A few changes to the circuit shown in Fig. 5 or 6, respectively, allow the use of a personal computer (PC), making the testing procedures far more flexible. The suggested changes are as follows.

Input 2 of the A/D converter must be grounded to make the converter accept 8 bit words and produce the corresponding voltage at the output. The switch IC-9 will be operated with the switch S-4. The pulses will be turned off with S-1. The logic inputs of the S&H IC's are to be switched over to the computer inputs marked PC. The logic level must be adapted with voltage dividers (8). The following features must be provided for operation with a PC: (i) 8 bit data channel for the control of the D/A-converter, (ii) 3 bit data channel for controlling the 3 S&H-stages, and (iii) two channel A/D converter for the current and voltage measurements.

Manuscript received Nov. 16, 1984. This was Paper 93 presented at the New Orleans, Louisiana, Meeting of the Society, Oct. 7-12, 1984.

Complex Plane and ^7Li NMR Studies of Highly Conductive Sulfide-Based Lithium Glasses

Steven J. Visco, Peter Spellane, and John H. Kennedy*

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

The activation energy for lithium diffusion in highly conductive $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ glasses with varying lithium concentrations is measured by ^7Li NMR linewidth techniques, and is compared to activation energies for ionic conductivity obtained by complex plane techniques. The ^7Li NMR spectra for the glasses have been examined as a function of temperature; the HB equation for motional narrowing was used to calculate the activation energies for lithium movement in the various glasses. From the NMR data, two activation energies were observed over the temperature range of -100°C to room temperature. The low temperature, high activation energy values correlate well with the activation energies obtained from ionic conductivity measurements, while the high temperature, low activation energy process is apparently due to some sort of short-range motion detected only by the ^7Li NMR measurements.

The desire for reliable high energy density batteries has led to exciting developments in the field of solid-state electrolytes. Batteries utilizing solid electrolytes for ionic conduction may provide the most efficient means of storing energy. Much of the work in this field to date has focused on crystalline materials; however there has been a recent shift into new areas such as glass and polymeric electrolytes. Glass electrolytes offer many advantages over polycrystalline ceramic electrolytes, including isotropic conductivity, absence of grain boundary resistance, wide compositional ranges, and ease of fabrication.

The use of lithium as an anode material offers obvious benefits; lithium has a low equivalent weight, yields high cell voltages, and is relatively easy to handle. Consequently, there has been a substantial amount of research effort devoted to finding suitable lithium electrolytes. The search for crystalline lithium electrolytes has not been very satisfactory. However, there have been recent exciting advances in the development of lithium ion conductive glasses (1-14). Various glasses have been synthesized (such as $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ and $\text{LiI-Li}_2\text{S-B}_2\text{S}_3$) that have Li^+ conductivities matching the best crystalline electrolytes ($\sigma = 10^{-3} \text{ S-cm}^{-1}$ at 25°C) and stability ranges appropriate for their use in lithium anode batteries (1-5, 10).

The structures and mechanisms for conduction in glass electrolytes have been less studied and consequently less understood than their crystalline counterparts. In order to further explore the nature of the ionic conductivity in glasses, we have applied the techniques of both solid-state NMR and ac impedance to study the highly conductive $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ glasses (1-5).

The application of NMR in solid electrolyte studies is a potentially powerful tool for exploring both the structural and dynamic nature of these materials (15-19). ^7Li NMR has been used effectively to study the diffusion of Li^+ in Li_3N , and very recently to study Li^+ movement in the conductive lithium borate glasses (17-19) and $\text{Li}_2\text{S-GeS}_2$ glasses (20). A predominant cause of NMR line broadening in solids is the magnetic dipole-dipole interaction between nuclei. Thermal activation of ions with increasing temperature tends to remove the dipole-dipole inter-

action between nuclei of activated ions, and the corresponding NMR line narrows. This phenomenon is called motional narrowing. From the NMR linewidth *vs.* temperature data, the Hendrickson-Bray (HB) equation can be used to calculate the activation energy for Li^+ motion in the solid (18, 19).

Bray and his co-workers have determined the activation energies for Li^+ motion in the $\text{Li}_2\text{O-B}_2\text{O}_3$ and $\text{LiX-Li}_2\text{O-B}_2\text{O}_3$ ($\text{X} = \text{F, Cl}$) glasses (18, 19), and correlated them with activation energies reported from conductivity studies. It is important to realize that more meaningful comparisons between the two techniques can be obtained when conductivity and NMR measurements are made on the same sample.

