocatalysts. Therefore, a high degree of electrocatalyst utilization is expected.

In a solid polymer electrolyte electrolyzer, the oxygen electrocatalyst is in contact with an anode support such as porous titanium foil. This, in turn, contacts the bipolar current collector which is usually made from a carbon-plastic composite (1). Because of corrosion problems, it has been necessary to coat this with a thin foil of titanium or platinum. Carbon oxidation can occur either via fast hydroxyl mobility on the porous titanium surface or via the surface conductance mechanism.

Solid polymer electrolyte fuel cells use platinum black as the electrocatalyst for both electrodes. Hydrogen can dissociate anywhere on the platinum and migrate to the membrane. Catalyst utilization is expected, therefore, to be high. In the presence of water, oxygen can interact with platinum to form adsorbed hydroxyl species (28). Fast mobility of the latter would yield high electrocatalyst utilization. A carbon-supported platinum catalyst would preclude such mobilities and would result in a low electrocatalyst utilization. Only the resistive surface conductance pathway would be available. There are no reports of the use of carbon-supported platinum electrocatalysts in solid polymer electrolyte fuel cells. Supported catalysts would require pathways for ionic conduction in the electrode structure (8, 18, 19) or catalyst supports that would permit surface mobility of adsorbed hydrogen or hydroxyl intermediates.

Conclusions

Cyclic voltammograms on platinum and gold screen electrodes pressed against Nafion membranes are almost

identical for those obtained for the same screens in aqueous acid electrolytes. This indicates that the various electrochemical adsorption and desorption processes can occur on parts of the screen that are not in direct contact with the membrane. A set of critical experiments was devised which indicated that two pathways can exist for the occurrence of electrochemical adsorption reactions on parts of the metal not in contact with the membrane. One is a fast process involving fast mobility hydrogen or hydroxyl species on the metal; the other is a resistive pathway involving surface conductance effects. This has important implications regarding the performance of electrochemical devices with Nafion membranes.

Open-Circuit Photopotentials and Photoelectrochemical Behavior of the Si-Doped α -Fe₂O₃ Semiconductor Electrode in Acetonitrile Solutions

Saeed Sahami and John H. Kennedy*

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

The photoelectrochemical behavior of Si-doped sintered polycrystalline α -Fe₂O₃ was investigated in acetonitrile solutions containing the redox couples ferrocene, Cl⁻, Br⁻, I⁻, Ru(bpy)₃²⁺, Fe(bpy)₃²⁺, and Fe(phen)₃²⁺. There was no oxidation in the dark at the iron oxide electrode for these couples, but they all showed photo-oxidation at potentials negative of their oxidation potential at Pt. Cathodic back reactions of all couples, except halides, were observed. This indicates that surface states capable of mediating electron transfer from the conduction band to the oxidized forms of the couples exist in the bandgap region of the iron oxide. In addition, open-circuit photovoltages were found to increase with increasing redox potentials of these couples. An open-circuit photopotential as high as 0.8V was obtained for Ru(bpy)₃^{2+/1+}.

Iron oxide (α -Fe₂O₃) has been widely investigated as a semiconductor electrode material for photoassisted electrolysis of water. This is due to the following facts: (i) it has high stability, (ii) it is inexpensive and electrode fabrication is easy, and (iii) it has a relatively small bandgap of 2.2 eV. Although photochemistry of variously prepared iron oxide electrodes has received considerable attention in aqueous media (1-26), little work has been performed in nonaqueous solvents (27-29). Fredlein and Bard have reported the behavior of iron oxide electrodes in acetonitrile (27) using Pb-doped single-crystal, Ti-doped sintered polycrystal, and chemical vapor deposited films of Fe₂O₃.

Since it has been shown by Kennedy and co-workers (13) that silicon is a better dopant for α -Fe₂O₃ than titanium (*i.e.*, higher photocurrents were observed for Si-doped α -Fe₂O₃ at less positive potentials), we decided to examine the behavior of Si-doped iron oxide in acetonitrile. In the present work, we report the properties of Si-doped α -Fe₂O₃ in acetonitrile solutions containing various redox couples, including polypyridine complexes and halides. In addition, open-circuit photovoltage measurements helped to understand the energetics of the α -Fe₂O₃/liquid junction interface.

Experimental

Preparation of sintered polycrystalline α -Fe₂O₃ electrodes doped with 1 atomic percent (a/o) SiC (n-type Fe₂O₃) have been previously described (22, 25). The electrodes were about 0.37 cm² area and 0.1 cm thick. Electrical contact to the α -Fe₂O₃ was made by sputtering gold film on one side. A Cu wire was attached to the sputtered gold using silver epoxy (Epoxy Technology Incorporated). The electrode and Cu wire were sealed in a glass tube with ordinary epoxy, leaving only one face of the α -Fe₂O₃ exposed. The resistances of the electrodes measured at 1 kHz in aqueous solution were 60-350 Ω .

A three-compartment electrochemical cell with α -Fe₂O₃ photoanode, a coiled Pt wire counterelectrode, and a silver quasi-reference electrode was used. The reference and counterelectrode compartments were separated from the main compartment by medium porosity fritted-glass disks. The main compartment (containing the working electrode) had an optically flat quartz window. The potential of silver electrode was determined during each ex-

periment from cyclic voltammograms of each couple at the Pt measured with respect to both silver and aqueous saturated calomel electrode (SCE). All potentials are reported *vs.* SCE. The cell was kept under a N₂ gas blanket which was passed through acetonitrile. All measurements were carried out at ambient temperature.

Cyclic voltammograms and photocurrent-voltage curves were obtained using an EG&G PAR 174A, and a Houston Omnigraphic Model 2000 X-Y recorder. Open-circuit photovoltages were measured with a multimeter (Keithley Model 179).

The light source was an Oriel 150W Xe lamp. The light path included a shutter (1 in.), an infrared filter, and a quartz lens. The light intensity was measured with an EG&G Model 450-1 radiometer/photometer and light absorbing neutral density filters. Light intensity at the electrode surface was \sim 450 mW/cm². Screen-type neutral density filters were used to reduce the light intensity when desired.

Spectroscopic-grade acetonitrile (Mallinckrodt) was used without further purification. Tetra-n-butylammonium perchlorate (TBAP) purchased from Alfa was dried in a vacuum oven at 80°C and used as the supporting electrolyte. Fe(bpy)₃(ClO₄)₂, Fe(phen)₃(ClO₄)₂, and Ru(bpy)₃Cl₂·6H₂O (where bpy = 2,2'-bipyridine and phen = 1,10-phenanthroline) were obtained from G. F. Smith Chemical Company. To eliminate the interference of chloride electrochemical oxidation (at both Pt and illuminated α -Fe₂O₃ in acetonitrile), Ru(bpy)₃(ClO₄)₂ was prepared from its chloride salt, using a previously published method (30). Ferrocene and anhydrous salts of LiCl, LiBr, and LiI were purchased from Alfa. The halide salts were dried in a vacuum oven prior to their use. For photovoltage measurements, the oxidized form of each couple was generated in solution by means of either constant potential or constant current coulometry.

Results and Discussion

Open-circuit photopotential measurements.—In order to determine the effect of the redox potential and chemical nature of the individual redox system on the energetic situation at the α -Fe₂O₃/electrolyte interface, the photovoltages of several redox couples dissolved in acetonitrile were measured. The ideal semiconductor/liquid junction model (31) predicts that the bandedges, E_{cb} and E_{vb} , are

*Electrochemical Society Active Member.

Fig. 1. Open-circuit photovoltage as a function of light intensity for various redox couples in 0.1M TBAP/acetonitrile solutions. 1: Ru(bpy)₃^{3+/2+}. 2: Fe(bpy)₃^{3+/2+}. 3: Cl₃⁻/Cl⁻. 4: Br₃⁻/Br⁻. 5: I₃⁻/I⁻. 6: Fe(phen)₃^{3+/2+}. 7: Ferricinium/ferrocene.

fixed and the amount of band bending depends on the redox potential of the couple. According to the model, the maximum open-circuit photovoltage, E_{oc} (max) for an n-type semiconductor is given by

$$E_{oc}(\text{max}) = E_{\text{redox}} - E_{\text{FB}}$$

where E_{FB} and E_{redox} are the flatband potential of the semiconductor and redox potential of the couple in the solution, respectively. Thus, in the absence of changes in the double layer or surface reaction, the photovoltage should increase proportionally with E_{redox} (32).

Plots of the open-circuit photovoltages of various redox couples in 0.1M TBAP in acetonitrile as a function of logarithm of light intensity are shown in Fig. 1. The slopes of the lines are in the range of 24–27 mV, except for polypyridine couples, where larger slopes were observed. The slopes for Ru(bpy)₃^{3+/2+}, Fe(bpy)₃^{3+/2+}, and Fe(phen)₃^{3+/2+} are 36, 38, and 58 mV, respectively. According to a simplistic model at 25°C a slope of 25.7 mV (*i.e.*, kT/e) is expected (31, 33). Although slopes close to this value have been observed in several previous cases (21, 33), larger slopes have also been reported (31, 33). Slopes greater than kT/e have been attributed to a nonequilibrium distribution of electrons and holes in the space-charge layer of the semiconductor electrode (31, 33).

In Fig. 2, the dependence of the photovoltages on redox potentials is represented. Values of E_{oc} are obtained at α -Fe₂O₃ electrodes using the highest light intensity available (~450 mW/cm²). Values of E_{redox} are the average of the cathodic and anodic peak potentials obtained from cyclic voltammograms at a Pt electrode. Tabulations of E_{oc} , E_{redox} , and anodic peak potentials at both Pt and illuminated α -Fe₂O₃ are presented in Table I. As can be seen from Fig. 2, the open-circuit photopotential generally rises with increasing E_{redox} . Although variation of E_{oc} for the polypyridine couples is less pronounced, it is obvious that the Fermi level pinning model (that predicts an E_{redox} independent photovoltage) is not entirely applicable to this system. However the behavior is far from the ideal expectation where a straight line with slope of 1 is anticipated. In addition to some Fermi level pinning, the negative deviation from the straight line for polypyridine complexes might also be due to their high molar absorptivity. High absorptivity (in addition to h^+e^- recombination processes) limits the light absorption by α -Fe₂O₃ which in turn prevents achieving the highest possible E_{oc} . The positive deviation of I₃⁻/I⁻ from the theoretical line may be partly due to its more negative E_{FB} , as discussed later.

It has been suggested by Wrighton and co-workers (34, 35) that the extent to which the photoanodic peak (at n-type semiconductors) is more negative than the anodic peak at Pt is a measure of the E_{oc} for fast redox couples.

Fig. 2. Open-circuit photovoltage vs. the redox potential in 0.1M TBAP/acetonitrile. 1: Ru(bpy)₃^{3+/2+}. 2: Fe(bpy)₃^{3+/2+}. 3: Cl₃⁻/Cl⁻. 4: Br₃⁻/Br⁻. 5: I₃⁻/I⁻. 6: Fe(phen)₃^{3+/2+}. 7: Ferricinium/ferrocene. Solid line is a theoretical line of slope one, starting from the flatband potential.

Comparison of the values of E_{oc} and ΔE_{pa} in Table I indicates that there is a relatively good agreement between these values for electrochemically reversible couples such as Ru(bpy)₃^{3+/2+}, Fe(bpy)₃^{3+/2+}, and ferricinium/ferrocene. The behavior of Fe(phen)₃^{3+/2+} is an exception. Although the redox potential of Fe(phen)₃^{3+/2+} is very similar to its analog bipyridine complex, its E_{oc} is smaller than that of Fe(bpy)₃^{3+/2+}. This indicates that surface energetics are sensitive not only to the E_{redox} but also to the chemical nature and electrochemical kinetics of the couple.

Voltammetric measurements.—In Fig. 3, current-potential scans for 0.1M TBAP in acetonitrile at α -Fe₂O₃ both in the dark and under illuminated polychromatic light are shown. The anodic currents in Fig. 3 are due to the oxidation and photo-oxidation of the supporting electrolyte (*i.e.*, ClO₄⁻) (27). The cathodic currents correspond to the reduction of iron oxide.

Flatband potentials were measured in separate acetonitrile solutions containing different couples, using the previously described transient photocurrent technique (25). E_{FB} in I⁻ solutions was found to be somewhat more negative (~0.1V) than those measured in other solutions. In general, though, E_{FB} for all acetonitrile solutions was 0.1 ± 0.1V vs. SCE. Knowing E_{FB} and E_{bg} , one can locate the valence and conduction bandedges, E_{vb} and E_{cb} , respectively, by recognizing that for a highly doped n-type semiconductor, E_{FB} is within 0.1V of E_{cb} . This means that for couples with E_{redox} between ~0.1 and 2.2V vs. SCE, Si-

Table I. Open-circuit photopotentials and cyclic voltammetric parameters for various redox couples at Pt and illuminated α -Fe₂O₃ in 0.1M TBAP/acetonitrile

Redox couple	E_{oc}^a	E_{redox}^b	$E_{\text{pa}}^{\text{Pt}c}$	$E_{\text{pa}}^{\alpha\text{-Fe}_2\text{O}_3d}$	ΔE_{pa}^e

Cl ₃ ⁻ /Cl ⁻	0.70	0.94	1.06	0.93	0.13

^a E_{oc} is the difference between the open-circuit potential of Pt vs. SCE and the open-circuit photopotential of α -Fe₂O₃ vs. SCE.

^b E_{redox} is the average of the cathodic and anodic peak potentials measured at a Pt electrode vs. SCE.

^c $E_{\text{pa}}^{\text{Pt}}$ is the anodic peak potential measured at Pt vs. SCE, with scan rate of 200 mV/s.

^d $E_{\text{pa}}^{\alpha\text{-Fe}_2\text{O}_3}$ is the anodic peak potential measured at an illuminated α -Fe₂O₃ electrode vs. SCE with scan rate of 200 mV/s.

^e ΔE_{pa} is the difference between $E_{\text{pa}}^{\text{Pt}}$ and $E_{\text{pa}}^{\alpha\text{-Fe}_2\text{O}_3}$.

Fig. 3. Linear scan voltammograms for Si-doped $\alpha\text{-Fe}_2\text{O}_3$ in 0.1M TBAP/acetonitrile in the dark and under illumination. Scan rate = 20 mV/s.

doped $\alpha\text{-Fe}_2\text{O}_3$ should be blocked to oxidation in the dark. However, upon illumination with light of energy ≥ 2.2 eV, their photo-oxidation should take place.

Linear and cyclic voltammograms at both dark and illuminated $\alpha\text{-Fe}_2\text{O}_3$ were obtained for a number of compounds that exhibit reversible or quasireversible behavior at Pt. Some of these voltammograms are shown in Fig. 4-8. All the redox couples studied have E_{redox} situated in the bandgap of iron oxide. As expected, there was no oxidation peak for the experiments performed in the dark while under illumination; photo-oxidations of all reduced forms of the redox couples began at potentials negative of their oxidation potentials at Pt.

Polypyridine complexes and ferrocene.—In Fig. 4-6, cyclic voltammograms of $\text{Ru}(\text{bpy})_3^{2+}$, $\text{Fe}(\text{phen})_3^{2+}$, and ferrocene at Pt and n-type $\alpha\text{-Fe}_2\text{O}_3$ are shown. In addition, their

linear sweep voltammograms with chopped illumination are presented. The polypyridine complexes studied all have high molar absorptivity in the visible region. Due to this absorbance, only low concentrations ($\sim 0.5\text{-}1$ mM) of the complexes were used. The photoanodic currents were all diffusion controlled. Cyclic voltammetric results at illuminated iron oxide and Pt for polypyridine complexes and ferrocene in 0.1M TBAP/acetonitrile are given in Table I. As was mentioned before, the photo-oxidations of all these couples occur at potentials negative of their reversible potentials. The magnitude of this negative shift increased as the standard potential of the redox couple increased.

Chopped illumination of all couples showed anodic current spikes decaying with time. During the dark period, cathodic spikes in the potential ranges of 0.5-0.9V for polypyridines and 0.2-0.3V for ferrocene were observed.

Fig. 4. Cyclic and linear sweep voltammograms of 0.5 mM $\text{Ru}(\text{bpy})_3(\text{ClO}_4)_2$ in 0.1M TBAP/acetonitrile. a: Pt electrode at 50 mV/s. b: dark $\alpha\text{-Fe}_2\text{O}_3$ at 200 mV/s. c: Illuminated $\alpha\text{-Fe}_2\text{O}_3$ at 200 mV/s. d: Transient photocurrent for $\alpha\text{-Fe}_2\text{O}_3$ of 20 mV/s and 0.2 Hz (i.e., light and dark periods = 2.5s each).

Fig. 5. Voltammograms of 1 mM $\text{Fe}(\text{phen})_3(\text{ClO}_4)_2$ in 0.1M TBAP/acetonitrile. Cyclic voltammograms at 200 mV/s: Pt electrode (a), illuminated $\alpha\text{-Fe}_2\text{O}_3$ (b) and transient photocurrent for $\alpha\text{-Fe}_2\text{O}_3$ at 20 mV/s and 0.2 Hz (c).

This behavior has been observed previously in acetonitrile solutions containing Ru(bpy)₃²⁺ and other species and was attributed to the back reduction of the product of the photo-oxidation (27). The reduction of the photo-oxidized species in the potential region positive of the E_{FB} is inconsistent with the ideal semiconductor/liquid electrolyte model (31, 36). These results, coupled with small variation observed in the open-circuit photovoltage measurements for the polypyridine complexes, imply that surface states, capable of mediating charge transfer, exist between E_{vb} and E_{cb} .

A comparison of our results for Ru(bpy)₃²⁺ with those of Fredlein and Bard (27), reveals that steady photocurrents observed in this work are at least four times more than the transient photocurrents obtained at 0.2% Ti-doped α -Fe₂O₃ for the same concentration of the complex. Any meaningful comparison requires the knowledge of the irradiation power at the electrode surfaces. Fredlein and Bard (27) have not mentioned the intensity of the light in their study. However, since they used a 250W lamp, one can assume that the light intensity at the electrode surface was not less than the light intensity used in the present work. This enhancement is due to the fact that Si is a better dopant for α -Fe₂O₃ than Ti (13). We observed that, upon increasing the concentration of ferrocene, the photoanodic current also increased. It reached a saturation value of ~ 2.8 mA/cm² at 1.0V vs. SCE for ~ 15 mM ferrocene.

Halides.—Acetonitrile solutions of LiI, LiBr, and LiCl were also investigated at iron oxide electrodes. Cyclic and linear sweep voltammograms for LiBr and LiI at illuminated α -Fe₂O₃ are shown in Fig. 7 and 8, respectively. Cyclic voltammograms at a Pt electrode are shown for comparison. It is known that halides (X⁻) give two anodic waves at Pt in acetonitrile solutions, producing X₃⁻/X₂ mixtures by the following reactions (37)

Our results at illuminated α -Fe₂O₃ also show two oxidation waves for halides of low concentrations (~ 20 mM or less). The position of peak potentials for the oxidation of halides at both Pt and illuminated iron oxide are not very reproducible, but they generally all show photoanodic currents at potentials negative of their anodic currents at Pt. In Table I, differences between the anodic peak potentials at Pt and illuminated α -Fe₂O₃, ΔE_{pa} , for X₃⁻/X⁻ halide couples are presented. Oxidation peaks of Br₃⁻/Br⁻ and Cl₃⁻/Cl⁻ at illuminated α -Fe₂O₃ occurred ~ 0.15 and ~ 0.13 V, respectively, negative of that at the Pt electrode. Although the photo-oxidation peak for I₃⁻/I⁻ is somewhat more positive than in oxidation peak at Pt, the onset of the photoanodic current is ~ 0.3 V more negative.

As can be seen from cyclic voltammograms and transient current behavior of halides at illuminated iron oxide, unlike the polypyridine and ferrocene couples, neither reduction peaks nor cathodic spikes are observed. This is probably due to the less reversible nature of the halides and would be expected for the ideal model for n-type semiconductors. However, the observation of two oxidation waves for halides at the illuminated iron oxide

Fig. 6. Voltammograms of 1 mM ferrocene in 0.1M TBAP/acetonitrile. a: Pt electrode at 50 mV/s. b: Illuminated α -Fe₂O₃ at 200 mV/s. c: Chopped illumination of α -Fe₂O₃ at 20 mV/s and 0.2 Hz.

Fig. 8. Cyclic voltammograms and steady-state photocurrent-potential curves of LiI in 0.1M TBAP/acetonitrile. a: Pt electrode in 6.7 mM LiI at 50 mV/s. b: Illuminated α -Fe₂O₃ in 6.7 mM LiI at 200 mV/s. c: Same as b, except in 25 mM LiI. d: Linear sweep at illuminated α -Fe₂O₃ in 6.7 mM LiI at 20 mV/s. e: Same as d, except in 25 mM LiI.

as found at Pt is in contrast to the ideal expectations. Within the ideal frame of semiconductor model (31, 32), one would expect a single wave for the total oxidation of X⁻ to X₂, rather than two separate waves for oxidation to X₃⁻ and X₂. This is because the photogenerated holes should thermodynamically be able to oxidize X⁻ to X₂. Similar results (*i.e.*, two peaks rather than one) have been found for biferrocene and tetramethyl-*p*-phenylenediamine (TMPD) at illuminated n-type CdTe and n-type MoSe₂ in acetonitrile solutions (34, 35). If, as suggested earlier, cathodic transients are caused by back reduction of photogenerated intermediates, we must conclude halide oxidation does not involve intermediates that are easily reduced or that are sufficiently long-lived to exhibit cathodic spikes.

As the concentration of halides increased above ~20 mM, the double waves at the illuminated iron oxide were replaced by a single wave. This is shown in Fig. 8 for I⁻, and the same behavior was observed for Br⁻. Apparently, at higher concentrations, the photocurrents are not diffu-

sion controlled and they are limited by photogenerated holes in the valence band. Therefore, a single wave, rather than two, is observed.

Electrodes Modified by a Thick Deposit of an Organic Compound

Mechanism of Electron Transfer

Loïc Roullier, Eric Waldner, and Etienne Laviron

Laboratoire de Synthèse et d'Electrosynthèse Organométalliques associé au CNRS (LA 33), Faculté des Sciences, 21100 Dijon, France

ABSTRACT

Electrodes modified by a thick crystalline deposit of an organic compound (phenazine, chloranil, azobenzene, benzo(c)cinnoline, 2,6-diaminoanthraquinone) are studied in aqueous medium by cyclic voltammetry and by the potential step method. When the deposit is thick enough, only a fraction of it is electroactive, and the loss of material by dissolution is small. The voltammograms have approximately the shape for a process controlled by diffusion in a confined space. It is shown that during the cathodic cycle, the process consists in a dissolution of the crystals of the oxidized form O, induced by the reduction of O at the electrode, followed by a crystallization of the reduced form R; the reverse process takes place during the oxidation cycle. The theoretical laws for diffusion in a confined space are approximately obeyed, because the system behaves as a thin layer placed near the electrode surface.

A large number of electrodes modified by redox polymers have been described (1); the diffusion-like transmission of the electrons through the coating can be limited by the hopping of electrons between redox sites, by diffusion of the counterion or of the solvent, or by the movements of the polymeric chain.

By contrast few studies concern electrodes covered by a thick deposit of a redox monomer, which can be organic [benzo(c)cinnoline (2), azobenzene, phenazine (3), chloranil (3, 4), phenoxazine (4), catechols (5), flavine adenine dinucleotide (6), tetrathiafulvalene (7)], organometallic [metal phthalocyanines (8)], or mineral [Prussian blue (9, 10), ruthenium purple (10), ferric ruthenocyanide (11), cupric hexacyanoferrate (12)].

We report and analyze in this paper results obtained with crystalline deposits of organic substances: phenazine (P), chloranil (QCl), azobenzene (AB), benzo(c)cinnoline (BC), and 2,6-diaminoanthraquinone (QNH₂). We have already briefly described the behavior of P, QCl, and AB in a preliminary note (3). On the basis of our results, we discuss the possible mechanisms of the reduction or oxidation of these films.