We now present data obtained from both NMR and electrical conductivity measurements on $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ glasses having varying LiI concentrations. These glasses are of particular interest because they possess very high Li^+ conductivities at ambient temperatures (1-5).

Experimental

The $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ glasses were prepared according to the procedure of Malugani and Robert (2). The glass compositions are determined by holding the mole ratio of Li_2S to P_2S_5 at 2:1 while varying the mole ratio of LiI . Since starting materials and end products are extremely hygroscopic, all manipulations were performed inside a helium dry box equipped with a purification train to keep residual H_2O and O_2 to less than 1 ppm. The reagents were mixed in the appropriate proportions, sealed into thick-walled quartz tubes, placed in Inconel alloy pipe explosion shields, and heated to approximately 900°C for about 1h. The melts were then either air or water quenched, depending on the cooling rate desired. The quenched glass was ground to a fine powder, and, for the NMR study, a portion of the glass sample was sealed under vacuum into 5 mm NMR tubes. The remaining powder was then uniaxially pressed into 1/4 in. diam rods with TiS_2 electrodes on both faces. The vitreous electrolyte rod was finally isostatically pressed at approximately 40,000 lb/in.² prior to ionic conductivity measurements.

Fig. 1. The complex impedance diagram for 0.10LiI-0.60Li₂S-0.30P₂S₅ glass with TiS₂ electrodes ($T = 156^{\circ}\text{C}$).

The ionic conductivity of the glasses was determined using a Solartron 1174 Frequency Response Analyzer interfaced to a Hewlett-Packard 9845B desktop computer and a General Radio 1435 programmable decade resistance box. A correction program was incorporated to compensate for inductive effects arising from electrode leads observed at high frequency (10^5 - 10^6 Hz). The signal across the sample was 100 mV. Complex impedance measurements were recorded from 10^{-2} to 10^6 Hz over the temperature range 25° - 120°C .

⁷Li NMR spectra were obtained on a Nicolet NT-300 Spectrometer. A broad band probe was tuned to 116.6157 MHz on a solution sample of LiCl and the magnetic field homogeneity was optimized for this sample at room temperature. The lithium glass sample was then placed in the magnet and cooled gradually to -100°C . The sample was not spun, and no further attempt was made to improve field homogeneity. Thermal equilibration time varied from 15 to 60 min, depending on the selected temperature. A 90° pulse was applied, and data from 1000 transients was Fourier transformed to yield one broad resonance and fit to a Lorentzian curve.

Results and Discussion

The complex impedance plots of the LiI-Li₂S-P₂S₅ glasses consisted of a straight line intersecting the real axis at approximately a 45° angle (Fig. 1). The real axis intercept was taken to represent the bulk resistance of the glass sample. For all glass compositions, the ionic conductivities follow the classical Arrhenius law, $\sigma = \sigma_0 \exp(-E_a/RT)$ (Fig. 2). The ionic conductivities and corresponding activation energies of the vitreous electrolytes are governed by the glass composition. As previously reported by Malugani *et al.* (2-4), the ionic conduc-

^c Conductivity at 25°C .

tivity of these glasses at a specific temperature increased and the activation energy decreased with increasing LiI concentration (Table I). The activation energies determined in this study were slightly higher than those reported in the literature (2-4). This could be the result of isostatically pressing the glass powders to less than maximum density.

The ⁷Li NMR spectra for the lithium glasses investigated exhibited a single ⁷Li resonance over the temperature range of -100° - 50°C (Fig. 3). The NMR linewidth *vs.* temperature data were analyzed using the HB equation for motional narrowing in solids written as

$$\ln(1/W-1/A) = -(E_a/kT) + \ln(1/B-1/A)$$

where W is the observed NMR linewidth, A is the experimentally determined rigid-lattice linewidth, and B is the high temperature linewidth. The rigid-lattice linewidth A is determined by lowering the sample temperature until the NMR linewidth no longer broadens. Due to the highly conductive nature of the LiI-Li₂S-P₂S₅ glasses and the fact that we are presently confined to a lower temperature limit of -100°C , it was necessary to extrapolate the rigid-lattice linewidth for the more conductive glasses containing high concentrations of LiI (*i.e.*, 30 mole percent). A plot of $\ln(1/W-1/A)$ *vs.* $1/T$ should produce a straight line with a slope of $-E_a$ and Y -intercept of $\ln(1/B-1/A)$.