Experimental

Materials.—Phenazine, azobenzene, chloranil, and 2,6-diaminoanthraquinone were commercial products and were used without further purification.

Apparatus.—All electrochemical experiments were carried out on a Tacussel Instrument (potentiostat PRT 30-01, differential amplifier, and GSTP function generator). The *i*-E curves were drawn on a SEFRAM TGM 164 X-Y recorder, and the *i*-t curves were recorded on a NICOLET 2090-III digital oscilloscope. The measurements were carried out in water (Britton-Robinson buffers 0.2M KNO₃ or NaCl), in 2M HClO₄, 5M NH₄Cl, or in 1M NaOH at 20°C. The potentials refer to the saturated calomel electrode.

Electrodes.—A platinum disk electrode (0.8 or 2 mm diam) or a glassy carbon disk electrode (Carbone Lorraine V 25, 3 mm diam) sealed in a glass tubing were employed. Prior to use, the electrodes were polished successively on abrasive disks (ESCIL, grain 400-1200) and on alumina (ESCIL A3, grain 0.5 μm), and then ultrasonically cleaned in acetone or dimethylformamide.

The modified electrodes were prepared by dipping the electrodes in CH₂Cl₂, C₂H₅OH, CH₃COCH₃, or CF₃CO₂H solutions containing 1-10 mg ml⁻¹ of electroactive product or by micropipetting a few microliters of the solutions onto the platinum or the carbon disk and allowing the solvent to air dry.

No significant difference has been found in the stability of the electrodes or in their electrochemical properties when the supporting electrolyte was changed (LiClO₄, NaCl, or KBr instead of KNO₃, for example).

Results

Cyclic voltammetry.—Examples of voltammograms are given in Fig. 1-3. At slow sweep rates, the peak is symmetrical and resembles that obtained in a thin layer cell (13). At higher sweep rates, a tailing appears, as for a diffusion-limited process (14). The sweep rate ν at which the tailing begins to develop is different for each peak; for phenazine at pH 2, it can already be seen for peak A' (Fig. 1a) for $\nu = 45 \text{ mV s}^{-1}$ whereas much larger rates are needed for other peaks (Fig. 1b). In the case of azobenzene at pH 2 (Fig. 3), the cathodic peak already has a tailing for $\nu = 20 \text{ mV s}^{-1}$, but the anodic peak remains symmetrical even for higher sweep rates. For chloranil, the limits are much lower ($\nu < 0.4 \text{ mV s}^{-1}$).

The peaks obtained during the first cycle are often different from those of the subsequent cycles; a typical example is shown in Fig. 4.

Another characteristic feature is the marked hysteresis of the curves. The cathodic and anodic peaks are often widely separated, even at slow sweep rates. The difference ΔE_p between the peak potentials is about 170 mV for peaks A/A', and 250 mV for peaks B/B' of phenazine at pH 2 (Fig. 1); it reaches 500 mV in the case of azobenzene at pH 2 (Fig. 3). It must be noted that a smaller system of peaks, less separated, is often observed at the foot of the main peaks (Fig. 3). These peaks might be attributed to monolayer adsorption.

Generally speaking, at slow sweep rates, the peak current i_p varies linearly with ν , whereas it becomes proportional to $\nu^{1/2}$ at higher sweep rates (Fig. 5). The rate for which the transition occurs depends on the substance; no transition, for example, is observed in the case of phenazine at pH 14 (Fig. 5b) or for chloranil (Fig. 5d).

With thick deposits, the electrodes are quite durable; for phenazine at pH 2, the loss of active material after ten consecutive cycles between +0.43 and -0.47V at 10 mV s⁻¹ is less than 3%; with azobenzene at pH 2, after ten cycles at 17 mV s⁻¹ between +0.9 and -0.8V, it is about 2%. The loss with chloranil is even smaller. The amount of electricity Q involved during the reduction or the oxidation, measured by integration of the voltammetric peak, is then always much smaller than the charge Q_t which would correspond to the reduction or oxidation of all the deposit; some values are given in Table I. The charge Q tends to increase slightly when ν decreases, but always remains much smaller than Q_t .

When the deposit is too thin, the voltammograms are not stable, and the peaks disappear after a few cycles.

***i*-t Curves at constant potential.**—The current obtained when the potential is stepped from a value where no electrochemical reaction occurs to a value well past the reduction (or oxidation) potential decreases with time. A few examples of the transform $i = f(t^{-1/2})$ are shown in Fig. 6.

Fig. 1. Cyclic voltammograms of phenazine on a platinum electrode (electrode area $S = 5 \times 10^{-3} \text{ cm}^2$) at pH 2 (0.2M KNO_3). v (mV s^{-1}) in a: curve 1, 300; curve 2, 225; curve 3, 150; curve 4, 112; curve 5, 90; curve 6, 45. v (mV s^{-1}) in b: curve 1, 45; curve 2, 30; curve 3, 22; curve 4, 15; curve 5, 11.

The curves have the general shape expected for a process limited by diffusion in a confined space (15), when

$$i = nFAD^{1/2}C_s\pi^{-1/2}t^{-1/2} \left[1 + 2 \sum_{k=1}^{k=\infty} (-1)^k \exp\left(\frac{-k^2l^2}{Dt}\right) \right]$$

D being the diffusion coefficient, C_s the concentration, and l the thickness of the layer. However, if a value of $D^{1/2}C_s$ is calculated from the slope of the linear part (15), and if the whole curve is simulated, by using this value, discrepancies appear (Fig. 6a, 6c). In certain cases, moreover, the curve does not show the characteristic dip of

current at long times (Fig. 6b). Also, the first curve usually differs from the following (Fig. 6a).

Visual observation of the deposit.—We have observed visually under a microscope the evolution of crystals of phenazine at pH 2 when the potential is stepped from +0.3 to -0.7V by using the cell described in Fig. 1 of Ref. (16), in which the carbon particles were replaced by glassy carbon fibers. Phenazine is present initially under the form of small yellow crystals. When the potential is applied, they dissolve, while other long blue green crystals of dihydrophenazine appear in the solution between the fibers.

Fig. 2. Cyclic voltammograms of phenazine on a glassy carbon electrode ($S = 0.07 \text{ cm}^2$) in 1M NaOH . v (mV s^{-1}): 1, 175; 2, 87.5; 3, 43.7; 4, 29.2; 5, 17.5; 6, 8.75; 7, 4.37.

Dissolution of the deposit in a thin layer cell.
 —Experiments were carried out with P, AB, QCl, and QNH_2 , as described below. A few microliters of a solution containing the compound were micropipetted onto the glass plate forming one of the walls of the thin layer cell [cf. Ref. (17) and Fig. 7] and allowed to air dry. The cell was then filled with the electrolytic solution, and a sheet of very thin paper was placed between the spacer and the electrode (Fig. 7), to ensure that the crystals would not be in contact with the electrode. The potential was scanned repetitively at a slow sweep rate ($v < 50 \text{ mV s}^{-1}$) between two potentials situated on either side of the redox peaks. A system of anodic/cathodic peaks appears gradually (Fig. 8) until a steady-state system is obtained; the same system is still observed when the electrode is lifted into the bulk of the solution. This shows that an electrochemically induced dissolution of the deposit followed by a crystallization on the electrode has taken place. Such experiments can be used to prepare the modified electrodes electrochemically. Besides, electrodes can also be coated by successive scans in a saturated alcoholic solu-

tion of the compound. A typical example of such an electrochemically modified electrode is given in Fig. 9.

Discussion

Two types of mechanisms can be considered for the reduction or oxidation of a crystalline deposit.

The first consists in a direct electron transfer between neighboring sites in the crystal. This is similar to the process observed in the case of redox polymer electrodes with fixed sites (1, 18). The electron transfer must be accompanied here also by the transport of a counterion in the crystal lattice.

The second mechanism involves an intermediate electrochemically induced dissolution of the solid, followed by a crystallization, according to

If the two mechanisms can coexist, as suggested to one of us (19), with possible redox exchanges between the ions in solution and in the lattice, a situation similar to that observed with polymer electrodes when the redox centers are electrostatically bound to the polymeric chain could be found. The theory developed for that case could eventually be applied (20).

It has been demonstrated conclusively that in the case of Prussian blue (9b) and its analogs (12), the first mechanism is operating. The crystal lattice of the reduced and oxidized forms are very similar, and the size of the counterion is critical; transport occurs if it is small enough to enter the lattice.

With crystalline deposits of organic compounds, on the contrary, the redox process takes place exclusively ac-

^a At pH 3.8 (0.2M KNO_3).

^b At pH 2 (0.2M KNO_3).

^c In 5M NH_4Cl .

According to the second mechanism, as shown by the experimental findings. No difference is found when the size of the counterion is changed. The visual observation that the crystals of the reactant dissolve while those of the reduced product grow in a different place and under a different form is a direct proof of the mechanism. The same direct observation of the dissolution process has been reported (16) in aqueous medium in the case of the oxidation of particles of ferrocene Fc to the ferricinium ion Fc^+ , which is soluble

This scheme, in which the formation of Fc^+ is not followed by a crystallization, is simpler, and can be treated mathematically (21). The experimental results obtained with ferrocene are in good agreement with the theory (16). That a direct electron transfer from one site to the other in the crystal cannot take place is also in keeping with the fact that the crystalline forms of the oxidized and reduced species are usually very different [see, e.g., the case of azo/hydrazobenzene (22)]. It also tallies with theoretical (23) and experimental (24, 25) results which show that in the case of quinones (24) and azobenzene (25) the transfer of electrons between the reduced and oxidized forms is

Fig. 10. Schematic representation of the electrode modified by a thick deposit.

very slow in solution, due to the participation of protons in the global exchange; it is likely that the same reaction would also be slow in the crystal. A last proof of the mechanism is given by the dissolution experiments in the thin layer cell (*vide supra*).

The characteristics of the voltammetric peaks (variations of i_p with v , shape of the peak) and of the $i-t$ curves point to a diffusional transport in a confined space. This can be explained schematically as shown in Fig. 10. Two zones can roughly be distinguished in the deposit, an inert part which is too far from the electrode to play a role in the process, and a layer near the electrode, where the dissolution and recrystallization take place. This active zone is similar to a thin layer cell (17), the inert part playing the role of the wall of the cell. The inert layer protects the active zone from dissolution into the bulk solution during the redox process, as shown by the fact that the deposit dissolves after a few cycles when it is too thin. This insulating role of the crystalline outer deposit has already been illustrated in the case of the deposition of ferrocene from a solution of ferricinium salt, which ceases when the thickness of the crystalline layer has attained a certain value (16).

The diffusional process follows only approximately the laws for a thin layer, because of the approximate (nonplanar crystalline) nature of the wall of the cell. The fact that the transition from a thin layer to a semi-infinite diffusional behavior depends on the substance is certainly linked with the shape and the size of the crystals, which determine the equivalent thickness of the thin layer.

On Ionic Association in Ambient Temperature Chloroaluminate Molten Salts

Analysis of Electrochemical and Conductance Data

Marek Lipsztajn and Robert A. Osteryoung*

Department of Chemistry, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

A simple model based on the validity of the Nernst-Einstein equation and a constant $u_i\eta$ product was applied to the interpretation of conductance data for $\text{AlCl}_3\text{-RCl}$ [$\text{R} = \text{N-(1-butyl)pyridinium}$ or $\text{1-methyl-3-ethylimidazolium}$] ambient temperature ionic liquids. The dissociation constants of RAlCl_4 and RAl_2Cl_7 were calculated, and the experimental values of specific conductivity were reproduced with an error not exceeding 5% from ionic mobilities calculated from electrochemically measured diffusion coefficients. This calculation suggests that about 50% of the ions are associated into ion pairs. For very basic melts ($\text{MC} \leq 0.6$), the formation of ion aggregates is postulated.

In the past several years, low temperature molten salt systems composed of aluminum chloride and either $\text{N-(1-butyl)pyridinium}$ chloride (BuPyCl) or $\text{1-methyl-3-ethylimidazolium}$ chloride (ImCl) have been found to be useful solvents for electrochemical and spectroscopic investigations of both organic and inorganic species (1-4). Certain physical and chemical properties of these ionic liquids have been found (5, 6) to be very dependent on the melt composition, defined here as the mole ratio of AlCl_3 to RCl taken for preparation of the melt ($\text{MC} = n_{\text{AlCl}_3}/n_{\text{RCl}}$). Here R^+ is either BuPy^+ or Im^+ . Because of this strong dependence of physical and chemical properties on melt composition, it is difficult to compare the results obtained in the melts of different values of the MC. Since the equilibrium reaction

occurs over the entire range of melt composition (3), the chemical properties of these melts have been related to the acidity function defined as the logarithm of chloride ion concentration, $p\text{Cl}$. This treatment, however, assumes that the $\log[\text{Cl}^-]$ is the only essential variable (like pH in aqueous solutions), which is satisfying only in some cases, e.g., the complexation of metal ions with chloride ions (7, 8).

In this paper, we will consider the binary molten salts as mixtures of two or three compounds: RCl , RAlCl_4 , and RAl_2Cl_7 ($\text{R}^+ = \text{BuPy}^+$ or Im^+). This treatment, supported by spectroscopic studies (9) indicating that only R^+ , Cl^- , AlCl_4^- , and Al_2Cl_7^- ions are present in the melts in significant quantities, will be used for the interpretation of electrochemical and conductance data. Each melt characterized by a different MC will be treated as a different ionic liquid.

Let one consider the reactions occurring during mixing of RCl and AlCl_3

for $\text{MC} = y/x \leq 1$, and

for $1 \leq \text{MC} \leq 2$. Reaction [2] corresponds to the formation of so-called "basic" melts, reaction [3] to the formation of so-called "acidic" melts. A very special case is when $\text{MC} = 1.00$, which corresponds to the formation of the "neutral" melt (10), i.e., pure, molten RAlCl_4 . If $\text{MC} = 2$, we obtain pure, molten RAl_2Cl_7 . These considerations will be now applied to the interpretation of conductance data in the literature (5, 6).

Let us consider the 2:1 $\text{AlCl}_3\text{-RCl}$ melt, as molten RAl_2Cl_7 , consisting of R^+ and Al_2Cl_7^- ions, partially associated into ion pairs

The degree of association of ions (or dissociation of ion pairs) can be estimated from an analysis of the specific conductance (κ) and electrochemical data (diffusion coefficients of R^+ and Al_2Cl_7^-) by using two rather simple equations

$$\kappa = F \sum_i u_i c_i \quad [5]$$

and

$$u_i = |z_i|FD_i/RT \quad [6]$$

where u_i , D_i , z_i , and c_i denote ionic mobility ($\text{cm}^2 \text{s}^{-1} \text{V}^{-1}$), diffusion coefficient ($\text{cm}^2 \text{s}^{-1}$), charge and concentration of ion i (mol cm^{-3}), respectively, and F , R , and T have their usual meanings. The controversial problem of the applicability of Eq. [6], the Nernst-Einstein equation, to molten salts will be discussed in the next section.

For pure, molten $\text{BuPyAl}_2\text{Cl}_7$, we obtain

$$\kappa/F = u_{\text{BuPy}^+} c_{\text{BuPy}^+} + u_{\text{Al}_2\text{Cl}_7^-} c_{\text{Al}_2\text{Cl}_7^-} \quad [7]$$

with $c_{\text{BuPy}^+} = c_{\text{Al}_2\text{Cl}_7^-}$. Experimental values of the diffusion coefficients and calculated mobilities are collected in Table I. Substituting the experimental and related values into Eq. [7] [the specific conductivity, κ , for 2:1 $\text{AlCl}_3\text{-BuPyCl}$ melt at 40°C is equal to $0.0104 \Omega^{-1} \text{cm}^{-1}$ (5, 11), the value of the total concentration of $\text{BuPyAl}_2\text{Cl}_7$ (c_0), calculated by use of the molecular weight of this salt and its density (5) is $c_0 = 3.034 \text{ mol dm}^{-3}$], we obtain $\alpha_{\text{diss}} = c_i/c_0 \approx 0.47$, and K_d of an assumed ion pair is equal to 1.3 mol dm^{-3} .

Unfortunately, the conductance data for $\text{AlCl}_3\text{-BuPyCl}$ melts are very incomplete [the specific conductance was measured for 2:1 (5) and 1:1 (11) melts]. Therefore, we will analyze conductance data as measured for $\text{AlCl}_3\text{-ImCl}$ melts (6).

Table I. Transport properties of 2:1 $\text{AlCl}_3\text{-BuPyCl}$ melt

Ion	Diffusion coefficient ^a at 313 K and $\eta = 0.145\text{P}$ ($\text{cm}^2 \text{s}^{-1}$)	$D\eta/T$ ($\text{g cm s}^{-2}\text{K}^{-1}$)	Ionic mobility calculated from Eq. [6] ($\text{cm}^2 \text{s}^{-1}\text{V}^{-1}$)
BuPy^+	1.15×10^{-6}	5.3×10^{-10}	4.26×10^{-5}
Al_2Cl_7^-	8.85×10^{-7}	4.1×10^{-10}	3.28×10^{-5}

^a The diffusion coefficients were measured (14) in almost neutral $\text{AlCl}_3\text{-ImCl}$ melt at 303 K. The value of the viscosity, $\eta = 0.156\text{P}$ (6), was recalculated to conditions of the 2:1 $\text{AlCl}_3\text{-BuPyCl}$ melt, $\eta = 0.145\text{P}$ at 313 K (5), under the assumption that the $D\eta/T$ product is constant and independent of the concentration of electrolyte (see Discussion section).

* Electrochemical Society Active Member.

Acidic Melts

The acidic $\text{AlCl}_3\text{-ImCl}$ will be considered as a mixture of ions and ion pairs of ImAlCl_4 and ImAl_2Cl_7 involving two equilibria

and

To find the concentrations of the ionic components (Im^+ , AlCl_4^- , and Al_2Cl_7^-) at a particular melt composition, the following system of equations is considered

$$\begin{aligned} K_1 &= [\text{Im}^+][\text{Al}_2\text{Cl}_7^-]/(c_{\text{ImAl}_2\text{Cl}_7} - [\text{Al}_2\text{Cl}_7^-]) \\ K_2 &= [\text{Im}^+][\text{AlCl}_4^-]/(c_{\text{ImAlCl}_4} - [\text{AlCl}_4^-]) \\ [\text{Im}^+] &= [\text{AlCl}_4^-] + [\text{Al}_2\text{Cl}_7^-] \end{aligned} \quad [10]$$

The parameters are equilibrium constants K_1 and K_2 , as well as the total concentration of salts in a mixture, $c_{\text{ImAl}_2\text{Cl}_7}$ and c_{ImAlCl_4} are obtained from the stoichiometry of the melt in the acid composition. We obtain a cubic equation in the form

$$\begin{aligned} &[\text{Im}^+]^3 + (K_1 + K_2)[\text{Im}^+]^2 + (K_1K_2 \\ &\quad - K_1c_{\text{ImAl}_2\text{Cl}_7} - K_2c_{\text{ImAlCl}_4})[\text{Im}^+] \\ &\quad - K_1K_2(c_{\text{ImAl}_2\text{Cl}_7} + c_{\text{ImAlCl}_4}) = 0 \end{aligned} \quad [11]$$

Introducing various values of K_1 and K_2 , which were, however, not very different from the value estimated for pure $\text{BuPyAl}_2\text{Cl}_7$, we were able to calculate the concentrations of ionic species across the range of acidity ($1 < \text{MC} < 2$). Fortunately, only one root of this cubic equation was positive, and no problem of choosing the proper root appeared. The calculated concentrations of ionic components were subsequently introduced into Eq. [5] formulated for each experimental value of specific conductivity measured for acidic melts and reported in Ref. (6) ($\text{MC} = 1.00, 1.04, 1.08, 1.27, 1.38, 1.50, 1.56, 1.78, 1.94, 2.0$, see Table II). Since our purpose was to find the best fit of the parameters of Eq. [5] but since the mobilities of ions are dependent on melt viscosity, we have used the values of specific conductivity normalized to the same viscosity, assuming the constancy of the Walden product. As a reference point, we have chosen the viscosity of the neutral $\text{AlCl}_3\text{-ImCl}$ melt at 25°C [$\eta = 0.178 \text{ P}$ (6)]. That is $\kappa_{\text{normalized}} = \eta \cdot \kappa_{\text{expt.}}/0.178$. Based on this normalization, ten separate equations were formulated (one for each MC), similar to Eq. [5], in which five parameters were involved; the three mobilities, u_{Im^+} , $u_{\text{Al}_2\text{Cl}_7^-}$, $u_{\text{AlCl}_4^-}$ and two equilibrium constants, K_1 , K_2 determining the concentrations of ions. (A more detailed explanation of this procedure is offered in the Appendix). The best fit was found by using the following set of parameters: $K_1 = 1.3 \text{ mol dm}^{-3}$, $K_2 = 1.2 \text{ mol dm}^{-3}$, $u_{\text{Im}^+} = 4.37 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1} \text{ V}^{-1}$, $u_{\text{Al}_2\text{Cl}_7^-} = 2.65 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1} \text{ V}^{-1}$, and $u_{\text{AlCl}_4^-} = 8.0 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1} \text{ V}^{-1}$. The largest difference between experimental and calculated value of specific conductivity did not exceed 5% (Fig. 1).

Basic Melts

The same procedure was used for basic melts, which were treated as mixtures of ImCl and ImAlCl_4 . Additionally, the equilibrium

was assumed. Using the value of $K_2 = 1.2 \text{ mol dm}^{-3}$ (for ImAlCl_4), the mobilities of Im^+ and AlCl_4^- , as in acidic melts, and the mobility of Cl^- ($u_{\text{Cl}^-} = 3.2 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1} \text{ V}^{-1}$) calculated according to Eq. [6] from a recently measured value of D_{Cl^-} ($D_{\text{Cl}^-} = 9.55 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ in 1:1 $\text{AlCl}_3\text{-ImCl}$ melt at 303 K , $\eta = 0.156 \text{ P}$) (12), the best fit for three points ($\text{MC} = 0.92, 0.72$, and 0.67) was found with $K_3 = 0.5 \text{ mol dm}^{-3}$. For two other, very basic melts ($\text{MC} = 0.56$ and 0.45), the values of normalized specific conduc-

Fig. 1. The dependence of normalized specific conductivity on melt composition for $\text{AlCl}_3\text{-ImCl}$ melts at 298 K . o: Experimental values taken from Ref. (6). x: Values calculated in this paper.

tivity were very high (even higher than that for the neutral melt). We assume this is due to an increase of the number of charge carriers, possibly because of the formation of charged ion aggregates.

Discussion

To initiate this section, we will summarize and discuss the assumptions of the calculations presented in the previous section. First, we assumed (i) a constant ionic mobility-viscosity product, *i.e.*, $u_1\eta = \text{constant}$, (ii) the independence of u_1 on the concentration of electrolyte, and (iii) no change of transport mechanism across the entire range of melt compositions. Second, we assumed the validity of the Nernst-Einstein equation (Eq. [6]). Third, we assumed the independence of ion pair dissociation constants on melt composition.

The assumption that the viscosity of the melt is the only factor influencing the mobilities of ions and the constancy of the Walden product in the form $u_1\eta = \text{const.}$ is supported by numerous electrochemical measurements performed in the low temperature molten salts. For example, Nanjundiah *et al.* (13) found adherence to the Stokes-Einstein relation for diffusion coefficients of Fe(III) and Fe(II) in $\text{AlCl}_3\text{-BuPyCl}$ melts, and the constancy of $D\eta/T$ value was subsequently extended to the $\text{AlCl}_3\text{-ImCl}$ melts (12). $D\eta/T$ was found to be constant for BuPy^+ reduction in basic and neutral $\text{AlCl}_3\text{-ImCl}$ melts (14). Angell *et al.* (15) have carried out physicochemical measurements and computer simulations on the role of cation coordination numbers on melt physical properties for ambient temperature $\text{AlCl}_3\text{-}\alpha\text{-picolinium chloride}$ melts. They reported that ionic mobilities generally scale with the melt fluidity (reciprocal viscosity), except near glass-transition temperature. The relation between transport properties of ions (diffusion coefficients) and the viscosity of ionic liquids has also been discussed in the literature in terms of the applicability of the Stokes-Einstein equation [see, *e.g.*, Ref. (16)], and the applicability of this equation was also found in $\text{AlCl}_3\text{-BuPyCl}$ ambient temperature melts (13).