The HB plots of the NMR data for the glass electrolytes clearly show two straight line segments, indicating that two types of motion in the glass are being observed (Fig. 4, 5). The low temperature line narrowing corresponds to

Fig. 3. ⁷Li nuclear magnetic resonance line obtained from sample of 0.20LiI-0.53Li₂S-0.27P₂S₅ glass at 10°C . Fit of 187 data points to Lorentzian function is shown.

Fig. 4. ${}^7\text{Li}$ NMR linewidth vs. temperature for the $0.66\text{Li}_2\text{S}-0.34\text{P}_2\text{S}_5$ sample. *: Experimental points. Solid line: calculated curve.

Fig. 5. The plot of $\ln[(1/W) - (1/A)]$ vs. $1/T$ for ${}^7\text{Li}$ motional narrowing data for the $0.10\text{LiI}-0.60\text{Li}_2\text{S}-\text{P}_2\text{S}_5$ glass exhibits two different processes that contribute to motional narrowing. The low temperature and high temperature activation energies obtained from this plot are 0.38 and 0.10 eV, respectively.

a high activation energy process, while the high temperature narrowing involves a low activation energy process (Table I). The activation energies for the low temperature narrowing correlate well with the activation energies obtained from the ionic conductivity measurements. The values for the parameter B corroborate this observation. Long-range motion (as in ionic conduction or diffusion) would eliminate the dipole-dipole interaction, whereas a local restricted motion would have far less effect in removing the interaction. Therefore, the value of B corresponding to long-range motion will be much smaller than that for short-range motion. As can be seen from Table I, the B values for the low temperature process exhibiting activation energies nearly equal to those obtained from conductivity measurements were several orders of magnitude smaller than the B values for the high temperature process. Bray *et al.* found the same trends for the lithium borate glasses (18, 19). The NMR results in Table I show

that the high activation energy for long-range motion in the glass decreased with increasing LiI concentration. This trend is mirrored by the activation energies for ionic conduction determined for the same glass samples.

The results in Table I also show that the low activation energy for short-range motion was essentially constant over the entire range of LiI concentrations, and little change was seen in the value of B . Thermal activation of the short-range motion in these glasses was apparently unaffected by the concentration of lithium ion, indicating that this process did not involve the presence of neighboring lithium ions. In addition, the constant low activation energy found in this study matched the analogous values determined by Bray *et al.* (19) for the $60\%\text{Li}_2\text{O}-40\%\text{B}_2\text{O}_3$ and $50\%\text{Li}_2\text{O}-\text{B}_2\text{O}_3$ glasses (0.11 eV).

Conclusion

It is clear that NMR investigations can yield useful information on the nature of the movement of Li^+ in solid electrolyte glasses. The activation energies for ${}^7\text{Li}$ motion determined from NMR line narrowing studies correlate well with the activation energies determined from ionic conductivity measurements on the same samples. Furthermore, the NMR measurements detect a type of short-range Li^+ motion that is apparently not detectable by electrical conductivity studies.

The Pitting Corrosion of Nickel in Different Electrolyte Solutions Containing Chloride Ions

D. V. Vasquez Moll, R. C. Salvarezza, H. A. Videla, and A. J. Arvia*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, Sucursal 4, 1900 La Plata, Argentina

ABSTRACT

The pitting corrosion of nickel in different electrolytes containing chloride ions was studied by using potentiostatic and potentiodynamic techniques complemented with scanning electron microscopy. The breakdown potential depends linearly on the logarithm of the chloride ion concentration. The logarithm of the induction time for pit initiation decreases linearly with the reciprocal of the applied potential. The overall process can be described by two stages. The first stage of pitting is explained through the formation of the passive layer in competition with the nucleation and growth of a chloride layer. The second stage, which is diffusion controlled, occurs when the salt precipitation conditions is reached. The proposed reaction model reproduces the potentiostatic current transients of nickel pitting by chloride in near-neutral buffered and alkaline solutions.

The corrosion of nickel in chloride containing solutions has been studied in previous papers (1-5). Localized corrosion of nickel is observed at potentials more positive than a certain critical value (E_b). Pits as small as 1 μm diam growing with current densities of the order of 1-100 A/cm² were detected on the nickel surface (2). The initiation and growth of nickel pitting were attributed either to the presence of a thin salt film on the metal surface (2) or to a mass transport process due to local changes in pH (6). In principle, it should be expected that low pH values and high chloride concentrations be associated with large pits as is the case of ferrous alloys (7). Crystallographic and bright hemispherical pits, depending whether the current density is smaller or greater than the current density at which salt precipitation occurs, are observed on nickel 200 in concentrated chloride solutions (8). Pit stabilization on both iron and nickel was related either to the formation of a salt layer by precipitation or to a contaminated oxide on the pit surface (9). The formation of a nickel hydroxide layer would produce pit stabilization (10). It was recently claimed that chloride ions mainly interfere with the repassivation process instead of breaking the passive film in pitting corrosion of nickel (11).

The present paper deals with the pitting corrosion of nickel in different solutions containing chloride ions covering a relatively wide range of pH. The corrosion process is studied using electrochemical techniques complemented with scanning electron microscopy. Pit initiation of nickel in the various systems investigated can be interpreted through the same complex mechanism already applied to the pitting corrosion of iron (12).

Experimental

Working electrodes (specimens) were made of polycrystalline 99.99 nickel rods (5 mm diam) axially embedded in Araldite holders to obtain circular exposed areas of 0.2 cm². The pretreatment of each specimen consisted of a gradual polishing, starting with fine grained emery paper, followed with diamond paste, and, finally, with alumina paste (1 and 0.3 μm). The polished specimen was successively rinsed with acetone, twice-distilled water, and then dried in air at room temperature. A fresh specimen was used in each run. Measurements were made in a conventional Pyrex glass cell at 25 \pm 0.1°C. The potential of the specimen was measured against a saturated calomel electrode (SCE) connected through a Luggin-Haber capillary tip. In the text, potentials are referred to the SCE scale. A platinum plate was used as counter-electrode. The following electrolyte solutions were used: (i) phosphate-borate buffer (0.1M KH₂PO₄ + 0.05M Na₂B₄O₇, pH 8.00); (ii) borate-boric acid buffer (0.075M Na₂B₄O₇ + 0.15M H₃BO₃, pH 9.00); (iii) carbonate-bicarbonate buffer (0.05M Na₂CO₃ + 0.75M NaHCO₃, pH 9.00); and (iv) 10⁻³M NaOH. Sodium chloride was added to each electrolyte solution in the 0.1M \leq c_{NaCl} \leq 1M concentration

range. Solutions were prepared from twice-distilled water and AR chemicals and purged with purified nitrogen during 3h previously to each run.

Single triangular potential sweep (STPS) voltammograms run between the cathodic ($E_{s,c}$) and the anodic ($E_{s,a}$) switching potential at the sweep rate (v) 0.02 V/s, and potentiodynamic polarization curves ($v = 0.02$ V/min) were obtained in the conventional way and presented as current density (i) vs. potential (E) plots. Prior to each run, the specimen was held either at -1.00V in one of the buffer solutions or at 1.30V in the sodium hydroxide solution during 90s to achieve a reproducible electroreduced surface (14). Current transients (i/t) at constant potential (E_s) were also recorded. For this purpose, preceding the potential step at E_s the working electrode was successively potential stepped to -1.00V (E_c) during 90s and to -0.5V (E_a) during 90s to form a passive layer. Recent results in weakly alkaline phosphate solutions show that at potentials close to -0.5V (SCE) a thin film of $\approx 5\text{\AA}$ is formed at $t < 60\text{s}$ (13). Conventional microscopic and SEM observations were also made.

Results

Voltammetric response.—The first voltammetric scan of nickel both in borate-boric acid and phosphate-borate buffers at 0.02 V/s between $E_{s,c} = -1.00\text{V}$ and $E_{s,a} = 0.50\text{V}$ (Fig. 1a) shows a broad anodic current peak at ca. -0.45V which corresponds to Ni(OH)₂ electroformation (13) followed by a poorly defined hump in the -0.40 to 0.1V range. In carbonate-bicarbonate buffer, the anodic peak at -0.45V (Fig. 1b) and another well-defined anodic peak at -0.25V are observed (Fig. 1b).

The first positive potential going scan from $E_{s,c} = -1.00\text{V}$ to $E_{s,a} = 0.0\text{V}$ run in the buffer solutions containing 0.05M NaCl is qualitatively similar to that recorded in the absence of chloride ions (Fig. 1a and 1b). In the alkaline solution, the anodic peak related to Ni(OH)₂ electroformation appears at -0.65V and the potential of the anodic peak changes according to the solution pH (13). Likewise, when $E_{s,a}$ exceeds 0.05V, there is a sharp increase in the anodic current, which remains during the returning scan. In this case, the voltammetric loop is related to the localized corrosion of nickel. The potential associated with the activation process is more positive in carbonate-bicarbonate buffer than in other solutions.