The change of the total concentration of electrolyte in going through the entire range of melt compositions is not very large (*e.g.*, for $\text{AlCl}_3\text{-ImCl}$ melts the total concentration changed from 4.6 mol dm^{-3} to 3.35 mol dm^{-3} for 1:1 and 2:1 $\text{AlCl}_3\text{-ImCl}$ melts, respectively), and should not significantly influence the mobilities or diffusion coefficients in the solvent. The most controversial question in our treatment of the problem is the applicability of the Nernst-Einstein equation (Eq. [6]) to the molten salt data. This problem has often been discussed in the litera-

ture, and it is not our purpose to present a review of this subject; a short discussion is in order.

The values of conductivity calculated from the Nernst-Einstein equation using experimental diffusion coefficients, usually measured by radiotracer methods, were found to be higher than experimentally determined values, and these positive deviations from the Nernst-Einstein equation usually increased with increasing temperature (17). Various interpretations of these facts have been given, both in terms of phenomenological and molecular theories.

Most important is a statement by Bockris and Hooper (18) that the Nernst-Einstein equation does not necessarily involve the laws of dilute solutions. This limitation is avoided in the conclusions of Mott and Gurney (19) and Carman and Stein (20).

The phenomenological "explanation" of deviations from the Nernst-Einstein equation can be derived from an irreversible thermodynamic approach [see, e.g., Ref. (21, 22)]. Using the Onsager phenomenological equations, it was found that the Nernst-Einstein equation is obeyed when the cross coefficients L_{\pm} and L_{\mp} , governing the influence of the driving force (\bar{F}_{\pm}) on the flow of the positive ions (J_{\pm}) and vice versa, are both equal to 0, i.e., when the flow of each species is unaffected by the driving forces on the other species. Since phenomenological treatments cannot throw light on the molecular mechanism responsible for the deviations from the Nernst-Einstein equation, several molecular explanations have been given. The common conclusion in all these explanations is that the extent to which the Nernst-Einstein equation holds is a measure of the similarity of the frictional interactions for the different modes of motion. If the frictional force in electrical conductance is taken to be the same as that in diffusion, the Nernst-Einstein relation results [see, e.g., Ref. (23)].

According to Borucka *et al.* (24), the measured diffusion includes displacements of entities which do not contribute to conduction (so-called "vacancy pair" or "molecule" diffusion). These authors apparently assumed that the Nernst-Einstein equation is applicable to molten salts if the "true" diffusion coefficients of ionic components, after subtraction of the noncontributing diffusion term corresponding to the displacement of entities which have a zero net charge during jumps and thus do not contribute to conduction, are used. Similar conclusions also have been given by Hansen and McDonald (25) in a molecular-dynamic study of a model in which the interionic pair potential consists of the coulombic term and an inverse-power repulsion, which is assumed to be the same for all ions. The relation between the self-diffusion coefficient and the electrical conductivity is discussed, and the observed deviations from the Nernst-Einstein equation are explained in terms of short-lived cross correlation and formation of ionic complexes which contribute to the diffusion flux but not to the electrical current. In both these papers, it was suggested that deviations from the Nernst-Einstein equation are not necessarily the result of a permanent association of ions of opposite charge.

The possibility of partial association of molten salts and its influence on transport properties was also considered (26-29). For example, Chemla and Lantelme (27), in discussing the validity of the Nernst-Einstein equation in molten salts, introduced the polyionic motion model. According to these authors, any experimental transport property should be the result of the motion of several species, i.e.

$$D_c = \sum x_i D_i \quad [13]$$

where x_i denotes the molar fraction of species i containing element c . These authors also found that the Nernst-Einstein equation is strictly obeyed in ionic single crystals.

Summarizing all these treatments one can see that the main problem is to find the proper value of the diffusion coefficients, or, in other words, to extract from the measured value of self-diffusion coefficients the diffusion

coefficients which could be attributed to the charged particles involved both in diffusion and conduction. We assume that the experimental values of the diffusion coefficients measured by using rotating disk electrode voltammetry as employed in this paper do not exceed the "true" values of ionic components, as was the case of self-diffusion coefficients measured by use of radiotracer method (24). If one considers the possibility that both the free ions and short-lived ion pairs contribute to diffusion, the diffusion coefficients measured here would be a weighted average of the respective values for free ions and ion pairs and thus would be smaller than the values for the free ion.

The assumption of the independence of the estimated equilibrium constants on melt composition (and concentration of electrolyte) is not new in the field of thermodynamics of reactions in molten salts. Similar assumptions have been implicit in all studies regarding the estimation of any other equilibrium constants, like that of reaction [1] (4) or complexation reactions (7, 8).

It is also worth mentioning that all the data taken to our analysis were measured at temperatures below the temperature $2T_0$, i.e., in the range of temperatures where the deviations from the Nernst-Einstein equation, according to Angell (30), are rather small. [T_0 is the temperature of configurational ground state for liquids, corresponding to the experimental value of the glass transition temperature; these parameters were reported by Wilkes *et al.* (6); the values of T_0 were estimated according to the Vogel-Tammann-Fulcher equation (31).]

Consequently, using all these assumptions, we were able to reproduce the conductivity data in the whole range of melt compositions, except in the very basic $\text{AlCl}_3\text{-ImCl}$ melts. As follows from Fig. 1, in this region of acidity a very significant increase of normalized conductivity is observed, presumably corresponding to a distinct increase of charge carriers. As follows from our calculations of concentrations of associated entities, $\text{Im}^+ \dots \text{AlCl}_4^-$ and $\text{Im}^+ \dots \text{Cl}^-$ (see Fig. 2 and Table II), the minimum of normalized conductivity is located at $[\text{Im}^+ \dots \text{Cl}^-]/[\text{Im}^+ \dots \text{AlCl}_4^-]$ ratio close to 1. For $r = [\text{Im}^+ \dots \text{Cl}^-]/[\text{Im}^+ \dots \text{AlCl}_4^-] > 1$, the steep increase of normalized conductivity is observed [the normalized equivalent conductance (κ_{norm}/c_0) is changing qualitatively in the same way (see Table II)]. This "strange" behavior of the conductivity can be explained if we consider the possibility of weak dipole-dipole-type interactions between $\text{Im}^+ \dots \text{Cl}^-$ and $\text{Im}^+ \dots \text{AlCl}_4^-$ at $r < 1$ and interactions $\text{Im}^+ \dots \text{Cl}^- - \text{Im}^+ \dots \text{Cl}^-$ accompanied with ion aggregate formation for $r > 1$. The hypothesis of ion aggregate formation in basic melts was considered by Wilkes *et al.* (32) in magnetic resonance studies of $\text{AlCl}_3\text{-ImCl}$ ionic liquids.

Fig. 2. The concentrations of different entities calculated in this paper for $\text{AlCl}_3\text{-ImCl}$ melts. The arrow at $MC = 0.58$ corresponds to $r = [\text{Im}^+ \dots \text{AlCl}_4^-]/[\text{Im}^+ \dots \text{Cl}^-] = 1$.

^a Values of density, viscosity, and specific conductivity are taken from Ref. (6); all concentrations are calculated in this paper.

The interpretation of normalized specific conductivity in the acidic and slightly basic region seems to be rather straightforward. Going from 2:1 AlCl₃-ImCl melt (pure, molten ImAl₂Cl₇) to 1:1 melt (pure, molten ImAlCl₄), the increase of normalized specific conductivity (as well as of normalized equivalent conductivity) can be related to the replacement of the less mobile anion (Al₂Cl₇⁻) with the more mobile one (AlCl₄⁻). By analogy, the small decrease of conductivity in going from neutral to basic melts can be explained in terms of dilution of the high conducting neutral melt with molten ImCl, containing chloride ions which are less mobile than AlCl₄⁻.

An example of the usefulness of this treatment is the analysis of the differences of normalized conductivities measured for 1:1 and 2:1 AlCl₃-RCl melts. Assuming that the degree of association for all these melts is similar, we can write Eq. [5] for each of these melts

$$\kappa_{norm}^{BuPyAl_2Cl_7} / \{\alpha F c_{0, BuPyAl_2Cl_7}\} = u_{BuPy^+} + u_{Al_2Cl_7^-} \quad [14]$$

$$\kappa_{norm}^{BuPyAlCl_4} / \{\alpha F c_{0, BuPyAlCl_4}\} = u_{BuPy^+} + u_{AlCl_4^-} \quad [15]$$

$$\kappa_{norm}^{ImAl_2Cl_7} / \{\alpha F c_{0, ImAl_2Cl_7}\} = u_{Im^+} + u_{Al_2Cl_7^-} \quad [16]$$

$$\kappa_{norm}^{ImAlCl_4} / \{\alpha F c_{0, ImAlCl_4}\} = u_{Im^+} + u_{AlCl_4^-} \quad [17]$$

Subtracting Eq. [14] from [15] and Eq. [16] from [17], we get expressions for the difference of mobilities of AlCl₄⁻ and Al₂Cl₇⁻ in the melts containing either BuPy⁺ or Im⁺ cations. Introducing experimental values, we find that these differences are almost exactly the same in both melts. The constant difference between $u_{AlCl_4^-}$ and $u_{Al_2Cl_7^-}$ calculated for both melts, which is in accord with chemical intuition, seems to indicate that the assumptions in our paper are reasonable.

Some comments can be made regarding the very high mobility of tetrachloroaluminate anion. This observation cannot be explained from the viewpoint of ionic radii of this ion, and we still do not have any reasonable explanation. However, a very high mobility of AlCl₄⁻ ion was postulated by Angell *et al.* (15) in a paper dealing with ambient temperature AlCl₃- α -picolinium chloride melts.

In view of the probable uncertainties inherent in the estimation of ionic mobilities, especially in the case of AlCl₄⁻ and Im⁺ (no corresponding diffusion coefficients were measured), no detailed analysis of these data will be

presented; however, it is difficult to avoid, for example, the problem of transference numbers in molten salt chemistry. However, for cases like the 2:1 AlCl₃-BuPyCl melt, where both diffusion coefficients were measured and the ratio of $D_{BuPy^+}/D_{Al_2Cl_7^-}$ was found to be about 1.26, one cannot expect that only cations are the charge carriers and $t_{M^+} = 1$. If we formally calculate the transference numbers in this particular case, we obtain the respective value for cation equal to 0.56. This result is supported by data for other molten salts containing large organic cations (5, 33) [see also Ref. (34)]. Recently, Hussey and Øye (35), by use of the Hittorf method, determined the external and internal transport numbers for the AlCl₃-ImCl ionic liquid in acidic melt compositions. The Im⁺ external and internal transport numbers were found to be 0.71 and 1.0, respectively, in the acidic range. This result is consistent with our findings only in the case of more acidic melts (MC close to 2).

Finally, we must emphasize that our very simple treatment, based on considering the mobilities of ions, seems to be more fruitful and predictable than the traditional treatment based on the analysis of changes of equivalent conductance with concentration. In our opinion, this latter treatment can be successfully used only for electrolyte solutions in "normal" solvents where no significant change of viscosity and composition occurs. The sense of equivalent conductance in binary molten salts is not very clear, however formally this property can be defined (5, 6).

APPENDIX

In the first step, we calculate from Eq. [10] the concentrations of ionic components: Im⁺, AlCl₄⁻, and Al₂Cl₇⁻ assuming 20 different sets of dissociation constants K_1 and K_2 . We assume these constants are (i) not very different from the value calculated for BuPy⁺...Al₂Cl₇⁻ ($K = 1.3 \text{ mol dm}^{-3}$) and (ii) smaller than that value (since the ra-

dus of Im^+ is smaller than of BuPy^+). We expect more pronounced ion pairing in the case of imidazolium salts and hence smaller dissociation constants.

In the next step, the concentrations calculated for the ionic components were introduced into Eq. [5] formulated for ten different melt compositions: MC = 1.00, 1.04, 1.08, 1.27, 1.38, 1.50, 1.56, 1.78, 1.94, 2.0. Before specific conductivities were introduced into Eq. [5], they were normalized to the same viscosity; the value of the viscosity of the neutral $\text{AlCl}_3\text{-ImCl}$ melt at 25°C was chosen arbitrarily. This normalization permitted the use of the same set of mobilities, u_{Im^+} , $u_{\text{AlCl}_4^-}$, and $u_{\text{Al}_2\text{Cl}_7^-}$, in all ten equations (one equation for one melt composition). A fixed set of dissociation constants, K_1 , K_2 , determined the concentrations of ions. At this point, we fitted the ten equations with three parameters (three mobilities) for 20 separate cases (various sets of K_1 and K_2). The initial value of $u_{\text{Al}_2\text{Cl}_7^-}$ employed was as calculated from the corresponding diffusion coefficient (see Table I), and the initial value of u_{Im^+} was assumed slightly greater than u_{BuPy^+} for the same reason as above (size of radius, see also Table I). The minimized sum of squares of the difference between calculated and experimental normalized specific conductivities was used to establish the "best" value for the mobilities and equilibrium constants.

In addition, the case of large K_1 and K_2 values (no ion pairing) was considered. We assumed $\alpha = 1$ and applied similar procedures to those described by Eq. [14]-[17]. That is, we considered the differences of normalized specific conductivities between 1:1 and 1.5:1 as well as between 1.5:1 and 2:1 melts. In these simple cases, we can rewrite Eq. [5] as

$$\kappa_{(1:1)}/c_{(1:1)} = u_{\text{Im}^+} + u_{\text{AlCl}_4^-} \\ = 4.91 \times 10^{-3} \Omega^{-1} \text{cm}^{-1} \text{mol}^{-1} \quad \text{for MC} = 1.0 \quad \text{[A-1]}$$

$$\kappa_{(1.5:1)}/c_{(1.5:1)} = u_{\text{Im}^+} + 0.5(u_{\text{AlCl}_4^-} + u_{\text{Al}_2\text{Cl}_7^-}) \\ = 3.78 \times 10^{-3} \Omega^{-1} \text{cm}^{-1} \text{mol}^{-1} \quad \text{for MC} = 1.5 \quad \text{[A-2]}$$

$$\kappa_{(2:1)}/c_{(2:1)} = u_{\text{Im}^+} + u_{\text{Al}_2\text{Cl}_7^-} \\ = 3.33 \times 10^{-3} \Omega^{-1} \text{cm}^{-1} \text{mol}^{-1} \quad \text{for MC} = 2 \quad \text{[A-3]}$$

Subtracting Eq. [A-2] from [A-1] and Eq. [A-3] from [A-2], we obtain

$$\text{[A-1]} - \text{[A-2]} = 0.5(u_{\text{AlCl}_4^-} - u_{\text{Al}_2\text{Cl}_7^-}) \\ = 1.12 \times 10^{-3} \Omega^{-1} \text{cm}^{-1} \text{mol}^{-1} \quad \text{[A-4]}$$

while

$$\text{[A-2]} - \text{[A-3]} = 0.5(u_{\text{AlCl}_4^-} - u_{\text{Al}_2\text{Cl}_7^-}) \\ = 0.45 \times 10^{-3} \Omega^{-1} \text{cm}^{-1} \text{mol}^{-1} \quad \text{[A-5]}$$

This significant discrepancy between Eq. [A-4] and [A-5] indicates that the "no ion pairing" model is not acceptable.

Magnetic and Transport Properties of Electrochemically Oxidized Polyacetylene

John R. Reynolds,* Joseph B. Schlenoff,* and James C. W. Chien

Department of Chemistry, Department of Polymer Science and Engineering, Materials Research Laboratories, University of Massachusetts, Amherst, Massachusetts 01003

ABSTRACT

The magnetic and transport properties of polyacetylene electrochemically oxidized in the presence of perchlorate ion have been determined. Room temperature dc conductivity is unaffected by doping between $10^{-6} < y \leq 10^{-3.5}$. A rapid conductivity increase occurs with increasing dopant level having a midpoint of transition at $ca. y \sim 8 \times 10^{-3}$. By comparison, the change in thermopower *vs.* y is sharper taking place within a tenfold increase in y with a midpoint at $ca. y \sim 3 \times 10^{-3}$. The unpaired spin concentrations remain constant as dopant concentration increases before the onset of a Dysonian lineshape at $ca. y = 10^{-2}$. The results are interpreted as the melting of a glassy carrier state causing the sharp change of transport properties. A phase separation into metallic domains occurs at $y = ca. 10^{-2}$. Side reactions involving the electrolyte complicate the electrochemistry of polyacetylene.

Polyacetylene, $[CH]_x$, can be doped to the highly conductive state by chemical, photochemical, or electrochemical processes (1). The last of the three (2) is the most versatile, since the level of doping can be controlled by the applied potential and the approach to equilibrium (3) can be monitored by the current. This technique has been used to study *cis-trans* isomerization (4) and changes in the midgap states (5). However, even though the magnetic and transport properties of chemically doped polyacetylene have been extensively investigated, especially in regard to the effect of dopant uniformity (6), the same cannot be said about the electrochemically doped materials. Studies on the electrochemical process have been confined up to now to high dopant concentration. The central purpose of this paper is to report the magnetic and transport properties of electrochemically oxidized *trans*- $[CH]_x$ from ppm to percent dopant level.

Experimental Techniques

Film preparation.—Free standing films of polyacetylene, approximately 100 μm thick, were prepared by the method of Ito *et al.* (7) at 195 K. The resulting *cis*-rich films were thermally isomerized to *trans*- $[CH]_x$ by heating at 453 K for 1 h *in vacuo*. Films were handled under N_2 in a Vacuum Atmospheres dry box and stored at 195 K under argon.

Doping method.—Electrochemical oxidation of *trans*- $[CH]_x$ was performed by loading a 1 cm diam circular specimen (*ca.* 10 mg) into a cell constructed from a Teflon stopcock (Fig. 1). The working electrode makes pressed contact with the film, which can be subsequently removed for characterization of the doped polymer. Lithium wire counter and reference electrodes were scraped clean under 1M LiClO_4 in propylene carbonate immediately prior to use. LiClO_4 was melt dried under dynamic vacuum; propylene carbonate was distilled under vacuum from anhydrous sodium carbonate and potassium permanganate. Potential was controlled (with IR compensation) by a Princeton Applied Research (PAR) 173 potentiostat/galvanostat. Charge was recorded with a PAR 179 digital coulometer. Open-circuit potential, V_{oc} , was measured with a Keithley 616 electrometer.

Oxidation of $[CH]_x$ was carried out by stepping the applied potential of the working electrode just high enough to pass 0.02–0.05 mA mg^{-1} of polymer. After each potential step, the low current, which assures a slow doping rate, was allowed to decay to less than 10% of the initial current before another potential increase was applied. The dopant level per CH unit, y , was determined coulometrically.

After doping to the desired level, the film was immersed in 5 ml of electrolyte for 5 or 10 days to study the interaction between doped $[CH]_x$ and the electrolyte. The

film was then washed thoroughly in distilled, degassed CH_2Cl_2 , and dried *in vacuo*. Alternatively, the doped film after washing and drying was allowed to stand in N_2 or argon atmosphere and changes in V_{oc} and room temperature dc conductivity (σ_{RT}) followed.

Measurement methods.—Conductivity was measured using the four-probe technique and the thermoelectric power coefficient (\mathcal{E}) was measured as described previously (6). EPR spectra were recorded with a Varian X-band spectrometer; the unpaired spin concentration was obtained by double integration of the EPR spectra and compared with a standard solution of tetramethylpiperidinoxyl free radical in hexadecane. However, EPR

spectra with Dysonian lineshapes cannot be integrated in the same way. V_{oc} 's of dried films were measured vs. Li/1M LiClO₄.

Experimental Results

Open-circuit potential.—It has been reported (3) that V_{oc} is linearly dependent on the degree of oxidation by

$$V_{oc} (24h) = 3.43 + 0.14 \ln y \quad [1]$$

where $5 \times 10^{-4} \leq y \leq 6 \times 10^{-2}$. It was observed that the values of V_{oc} decrease with time of contact between doped [CH]_x and the electrolyte. We extended this experiment to $10^{-6} < y < 9 \times 10^{-2}$ and increased the time of equilibration to 5 and 10 days (Fig. 2). The results showed that Eq. [1] is valid only for the range of y studied by Kaneto *et al.* (3). The shape of the V_{oc} vs. $\log y$ plot resembles, to a certain extent, the $\log \sigma$ vs. $\log y$ plots.

Figure 3 shows that a [CH(ClO₄)_{0.05}]_x film retains its initial conductivity when stored in nitrogen after rinsing and removal of solvent, whereas a similar film in contact with electrolyte loses conductivity steadily.

Transport properties.—The variation σ_{RT} with dopant level is shown in Fig. 4. There is no significant change in σ for $10^{-6} < y < 10^{-3.5}$ above which there is a 10⁷-fold increase in σ between $10^{-3.5} < y < 10^{-1.5}$. If one takes the midpoint of this transition at $\sigma = 10^{-2} (\Omega\text{cm})^{-1}$, this corresponds to a y value of ca. 8×10^{-3} .

The open squares in Fig. 4 are those of specimens equilibrated with the electrolyte for 21 days. They have, in general, much lower conductivities than those equilibrated for a shorter time.

There is a small decrease of the thermopower coefficient, \mathcal{S} , between $10^{-6} \leq y \leq 10^{-3}$ (Fig. 5). A precipitous drop in \mathcal{S} occurs between $10^{-3} \leq y \leq 10^{-2}$ with the midpoint of the transition at $y \sim 3 \times 10^{-3}$. Therefore, without the interfibril contribution to resistance observed by dc conductivity, the intrinsic transition in transport property according to \mathcal{S} occurs over a narrower range and at a lower value of y .

Magnetic properties.—The unpaired spin concentrations of electrochemically doped polyacetylene remain virtually constant for $10^{-6} \leq y \leq 10^{-2}$ (Table I), over which range the EPR spectra can be doubly integrated. The Cu-

rie dependence decreases with increasing y (Fig. 6) as determined by spin concentration vs. T^{-1} between 133 and 278 K. When the films attain a $\sigma > 10 (\Omega\text{cm})^{-1}$ at $y > 10^{-2}$, the EPR spectra assumed a Dysonian lineshape (Fig. 7).

Discussion

The questions of homogeneity in doping and semiconductor to "metal" transition have been the subjects of numerous publications. We have proposed several criteria for homogeneity in the case of chemical doping (6). In the case of electrochemical doping, the process can be monitored continuously. Due to the nature of electrochemical doping, one must consider the homogeneity of dopant ion

distribution at two morphological levels. The first is the macroscopic distribution across the thickness of the 100 μm film and the second is that across the $[\text{CH}]_x$ fibrils from its surface to the core.

For the macroscopic $[\text{CH}]_x$ film, initial oxidation will occur at the Pt-polymer contact. Further removal of electrons proceeds across the thickness of the film. To study this process, an experiment was carried out with two $[\text{CH}]_x$ films sandwiched together and placed into a doping vessel. A potential of 3.7V was applied for 24h, and the

two films were separated, washed, and dried. We found compositions of $[\text{CH}(\text{ClO}_4)_{0.04}]_x$ and $[\text{CH}(\text{ClO}_4)_{0.03}]_x$ by elemental analysis with respective conductivities of 11 and 9 $(\Omega \text{ cm})^{-1}$. This small difference was similar to that observed by Castaing microprobe studies (8).