The potentiodynamic E/I profiles recorded at 0.02 V/min in buffer solutions containing NaCl exhibit a breakdown potential (E_{bv}) associated with pitting corrosion of nickel. Current oscillations probably related to the nickel activation-repassivation processes are observed in a small potential region preceding E_{bv} (9).

The increase in NaCl concentration (c_{NaCl}) shifts E_{bv} toward more negative values according to the following equation

$$E_{bv} = a - b \log c_{\text{NaCl}} \quad [1]$$

*Electrochemical Society Active Member.

Fig. 1. STPS recorded at 0.02 V/s between $E_{s,c} = -1.00V$ and $E_{s,a} = +0.50V$ in: (a) (—) borate-boric acid buffer, (---) borate-boric acid + 0.5M NaCl; and (b) (—) carbonate-bicarbonate buffer, (---) carbonate-bicarbonate + 0.5M NaCl.

Equation [1] is fulfilled in both buffered and nonbuffered electrolytes (Fig. 2).

Current transients.—The current transients under a constant potential step in the $-0.50V < E_s < 0.40V$ range, in both buffer solutions and $10^{-3}M$ NaOH, in the absence of chloride ions, show a slow continuous decrease in current (Fig. 3). A similar behavior is observed in 0.5M NaCl when E_s is more negative than the potential range where current oscillations are observed.

When E_s falls within the region of current oscillations ($E_s \approx E_{bv}$), the current initially increases up to a maximum, and finally decreases again to approach a value which is slightly greater than that recorded in chloride-free solutions (Fig. 4). The maximum current may result from at least two competing processes such as those associated with pit formation and pit repassivation (10). In this case, few irregular pits are initially formed which are later repassivated. In the potentiostatic mode, pit stabilization occurs at $E_s \gg E_{bv}$.

When $E_s \gg E_{bv}$, the current initially decreases to a minimum and later increases to reach a large randomly

Fig. 2. E_{bv} vs. $\log C_{NaCl}$ in (◆) phosphate-borate buffer, (×) $1 \times 10^{-3}M$ NaOH, and (■) carbonate-bicarbonate.

Fig. 3. Current transients at constant potential recorded in phosphate-borate buffer at different potential values. (●): Experimental data. (—): Obtained using Eq. [5] and [6].

fluctuating current value. The anodized test specimens become covered with a thick white-green product, probably hydrated $Ni(OH)_2$, which spalls away from the metal surface. In this case, solution stirring removes the corrosion product and slightly decreases the corrosion current. Microphotographs of the test specimens after anodization at 0.40V during 100s show large hemispherical bright pits. The initial part of the current transients ($E_s \gg E_{bv}$), in solutions containing 0.5M NaCl (Fig. 5a-5d), exhibits an induction time (t_i) which decreases as E_s increases. No pits were detected by conventional microscopic examination of electrodes anodized at $t < t_i$. At a constant E_s , the pitting current vs. time (t) relationships fit the Engell-Stolica equation (Fig. 6)

$$(i_t - i_c) = k_0(t - t_i)^b \quad [2]$$

where i_t is the overall current and i_c is the background current, and k_0 and b are constants. The values of b , which are in the 1.4-2.0 range for $t \rightarrow 0$, decrease later to the 0.33-0.76 range. The transition time (t_i) related to the change of b decreases as the applied potential increases.

The potential dependence of t_i is given by the equation

$$\log t_i/t_0 = k'(E_s - E_n)^{-1} \quad [3]$$

where E_n is taken as the potential value at which there is

Fig. 4. Current transients recorded in different solutions containing 0.5M NaCl at potential values close to E_{bv} . a: $1 \times 10^{-3}M$ NaOH. b: Carbonate-bicarbonate.