With regard to the microscopic homogeneity of electrochemical doping, Kaneto *et al.* (3) attributed the voltage

decrease of $[\text{CH}(\text{ClO}_4)_y]_r$, on standing after doping, to the diffusion of dopant ions from the exterior to the interior of the ca. 20 nm diam polymer fibrils. This process is said to be slow and a diffusion-limited equilibrium attained after 24h (3). Since the V_{oc} is determined by that portion of the $[\text{CH}(\text{ClO}_4)_y]_r$ in contact with the electrolyte, its value will decrease with time on standing as the extent of oxidation at the exterior of the fibrils decreases while the degree of oxidation in the fibril interior increases by the diffusion of the ClO_4^- ion. A theory of electric field enhancement of diffusion was proposed (9) to explain how high power and current densities can be generated by a $[\text{CH}]_r$ battery cell despite the postulated slow diffusion and low ionic mobility in polyacetylene. We have found (10) that for ultrathin $[\text{CH}]_r$ films (~ 100 nm) complete and uniform electrochemical doping took only a few seconds. In these samples, there are an abundance of microfibrils only 2-3 nm in diameter. For the more conventional $[\text{CH}]_r$ film, *i.e.*, prepared by the procedure of Ito *et al.* (7) comprised of thicker fibrils of 20-30 nm in diameter, we found equilibrium electrochemical doping to take 1.5-2h.

The following results show definitively that side reactions involving the electrolyte present complications to the electrochemical behavior of $[\text{CH}]_r$. For instance, if $[\text{CH}]_r$ is doped to $V_{oc} = 3.67\text{V}$, washed, dried, and kept in argon, there is only a 0.05V drop in V_{oc} after 400h. However, if the same film remains immersed in the electrolyte, the V_{oc} drops rapidly and asymptotically to 3.5V. There is little further decrease of V_{oc} after 24h as reported and V_{oc} is virtually unchanged after 5 and 10 days, as shown in Fig. 2 for $y \geq 3 \times 10^{-4}$. This result is best interpreted as reactions of doped $[\text{CH}]_r$ at high potential occurring with electrolyte until all the doped surface sites have reacted. The same behavior was found for conductivity. In Fig. 3, a $[\text{CH}(\text{ClO}_4)_{0.05}]_r$ sample, rinsed, dried, and kept under nitrogen, shows no decrease of σ_{RT} after 230h. But, a similar sample immersed in electrolyte has exponential decay in conductivity. Figure 4 shows that, even though σ_{RT} (5 days) $\approx \sigma_{RT}$ (10 days), longer contact with electrolyte can reduce σ_{RT} further, indicating slow but further reaction between doped $[\text{CH}]_r$ and the electrolyte.

The side reaction occurs more slowly for $[\text{CH}]_r$ doped to lower $V_{oc} < 3.05\text{V}$ (*i.e.*, $y < 10^{-4}$). Figure 2 shows that at a given dopant concentration the V_{oc} is smaller for samples immersed in electrolyte for 10 days than after 5 days. In other words, side reactions with electrolyte are still progressing between 5 and 10 days. The slower side reaction may be mainly due to the fact that the $[\text{CH}]_r$ is at lower oxidation potential. An additional factor may be that decay of V_{oc} continues until the surface is covered with species formed in the reaction with the electrolyte.

One observation we have made is that, following the doping of $[\text{CH}]_r$ and removal of the electrode, the electrolyte solution turned very dark in color after about 3 weeks. Electrolyte which was not used in the doping process remains clear indefinitely. Therefore, there are oxidation products dissolved in the electrolyte which were formed during the doping process.

Finally, Eq. [1] is applicable only to a limited range of high dopant concentrations. Figure 2 shows that the V_{oc} vs. $\log y$ is sigmoidal in shape, which reflects the change of $\log \sigma_{RT}$ vs. $\log y$ (Fig. 4). Our results cannot be reconciled with the conclusion of Kaneto *et al.* (3) that the drop of V_{oc} with time is due to diffusion of dopant ions from the surface to the interior of the $[\text{CH}]_r$ fibrils.

The changes in σ and \mathcal{E} vs. y observed here (Fig. 4 and 5) are nearly as sharp as those reported for $[\text{CH}]_r$ very slowly doped with I_2 and AsF_5 (6). This large increase of transport properties, commonly referred to as the semiconductor-metal transition, occurs at a much lower dopant concentration than the few percent suggested previously. The term semiconductor-metal transition is a misleading one. Lightly doped $[\text{CH}]_r$ is not a classical intrinsic or extrinsic semiconductor. Heavily doped $[\text{CH}]_r$ is not a true metal, though the conductivity approaches that of metals having low conductivity. It does not exhibit the

metallic properties of increasing conductivity with decreasing temperature.

We tend to view the sharp conductivity changes with y reported here and previously (6) as a phase transition. At low dopant concentrations the carriers are strongly pinned by the coulombic potential of the counterions. They are rather immobile and can hop only with significant activation. One can speak of a "glassy" state for the charge carriers. At high dopant concentrations, the pinning potentials are screened and the mobility of the carriers increases greatly. One can think that the carriers are in a "liquid" state. Thus, the sharp increase of transport properties with y may be considered to be a "glass" transition of the carriers in a frozen state to a melt state. Above this transition, any further increase of conductivity is largely due to an increase in the number of carriers.

Comparison of the EPR and conductivity results of *trans*- $[\text{CH}]_r$ chemically doped with I_2 and AsF_5 (6) very slowly and homogeneously and that of electrochemically doped materials (Fig. 6 and 7) show similarities as well as significant differences. The midpoint of the large decrease in thermopower occurs at $y \sim 8 \times 10^{-4}$ for I_2 and AsF_5 doped $[\text{CH}]_r$ (6); it occurs at a higher dopant concentration of $y \sim 3 \times 10^{-3}$ for $[\text{CH}(\text{ClO}_4)_y]_r$. According to the above interpretation of the "carrier glass transition," there should be some dependence on the size, charge density, and polarizability of the counterion. The EPR intensity of unpaired spins in I_2 - and AsF_5 -doped $[\text{CH}]_r$ decreases precipitously in the vicinity of y for the carrier glass transition (6, 14). However, the unpaired spin concentration of electrochemically doped $[\text{CH}]_r$ did not show any decrease over the entire dopant range studied. With increasing extent of oxidation, the EPR intensity becomes less temperature dependent, *i.e.*, the Curie susceptibility decreases (Fig. 6). At high doping levels, the EPR is temperature independent indicative of Pauli susceptibility.

There are several ways oxidation of $[\text{CH}]_r$ can occur.

First, it can occur by direct oxidation of a neutral defect (there are ca. 10^{-3} unpaired spins/CH in *trans*- $[\text{CH}]_r$)

Second it can occur by oxidation of a C=C double bond; formation of a polaron

Third it can occur by bipolar doping resulting in two charged carriers

Electrochemical oxidation

Feldblum *et al.* (5) have interpreted optoelectrochemical oxidation and reduction of $[\text{CH}]_x$ data as doping by polaron injection and undoping by soliton removal.

In case [2] above, if the chain contains a neutral defect, then it can interact with the polaron to form a positive carrier annihilating two spins

At low dopant levels, $y < 10^{-3}$, the changes in unpaired spin concentrations are small because of the intrinsic spin concentration of about 10^{-3} in pristine *trans*- $[\text{CH}]_x$. For $y > 10^{-3}$, the changes in unpaired spin concentration would depend upon which of the above doping pathways dominate. The present electrochemical doping results appear to be consistent with predominance of production of bipolaron pairs by successive oxidations of nearby chains or segments of a chain. Increased doping produces domains of metallic electrons which may or may not include the initial neutral defects of the pristine polymer. The other mechanism, found previously in I_2 and AsF_5 doping (6, 15), reactions [2a], [3a], and [5] are probably dominant, resulting in the disappearance of Curie susceptibility with the increasing y .

The decrease of the Curie susceptibility with chemical p doping has been widely reported for other systems: SbF_5 doping of *cis*- $[\text{CH}]_x$ (16), Br_2 doping of *trans* $[\text{CH}]_x$ (17), NOHSO_4 doping of $[\text{CH}]_x$ (18), and electrochemical reduction of *cis*- $[\text{CH}]_x$ (19). Furthermore, Dysonian EPR lineshapes are obtained in saturation chemically doped samples such as Li-benzophenone doping of *cis*- $[\text{CH}]_x$ (19), $\text{Fe}(\text{ClO}_4)_3$ doping of *trans*- $[\text{CH}]_x$ (20), and NOHSO_4 doping of *trans*- $[\text{CH}]_x$ (21). Therefore, phase separation into metallic domains occurs in chemical as well as electrochemical oxidation of $[\text{CH}]_x$. In the case of $[\text{CH}]_x$ cyclically doped with I_2 and AsF_5 (6, 15) to saturation levels which show no Dysonian EPR, it is likely that the carriers are homogeneously distributed without a phase separation.

Characterization of Low Oxidation States of Tungsten and Tungsten Electrodes in $\text{AlCl}_3\text{-NaCl}$ Melts by X-Ray Photoelectron Spectroscopy

A. G. Cavinato, G. Mamantov,* and X. B. Cox III[†]

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37996-1600

ABSTRACT

The ultimate products of the electroreduction of WCl_6 in acidic $\text{AlCl}_3\text{-NaCl}$ melts at tungsten and platinum electrodes were investigated by x-ray photoelectron spectroscopy (XPS). The XPS analysis reveals the presence of tungsten species, having formal oxidation state between 0 and +2, on electrode surfaces. Evidence for the formation of metallic tungsten at platinum electrodes was also obtained. An XPS study performed on tungsten electrodes electrolyzed in acidic chloroaluminates at the chlorine evolution potential revealed no protective polymeric tungsten chloride film.

The chemistry of tungsten is among the most complex of the transition elements. Tungsten exhibits a variety of oxidation states. The lower oxidation states of tungsten are characterized by metal-metal bonding and the formation of metal atom clusters, such as the octahedral $\text{W}_6\text{Cl}_8^{4+}$ (1).

The electrochemistry and chemistry of several refractory group metals (groups IVB-VIB) in molten $\text{AlCl}_3\text{-NaCl}$ have been investigated previously by our group (2-6) and others (7). For several metals, such as niobium, tantalum, and tungsten, formation of metal clusters was found to occur in acidic (AlCl_3 -rich) melts. In the case of tungsten (6), the cluster $\text{W}_6\text{Cl}_8^{4+}$ is formed by the electroreduction of WCl_6 and several other solute species. The electrochemical reaction sequence is very complex and not fully understood. It was found (6) that $\text{W}_6\text{Cl}_8^{4+}$ can be reduced further electrochemically; the essentially insoluble product of this reduction was not characterized in this early study.

In this paper, we report on the x-ray photoelectron spectroscopic (XPS) studies of the final products of the electroreduction of WCl_6 in acidic chloroaluminate melts at tungsten and platinum electrodes.

In addition, since tungsten is a very good electrode in chloroaluminate melts for studies of reactions occurring at very positive potentials, such as the oxidation of sulfur to tetravalent sulfur (a process that occurs close to the anodic limit of the melt) (8), we examined, using XPS, tungsten electrodes which were employed for chlorine evolution. It was thought that this unusual resistance of tungsten to oxidation may be due to the formation of a protective halide cluster layer.

Other electrochemical studies of tungsten in molten salts have been performed by Senderoff and Mellors in molten fluorides (9), Johnson and Mackenzie in molten LiCl-KCl (10), Sabbatini *et al.* in molten nitrates (11), and, most recently, by Scheffler and Hussey in the basic AlCl_3 -methylethylimidazolium chloride melt (12).

Experimental

Dry box system.—Because of the air- and moisture-sensitive nature of the compounds used, all handling of materials was performed under a nitrogen atmosphere inside a Vacuum Atmospheres dry box equipped with a dry train/oxygen removal column. The moisture level of the atmosphere was monitored with a Panametrics Model 700 hygrometer. The moisture level was typically less than 3 ppm.

Materials.—The chloroaluminate melts were prepared from aluminum chloride (Fluka, anhydrous), purified twice by sublimation at $\approx 210^\circ\text{C}$ and from sodium chloride (Fisher) dried under vacuum at 400°C . The melt preparation has been described previously (13). Tungsten foil (0.127 mm thick), 99.99% purity (Alfa Products), and platinum foil (0.0254 mm thick), 99.99% purity (Fisher), were used.

*Electrochemical Society Active Member.

num foil (0.0254 mm thick), 99.99% purity (Fisher), were used. Tungsten (VI) chloride, resublimed, 99% (Alfa Products), was purified by heating at 180°C under vacuum in a Pyrex tube to allow the more volatile tungsten oxychlorides (WOCl_4 , WO_2Cl_2) to sublime off. The Pyrex tube was then sealed and the temperature raised to 210°C , at which point WCl_6 sublimed to the cool portion of the Pyrex tube.

Sulfur dioxide, anhydrous, 99.98% (Matheson), and prepurified nitrogen (MG Scientific Gases) were used for the removal of the melt from the electrode surfaces (*vide infra*).

Electrochemical measurements.—Current-voltage curves were recorded using a Princeton Applied Research Model 174 Polarographic Analyzer coupled with a PAR 175 Universal Programmer. Controlled potential electrolyses were performed with a PAR 173 Potentiostat/Galvanostat. The electrochemical cell was a Pyrex vessel equipped with threaded glass connectors and Teflon bushings with Teflon ferrules (Ace Glass, Incorporated) to position the electrodes. The working electrodes were tungsten (0.75 mm diam) or platinum (0.5 mm diam) wires sealed in glass tubes; the reference electrode was an aluminum wire (0.75 mm diam), and the counterelectrode was a tungsten spiral. Both counter and reference electrode compartments were separated from the working compartment by means of fine porosity (4.5-5 μm pore size) frits. Samples prepared for examination by XPS employed a working electrode made of tungsten or platinum foil with an area approximately 0.4 cm^2 . The platinum foils were cleaned in concentrated HCl; the tungsten foils were cleaned as described below, and sealed under vacuum to avoid contamination during transport to the spectrometer.

XPS measurements.—All of the spectra were obtained using an XPS/Auger spectrometer, Physical Electronics Model 548, operated in the Fixed Analyzer Transmission (FAT) mode, using $\text{MgK}\alpha$ x-ray radiation. The operating pressure in the sample chamber varied from 10^{-8} to 10^{-9} torr. Preliminary XPS studies on the cleaning of tungsten, as well as the characterization of $(\text{H}_2\text{O})_2[(\text{W}_6\text{Cl}_8)\text{Cl}_6] \cdot 6\text{H}_2\text{O}$, were carried out at the Oak Ridge National Laboratory (Oak Ridge, Tennessee), while the studies of cluster films on electrodes were performed at the University of North Carolina (Chapel Hill, North Carolina). The spectra were calibrated with respect to the $\text{W } 4f_{7/2}$ metal peak (31.0 eV) and to the $\text{Au } 4f_{7/2}$ peak (84.0 eV). Spectra are plotted to express the photoelectron binding energy of the tungsten compounds relative to that of the tungsten metal (*i.e.*, the chemical shift of the photoelectrons). Powders were analyzed by pressing them on an indium foil; the $3d_{5/2}$ (443.6 eV) peak of indium was also used as a standard in the calibration of these spectra. To determine the contribution of different oxidation states of tungsten to the $\text{W } 4f$ photoelectron peak shape, data obtained at UNC were

subjected to curve fitting by means of an iterative least squares curve fitting computer program (14), which, with interactive feedback from the operator, determines the best fit of gaussian-lorentzian peaks with S-shaped base lines to the data.

In this study, the inherent (instrumentally limited) peak width is 0.50 eV (25 eV pass energy), and the gaussian-lorentzian peak components are 40% gaussian and 60% lorentzian. The computer used was an in-house built microcomputer based on a Z-80 microprocessor.

To prevent possible contamination of the tungsten clusters, special care was taken in introducing the samples into the spectrometer. A glove bag was mounted around the sample introduction rod, sealed carefully, and maintained under a constant flow of nitrogen (ultrapure grade).

SO₂ cleaning apparatus.—A prior removal of the relatively thick layer of the chloroaluminate melt without introducing moisture contamination must be performed before the XPS analyses of the electrode surfaces. Liquid sulfur dioxide is a very good solvent for covalent substances; aluminum chloride has a very high solubility in liquid SO₂, while sodium chloride is completely insoluble (15). However, in the case of a ternary system (16), the solubility is enhanced by the formation of compounds of the type NaAlCl₄ · nSO₂. The apparatus for melt removal is shown in Fig. 1. It consists of a vessel (g) that can be opened for sample introduction at clamp (f). Kimax process pipes with beaded ends linked with a coupling assembly (stainless steel outer band with T-bolt and hex nut, Viton liner, and a TFE seal ring from Laboratory Glass, Incorporated) were used. The vessel also contains a medium porosity (10-20 μm pore size) frit (k) on which the sample (h) is positioned. The vessel is connected to three independent lines: one for SO₂, the second for nitrogen, the third to vacuum, and, on the other side, to a trap (n) filled with concentrated sulfuric acid which converts SO₂ into H₂SO₄. All the joints between the glass and the stainless steel tubing were made using ultra-torr Swageloks (a). A safety valve (d) is placed between the vessel and the

trap. During the cleaning operation, the vessel was maintained at -25° to -20°C in an ethanol-Dry Ice bath. The system is designed for samples that cannot be exposed to air; the main vessel can be sealed with two Teflon stopcocks (b, c) and transferred into a dry box for loading. After the sample is positioned, all the lines up to the inlet stopcock (b) in the vessel are evacuated below 10⁻² torr; prepurified nitrogen is flushed through the system before the sulfur dioxide is allowed to flow. The sulfur dioxide pressure is kept below 5 psi. After the sulfur dioxide has condensed above the frit and been in contact with the sample long enough to dissolve the melt covering the surface, a pressure of nitrogen (about 3 psi) is used to force the liquid through the frit. This operation can be repeated several times. Finally, nitrogen is passed through the system and the temperature is allowed to reach the room temperature value so that the sulfur dioxide slowly evaporates and is carried away by the nitrogen. After the cleaning operation, the vessel is transferred into a dry box and the samples are sealed under vacuum.

Results

XPS characterization of (H₃O)₂[(W₆Cl₈)Cl₆] · 6H₂O.—An XPS study of the products of the electroreduction of WCl₂ (or [W₆Cl₈]Cl₄) involves the knowledge of the binding energy for the unit W₆Cl₈⁴⁺ (formal oxidation state W⁺²). For the W-Cl system, no XPS data on W⁺² have been previously reported.

The binding energy for the W 4f peaks (split by spin-orbit splitting) for the unit W₆Cl₈⁴⁺ was determined on the cluster (H₃O)₂[(W₆Cl₈)Cl₆] · 6H₂O. The hydrate form instead of (W₆Cl₈)Cl₄ was used because of the high moisture sensitivity of the anhydrous cluster which also showed some decomposition to higher oxidation states as shown by the XPS spectra. The synthesis of (H₃O)₂[(W₆Cl₈)Cl₆] · 6H₂O was performed according to Dorman and McCarley (17); the product was characterized by x-ray powder diffraction. The chemical shift for the W₆Cl₈⁴⁺ unit, as compared to tungsten metal, is 1.8 eV (see Fig. 2). Spectra recorded in the chlorine 2p region show two different chlorine contributions, in accordance with the structure of the cluster, in which at least two different kinds of chlorine should be detected (18).

XPS studies of tungsten-surface cleaning techniques.—Particular care was taken to provide very clean tungsten surfaces to use as the electrode material in the elec-

trochemical study of the tungsten cluster film. A tungsten surface is usually covered by a layer of oxides, particularly WO₃, that would limit the XPS detection of lower oxidation state tungsten species. Figure 3A shows the spectrum for the W 4f region for tungsten foil "as received." The spectrum shows the presence of oxide (doublet d) on the left of the metal peaks (doublet a) that, on the basis of the chemical shift of 4.5 eV, can be attributed mainly to W(VI) oxide (19). Figures 3B-3D show results obtained with different cleaning procedures. The spectrum shown in Fig. 3B was recorded on the sample WA electrolyzed in 50% NaOH solution containing 5 weight percent NaNO₂ at ~200 mA/cm² for 2h. The metal doublet is now very sharp while a small shoulder on the left is still present, which, on the basis of the chemical shift, can be attributed mainly to W(VI) oxide. Similar results were obtained by electrolyzing sample WB for a longer period of time (Fig. 3C). Figure 3D shows the W 4f doublet for the sample WC reduced in hydrogen at 500°C. In Table I, the percentage amounts, calculated as areas, of the tungsten species detected, are reported. It may be seen that both cleaning techniques result in clean metal tungsten surfaces. The similarity in the results suggests that the residual oxide still detected is formed after the cleaning operation, possibly during the introduction of the sample in the XPS spectrometer.

XPS studies of the sulfur dioxide cleaning technique.—The cleaning power of the method was tested by analyzing with x-ray photoelectron spectroscopy the surface of two tungsten samples. The samples were also checked for possible surface modifications due to the contact with liquid sulfur dioxide. The two samples, initially cleaned

Table I. Percentage amounts of tungsten species detected by XPS

Sample	Percentage of W(O) ^a (%)	Percentage of W(VI) (%)
W "as received"	34	66
WA	96	4
WB	95	5
WC	97	3

^a The areas were measured manually; the differences between samples WA, WB, and WC are not significant.

by electrolysis as described previously, were dipped for a short time in an AlCl₃-NaCl (63-37 mole percent) melt. One sample was sealed under vacuum while still covered with the melt; the other was cleaned according to the procedure described in the Experimental section. Figures 4A and 4B show a comparison of the W 4f spectra recorded on the two samples. A sharp signal due to metallic tungsten is clearly present in the cleaned sample. The liquid sulfur dioxide does not affect the tungsten surface; the relative percentage of oxide and metal is the same as in cleaned tungsten surfaces not exposed to sulfur dioxide

Fig. 5. Tungsten 4f spectrum of a tungsten sample electrolyzed at 0.10V for 60 min. Initial [WCl₆] = 7.9·10⁻³M. Peak assignments: (a) tungsten (O) doublet, (b) reduced cluster doublet. In this figure and Fig. 6-8, the "erratic" curve represents experimental data; the smooth curve is the result of the calculated curve fit. The curve fit doublets are based on initially assigned parameters consistent with values derived from analysis of pure compounds.

(compare Fig. 3B and 4B). A survey spectrum shows that the amount of sulfur contamination on the surface is very low.

XPS study of cluster films on tungsten and platinum electrodes.—When W(VI) chloride is added to an $AlCl_3$ -rich chloroaluminate melt, four reduction waves can be detected; the last wave, occurring at +0.30V vs. the Al(III)/Al reference electrode, has been attributed to the electroreduction of $(W_6Cl_8)Cl_4$ to an insoluble product (6). XPS analyses were performed on tungsten electrodes electrolyzed at this and more negative potentials in order to define the nature of the product formed on the electrode surface. An example of an XPS spectrum for such a sample and curve fitting is shown in Fig. 5. The doublet a is due to the tungsten metal of the substrate, while the doublet b at a binding energy 1.13 eV higher may be attributed to a “reduced cluster” with tungsten oxidation

Fig. 7. Tungsten 4f spectrum of a platinum substrate electrolyzed at 0.10V for 25 min. Initial $[WCl_6] = 1.99 \cdot 10^{-2}M$. Peak assignments: (a) tungsten (O) doublet, (b) reduced cluster doublet, (c) $W_6Cl_8^{4+}$ doublet, and (d) tungsten (VI) doublet.

Table II. Parameters from the curve fitting of the W 4f peaks of tungsten species on a platinum substrate

Peak	Position (B.E.) (eV)	FWHM 4f (eV)	Separation from W(O) (eV)
a	$4f_{7/2}$	31.06	1.22
	$4f_{5/2}$	33.33	1.17
b	$4f_{7/2}$	32.19	1.23
	$4f_{5/2}$	34.09	1.24
c	$4f_{7/2}$	32.86	1.28
	$4f_{5/2}$	34.81	1.84
d	$4f_{7/2}$	35.52	1.43
	$4f_{5/2}$	37.42	1.83

state less than +2, formed electrochemically on the tungsten electrode. Attempts to fit an oxide component were unsuccessful; however, the high binding energy tail may include shake-up peaks overlapping with a tungsten oxide component. Figure 6, obtained for a more concentrated sample electrolyzed for a shorter time, only shows the presence of the reduced cluster and a possible tungsten oxide component. At longer times, some peeling of the film was observed which explains the detection of the underlying metal in some of the samples.

The presence of the reduced cluster was also detected on a different substrate (namely, platinum), as shown in Fig. 7. Curve fitting indicates the presence of four oxidation states: (a) the metal, (b) the reduced cluster, (c) W(II), and (d) tungsten oxide. Table II lists some XPS parameters for these species.

XPS study of tungsten anodization in chloroaluminate melts.—Figure 8 shows the XPS spectrum and the curve fitting for a tungsten sample electrolyzed at the chlorine evolution potential for 60 min. The analysis of the parameters shows only the presence of metallic tungsten; the higher binding energy peak represents energy loss features, probably shake-up peaks, and a small contribution of tungsten oxide.

Discussion

The XPS results show that the reduction of tungsten (VI) chloride in acidic chloroaluminate melts leads ultimately to the formation of a cluster film in which tungsten has a very low oxidation state, between W(II) and the metal. The same product is obtained at either platinum or tungsten electrodes. At platinum, evidence for metallic

Fig. 8. Tungsten 4f spectrum of a tungsten sample electrolyzed at +2.5V for 60 min. Peak assignments: (a) tungsten (O) doublet.

tungsten was also obtained. No evidence for the formation of the metal was obtained from purely electrochemical studies (6), although Phillips and Osteryoung (7) assume Mo(O) to be the final oxidation state of the reduction of molybdenum chloride in basic chloroaluminates. It was found that the chlorine-evolution reaction occurs at a metallic tungsten surface. The hypothesis of the formation of an insoluble polymeric tungsten chloride that protects the tungsten surface is not supported by these results.

Acknowledgments

This research was supported by the Department of Energy through the University of California Subcontract 4502810 and the Atlantic Richfield Company. Initial studies on this problem were undertaken by J. S. Ledford and O. R. Melroy. We are grateful to R. E. Clausing and L. Heatherly, Jr., for the use of their XPS/Auger spectrometer at the Oak Ridge National Laboratory and to R. W. Linton for access to the XPS/Auger spectrometer at the University of North Carolina. Surface Potential Difference of Anodized Al₂O₃ Electrets

J. J. Bernstein*,¹ and R. M. White

Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, California 94720

ABSTRACT

The surface potential difference (SPD) across barrier-type anodic Al₂O₃ films is much larger than previously thought. SPD's as high as 60V have been measured across these anodized electrets, using an improved SPD measuring apparatus and a new rinsing procedure which removes compensating ions from the Al₂O₃ surface. The intense electric field at the surface of these films has been used to make air-gap electret ultrasonic transducers with a sensitivity of 1.5 × 10⁸ V/m. Theoretical and experimental results are presented on the decay of SPD by surface and volume conduction.

This paper is a study of charge retention in Al₂O₃ electrets formed by anodization. These thin film electrets have been used to make transducers for bulk ultrasonic waves (1-3). Previously reported values for the surface potential difference (SPD) across anodic oxide films ranged from 0.5 up to 10V (4-6), however, we have measured SPD's as high as 60V across barrier-type Al₂O₃ films by using a new rinsing procedure which completely removes compensating ions left on the oxide surface by the anodizing electrolyte.

In the Theory section of this paper, we analyze the charge decay in a thin film electret due to surface and volume conduction. Using conductivity data from the literature, volume conduction is predicted to be negligible after a brief initial transient. This is confirmed in the Results section, where surface conduction is shown to be the dominant decay mechanism. In the Experimental Procedures section, a new rinse procedure which removes compensating ions from the anodic oxide surface is described. An improved apparatus for measuring SPD is also described, and data taken with this apparatus are used to follow the decay of SPD as a function of the

anodizing electrolyte, atmospheric humidity, temperature, and the surface roughness of the film.

Theory of Charge Decay in an Anodized Electret

In this section, we consider the decay of charge in a thin barrier-type anodic oxide film following anodization. We examine first volume conduction, solving for both the instantaneous decay time-constant and the explicit time evolution of the electric field. We then look briefly at the surface conduction problem. The bulk of the mathematical derivations are confined to the Appendixes in order to clarify the presentation.

Figure 1 shows the evaporated aluminum films on glass used in this investigation. For the volume conduction problem, the current flow is assumed to be parallel to the film normal; hence, the problem is one-dimensional and the shape and size of the anodized area are unimportant. However, for the surface conduction problem, the size and shape of the anodized region are important because the boundary conditions are applied at the edge. Because the aluminum samples were chosen to be disk-shaped, the surface conduction problem is also one-dimensional (in r), but the length of the surface conduction path increases with increasing sample size.

Fig. 1. Configuration of the anodization samples. Aluminum pattern formed by evaporation through shadow mask onto glass slides. Photoresist stopoff is then applied at waterline to prevent arcing.

The relation between current density (J) and electric field (E) in the anodic film at constant temperature is (7)

$$J(t) = J_0(e^{E(t)/E_0} - 1) \quad [1]$$

where J_0 and E_0 can be derived from various atomistic models (7) but are considered here to be simple empirical constants. Although other, more complicated current-field relations have been derived, Eq. [1] fits the experimental data very well, and in the low electric field regime of primary interest here ($E \leq E_0$), most of the more complicated equations reduce to Eq. [1].

From Eq. [1], the conductivity σ of the oxide is

$$\sigma(t) = \frac{J(t)}{E(t)} = \frac{J_0}{E(t)} (e^{E(t)/E_0} - 1) \quad [2]$$

Under the conditions of the anodization (high electric field), the conductivity is large and ionic currents flow. After anodization, the electric field decays to lower values, and the conductivity decreases to a low field limiting value $\sigma_{\min} = J_0/E_0$ for $E \ll E_0$. Under these low field conditions, the anodic oxide is a very good insulator and can hold charge and serve as an electret.

We now extend the concept of dielectric relaxation time constant, which is strictly applicable only when the conductivity is constant, to the instantaneous decay time, which is shown in Appendix A to be

$$\tau_{\text{inst}}(t) \equiv \frac{-\rho}{(\partial\rho/\partial t)} = \frac{\epsilon E_0}{J_0} e^{-E/E_0} \quad [3]$$

As the charge density and the electric field decay, the instantaneous decay time increases, approaching asymptotically a low field value

$$\tau_{\text{max}} = \frac{\epsilon E_0}{J_0} \quad [4]$$

Qualitatively, then, we expect the initial decay of the electric field to be rapid, gradually approaching an exponential decay with time constant τ_{max} . These expectations are confirmed both by the experimental data and by the explicit solution for the time evolution of the electric field, derived in Appendix B. The equation for the electric field $E_2(t_2)$ is (from Appendix B)

$$E_2(t_2) = -E_0 \ln [1 - e^{-t_2/\tau_{\text{max}}}(1 - e^{-E_1/E_0})] \quad [5]$$

where E_1 is the electric field at $t = 0$. For large t_2 , $\ln(1+x) \approx x$ gives

$$E_2 = E_0(1 - e^{-E_1/E_0})e^{-t_2/\tau_{\text{max}}} \quad [6]$$

confirming our earlier conclusion that the decay is a simple exponential for long times. For very short times, assuming $E_1 \gg E_0$, we have

$$E_2(t_2) \approx -E_0 \ln(1 - e^{-t_2/\tau_{\text{max}}}) \approx -E_0 \ln\left(\frac{t_2}{\tau_{\text{max}}}\right) \quad [7]$$

The initial rapid decay should be logarithmic.

We would like to rewrite (5) in terms of SPD (surface potential difference) because this is what our experiments measure. This can be done if we make the simplifying assumption that the electric field and polarization are constant throughout the film. This assumption is equivalent to assuming that the space charge is zero in the film, (i.e., surface charge only, no volume charge), which probably is not true. The effect of this approximation is to underestimate the decay of SPD, because the decay rate increases exponentially with electric field, and the average field is lower than the peak field.

Proceeding under the assumption of uniform field, Eq. [5] becomes

$$V(t) = -dE_0 \ln [1 - e^{-t/\tau_{\text{max}}}(1 - e^{-V_0/dE_0})] \quad [8]$$

where d is the film thickness and V_0 is the surface potential difference at time $t = 0$ (assumed equal to the peak anodizing voltage). In the Results section, we will examine this equation using values of E_0 and J_0 from the literature.

Charge Decay by Surface Conduction

We analyze here the decay by surface conduction of a disk-shaped anodic oxide film charged to a voltage V_0 with respect to a conducting substrate. The analogous problem for heat conduction has been solved (8). The problem can be stated mathematically as follows

$$\frac{\partial V(r, t)}{\partial t} = \frac{\sigma_{\text{surf}}}{C_A} \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial V(r, t)}{\partial r} \right) \quad [9]$$

Initial condition

$$V(r, 0) = V_0$$

Boundary condition

$$V(a, t) = 0$$

where $V(r, t)$ is the voltage at a distance r from the center of a disk of radius a , σ_{surf} is the surface or sheet conductivity of the anodic oxide film (Ω^{-1}), and C_A is the capacitance per unit area of the film. C_A is also the constant of proportionality between the surface voltage $V(r, t)$ and the surface charge density. The solution is

$$V(r, t) = \frac{2V_0}{a} \sum_{n=1}^{\infty} \exp\left(-\frac{\sigma_{\text{surf}}}{C_A} \alpha_n^2 t\right) \frac{J_0(r\alpha_n)}{\alpha_n J_1(\alpha_n a)} \quad [10]$$

where $J_0(J_1)$ is the Bessel function of the first kind of order zero (one), and α_n is the n th positive root of the equation $J_0(\alpha a) = 0$. The average potential over the entire disk is

$$V_{\text{avg}} = \frac{4V_0}{a^2} \sum_{n=1}^{\infty} \frac{\exp\left(-\frac{\sigma_{\text{surf}}}{C_A} \alpha_n^2 t\right)}{\alpha_n^2} \quad [11]$$

which, because of the large probe size of our SPD measuring equipment, was the potential actually measured.

For large t , the higher-order terms drop out, leaving only the first term. We conclude that surface conduction, like volume conduction, will lead to an initial rapid voltage decay followed by a slow exponential decay with time constant

$$\tau_{\text{max}} = \frac{C_A}{\alpha_1^2 \sigma_{\text{surf}}} = \frac{a^2 C_A}{5.78 \sigma_{\text{surf}}} \quad [12]$$

We can use Eq. [12] to calculate σ_{surf} from τ_{max} obtained from SPD decay measurements

$$\sigma_{\text{surf}} = \frac{a^2 C_A}{5.78 \tau_{\text{max}}} \quad [13]$$

This is a possible way to measure surface conductivities too small to be measured by other means.

In the Results section, we will compare the voltage decay predicted by volume and surface conductivity with

Fig. 2. Sketch showing rinse with voltage on, which removes compensating ions from anodic oxide film surface.

the measured voltage decay. From the sensitivity of voltage decay to atmospheric humidity and surface roughness, it will be concluded that surface conduction is the dominant decay mechanism.

Experimental Procedures

Aluminum films 300 nm thick and 99.999% pure were evaporated through a shadow mask onto clean glass microscope slides, giving the pattern shown in Fig. 1. These films were then anodized at 50 A/m² to 180V, using photoresist (Shipley AZ1350J) as a stopoff and an aluminum foil counterelectrode. The electrolytes used were 4.0, 2.0, 1.0, and 0.1 weight percent (w/o) H₃PO₄ and 1.0 and 0.1 w/o APB. All anodizations were done at 4° ± 0.1°C.

To avoid charge compensation, the anodic oxide is rinsed with a stream of deionized water from a plastic squeeze bottle and dried before the voltage is turned off (Fig. 2). This rinsing with voltage on procedure results in a factor of ten higher surface charge than rinsing with voltage off. During this rinse procedure, the water draining from the anodic film into the electrolyte bath below completes an electrical circuit, and a current of several microamperes can be observed. As the ions are washed away, the current decreases, which could be used for process end-point detection.

Measurements of SPD (surface potential difference) were made by the vibrating electrode method (6). In this

method, a vibrating electrode (voltage biased through a large resistor) is brought near the unmetallized surface of an electret. The bias voltage is varied to achieve a null in the ac signal (at the frequency of vibration) between the vibrating electrode and the electret back metallization. When the null is achieved, the electric field between the vibrating electrode and the electret surface is zero, and the bias voltage is therefore equal to the SPD. In our apparatus, an aluminum foil vibrating electrode was fastened to the end of a plastic tube, and forced to vibrate by a small loudspeaker in a funnel at the other end of the tube. The ac signal was buffered by a JFET input op-amp and amplified by an HP 415B SWR meter, which has a narrow bandpass filter at 1 kHz, the frequency of vibration.

The effective surface charge was measured by pressing an aluminum foil top electrode against the oxide film, and using the resulting air gap electret transducer to detect a known acoustic signal. An electrical pulser (Panametrics 5052 PR) connected to a 10 MHz resonant piezoelectric transducer produced a known displacement δ (1.6 nm). The electric field was computed as the output voltage V divided by the displacement δ . The surface effective charge is related to the surface field by Gauss's law. Electric fields as high as 1.5×10^8 V/m have been measured this way on anodic Al₂O₃ films, corresponding to surface charges of 1.3×10^{-3} C/m².

Results

Figure 3 shows the decay of SPD with time for anodic Al₂O₃ films produced in a variety of electrolytes. Included are various concentrations of ammonium-pentaborate (APB), which forms a nearly ideal barrier-type film, and phosphoric acid, which forms films with an interior barrier layer and a porous surface layer (9, 10). It is clear that the anodic films formed in H₃PO₄ solutions retain their charge far longer than those formed in APB. This may be due to the greater surface roughness of the more porous phosphate films, which leads to a much longer surface conduction path in comparison to a smooth barrier film. Another possible explanation for the different charge retention properties of the films is the incorporation of phosphate or borate ions into the film, which would be expected to modify the surface and volume conductivity of the film.

To predict τ_{\max} from the volume conduction theory developed earlier (Eq. [4]), we need values of E_0 and J_0 . Values for barrier-type films taken from the literature vary widely. For example, Ref. (11) gives $E_0 = 2.33 \times 10^7$ V/m and $J_0 = 3.87 \times 10^{-16}$ A/m², yielding $\tau_{\max} = 1.42 \times 10^5$

Fig. 3. Decay of surface potential difference (SPD) for Al₂O₃ films formed to 180V in the following electrolytes: 1.0 w/o H₃PO₄ (curve a), 2.0 w/o H₃PO₄ (curve b), 4.0 w/o H₃PO₄ (curve c), 0.1 w/o H₃PO₄, 1.0 w/o ammonium penta-barate (APB) (curve e), and 0.1 w/o APB (curve f).

Fig. 4. Variation of surface potential difference (SPD) with time after anodization for Al_2O_3 electret stored in air. Theoretical curve is a plot of Eq. [4].

yr. Reference (13) gives $E_0 = 2.9 \times 10^7$ V/m and $J_0 = 2.46 \times 10^{-11}$ A/m², giving $\tau_{\text{max}} =$ only 2.78 yr. In the absence of reliable numbers, one can regard Eq. [4] as a two-parameter equation to be fit to the experimental data, as we have done in Fig. 4. We do not regard the good fit as proof of the validity of Eq. [4], but we note that the general shape of the decay curve is matched by the equation.

The effect of ambient humidity was investigated by preparing two identical films and storing one in a petri dish at atmospheric pressure and humidity, and storing the other in a desiccator with Drierite (CaSO_4) desiccant and air at a pressure of 3.1×10^4 Pa (0.3 atm). The decay of the SPD for the two samples is shown in Fig. 5. The change from humid air to dry air at 1/3 atm increased the lifetime dramatically from 72 to 1068h. This indicates that surface conduction is the dominant contribution to charge decay.

To further investigate the effects of atmosphere on the decay of SPD, an anodic film was sealed in a glass ampul at a pressure of 10^{-4} Pa and stored for 6 months. A very small change in SPD was detected after storage (30 mV), which yielded an extrapolated lifetime of 18 yr for the anodic Al_2O_3 electret in vacuum.

The effect on SPD of heating an Al_2O_3 electret to 100°C for 1h in air is shown in Fig. 6. During the 1h, the SPD dropped from 22.4 to 8.4V, after which the decay paralleled the decay of an identically prepared sample which was not heated. Presumably, both surface and volume conductivity increase with temperature and, therefore, heating did not help elucidate the decay mechanism.

The effect of increasing surface roughness on SPD decay was investigated without changing the chemical com-

Fig. 5. Decay of SPD for two identical Al_2O_3 electrets stored in desiccator at 1/3 atm (a) and air at atmospheric pressure (b).

Fig. 6. Effect of heating to 100°C for 1h on SPD of an Al_2O_3 electret. Control was kept at room temperature.

position of the anodization electrolyte by anodizing aluminum films that had been lightly abraded with cotton prior to anodization. Pores are known to nucleate preferentially at surface irregularities such as scratches (13). Hence, surface roughness of the anodic film was greatly increased by the abrasion process. Charge retention was observed to increase in the anodic films formed on the abraded aluminum films.

Discussion

The strong dependence of charge decay on surface roughness and humidity indicate that surface conduction is the dominant decay mechanism, although theory predicts that volume conduction contributes to the initial rapid decay from the peak anodizing voltage (180V in our experiments) to the values measured several minutes after anodization and rinsing (about 60V in our experiments). Equation [12] predicts that τ due to surface conduction is proportional to the square of the disk radius (conduction path), which for a rough film may be much greater than the apparent disk radius. The experiment with abraded films removes the oxide-composition variable by comparing decay on oxide films of identical chemical composition but different surface roughnesses. The dependence of charge decay on humidity also points towards surface conduction, because it seems unlikely that atmospheric humidity would have a strong effect on the bulk conductivity of the Al_2O_3 . Because of this humidity sensitivity, any devices made from anodic oxide electrets [such as air-gap or polymer-gap ultrasonic transducers (3)] would need to be hermetically encapsulated with water-impervious material.

The new rinse-with-voltage-on technique is superficially similar to the electrochemical charging technique (14), but there are several important differences. Electrochemical charging of uncharged polymer sheets is done with electrolytic solutions such as HCl containing ions which are injected into the polymer surface to create the electret. Our rinsing procedure is only successful with high resistivity deionized water, because we are removing charge compensation ions from the surface of a charged anodic oxide film.

It is interesting to compare anodized aluminum electrets to commercial state-of-the-art Teflon polymer electrets. The thin film electrets produced by anodization (typically 200 nm thick) have a higher surface charge and hence higher surface field than Teflon sheet electrets (typically 20 μm thick) precisely because they are so thin and can, therefore, achieve high electric fields at relatively low voltages. This higher electric field results in higher sensitivity for transducers made from thin film electrets compared to transducers made from thick film Teflon electrets.

A common limit to the voltage to which an electret can be charged is Paschen breakdown (15). When a counter-electrode is brought near the surface of an electret, an

electrical breakdown can occur if the voltage across the gap is greater than a certain breakdown value. This breakdown voltage is a function of the product of gas pressure and gap separation (Paschen's law). For air, the minimum breakdown voltage is 380V at a pressure times gap product of 0.54 Pa m. Although this limits the voltage to which Teflon sheet electrets can be charged, Paschen breakdown is not a limitation on anodized aluminum electrets because the voltage across the anodized electret (the SPD) is usually less than 380V, even during anodization.

Manuscript submitted Jan. 3, 1984; revised manuscript received Nov. 5, 1984.

APPENDIX A

Derivation of Instantaneous Decay Time

In this appendix, we derive the instantaneous decay rate as a function of the residual field in an anodic oxide film. Gauss's law in one dimension is

$$\nabla \cdot E = \frac{\partial E}{\partial x} = \frac{\rho}{\epsilon} \quad [\text{A-1}]$$

Conservation of charge yields

$$-\frac{\partial \rho}{\partial t} = \nabla \cdot J = \frac{\partial J}{\partial x} \quad [\text{A-2}]$$

Substitution of Eq. [1] into [A-2] gives

$$-\frac{\partial \rho}{\partial t} = \frac{J_0}{E_0} e^{E/E_0} \frac{\partial E}{\partial x} = \frac{J + J_0}{E_0} \nabla \cdot E \quad [\text{A-3}]$$

Substituting Eq. [A-1] for $\nabla \cdot E$ gives

$$-\frac{\partial \rho}{\partial t} = \frac{J + J_0}{\epsilon E_0} \rho = \frac{\rho}{\tau} \quad [\text{A-4}]$$

where τ is the instantaneous decay time and is given by

$$\tau = \frac{\epsilon E_0}{J_0} e^{-E/E_0} \quad [\text{A-5}]$$

APPENDIX B

Open-Circuit Decay of Electric Field in an Exponentially Conducting Dielectric

The electric field as a function of time can be derived as follows. Differentiating Eq. [A-1] with respect to time and using Eq. [A-2] yields

$$\frac{\partial^2 E}{\partial x \partial t} = \frac{-1}{\epsilon} \frac{\partial J}{\partial x} \quad [\text{B-1}]$$

Rearranging this, we have

$$\frac{\partial}{\partial x} \left(\frac{\partial E}{\partial t} + \frac{J}{\epsilon} \right) = 0 \quad [\text{B-2}]$$

Since $E = J = 0$ for $x < 0$, $(\partial E/\partial t + J/\epsilon)$ must be 0 everywhere. Substituting for J from Eq. [1], we have

$$\frac{\partial E}{\partial t} = -\frac{J_0}{\epsilon} (e^{E/E_0} - 1) \quad [\text{B-3}]$$

This equation can be solved exactly by separation of variables. Let $Y = E/E_0$, $u = (1 - e^{-Y})$ and $du = e^{-Y} dY$. Then Eq. [B-3] becomes

$$\frac{dE/E_0}{(e^{E/E_0} - 1)} = -\frac{J_0}{\epsilon E_0} dt = -\frac{dt}{\tau_{\max}} = \frac{du}{u} = -\frac{dt}{\tau_{\max}} \quad [\text{B-4}]$$

Integrating from t_1 to t_2 gives

$$\ln \left(\frac{1 - e^{-E_2/E_0}}{1 - e^{-E_1/E_0}} \right) = \frac{t_1 - t_2}{\tau_{\max}} \quad [\text{B-5}]$$

Letting $t_1 = 0$ and solving for E_2 , we have

$$E_2(t_2) = -E_0 \ln [1 - e^{-t_2/\tau_{\max}}(1 - e^{-E_1/E_0})] \quad [\text{B-6}]$$

This is the explicit expression for the decay of the electric field as a function of time under open-circuit conditions.

Measurement of Concentration Profiles of Cu^{2+} Ion and H^+ Ion near a Plane Vertical Cathode by Two-Wavelength Holographic Interferometry

K. Denpo, T. Okumura, Y. Fukunaka, and Y. Kondo*

Department of Metallurgy, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, Japan

ABSTRACT

A technique of two-wavelength holographic interferometry was applied to simultaneously measure the concentration profiles of Cu^{2+} ion and H^+ ion near a plane vertical cathode placed in an unstirred aqueous solution containing CuSO_4 and excess H_2SO_4 . It was revealed that the measured concentration profiles of Cu^{2+} ion and H^+ ion are approximated with the parabolic equations of horizontal distance from cathode surface and that the concentration gradient of Cu^{2+} ion at the cathode surface is larger in $\text{CuSO}_4\text{-H}_2\text{SO}_4$ solution than in CuSO_4 solution at the same cathodic current density and vertical distance. The following matters were also clarified: (i) the nondimensional rate of ionic mass transfer is shown as a function of Rayleigh number based on the boundary layer theory, and (ii) the effect of the addition of excess H_2SO_4 is expressed by a parameter f which is the ratio of Rayleigh numbers in $\text{CuSO}_4\text{-H}_2\text{SO}_4$ solution and in CuSO_4 solution under the conditions of the uniform distribution of cathodic current density and an excess of H_2SO_4 .