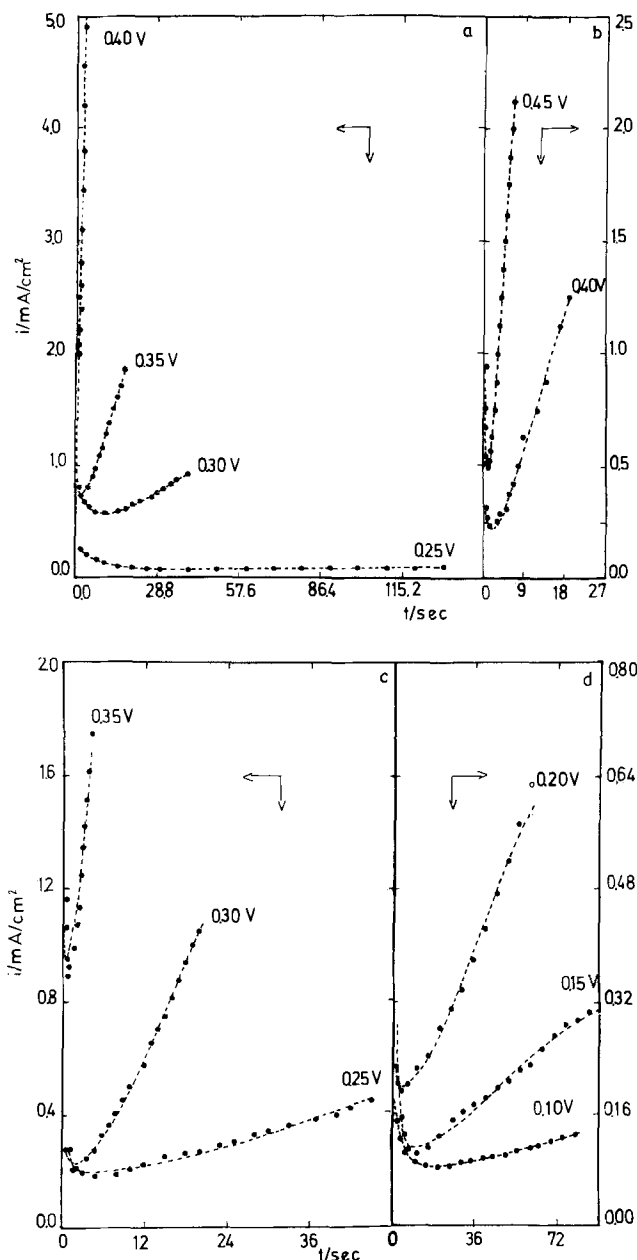

Fig. 5. Current transients at constant potential ($E_s \gg E_{bv}$) recorded in: (a) phosphate-borate + 0.5M NaCl, (b) carbonate-bicarbonate + 0.5M NaCl, (c) borate-boric acid + 0.5M NaCl, and (d) 1×10^{-3} M NaOH + 0.5M NaCl. (●): Experimental data. (—): Calculated using Eq. [5], [12], and [13].

no evidence of pit nucleation (absence of current oscillations), and k' and t_0 are constants.

SEM observations.—SEM patterns of test specimens anodized at $E_s \gg E_{bv}$, in phosphate-borate solution containing 0.5M NaCl, indicate the initial formation of crystallographic pits which during the pit growth transform into hemispherical bright pits (Fig. 7). The pit density in 10^{-3} M NaOH containing 0.5M NaCl increases slightly with the applied potential. In the 0.05-0.25V range, a linear pit density/potential relationship can be obtained (Fig. 8).

Discussion

The complex electrochemical response of nickel in nearly neutral buffered and alkaline solutions containing sodium chloride depends on the applied potential, as it involves nickel hydroxide formation, passivity onset, and pitting corrosion caused by the aggressive chloride ions. Besides, the change in both the morphology and kinetics of pit formation at $t = t_i$ points out that at least two stages should be distinguished in the pitting process.

Fig. 6. $\log(i_t - i_c)$ vs. $\log(t - t_i)$ plots in (■) phosphate-borate + 0.5M NaCl, (×) carbonate-bicarbonate + 0.5M NaCl, and (+) 1×10^{-3} M NaOH + 0.5M NaCl.

The first stage of nickel passivation is related to the electroformation of a hydrous $\text{Ni}(\text{OH})_2$ (14) layer, which undergoes a series of chemical and electrochemical transformations, yielding the final passive NiO layer (15-16). The influence of chloride ions to promote pitting can be explained through the formation of nickel chloride nuclei interfering with the passive film formation (3) at potential values slightly lower than E_{bv} . Therefore, the initiation of pitting can be interpreted through the adsorption of chloride ions on a nickel surface which is nonhomogeneously covered with passive film. At $E_s > E_{bv}$ the interaction between the aggressive anion and the metal surface becomes strong enough to remove metal atoms as solvated complex ions out from the lattice.