The measurement of cathodic concentration profile of ion is important for elucidating not only the ionic mass transfer itself, but also the effect of supporting electrolyte (1, 2). The optical methods such as Jamin (3), Mach-Zehnder (4), and holographic interferometry (5, 6) are effective for the measurement in the single-component aqueous solutions because of the proportionality between the ionic concentration and the refractive index of the solution.

In the industrial electrolysis, such as the electrolytic refining of copper, for example, an excess of sulfuric acid is added. In the multicomponent aqueous solutions, the above proportionality no longer holds and the measurement of concentration profiles of ions becomes more difficult.

An experimental technique using an image sensor of one-dimensional photodiode array was developed in order to measure the concentration profile of Cu^{2+} ion in aqueous $\text{CuSO}_4\text{-H}_2\text{SO}_4$ solution (7). In this measurement of the light absorbance distribution, however, a noise caused by the light diffraction near the cathode surface was superimposed on the output signal, and the concentration of Cu^{2+} ion on the cathode surface was estimated by extrapolating the profile toward the cathode surface. The estimation of the concentration of H^+ ion on the cathode surface was tried by subtracting the light absorbance due to Cu^{2+} ion from the refractive index of the solution measured by the conventional holographic interferometry (5). Due to the error of the measurements and the extrapolation, however, the precision and accuracy of the estimated H^+ ion concentration was relatively poor.

It is the intent of the present work to carry out the simultaneous measurement of concentration profiles of Cu^{2+} ion and H^+ ion in the cathodic boundary layer by using a technique of two-wavelength holographic interferometry which is based on the dispersion effect of refractive index of the solution. The problem due to diffraction pattern appearing near the cathode surface can be avoided in this measurement, because the interference pattern is set up as being at right angles with the diffraction pattern.

The principle of the two-wavelength holographic interferometry is shown in Fig. 1. The profiles of refractive index in the cathodic boundary layer are measured simultaneously at two different wavelengths, and the phase differences S_i ($i = \text{I, II}$) at a horizontal distance $y = y$ from the cathode surface are calculated. Then the differences in the refractive index Δn_i ($i = \text{I, II}$) are calculated at both wavelengths by using the ideal interferometer equation (8-11). When the regression equations of the difference in the refractive index upon the concentration of CuSO_4 and H_2SO_4 are given at each wavelength, both concentration profiles of Cu^{2+} ion and H^+ ion are obtained.

Experimental Arrangement

The optical arrangement for the two-wavelength holographic interferometry is schematically illustrated in Fig. 2. An argon ion laser emitter (Lexel 95-2) and a helium-neon gas laser emitter (Nihon Kagaku Engineering NEO-20M) were used as the light sources. The laser beams were mixed at a half-mirror B_1 to form a single beam with the same optical axis. The mixed beam was split into two beams of objective and reference waves, respectively, by another half-mirror B_2 , after it passed through a half-wavelength plate $\lambda/2$ and a shutter S . The objective wave was collimated to a beam of 1.2 cm diam by an objective lens E_1 (magnification: 10 times) and a lens LE_1 ($f = 200$ mm). After passing through the vicinity of cathode surface in the electrolytic cell C , it was projected on a holographic plate H , on which the image of the cathode surface was recorded.

The center line of the cathode surface was focused on the holographic plate by a lens LE_2 ($f = 135$ mm) which removes the chromatic aberration caused by the different color of the laser beams. The reference wave was collimated to a beam of 50 mm diam by a lens E_2 (magnification: 40 times) and a lens LE_3 ($f = 200$ mm). It was superimposed with the objective wave on the same holographic plate. In order to improve the contrast of the interferogram, it was required to adjust the relative intensity of both waves. Two polarizers P_1 and P_3 were installed for this purpose, while the other polarizers P_2 and P_4 were used to maintain the same polarization plane as the emitted laser beam from the light source. The recon-

structured interferograms were taken with a camera. In order to eliminate any mechanical vibration during the measurement, all optical instruments shown in Fig. 2 were mounted on a vibration-free table.

A real-time technique was used for producing a holographic interferogram. In order to assure the optical reproducibility of measurement at these two wavelengths, the profile of refractive index formed during a steady electrolysis under the respective experimental conditions was first recorded on a holographic plate. It was then reconstructed and interfered with the objective wave of a uniform profile of refractive index which was obtained after interrupting the electrolysis. It is thought that by this technique the profile of refractive index is recorded on a holographic plate for each wavelength under exactly the same optical configuration.

The copper rod electrodes were 0.5 cm square, and the effective electrode area was 0.5×8.0 cm². The distance between both electrodes was maintained at 4.8 cm. The details of the electrolytic cell and experimental conditions were already described in the previous paper (7).

Experimental Results

A few examples of the interferogram obtained by the two-wavelength holographic interferometry are demonstrated in Fig. 3. Electrolysis was carried out at a cathodic current density of 0.946 mA/cm². Figure 3a is the holographic interferogram reconstructed simultaneously by both argon ($\lambda_I = 488$ nm) and helium-neon ($\lambda_{II} = 633$ nm)

laser beams. The dispersion effect is clearly shown. Figures 3b and 3c are the interferograms separately reconstructed by argon and helium-neon laser beam, respectively.

The apparent phase differences S in the cathodic boundary layer in these interferograms were obtained from the measured profiles of refractive index. Then the true phase differences were calculated for both wavelengths according to the correcting procedures similar to Hauf *et al.* (8) and Mayinger *et al.* (10). Then the concentration profiles of Cu²⁺ ion and H⁺ ion were obtained by using the ideal interferometer equation and the regression equations (12) of refractive index upon the concentration of Cu²⁺ and H⁺ ions at the two wavelengths. The regression equations were obtained as

$$\Delta n_I = 0.023718\theta_1 - 0.010912\theta_2 \quad (\lambda_I = 488 \text{ nm}) \quad [1]$$

$$\Delta n_{II} = 0.023257\theta_1 - 0.010118\theta_2 \quad (\lambda_{II} = 633 \text{ nm}) \quad [2]$$

Different numerical coefficients in Eq. [1] and [2] are due to the dispersion effect (see Appendix).

A few examples of the concentration profile of Cu²⁺ ion at a vertical distance of $x = 4$ cm from the lower edge of cathode in 0.05M CuSO₄ solution are shown in Fig. 4. It is seen that the concentration difference between cathode surface and bulk electrolyte and the concentration gradient at the cathode surface are larger at higher current densities. It is also shown that the concentration profiles of Cu²⁺ ion at a current density of 0.946 mA/cm² measured by the conventional holographic interferometry (5), by the light absorbance distribution (7), and by the two-wavelength holographic interferometry are compared, and the agreement is satisfactory.

The concentration profiles of Cu²⁺ ion at various current densities in 0.05M CuSO₄-1.85M H₂SO₄ solution are demonstrated in Fig. 5. It is seen that the concentration difference between bulk electrolyte and cathode surface and the concentration gradient at the cathode surface increase and the thickness of the concentration boundary layer decreases with the increase of the current density. The limiting current density was obtained from a current-potential curve shown in Fig. 6 at 1.96 mA/cm², and it is seen that the surface concentration of Cu²⁺ ion is zero at this current density.

The concentration profiles measured under the same electrolytic conditions in 0.05M CuSO₄ and 0.05M CuSO₄-1.85M H₂SO₄ solutions are compared in Fig. 7. The concentration difference between bulk electrolyte and cathode surface and the concentration gradient at the cathode surface in 0.05M CuSO₄-1.85M H₂SO₄ solution are far larger than in the 0.05M CuSO₄ solution.

Fig. 3. Holographic interferograms of cathodic diffusion layer (0.05M CuSO₄-1.85M H₂SO₄, $x = 4$ cm, $i = 0.946$ mA/cm²). a: Reconstructed by both Ar laser and He-Ne laser. b: Reconstructed by Ar laser. c: Reconstructed by He-Ne laser.

(---): Measured by conventional holographic interferometry (5).
 (---): Measured by light absorbance distribution (7).

Since the cathodic polarization curves with the same copper reference electrode in both solutions are virtually identical at the lower current densities as shown in Fig. 6, the overpotential for electrodeposition of Cu^{2+} ion is not influenced by the presence of H_2SO_4 . The transference number of Cu^{2+} ion in the solution containing CuSO_4 and excess H_2SO_4 is remarkably lowered due to the high mobility of H^+ ion, and the prevailing mechanism of mass transfer of Cu^{2+} ion in the CuSO_4 - H_2SO_4 solution is diffusion and convection. Then the increase of concentration difference and concentration gradient at the cathode surface is expected in order to maintain the same overall rate of electrodeposition as in the CuSO_4 solution. At the same time, hydrogen ion is accumulated near the cathode surface, and the concentration profile is due to the mass balance among the fluxes of migration, diffusion, and convection.

A few examples of the measured concentration profile of H^+ ion are shown in Fig. 8. It is seen in this figure that the concentration of H^+ ion increases from the bulk electrolyte toward the cathode surface. It is also seen that the concentration difference between cathode surface and bulk electrolyte and the absolute value of the concentration gradient at the cathode surface are larger, while the thickness of the concentration boundary layer of H^+ ion is smaller at higher current densities.

Discussion

It was shown that the concentration profile of Cu^{2+} ion in the cathodic boundary layer is affected by the addition of H_2SO_4 . The effect of H_2SO_4 on the concentration profile of Cu^{2+} ion and the concentration profile of H^+ ion itself in the cathodic boundary layer are considered below.

The concentration profiles of Cu^{2+} ion and H^+ ion in the cathodic boundary layer are expressed as

$$\theta/\Theta = (1 - y/\delta)^\omega \quad [3]$$

The numerical value of parameter ω was estimated in both 0.05M CuSO_4 and 0.05M CuSO_4 -1.85M H_2SO_4 solutions: the logarithm of θ'/Θ' in 0.05M CuSO_4 solution¹ was plotted against $\log(1 - y/\delta')$ in Fig. 9, and the ω' value for Cu^{2+} ion was obtained to be 1.80 by the least squares method. Similarly, ω_1 and ω_2 values (for Cu^{2+} ion and H^+ ion, respectively) in 0.05M CuSO_4 -1.85M H_2SO_4 solution were obtained at 1.98 and 2.00, respectively. No significant difference was detected by the statistical test

¹Quantities specified with prime are defined for aqueous CuSO_4 solution.

Fig. 7. Comparison of Cu^{2+} ion concentration profiles in the cathodic diffusion layer of aqueous 0.05M CuSO_4 solution and 0.05M CuSO_4 -1.85M H_2SO_4 solution ($i = 0.946$ mA/cm², $x = 4$ cm).

Fig. 8. Concentration profiles of H^+ ion in the cathodic diffusion layer (0.05M $CuSO_4$ -1.85M H_2SO_4 solution, $x = 4$ cm).

among the obtained numerical values of ω' , ω_1 , and ω_2 . These values are lower than 2.3 obtained for Cu^{2+} ion in aqueous $CuSO_4$ solution by Ibl and Müller (3). It is known, however, that the results of calculation by the von Kármán-Pohlhausen integral method are not very sensitive to the numerical value of parameters. Then it can be presumed that the above-mentioned ω values are virtually the same and that the concentration profiles of Cu^{2+} ion in these two solutions are similar.

The velocity profile of natural convection is written as (7)

$$u/u_m = \left(\frac{1}{\lambda - 1}\right) \left\{ \lambda \left(\frac{y}{\tau}\right) - \left(\frac{y}{\tau}\right)^\lambda \right\} \quad 0 \leq y \leq \tau \quad [4]$$

$$u/u_m = 1 - \frac{y - \tau}{\epsilon \tau} \quad \tau \leq y \leq (\epsilon + 1)\tau \quad [5]$$

Fig. 9. Plot of $\log(\theta'_1/\theta'_1)$ vs. $\log(1 - y/\delta'_1)$ with aqueous 0.05M $CuSO_4$ solution.

It is assumed that the values of numerical parameters ϵ , λ , τ which determine the velocity profile of natural convection are similar in the two solutions.

Fundamental equations describing laminar natural convection along the cathode surface in a solution containing $CuSO_4$ and excess H_2SO_4 are the momentum balance equation and ionic mass balance equations regarding a volume element of height dx and length $\delta_u(x)$ and the ionic mass flux equation at the cathode surface (7). They are as follows

$$\frac{d}{dx} \int_0^{\delta_u(x)} u^2 dy = -\nu \frac{\partial u}{\partial y} \Big|_{y=0} + \alpha_1 g \int_0^{\delta_u} \theta_1 dy + \alpha_2 g \int_0^{\delta_u} \theta_2 dy \quad [6]$$

$$\frac{d}{dx} \int_0^{\delta_u} u \theta_1 dy = \frac{i(1 - t_1)}{z_1 F} \quad [7]$$

$$\frac{d}{dx} \int_0^{\delta_u} u \theta_2 dy = -\frac{i t_2}{z_2 F} \quad [8]$$

$$k_1 \frac{\partial \theta_1}{\partial y} \Big|_{y=0} = \frac{i(1 - t_1)}{z_1 F} \quad [9]$$

$$-k_2 \frac{\partial \theta_2}{\partial y} \Big|_{y=0} = \frac{i t_2}{z_2 F} \quad [10]$$

respectively. These equations were solved by the von Kármán-Pohlhausen integral method (7), and the following nondimensional rate equations for $CuSO_4$ solution and $CuSO_4$ - H_2SO_4 solution were derived

$$Sh'_x = A' \cdot (Ra^*_{x'})^{1/5} \quad [11]$$

$$Sh_x = A \cdot (Ra^*_{x})^{1/5} \quad [12]$$

where

$$Sh_x = \frac{i(1 - t_1)x}{z_1 F k_1 \theta_1} \quad [13]$$

$$Ra^*_{x} = \frac{g \alpha i (1 - t_1) x^4}{z_1 F \nu k_1^2} \quad [14]$$

Under the assumptions of higher Schmidt number and the similar profiles of velocity and concentration, numerical coefficients A' and A become equal and

$$Sh_x/Sh'_x = f^{1/5} \quad [15]$$

The parameter f is defined as

$$f = \frac{Ra^*_{x'}}{Ra^*_{x}} = \left(\frac{\alpha_1 - \gamma \sigma^2 \alpha_2}{\alpha'_1} \right) \cdot \left(\frac{1 - t_1}{1 - t'_1} \right) / \left(\frac{k_1}{k'_1} \right)^2 \cdot \left(\frac{\nu}{\nu'} \right) \quad [16]$$

When effective diffusivity of Cu^{2+} ion is regarded as being the same as the diffusivity of $CuSO_4$ since each Cu^{2+} ion is surrounded by SO_4^{2-} ions to satisfy the electroneutrality principle in the solution containing $CuSO_4$ and excess H_2SO_4 , the f value is obtained from Eq. [16]. The numerical coefficients A' and A in Eq. [11] and [12] were calculated to be 0.628 at Schmidt number of 3000 from the similarity principle described elsewhere (7, 12). Thus the rate of ionic mass transfer in $CuSO_4$ and $CuSO_4$ - H_2SO_4 solutions is given by

$$Sh'_x = 0.628(Ra^*_{x'})^{1/5} \quad [17]$$

$$Sh_x = 0.628(Ra^*_{x})^{1/5} \quad [18]$$

respectively. Logarithmic Sh'_x and Sh_x were plotted against $\log(Ra^*_{x'})$ and $\log(Ra^*_{x})$, respectively, for both

Fig. 10. Relationship between $\log (Sh_x)$ and $\log (Ra_x^*)$. \odot : Measured by light absorbance distribution (7).

solutions in Fig. 10. It is seen that the agreement between the theoretical correlations in the form of Eq. [17] and [18] and the obtained experimental results is satisfactory.

In the same figure, the experimental results obtained by the measurement of light absorbance distribution (7) were also plotted. It is again seen that the agreement is excellent.

From this agreement between the theory and the two kinds of independent measurements, it can be said that the correlation Eq. [17] and [18] are valid and that the parameter f defined by Eq. [16] is meaningful to reveal the effect of added H_2SO_4 on the cathodic ionic mass transfer. Once f value is obtained from the property constants of the solutions, the rate of mass transfer of Cu^{2+} ion in $CuSO_4-H_2SO_4$ solution can be estimated from the rate of ionic mass transfer in $CuSO_4$ solution, so far as the assumptions of uniform distribution of current density and the presence of excess H_2SO_4 are satisfied.

With regard to the concentration of Cu^{2+} ion and H^+ ion at the cathode surface, the ratio of Θ_1 and Θ_2 is given as

$$\Theta_2/\Theta_1 = -\gamma\sigma \quad [19]$$

which was derived from the electroneutrality principle (7). The γ and σ values were calculated as

$$\gamma = \frac{1+a}{1+2a} = 0.809 \quad [20]$$

$$\sigma = \delta_2/\delta_1 = 1.27 \quad [21]$$

respectively (7). With these γ and σ values

$$\Theta_2/\Theta_1 = -1.03$$

However, it was obtained from the experimental results of Fig. 5 and 8 that

$$\Theta_2/\Theta_1 = -1.07$$

The standard deviation of this experimental value is 0.10. Again, the agreement is satisfactory.

Summary

Though it is possible to obtain the cathodic concentration profile of ion in a single-component solution by measuring the distribution of refractive index of the solution, it cannot be applied for obtaining the ionic concentration profiles in the multicomponent solutions such as the aqueous solution containing $CuSO_4$ and excess H_2SO_4 , because the refractive index of the solution is a function of all ionic concentrations. A new technique of two-wavelength holographic interferometry was developed to measure the concentration profiles. In this technique, the dispersion effect of refractive index is utilized.

After the optical distortions in the cathodic concentration boundary layer were corrected, the concentration profiles of Cu^{2+} ion and H^+ ion were obtained from the re-

gression equations of refractive indexes measured at each wavelength upon the concentration of Cu^{2+} and H^+ ions.

It was elucidated from the electrolysis of 0.05M $CuSO_4-1.85M H_2SO_4$ solution that the concentration difference of Cu^{2+} ion between bulk electrolyte and cathode surface and the concentration gradient at the cathode surface increase and the thickness of concentration boundary layer decreases with the increase of the current density. It was also revealed from a comparison of the concentration profiles of Cu^{2+} ion in $CuSO_4$ and $CuSO_4-H_2SO_4$ solutions under the same electrolytic conditions that the concentration difference between bulk electrolyte and cathode surface and the gradient at the cathode surface are larger in $CuSO_4-H_2SO_4$ solution. This effect was explained by the reduced contribution of migration of Cu^{2+} ion in the $CuSO_4-H_2SO_4$ solution to the total current density. The concentration difference of H^+ ion between cathode surface and bulk electrolyte is larger at higher current densities. The numerical values of a parameter ω of the concentration profile of cations were found similar. They were about 2.0.

Based on the experimental results with the two-wavelength holographic interferometry and the light absorbance measurement, the rate of mass transfer of Cu^{2+} ion in $CuSO_4$ solution and $CuSO_4-H_2SO_4$ solution was represented by the correlation equation of

$$Sh'_x = 0.628(Ra_x^*)^{1/5}$$

and

$$Sh_x = 0.628(Ra_x^*)^{1/5}$$

respectively. They are based on the similarity principle applied to the present laminar natural convection. Furthermore, these two equations are mutually related by a parameter f , which is the ratio of the Rayleigh numbers in both solutions. This parameter is predictable from the physical properties of the electrolytes. The concentration difference of H^+ ion in the cathodic concentration boundary layer is estimated from the relationship of

$$\Theta_2/\Theta_1 = -\gamma\sigma$$

which is based on the electroneutrality principle.

Acknowledgments

The authors wish to thank Dr. J. Tsujiuchi, Dr. S. Ueha, and Dr. T. Honda, Tokyo Institute of Technology, and Dr. R. Nagata and Dr. K. Iwata, University of Osaka Prefecture, for their valuable discussions on the optical measurement. Their thanks are also extended to Dr. Y. Nishijima and Dr. T. Fujimoto, Kyoto University, and Mr. K. Kobayashi, Leonix Company, Limited. Further, they express their appreciation to Dr. F. Mayinger and Dr. W. Panknin, Hannover Technical University, Hannover, Germany. Part of this work was carried out under the financial aids given to the authors by the Ministry of Education, Science and Culture (Project no. 57470045), and by the Kurata Foundation, to which the authors are grateful.

APPENDIX

The following procedure has been carried out to obtain the concentration profiles of Cu^{2+} and H^+ ion from the interferograms (12).

1. The location of cathode surface is determined from the theory of Fresnel diffraction pattern (7).

2. The distance, y , from cathode surface and the number of fringe shift, S_i^M , at that position are simultaneously measured on each picture to obtain the regression equation in a form of

$$S_i^M = a_i y^2 + b_i y + c_i \quad (i = I, II) \quad [A-1]$$

The ratio of sum of squares due to regression to the total sum of squares was calculated to be 0.998.

3. In the present measurement, the focal plane is set up at the center of effective cathode surface whose width is $2b$. The interference equation is thus given by

$$S_1^M \lambda_i = S_1 \lambda_i + \Delta S_1^D \lambda_i + \Delta S_1^E \lambda_i \quad [\text{A-2}]$$

where

$$\Delta S_1^D \lambda_i = -\frac{n_{\infty 1}}{12} \left(\frac{\lambda_i}{b} \right)^2 z_1 \quad [\text{A-3}]$$

and

$$\Delta S_1^E \lambda_i = \frac{2}{z_1} S_1 \sqrt{\delta^2 - y^2} \lambda_i \quad [\text{A-4}]$$

The first term in Eq. [A-2] is the ideal shift, and the second represents the phase difference due to the light deflection in the concentration boundary layer. The last term is due to the end effect of the concentration boundary layer, which extends over the effective cathode surface to the electrolytic cell wall. Roughly speaking, the ratios of ΔS_1^D and ΔS_1^E to the true phase difference are about 0.1 and 0.3, respectively.

All other errors due to chromatic aberration, spherical aberration, parallelness of laser beam, and glass effect of electrolytic cell are negligibly small in comparison with ΔS_1^D and ΔS_1^E .

LIST OF SYMBOLS

A	numerical value
a	degree of dissociation of bisulfate ion
c	concentration (mol/cm ³)
$*c$	concentration in bulk electrolyte (mol/cm ³)
c^s	concentration at cathode surface (mol/cm ³)

Electrocatalytic Activity of Phthalocyanines in Secondary Lithium Cells¹

D. Wöhrle and M. Kirschenmann

Organische und Makromolekulare Chemie, FB 2-Chemie, Universität Bremen, D-2800 Bremen 33, Germany

N. I. Jaeger*

Angewandte und Physikalische Chemie, Angewandte Katalyse, FB 2-Chemie, Universität Bremen, D-2800 Bremen 33, Germany

The feasibility of cathodes containing low molecular unsubstituted phthalocyanines (Pc, I) in secondary lithium cells was studied by Yamaki and Yamaji (1). They reported values of discharge capacities of more than 17 electrons per molecule of phthalocyanine requiring the intercalation of the equivalent number of charge compensating lithium cations. The extensive literature

¹ Part IX of "Polymeric Phthalocyanines and Their Precursors."

* Electrochemical Society Active Member.

concerning the properties of phthalocyanines (2-5), namely, electrochemical and chemical redox equilibria (6-8), suggests a reversible reduction of up to four electrons per molecule. The apparent discrepancies gave rise to a more detailed investigation of the electrochemistry of the cell. At the same time, the properties of low molecular copper octacyanophthalocyanine 2 (9) and copper polyphthalocyanine 3 (10, 11) were tested in the same cell reaction. The structures of the compounds are given in Fig. 1.

Fig. 1. Structure of Mt-phthalocyanine **1** with Mt = H₂, Cu; copper octacyanophthalocyanine **2** and copper polyphthalocyanine **3**.

Experimental

β -H₂Pc **1**, β -CuPc **1**, **2**, and **3** used in the experiments were synthesized following procedures given in Ref. (2, 3, 9, 10). The compounds **1** were purified by sublimation (12). Test cells were constructed in analogy to the method described in Ref. (1). The lithium anodes (3.14 cm²) were punched from Li foil (99%, Goodfellow Metals). The cathode material contains 0.1g acetylene black (Fa. Hoechst, Germany) acting as a current collector and different amounts of phthalocyanine. The powders were thoroughly mixed in a ball mill for several hours and used directly without further treatment. A polypropylene separator foil (Freudenberg, Weinheim, Germany) soaked with the electrolyte for several days was used to prevent contact between cathode material and the anode. The separator foil was clamped on the powder at the bottom of the cell by means of a PTFE stamp, which was screwed finger tight into the cell. Otherwise, no pressure was exerted on the cathode. The electrolyte was found to soak the cathode material completely.

The electrolyte was 1M LiClO₄ in propylenecarbonate, which had been dried over a molecular sieve (Linde 3 A) and distilled several times under vacuum. The experiments were carried out in a dry box under dry oxygen-free argon.

The stability of the electrolyte during discharge was followed by gas chromatography and mass spectroscopy taking samples from a test volume into which the cell could be vented. The phthalocyanines were tested by infrared spectroscopy before and after discharge.

Results and Discussion

The discharge capacity of a cell for a given amount of β -H₂Pc **1** could be optimized by the amount of acetylene black in the cathode mixture. Figure 2 depicts results obtained for acetylene black to phthalocyanine ratios (by weight) ranging from 0.2 to 10.0. The highest absolute discharge capacities are obtained at the ratio 1.0, since for lower ratios (higher amounts of **1**) the conductivity of the mixture and for higher ratios (higher amounts of acetylene black) the amount of **1** is too low. The corresponding specific discharge capacities are listed in Table I. A blank test run without the cathode active material yielded no capacity. The absolute cell capacity is highest for the acetylene black to β -H₂Pc ratio of 1.0. The specific energy based on H₂Pc weight, however, increases with decreasing amounts of β -H₂Pc in the mixture. The capacities are higher than those reported in Ref. (1).

Table I. Specific discharge capacities of β -H₂Pc **1** in dependence on the ratio of acetylene black to β -H₂Pc in the cathode mixture (0.1g acetylene black in each case). Discharge current 3.14 mA, 1V cutoff.

Ratio acetylene black to β -H ₂ Pc	Specific discharge capacity of β -H ₂ Pc (Ah/kg)	Specific energy related to β -H ₂ Pc (Wh/kg)	Cell capacity (mAh)
0.2	190	285	95
1.0	1014	1521	101
2.0	1193	1789	60
10.0	1256	1884	13
0 (blank)	0	0	0

Fig. 2. Discharge capacities *V* of Li- β -H₂Pc **1** cells in dependence on the ratio (by weight) of acetylene black (0.1g) to cathode active material; discharge current 3.14 mA.

Fig. 3. Discharge capacities of Li- β -H₂Pc **1** cells in dependence on the discharge current. Cathode composition: 0.1g **1**, 0.1g acetylene black.

Cell characteristics and discharge capacity in dependence on the discharge current are given in Fig. 3. For a 1V cutoff, a specific discharge capacity of up to 1340 Ah kg⁻¹ could be achieved corresponding to about 26 electrons per molecule of phthalocyanine.

Since the reversible reduction of phthalocyanines exceeding four electrons per molecule can be ruled out (6-8), the electrocatalytic activity of the material toward the decomposition of propylene carbonate was held responsible for the high discharge capacity of the cell. No irreversible changes in the phthalocyanine structure could be detected by IR spectroscopy following the discharge of the cell. Quantitative analysis by gas chromatography (using standard mixtures of different hydrocarbons) and also the determination of the gaseous reaction products by mass spectrometry shortly after start of the discharge procedure led to the following results: ~70% propene (m/e 42), ~30% mixtures of butenes (m/e 56), and ~0.5% of unidentified hydrocarbons. Therefore, the phthalocyanines exhibit electrocatalytic activity in the decomposition of the electrolyte mainly under formation of propene (13)

CuPc **1** also shows high specific capacities (Table II) in analogy to Ref. (1). Considerably lower capacities were obtained for **2** and **3**. From these results, a drop in the electrocatalytic activity in the order β -H₂Pc **1** > β -CuPc **1** > **3** > **2** can be inferred quite in contrast to the electrocatalytic activity of these compounds (**1**, **3** containing Co or Fe as metal atom) in the reduction of dioxygen (14,15).

Table II. Specific discharge capacities of cathode materials containing β -CuPc 1, copper octacyanophthalocyanine 2, and copper polyphthalocyanine 3

Compound	(g)	Acetylene black (g)	Discharge current (mA)	Specific discharge capacity (Ah/kg)	Specific energy (Wh/kg)	Cell capacity (mAh)
1	0.1	0.1	1.00	1008	1512	101
	0.1	0.1	3.14	455	637	46
	0.2	—	1.00	168	218	34
2	0.1	0.1	1.00	260	364	26
	0.1	0.1	3.14	55	72	6
	0.2	—	1.00	98	157	20
3	0.1	0.1	1.00	350	490	35
	0.1	0.1	3.14	251	301	25
	0.2	—	1.00	100	110	20

Even though Li-SOCl₂ cells are superior to Li-propylene carbonate cells in theoretical charge density by about 20% and in theoretical energy density by about 30%, it could be worthwhile to look into the electrocatalytic activity of the phthalocyanines in more detail.

Cyclic Voltammogram of SnCl₂ and SnCl₂ + PdCl₂ Sensitizing Solution

Thomas M. Tam*

Lockheed Missiles and Space Company, Incorporated, Sunnyvale, California 94086

A mixed SnCl₂/PdCl₂ sensitizing solution is commonly used to initiate dielectric surface for subsequent metal deposition (1, 2). The catalytic activity of this mixed solution depends upon several parameters: temperature (100°F), specific gravity (1.12 minimum); concentration of Sn²⁺ (50-63 mM) and Pd (1.0-3.8 mM). The most frequently changing parameters are the concentration of Sn and Pd, and these must be adjusted periodically. In order to control these two parameters, it is important to design an *in situ* analytical sensor to monitor the concentration of Sn and Pd.

This communication describes a cyclic voltammetric method for analyzing a Sn-Pd sensitizing solution. Quantitative data will be presented to verify that the technique is simple, rapid, and easily adaptable to automation.

Experimental

Chemical and solutions.—The solvent used in this study was prepared by dissolving 270g of Cataprep 404 salt (Shipley Company, Newton, Massachusetts) into 1 liter of deionized water. The resulting solution is highly acidic and has a high chloride ion concentration. As the Cataprep 404 salt used here is a proprietary salt, the exact composition of other ingredients are not known. This solution is used (i) as a prep solution to activate a noncon-

ducting material for subsequent treatment and (ii) to dilute concentrated Sn-Pd catalyst provided by the vendor (Cataprep 44, Shipley Company, Newton, Massachusetts). The procedure below was used to prepare solutions for this study. The chloride salts of tin (II, IV) and palladium (II) were obtained from Alfa Products. The Sn and Pd content of the salts were determined by Inductive Couple Plasma Atomic Spectrophotometer (Instrument S. A.) and were used to calculate their concentrations in the solutions.

Solutions containing tin were prepared by dissolving known weight of tin salts into Cataprep 404. The tin-palladium (Sn-Pd) solutions were prepared by dissolving known weight of SnCl₂ · 2H₂O and PdCl₂ in separate Cataprep 404 solutions. The two solutions were mixed and left to stand overnight before being used in measurements. Color changes of the solution after being mixed were similar to that reported in the literature (1, 2). These color changes are due to the formation of Sn-Pd colloid suspended in the solution. The catalyst prepared in this manner may not have the optimum activity required, but it is adequate for evaluating the analytical technique described herein.

Cyclic voltammetric measurements.—A 250 ml Brinkmann titration vessel was used to hold the platinum working, auxiliary (copper wire), and Ag/AgCl reference

* Electrochemical Society Active Member.

electrodes. This working electrode was prepared by pressing a 0.32 cm diam platinum rod into 0.953 cm diam stainless steel rod. The electrode body was sealed by using Microstop (Michigan Chrome and Chemical Corporation), and the exposed platinum surface was polished with 600 grit silicon carbide paper. The surface area of the electrode was 0.08 cm². The electrode was rotated at 3000 rpm using a Dietzen Motor equipped with a rotating mercury contact (Mercota, Incorporated). The potential was driven by an in-house built cyclic voltammetric unit (3). A Soltec X-Y recorder (U. P. 64325) was used to record the voltage and current change. The potential was scanned between -0.8 and +0.65V¹ at a rate of 80 mV/s. All voltammograms were run at room temperature (21° ± 1°C).

The peak intensity is defined as area under the peak, which can be converted into total number of coulombs, *I*, by using a proportioning factor. The cyclic voltammetric system currently used does not have an area integrator. Therefore, to obtain the area, the voltammogram obtained from the X-Y chart recorder is photocopied. On the photocopied voltammogram, base lines were drawn under the peaks. The peaks were then cut out along the trace and weighed. Using a proportionality factor, the weight was then converted to *I*.

Results and Discussion

Voltammograms of SnCl₂/SnCl₄ + PdCl₂ in Cataprep 404.—The cyclic voltammetric technique has been used by Osaka *et al.* (4) and Horkans (5) for studying the chemistry of Sn-Pd mixed catalyst. Each of the authors used different electrodes and solutions in their studies, which are quite different from the present work. In this work, the voltammograms are obtained *in situ* by immersing the three electrodes into solution containing SnCl₂, SnCl₄, and SnCl₂ + PdCl₂.

Voltammograms of Sn²⁺ and Sn⁴⁺ in Cataprep 404 are characterized by a set of anodic and cathodic peaks (Fig. 1A); the anodic peak (SnA) is at -0.41V and the cathodic peak is at -0.53V (SnC). As SnC is easier for analysis, it is used for obtaining quantitative data. When PdCl₂ is added to the Sn²⁺ solution, an anodic peak (Pd1) at -0.21V is also observed (Fig. 1A). This peak can be used for the analysis of Pd²⁺ quantitatively.

An additional palladium peak (Pd2) can be observed by treating the platinum electrode as follows. (i) The platinum electrode is immersed in a Sn-Pd containing solution and is cycled three times between -0.8 and +0.65V.

¹All potentials are measured against Ag/AgCl reference electrode.

Fig. 1. Cyclic voltammogram of Sn²⁺ + Pd²⁺ in Cataprep 404. Temp. = 21°C. Scan rate = 80 mV/s. C_{Sn²⁺} = 54 mM; C_{Pd²⁺} = 9.3 mM.

Table I. Parameters of the straight line plot shown in Fig. 2 and 3

	Slope (C/mM)	Intercept (C)	Coeff. of DTM. (r ²)	Figure no.
<i>I</i> _{SnC} vs. C _{Sn²⁺/Sn⁴⁺}	5.69 × 10 ⁻⁵	-3.3 × 10 ⁻⁴	0.98	2
<i>I</i> _{Pd1} vs. C _{PdII}	1.45 × 10 ⁻⁴	-2.22 × 10 ⁻⁵	0.97	3
<i>I</i> _{Pd2} vs. C _{PdII}	4.44 × 10 ⁻⁴	-2.87 × 10 ⁻⁴	0.99	3

(This peak intensity increases with the number of cycles scanned). (ii) Rinse the electrode, immerse the electrode into Cataprep 404 solution, and scan the voltage anodically while rotating the platinum electrode at 3000 rpm. A single anodic peak is observed at +0.51V (Pd2, Fig. 1B). This procedure was followed in our experiments on Pd²⁺ because of its reproducibility to obtain quantitative data for the Pd2 peak.

Intensity of SnC Peak (*I*_{SnC}).—The linear dependence of *I*_{SnC} vs. C_{Sn²⁺} and C_{Sn⁴⁺} is shown in Fig. 2, and the properties of the straight line plot are shown in Table I. The behavior of *I*_{SnC} vs. C_{Sn²⁺} and C_{Sn⁴⁺} is identical and therefore can be considered as one plot. In order to identify the SnC peak, Joisson and Devand's (6) work was repeated using a differential polarography technique to study Sn²⁺ and Sn⁴⁺ in 0.1M HCl/4M NH₄Cl solution. We found that the reduction of Sn⁴⁺ and Sn²⁺ appeared at -0.286V and -0.482V, respectively. The peak intensity measured from the Sn⁴⁺ solution is approximately one-tenth that of Sn²⁺, although the concentrations of the two species are approximately equal (10 ppm). The reason for this is not yet clear. Based upon these results, SnC was designated as the reduction of Sn²⁺ to Sn⁰, and SnA as the dissolution of Sn⁰ in Cataprep 404. For a Sn⁴⁺ solution, the peak at -0.286V due to the reduction of Sn⁴⁺ should be observed. However, the peak in this region could be relatively small and broad so that we are unable to observe it. As a result, only the SnC peak is observed. The data points for *I*_{SnC} vs. C_{Sn²⁺} with constant amount of PdCl₂ added are also shown in Fig. 2. At low C_{Sn²⁺}, the data points can be fitted onto the straight line. As the C_{Sn²⁺} increases, the data points begin to deviate from the straight line.

The effect of Pd²⁺ on *I*_{SnC} was measured by using solutions containing an approximately constant amount of Sn²⁺ (60 ± 1.5 mM) and varying amounts of Pd²⁺ (0.7-17 mM). The apparent peak intensity, *I*_{SnC}/C_{Sn²⁺}, remains relatively constant, 4.0 ± 0.4 × 10⁻⁵ C/mM.

Intensity of Pd1 peak (*I*_{Pd1}).—When PdCl₂ is added to the Sn²⁺ containing solution, a small anodic peak at -0.21V is also observed. The intensity of this peak (*I*_{Pd1})

Fig. 2. *I*_{SnC} vs. C_{Sn²⁺/Sn⁴⁺}. Experimental conditions, see Fig. 1. ●, Sn²⁺; □, Sn⁴⁺; ▲, Sn²⁺ + Pd²⁺.

Fig. 3. I_{Pd1} and I_{Pd2} vs. $C_{Pd^{2+}}$. Experimental conditions, see Fig. 1. $C_{Sn^{2+}} = 60$ mM.

Fig. 4. I_{Pd1} vs. $C_{Sn^{2+}}$. Experimental conditions, see Fig. 1. $C_{Pd^{2+}} = 1.64$ mM.

increased linearly with respect to $C_{Pd^{2+}}$ (Fig. 3). The parameters of the straight line are shown in Table I. The effect of Sn^{2+} on I_{Pd1} is shown on Fig. 4. Notice at low $C_{Sn^{2+}}$ (20-40 mM) the effect of Sn^{2+} is negligible, but at higher concentrations the intensity of the peak decreases. It is apparent that this peak can be directly related to the $C_{Pd^{2+}}$ in solution. It is unlikely that this peak is due to the dissolution of palladium deposited on the electrode surface. Both Osaka *et al.* (4) and Horkans (5) suggested that in this region the observed anodic current is due to the desorption of hydrogen (7). Another hypothesis is that, as the Pd-Sn colloid is deposited onto the electrode surface during cathodic scan, quantitative amounts of hydrogen are absorbed on the palladium surface. During the anodic scan, the desorption of hydrogen gives rise to the anodic current. But as the concentration of Sn^{2+} increases, it competes with hydrogen for the coordinate site of palladium, causing the peak intensity to drop.

Intensity of Pd2 peak (I_{Pd2}).—Interestingly, this peak is not observed in a Sn-Pd sensitizing solution. It will show when the electrode is treated by the steps described in the experimental section. The peak intensity I_{Pd2} increases linearly with respect to the concentration of Pd in solution (Fig. 3, Table I). Using a different procedure, Osaka *et al.* (4) observed a similar peak. There is little doubt that Pd2 is due to the dissolution of Pd^0 (4, 8). The metallic palladium can be produced on the electrode in two ways: (i) activation, the result of a reaction between

Sn^{2+} and Pd^{2+} on the electrode; or (ii) electroposition, as the result of pretreatment by potential cycling.

In a Sn-Pd sensitizing solution, it is likely that Pd is well protected, or insulated by the excess Sn^{2+} (stabilizing Sn^{2+}) (9, 10). As the electrode is immersed into a pure Cataprep 404 solution, the stabilizing Sn is dissolved and Pd is then exposed to the high chloride solution. As a result, the dissolution process is possible.

The following two experiments were done to test the above hypothesis.

1. The Sn-Pd colloid is deposited onto the electrode surface as described, rinsed, and anodically stripped in a Sn^{2+} containing Cataprep 404 solution. The Pd2 peak does not show up. If the same electrode is further stripped in a pure Cataprep 404 solution, the expected Pd2 peak shows up.

2. Six 1×1 cm² platinum plates were coated with Sn-Pd complex similar to the technique used above. Three of the plates were rinsed with deionized water (set 1), and the rest were rinsed with Cataprep 404 (set 2). The surface of the Sn-Pd coat was investigated using Auger electron spectroscopy. We have found the atomic ratio of Pd and Sn on the surfaces are: set 1, Pd:Sn = 0.17:0.83; set 2, Pd:Sn = 0.37:0.63. The standard deviation of these values is ± 0.03 .

Experiment 1 shows that Sn^{2+} in Cataprep 404 will inhibit the dissolution of Pd^0 . Experiment 2 shows that significant amount of Sn^{2+} on the electrode surface can be leached (stabilizing Sn^{2+}) by rinsing it with high chloride containing solution. The remaining Sn could be the complexed Sn.

Conclusion

The cyclic voltammetric technique described in this communication can be used in monitoring the concentration of Sn and Pd in Sn-Pd sensitizing solution. The advantages of this sensing system are (i) measurement of Sn and Pd *in situ*; (ii) measurement of Sn and Pd simultaneously in one scan cycle (SnC , PdI); and (iii) two measurements on Pd ($Pd1$, $Pd2$).

The system used in the laboratory has an accuracy of $\pm 10\%$. Improvement is possible by automation of the system. The system cannot measure specifically the Sn^{2+} and Sn^{4+} concentrations.

Potentiostatic High Overpotential Studies of Copper Deposition from Electroless Copper Solutions

Milan Paunovic*

Kollmorgen Corporation, PCK Technology Division, Melville, New York 11747

The mechanism of electroless metal deposition has been studied so far from two aspects: electrochemical and structural. First, some mechanistic aspects of charge transfer processes in electroless metal deposition were studied by transient and quasi-steady-state electrochemical techniques (1-6); second, the mechanistic aspects of lattice formation processes were studied by scanning and transmission electron microscopy (7-9). One unsolved problem is a correlation between the electrochemical and structural kinetic parameters.

The purpose of this study is to initiate work on the elucidation of the above unsolved correlation problem. For these studies, we have chosen the potentiostatic transient method (10-13).

In this communication, we report potentiostatic current-time transients obtained in the studies of the cathodic partial reaction in electroless copper deposition using palladium and platinum electrodes. Results obtained using a copper electrode were reported previously (13). These measurements are the first applications of the potentiostatic current-time technique to the study of processes in electroless metal deposition.

Experimental

The solutions were prepared with analytical-grade reagents and distilled water. The electroless copper solution used for these studies contained 0.05M CuSO_4 , 0.15M EDTA (ethylene-diaminetetraacetic acid), 0.25M Na_2SO_4 , 0.074M CH_2O , $3.0 \times 10^{-4}\text{M}$ NaCN, and NaOH to give a pH of 12.50. The formaldehyde was a 37% solution of an analyzed reagent grade. Oxygen was removed by bubbling argon. The temperature was 25°C.

An all-glass, three-compartment cell with three electrodes with 500 ml of solution was used. The reference electrode compartment was connected to the test electrode compartment via a Luggin capillary. The test electrode was either (i) a platinum disk, 0.442 cm^2 in area, or (ii) a palladium disk, 0.500 cm^2 in area. The auxiliary electrode was a platinum cylinder (1 cm^2 in area) electroplated with copper in an acid copper solution (1), and a saturated calomel electrode (SCE) was used as a reference electrode. The test electrode was polished to a mirror finish using 0.05 μm alumina powder. Between tests, deposited copper was stripped in a persulfate solution ($\text{Na}_2\text{S}_2\text{O}_8$ 40 g/liter and H_2SO_4 to give a pH of 2.5) and the electrode was polished with 0.05 μm alumina powder. The test electrode was introduced into the solution at the test potential and recording of the current-time curves was started simultaneously with establishment of the electrode-solution contact.

Potentiostatic current-time transients were obtained with a PAR (Princeton Applied Research, Princeton, New Jersey) Model 173 potentiostat-galvanostat. The current-time (i-t) curves were recorded on a Hewlett-Packard 7004 recorder.

Results and Discussion

Two typical sets of potentiostatic current-time transients for the reduction of cupric ions in the absence of formaldehyde are shown in Fig. 1. Figure 1 shows that these curves exhibit a maximum (i_m) and that the height and the position of this maximum on the time coordinate (t_m) are a function of the potential. These potentials are relatively high. The rest potentials for Pt and Pd were -50 and -200 mV vs. SCE, respectively.

Fig. 1. Potentiostatic current-time transients for the deposition of copper from the solution containing 0.05M CuSO_4 , 0.15M EDTA, 0.25M Na_2SO_4 , $3.0 \times 10^{-4}\text{M}$ NaCN, and NaOH to give a pH of 12.50. Absence of CH_2O . a (top): A platinum electrode. b (bottom): A palladium electrode.

Two sets of current-time transients for the deposition of copper from the electroless copper solution, in the presence of formaldehyde, are shown in Fig. 2. Figures 1 and 2 show that the curves recorded at the Pt and Pd electrodes in the solution in the absence of formaldehyde exhibit essentially the same shape as those in the presence of formaldehyde. One significant difference is that, at certain

Fig. 2. Potentiostatic current-time transients for the deposition of copper from the electroless copper solution. a (top): A platinum electrode. b (bottom): A palladium electrode. The mixed potential of a copper electrode in this solution is -720 mV vs. SCE. The composition of the solution is given in the Experimental section.

potentials in the presence of formaldehyde, two maxima are clearly visible; the analysis of these maxima will be published elsewhere.

A comparison between Fig. 1 and 2 shows that the height and the position of the maxima are in the same current and time range for the both types of solutions (the presence and the absence of formaldehyde). Figure 3 shows that the height and the position of this maximum on the time coordinate depend on the additive present in the solution.

Plots of $\log i_m$ vs. overpotential are linear and, when extrapolated to $\eta = 0$, they yield intercepts ($i_{m,0}$) of 3.0×10^{-5} and 3.5×10^{-5} A/cm², for Pd and Pt, respectively (Fig. 4). The intercept $i_{m,0}$ is analogous to that in the classical Tafel relation, i_0 , and the reversibility parameter $i_{m,0}$ observed for the case of the nucleation and growth process control (14). At the present, there is no theoretical equation for the diffusion-controlled processes giving $i_{m,0}$ in terms of the nucleation rate constant, diffusion coefficient, and overpotential.

Slightly different values of $i_{m,0}$ for different substrates (e.g., Fig. 4) are due to differences in the interaction energies between the substrate and the first layer, which are different for different substrates (14).

It was shown earlier (6), using a rotating disk electrode, that reduction of complexed copper ions in an electroless copper solution, at the Cu²⁺ ion concentration of 0.05M, is diffusion controlled. Also, in the preliminary experiments in this work, we have found that the height of the potentiostatic i - t maxima depend on the rate of rotation of the test electrode; thus, these maxima are diffusion controlled, and are the result of two opposing effects: first, an increase in the current due to the increase in the surface area of growing nuclei, and second, a decrease in the current due to (i) overlap and (ii) an increase in the thickness of the Nernst diffusion layer δ , $\delta(t) \propto t^{1/2}$ (12) and $i \propto (1/\delta)$.