The analysis of potentiostatic current transients can be used to estimate the extent of participation of the various processes during the anodization of nickel. The instantaneous average anodic current (i_t) can be associated with three main current contributions: namely, the passive layer growth (i_p), the metal corrosion through the passive film (i_c), and the randomly distributed salt nuclei growth (i_s) on the metal surface. Thus

$$i_t = i_p + i_s + i_c \quad [4]$$

Fig. 7. SEM microphotograph of the metal surface after anodization at 0.35V during 50s in phosphate-borate + 0.5M NaCl.

Fig. 8. Pit density vs. E_s plot in $1 \times 10^{-3} \text{ M NaOH} + 0.5 \text{ M NaCl}$. $t_s = 300\text{s}$.

where i_p and i_c are the relevant contributions in the absence of pitting. The passive layer growth can be interpreted in terms of an instantaneous nucleation and circular bidimensional growth under diffusion control (17). In this case, the instantaneous value of i_p is then given by an expression such as

$$i_p = P_1 \exp(-P_2 t) \quad [5]$$

where $P_1 = q_{\text{mon}} \pi K_e D N_0$, $P_2 = \pi K_e D N_0$, D is the diffusion coefficient of the reacting species, q_{mon} is the charge density required for the constant thickness full coverage of the metal surface by the passive layer, K_e is a proportionality constant, and N_0 is the number of sites available for nucleation.

However, the rate of metal corrosion through either the prepassive or passive layer appears as the dissolution of tridimensional nuclei under diffusion control following the rate equation (18)

$$i_c = \frac{P_3}{\sqrt{t}} [1 - \exp(-P_4 t)] \quad [6]$$

where $P_3 = zFD^{1/2} \Delta c/\pi^{1/2}$ and $P_4 = \pi N_0' k_e D'$. Δc is the concentration difference of the diffusion species. N_0' is the number of sites available for the dissolution process, D' is the diffusion coefficient of the species involved in the process, and k_e is a proportionality constant. When $P_4 t \rightarrow \infty$, Eq. [6] becomes

$$i_c = P_3/\sqrt{t} \quad [7]$$

In the absence of pitting, Eq. [5] and [6], with the parameters assembled in Table I, reproduce the current transients for the passive nickel within 1% (Fig. 3). The time dependences of i_c and i_p are considerably different (Fig. 9). The contribution of the passive film growth principally appears at $t < 2\text{s}$. At $t > 2\text{s}$ $i_c \rightarrow i_t$, in agreement with data already reported for nickel electrodisolution in borate-boric acid buffer (19).

The oxide growth can be assigned to the diffusion of oxygen containing species (20) through the prepassive layer. The P_1/P_2 ratio gives the charge density required to complete the passive layer. The value is comprised between 0.33 and 0.21 mC/cm^2 . The average thickness of the layer formed during the potential step can be roughly estimated from the equation

Fig. 9. Total anodic current (i_t), passive layer growth current (i_p), and dissolution current (i_c) for the current transient recorded at 0.20V in the phosphate-borate buffer.

$$h = \frac{M}{zF\rho} \frac{P_1}{P_2} \quad [8]$$

where M is the molecular weight and ρ is the density of the layer component. If the stoichiometry of the latter is taken as $\text{Ni}(\text{OH})_2$, then $M = 92.71 \text{ g/mol}$, $\rho = 4.10 \text{ g/cm}^3$, and a value of h of between 3 and 4\AA results.

The rate of metal corrosion (i_c) can be related to cation diffusion through the passive layer. The cation diffusion from the metal/layer to the layer/solution interface results in dissolution at the metal/layer interface (20). From the expression of P_3 , Δc (the difference of cation concentration between the metal/layer (c_0) and the layer/solution interface (c_h)) can be estimated. Taking $D' = 1.0 \times 10^{-15} \text{ cm}^2/\text{s}$ (21), the value of Δc calculated from $P_3 \approx 10^{-2} \text{ mol/cm}^3$. However, the c_0/c_h ratio can be estimated from the electrical potential gradient (ϵ) which, in layer of $h = 20\text{\AA}$, is close to 10^6 V/cm , through the equation

$$\epsilon h = \frac{kT}{ze} \ln \frac{c_0}{c_h} \quad [9]$$

where e is the electron charge and k is the Boltzmann constant.