If diffusion of electrodepositing ions from the solution to the nuclei is rate-determining, and if the overlap effect is taken into account (10-12), then the theoretical values of the product $i_m^2 t_m$ for hemispherical diffusion are given for instantaneous nucleation by (11)

$$i_m^2 t_m = [0.163 (nFc)^2 D] = 1.52 \times 10^{-4}$$

and for progressive nucleation by

$$i_m^2 t_m = [0.260 (nFc)^2 D] = 2.42 \times 10^{-4}$$

for $c = 5 \times 10^{-5}$ M/cm³, $n = 2$, and $D = 1 \times 10^{-5}$ cm²/s,

Fig. 3. Potentiostatic current-time transients of a Pt electrode in electroless copper solution showing effect of NaCN. $E = -900$ mV.

Fig. 4. Plot of η vs. $\log i_m$ of Pd and Pt electrodes in electroless copper solution

where c is the concentration of copper ions, n the number of electrons, F the Faraday constant, and D the diffusion coefficient.

The experimental values at -1000 mV vs. SCE, for the electroless solution, are 1.98×10^{-4} and 1.18×10^{-4} for Pt and Pd electrodes, respectively. This relatively good agreement between the experimental and theoretical (instantaneous nucleation) values can be taken as a confirmation of the diffusion control.

Other types of analysis of the current-time curves and correlation of these to our structural studies (7) will be published elsewhere. Also, by changing, the concentration of copper ions, controls other than diffusion will be studied.

The current-time curves (and the above-mentioned correlation) are of great theoretical and practical significance since they enable us to determine (i) number of nuclei N , from $i = F(D, t, N)$ for the instantaneous nucleation, (ii) the nucleation rate constant k , from $i = F(D, t, k)$, for the case of the progressive nucleation, and (iii) geometry of nuclei by electrochemical methods. The electrochemical methods are much faster than methods used in structural studies (7) and are capable of being computerized for the continuous monitoring of quality of metal deposition.

Conclusions

It was shown that the potentiostatic transient technique using high overpotentials can be used to study (i) processes comprising electroless copper deposition and (ii) the effect of additives on these processes. The use of high overpotentials in the potentiostatic step functions is a limitation when this technique is applied to the studies of electroless copper deposition. The dependence of $i = f(t)$

transients on (i) the type (morphology, geometry) and (ii) the number of nuclei is an advantage of the potentiostatic technique over electrochemical techniques used previously. This advantage enables one to establish a correlation between the electrochemical and structural kinetic parameters and provide a new method for copper quality control.

Electrocatalytic Oxidation of Demineralized Oil Shale

Patrick M. Dhooge and Su-Moon Park*

Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131

K. M. Jeong

Gulf Research & Development Company, Pittsburgh, Pennsylvania 15230

Electrochemical oxidation of coal slurries has recently been suggested as a means of gasifying coal at low temperatures by Coughlin *et al.* (1-3). Subsequent studies by other investigators (4, 5) indicated that electrolytic currents observed from the coal slurry in 1M sulfuric acid were attributed to the oxidation of iron(II) leached out from the coal. We (6-8) and Lalvani *et al.* (9) have more recently shown through various experiments that coal slurries are catalytically oxidized by iron(III); the reduced ion, iron(II), produced in the electron-transfer process is then oxidized back to Fe(III) at the anode, completing a catalytic cycle. The oxidation products for this reaction were carbon dioxide and hydrogen, and oxygen atoms in the product, CO₂, were shown to be derived from water. Thus, the overall reaction resembles that of the coal gasification reaction. This electrochemical reaction, however, has the advantages that hydrogen is produced as a pure gas product suitable for use in fuel cells or synthetic processes and that high temperature operations are not necessary to produce hydrogen from the coal. Peat has also been shown to oxidize to produce a good yield of regenerated humic acids in alkaline media (10), and we have suggested the possibility that other organic matrices and wastes might be oxidized by this process to produce hydrogen as a useful product (6).

Experimental

In our current communication, we report our recent results on electrochemical oxidation of oil shale. Similar results to those shown with coal were obtained with lower reaction rates than shown by New Mexico subbituminous coal.

The Colorado Green River oil shale taken from the Mahogany Zone (C-a tract) was reduced to 50 × 100 mesh samples (44 GPT, density = 1.65 g cm⁻³) by a mechanical pulverizing and sieving procedure. The shale was washed first with 6N HCl and then with a (1:3) mixture of 6N HCl and 50% HF at room temperature under the nitrogen atmosphere to minimize or eliminate air oxidation. This washing procedure was made to remove minerals and to concentrate kerogen. Elemental analysis of this sample showed 58.4% C, 7.65% H, 4.96% O, 1.64% N, and 4.12% S. The experimental apparatus and various reagents used have been described elsewhere (6, 7). Cyclic voltammograms were recorded using a Bioanalytical Systems (West Lafayette, Indiana) Model CV-1 voltammetry unit as a function generator along with a Princeton Applied Research Model 173 as a potentiostat. All the experiments were run in 1M sulfuric acid solution using platinum working and counterelectrodes, and the Hg-mercury sulfate (saturated) electrode as a reference electrode. The potentials shown in current-potential curves were all calibrated to give values against the normal hydrogen electrode (NHE).

Results and Discussion

Cyclic voltammograms (CV) recorded from an oil shale slurry in 1M H₂SO₄ solution (unstirred) are shown in Fig. 1. The CV recorded from the initial slurry (Fig. 1, curve a) shows peaks attributable to the oxidation/reduction of the Fe(II)/Fe(III) pair. Peaks shown at lower potentials are attributed to reduction/oxidation of protons in acidic solution. After this solution was stirred for about 50h (Fig. 1, curve b), we notice that the former peaks grew significantly,

indicating that electroactive material was being built up. This is because a reversible, stable redox pair was leached out by the acid solution. The redox pair was identified by a standard addition method as shown in Fig. 1, curve c. This CV was recorded after the addition of 1.0 × 10⁻²M Fe(III). This procedure not only helps confirm the identity of the electroactive materials, but also allows the determination of its concentration. The amount of iron extracted after about 50h was thus estimated to be 1.2 × 10⁻³M, or approximately 0.27% by weight in the oil shale used here. This was confirmed by analyzing the electrolyte with atomic absorption methods.

The source of iron leached out should be pyrite, which survived the HF-HCl treatment. The iron content was down to 0.96% after the acid enrichment from 3.7% for the untreated sample.

Figure 2 gives the current-voltage characteristics for the oil shale slurry under steady-state conditions. That is, the current-potential measurements were made while the solution was stirred. Steady-state measurements were made to determine the oxidation state of iron ions extracted. Curve b gives the *i*-*E* characteristics for the oil shale slurry, whereas curve a is for the acid solution alone. These figures show that part of the iron leached from the oil shale is in the +2 state, indicating that iron(III) extracted is already in the +2 state or has been reduced in the oxidation of organic materials as in coal oxidation. After oxidation of this solution overnight at +1.0V *vs.*

Fig. 1. Cyclic voltammograms (CV) of oil shale slurries. CV's were recorded in a slurry containing 5.0g of oil shale in 200 ml of 1.0M H₂SO₄ at a platinum electrode (area = 10 cm²) with a scan rate of 20 mV/s. These were recorded from a freshly prepared slurry (curve a), after 50h in the 1.0M H₂SO₄ solution (curve b), and with 1.0 × 10⁻²M Fe(III) added (curve c).

*Electrochemical Society Active Member.

Fig. 2. The steady-state current-voltage characteristics. a: 1.0M H_2SO_4 solution without shale added. b: 5.0g oil shale in 200 ml of 1.0M H_2SO_4 solution. c: After oxidation overnight at +1.0V. d: After addition of 1.0×10^{-2} Ce(IV) was added to the solution of curve c.

NHE, curve c is obtained. The oxidation current level has dropped considerably, and some of the iron is still in the +3 state. This observation indicates that the rate of oxidation of iron(II) at the electrode is faster than the reaction to regenerate the iron(II) in the solution. Addition of cerium(IV) to this solution gives the i-E characteristics shown in curve d, where both anodic and cathodic currents are observed for the Ce(IV)/Ce(III) pair around its reversible redox potential. This indicates that cerium(IV) oxidizes both iron(II) and organic functional groups quickly.

The electrocatalytic nature of the oil shale oxidation is also shown by the time dependency of the electrolytic current. If the oxidation of iron(II) extracted is the only source of the anodic current, the current should approach to zero upon complete depletion of iron(II). This was not the case, however, as shown in Fig. 3, curves a and b. The anodic current leveled off after about 15h of electrolysis, maintaining the same current level for a few days until the cell was disconnected. The solution was continuously stirred while the measurements were made. This observa-

Fig. 3. a: Current level vs. time for 5.0g oil shale in 200 ml of 1.0M sulfuric acid at +1.0V vs. NHE at the Pt electrode (area = 10 cm^2). b: Same as in curve a, except at 1.5V vs. NHE. c: With 1.0×10^{-2} M Ce(IV) added at 1.5V.

tion indicates that iron(II) was continuously regenerated through the process

as was shown in the oxidation of coal (6, 7). When Ce(IV) was added to the solution (Fig. 3, curve c), essentially similar processes occurred but with higher steady-state currents observed, indicating a higher catalytic reaction rate with Ce(IV) than with Fe(III). The same was shown to be the case for coal oxidation. This would be expected because the oxidation potential of Ce(IV) is higher than that of Fe(III). Many organic functional groups that are not oxidized by Fe(III) can be oxidized by Ce(IV).

The catalytic current increased with the amount of catalyst ions added, as can be seen in Fig. 4. The addition of iron(III) did not increase the current as much as with the addition of Ce(IV). The case shown here resembles that shown by the electrocatalytic oxidation of Norit A (6) (amorphous carbon used as an organic decolorizing agent). In the case of Norit A oxidation, we surmised that there were very few functional groups oxidizable with Fe(III). Cerium(IV), however, is a strong enough oxidant to oxidize many more resistant functionalities.

The results shown here indicate that electrocatalytic oxidation of oil shale resembles that of coal in many respects. Oxidizable functional groups on oil shale are electrocatalytically oxidized by iron(III) leached from the shale, as was found for coals. The reason for the lower catalytic current with oil shale is perhaps due to the fraction of aliphatic hydrocarbons (*i.e.*, shale kerogen), which is higher than that in coal. Many of these compounds require an oxidant with more positive standard electrode potentials to get oxidized. Oxidation currents might be from alcohol, aldehyde, phenolic, quinone, or some carboxylic acid functional groups, which were shown to be present in the oil shale used in this study (11). Iron(III) should account for most of the catalyst ions, since other major minerals present are shown to be Al, Ca, K, Mn, and Si. Manganese is present in a trace amount, approximately 100 ppm in an untreated, original sample. Further, oxidation of Mn(II) to its higher oxidation state, Mn(VII), for example, requires higher potentials than +1.0V, which was the potential applied in most of our experiments.

Also, the large enhancement in catalytic current, when Ce(IV) is added, is consistent with the results obtained from coal oxidation. As pointed out, Ce(IV) has a higher oxidation potential than Fe(III) and therefore is capable of oxidizing many organic functional groups indiscriminately (12).

Current densities observed in our experiments with oil shale may not be high enough to justify the use of oil shale as an anodic depolarizer for the electrolytic produc-

Fig. 4. a: Current level vs. concentration of added Fe(III) at +1.0V vs. NHE at 10 cm^2 Pt electrode, 5g oil shale in 200 ml of 1.0M H_2SO_4 . b: Same as in curve a, but corrected for the amount of iron leached from the oil shale. c: Current level vs. concentration of added Ce(IV) at +1.5V vs. NHE, 10 cm^2 Pt electrode, 5g oil shale in 200 ml of 1.0M H_2SO_4 solution.

tion of hydrogen. Electrolytic procedures, however, may turn out to be useful for washing and concentrating oil shale, and the hydrogen gas produced at the cathode would be a useful byproduct. Further work is in progress along these lines in our laboratory.

Oxygen Reduction Kinetics in Deuterated Phosphoric Acid

M. M. Ghoneim,¹ S. Clouser,* and E. Yeager*

Case Center for Electrochemical Sciences and Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

Despite the substantial research on the reduction of O₂ on platinum in phosphoric acid, the mechanistic aspects still remain very uncertain. The situation has become even more in question with the recent observation that the Tafel slope is almost independent of the temperature over the range 298–500 K, indicating that the apparent transfer coefficient is proportional to the temperature (1). In an attempt to gain further insight into the mechanistic aspects, polarization measurements for O₂ reduction on Pt have been carried out in deuterated and undeuterated 85% H₃PO₄ at 25°C. This article reports the preliminary results.

Experimental

The most critical aspect of such isotope studies is that of reproducibility of surface and electrolyte conditions between the deuterated and undeuterated acid solutions. A major effort has been made to reproduce conditions and to eliminate impurity effects.

The O₂ reduction measurements have been made with the rotating disk electrode technique. The measurements were carried out in two identical Teflon cells, each consisting of a main working electrode compartment and two separate compartments for the reference and counterelectrodes (2). The working electrode was a disk electrode (Pine Instruments Company) with an area of 0.46 cm². The reference electrodes were reversible H₂/H⁺ and D₂/D⁺, using a platinized-platinum surface. The counterelectrode was bright Pt.

The working electrode surface was first polished with alumina (0.05 μm) to a mirror finish, submerged in distilled water for 15 min with ultrasonic vibrations, and then rinsed in distilled water, followed by purified H₃PO₄. The distilled water used in this work was prepared by reverse osmosis of tap water followed by distillation with a counterflow of N₂ to purge volatiles such as CO₂ and organics. The reverse osmosis-distillation system was assembled by B. D. Cahan at Case Western Reserve University and is based on a design developed by Gilmont and Silvis (3).

A Pine Instruments RDE-3 bipotentiostat with input impedance of 10¹²Ω in the reference circuit and built-in triangular sweep generator was used for all measurements. The current-potential curves were recorded on a Yokagawa Electric Works Type 3086 X-Y recorder. Prior to electrochemical measurements, the Pt disk electrode was cycled several times between potentials of 1.0 and 0.3V vs. a reversible hydrogen or deuterium electrode (p = 1 atm) at a sweep rate of 10 mV/s.

For preparation of the D₃PO₄ and H₃PO₄ electrolytes, Mallinckrodt 85% H₃PO₄ was first purified with H₂O₂ ac-

cording to the procedure of Ferrier *et al.* (4). Two samples of this purified H₃PO₄, each 120 ml, were then placed in Teflon containers and concentrated by boiling out the H₂O until the acid samples became concentrated to ~96% at 150°C while passing N₂ gas through the boiling acids. After cooling, 50g of D₂O (99.8% D, Stohler Isotope Chemicals) were added to one acid sample (A). At the same time, 50g of distilled H₂O were added to the other sample (B). The two samples were reconcentrated by boiling until they reached 150°C while bubbling purified D₂ gas and H₂ gas through samples A and B, respectively. The additions of D₂O or H₂O were repeated ten times. The last step was dilution of each sample with D₂O and H₂O to the original volume (120 ml each). Proton NMR measurements indicated that the deuterated acid sample was 98% D. The deuterated and undeuterated acids were further purified by adding 4g of Na₂O₂ (Fisher certified ACS reagent) to each, then heating to 50°C for 3h until the H₂O₂ and D₂O₂ produced from Na₂O₂ were completely decomposed. This procedure is similar to that of Ferrier *et al.* (4), except that Na₂O₂ is added instead of H₂O₂ in the present work, to avoid introduction of H into the D₃PO₄ solution. Earlier work has shown that sodium phosphate has no appreciable effect on O₂ reduction on Pt in 85% H₃PO₄ (5). The two acid solutions were next deoxygenated by passing purified N₂ through them. The O₂ was removed by passing the gas over heated copper turnings while trace organics in the N₂ were removed with molecular sieves at Dry Ice-ethanol temperatures. To each acid, 0.2g of Pt black (Engelhart fuel cell-grade) were added and H₂ or D₂ bubbled through the acid for 48h. Finally, purified N₂ was bubbled through the acids to remove the H₂ or D₂ gas.

Results and Discussion

The voltammetry curves for Pt in the deuterated and undeuterated acids (Fig. 1) are similar but not identical in the double-layer and anodic film regions. The voltammetry curves differ significantly in the hydrogen region. Two sets of principal adsorption/desorption peaks are present in both curves. The peaks are shifted anodically for the deuterated acid by ~30 mV and are more pronounced, particularly for the weaker bound H/D peaks I and I'. The hydrogen oxidation peak III appears more reversible in the D₃PO₄ than in the H₃PO₄. The conditions for the D₃PO₄ and H₃PO₄ differ in temperature (30° and 25°C) and slightly in acid concentration (86 vs. 85%), but prior experience with H₃PO₄ indicates that these factors are not the principal source of the differences in the hydrogen region of the voltammetry curves. The authors believe that the principal factor responsible for the difference in the voltammetry curves is the isotopic difference and not impurity effects.

Fig. 1. Voltammogram for Pt disk in purified 85% H_3PO_4 at 25°C (curve a) and 86% D_3PO_4 at 30°C (curve b). Sweep rate: 100 mV/s; N_2 saturated. Reference electrodes for curve a: H_2 (1 atm)/ H^+ ; for curve b: D_2 (1 atm)/ D^+ .

The polarization curves for O_2 reduction using the rotating disk electrode are shown in Fig. 2 for 400 and 1600 rpm. The Pt electrode was first cycled between 1.0 and +0.3V vs. RHE or RDE and then held for a few seconds at $\sim 1.0\text{V}$ before sweeping the potential in the cathodic direction at 10 mV/s. The rise in the curves at $\sim 0.3\text{V}$ is due to the H/D adsorption region. The apparent difference in the limiting current densities in Fig. 2 may not be significant since it is difficult to saturate the solution with O_2 to the same degree. The corresponding Tafel plots are shown in Fig. 3 with a correction for mass transport using the diffusion limiting current evaluated from the dotted section of each curve at $\sim 0.3\text{V}$ in Fig. 2. The O_2 reduction appears to proceed about two times faster in the deuterated acid than in the undeuterated acid at the same potential vs. the reversible deuterium and hydrogen reference electrodes. The Tafel slope differences are small. At a given current density in the middle of the Tafel linear region, the potential for the O_2 electrode in the deuterated specimen is $\sim 0.055\text{V}$ more positive than that in the undeuterated acid at a given current density.

Fig. 2. Rotating Pt disk data for O_2 reduction at 400 and 1600 rpm in purified Mallinckrodt 85% H_3PO_4 at 25°C (curves 1, 3) and 86% D_3PO_4 at 30°C (curves 2, 4). Sweep rate: 10 mV/s; O_2 saturated. Reference electrodes for curves 1, 3: H_2 (1 atm)/ H^+ ; for curves 2, 4: D_2 (1 atm)/ D^+ .

Fig. 3. Tafel plots obtained for rotating Pt disk data in purified Mallinckrodt 85% H_3PO_4 at 25°C (curve a) and 86% D_3PO_4 at 30°C (curve b). Rotation rate: 1600 rpm. Reference electrodes for curve a: H_2 (1 atm)/ H^+ ; curve b: D_2 (1 atm)/ D^+ . Current is in microamperes per centimeter.

To obtain the difference in the overpotentials in the deuterated and undeuterated acids at a given current density, it is necessary to take into account the difference in the reversible potentials of the O_2 electrode vs. the reversible deuterium and hydrogen electrodes, i.e., the potential difference of the cells

The potential for each is given by

$$E_{\text{D}} = E_{\text{D}}^{\circ} - \frac{RT}{4F} \ln \frac{(a_{\text{D}_2\text{O}})^2}{(p_{\text{D}_2})^2(p_{\text{O}_2})} \quad [1]$$

and

$$E_{\text{H}} = E_{\text{H}}^{\circ} - \frac{RT}{4F} \ln \frac{(a_{\text{H}_2\text{O}})^2}{(p_{\text{H}_2})^2(p_{\text{O}_2})} \quad [2]$$

where the activities of the gases have been taken as equal to their pressures and the activities of D_2O and H_2O are referred to the pure liquids as 1. Thus the difference in the potentials of the reversible O_2 electrode in the two acid samples vs. the reversible deuterium and hydrogen electrodes is

$$E = E_{\text{D}} - E_{\text{H}} = E_{\text{D}}^{\circ} - E_{\text{H}}^{\circ} - \frac{RT}{2F} \ln \frac{(a_{\text{D}_2\text{O}})}{(a_{\text{H}_2\text{O}})} \quad [3]$$

The value of $E_{\text{D}}^{\circ} - E_{\text{H}}^{\circ}$ corresponds to the difference in the standard free energy of formation of liquid D_2O and H_2O , which is $\Delta G_{\text{D}_2\text{O}}^{\circ} - \Delta G_{\text{H}_2\text{O}}^{\circ} = -1.51 \text{ kcal/mol}$ (6) at 25°C. The calculated value for $(E_{\text{D}}^{\circ} - E_{\text{H}}^{\circ})$ is then +0.033V at 25°C. Since the boiling points of the 86% D_3PO_4 and 85% H_3PO_4 were virtually identical, this provides evidence that the ratio $(a_{\text{D}_2\text{O}}/a_{\text{H}_2\text{O}})$ is ~ 1 and hence $\Delta E = +0.033\text{V}$. Thus the overpotential for the O_2 reduction reaction is $\sim 0.02\text{V}$ less in the deuterated vs. undeuterated acid and the reaction at the same overpotential is $\sim 40\%$ faster in the deuterated acid.

This relatively small factor can be explained on the basis of the 5°C higher temperature of the deuterated acid during the polarization measurements. Using an apparent Arrhenius energy of $A = 10 \text{ kcal/mol}$ (2) for O_2 reduction on Pt in 85% H_3PO_4 , the Arrhenius equation yields

$$(k_{303}/k_{298}) = \exp \frac{A}{R} \left| \left(\frac{1}{298} - \frac{1}{303} \right) \right| = 1.32$$

where k_{303}/k_{298} is the ratio of the rate constants at the indicated absolute temperature at constant overpotential and R is the perfect gas constant. Thus the observed ratio of 1.4 is mostly due to the temperature difference and the kinetic isotope effect is negligible.

The lack of any appreciable kinetic isotope effect provides evidence that the rate-controlling step in concentrated phosphoric acid does not involve the making or breaking of any bonds involving protons (or deuterons). For the situation to be otherwise would require the coincidence of virtually completely compensating isotope effects. This observation has important mechanistic implications.

ABSTRACT

At temperatures between 500° and 950°C, in an oxygen ambient, a flux of either negative or positive oxygen ions, generated via a point-to-plane corona discharge, is directed to the front side of a silicon wafer. Electrical contact to the wafer was made via the back side. Both ion beam polarities lead to oxidation enhancement, but with very different oxide thickness profiles, even though the ion beam current density profiles in the gas phase at the surface are almost identical. Wafer orientation, P_{O_2} , current, temperature, and time dependences have been studied.

Abundant studies have been conducted on the thermal oxidation of silicon which manipulate the conventional thermodynamic state variables of the system (concentration, temperature, and pressure). Studies have also been conducted to investigate the electrochemical nature of the oxidation process, and this has led to extensive controversy over the charge state of the oxidant species (1-16). The plasma oxidation studies being pursued in many quarters today are a measure of the generally recognized benefits to be derived from control of the electrochemical state of the oxidizing species. However, in plasma oxidation, one has the intermixing of (i) oxygen ion species effects, (ii) neutral diatomic and monatomic oxygen species effects, (iii) electric field effects, and (iv) UV radiation effects. In an attempt to understand these effects more fully and to learn more about oxidation at low temperatures, we have investigated some effects on thermal oxidation associated with isolated studies of these individual factors. In this paper, we restrict our attention to only negatively and positively charged oxygen ion beam effects since studies involving only electric field effects (11) and only laser light (12) are described elsewhere.