As the c_0/c_h ratio comes out close to 10^6 , then $\Delta c \approx c_0 k_e$ can be calculated from the equation

$$k_e = \left(\frac{8\pi c_0 M}{\rho} \right)^{1/2} \quad [10]$$

For nickel, $M = 58.69 \text{ g/mol}$ and $\rho = 8.90 \text{ g/cm}^3$ and $k_e = 1.28$. Consequently, from the expression of P_4 , the value of N_0' can be estimated. Thus, for $P_4 = 330/\text{min}$, N_0' becomes equal to $10^{15}/\text{cm}^2$. This figure suggests that the corrosion process occurs practically on the whole metal/layer interface.

In the pitting region ($E_s \gg E_{\text{bv}}$), the rate equation of the corrosion process becomes more complex, as follows

$$i_c = \frac{P_3}{\sqrt{t}} [1.0 - \exp(-P_4 t)] + P_5 \quad [11]$$

Table I. Parameters used in simulation of potentiostatic current transients shown in Fig. 3

Electrolyte	E_s (V)	P_1 (mA/cm^2)	P_2 (min)	P_3 ($\text{mA min}^{1/2}/\text{cm}^2$)	P_4 (min)
Phosphate-borate	0.40	0.652	117	0.022	340
Phosphate-borate	0.20	0.507	143	0.010	315
Phosphate-borate	-0.20	0.647	173	0.014	339

where P_5 can be assigned to the corrosion current through either the prepassive or the passive layer induced by the accumulation of the aggressive anions at certain sites. Considering that

$$P_5 \gg \frac{P_3}{\sqrt{t}} | 1.0 - \exp(-P_4 t) |$$

Eq. [11] becomes

$$i_c \equiv P_5 \quad [12]$$

The large values of i_c suggest that at the sites of attack the prepassive layer was totally removed and at these points the nucleation and growth of a salt layer containing the aggressive anion takes place. Both SEM observation and the slight dependence of pit density on potential (Fig. 8) suggest that the mechanism of salt nuclei formation corresponds to an instantaneous nucleation and tridimensional growth. This process probably implies the electro-dissolution of nickel leading to pitting corrosion.

The instantaneous value of i_s can be calculated from the rate equation for conical pit growth under a charge-transfer control (22)

$$i_s = P_6 [1 - \exp(-P_7 t^2)] \quad [13]$$

where $P_6 = zFk_{3c}'$, $P_7 = \pi M_s^2 k_{3c}^2 N_{os} / \rho_s^2$, k_{3c} and k_{3c}' are the formal rate constants for the layer growth in the directions parallel and perpendicular to the metal plane, respectively, ρ_s is the salt (NiCl₂) density whose molecular weight in M_s , and N_{os} is the number of sites available for salt nuclei formation. When the salt nuclei formation implies an induction time (t_{is}), Eq. [13] becomes

$$i_s = P_6 | 1 - \exp[-P_7 (t - t_{is})^2] | \quad [14]$$

Equations [13] and [14], after a series expansion, yield the following relationships

$$i_s = P_6 P_7 t^2 \quad [15]$$

$$i_s = P_6 P_7 (t - t_{is})^2 \quad [16]$$

which correspond to particular cases of the Engell-Stolica equation, where $b = 2$. This value is approached at potentials close to E_{bv} in the early stages of pit growth.

The current transients recorded for $E_e \gg E_{bv}$ in solutions containing 0.5M NaCl are reproduced within a maximum error of 5% with Eq. [5], [12], and [13] using the parameters assembled in Table II (Fig. 5a-5d). In this case, the values of t_{is} are negligible in the time scale of the current transients. Consequently, large values of the nucleation rate are expected in agreement with an instantaneous nucleation process. The potential dependence of both P_6 and P_7 approach a linear semilogarithm relationship. The slope $dE/d \log P_6$ covers from 0.12 to 0.14 V/decade, and the slope $dE/d \log P_7$ is close to 0.06 V/decade. These results are comparable to the dependence of the pit current density on potential already reported by different authors (23-26). It is likely that P_6 and P_7 be related to the corrosion rate at the pit surface where a chloride condensed phase detected in small pits (27) impedes metal

repassivation. At this stage, pits are bounded by low crystal faces which are covered by chloride (28-29).

Considering that $k_{3c} \approx k_{3c}'$ and that at $t = t_i$ the pit area is close to 0.001% of the total metal surface area, the N_{os} values can be obtained from P_7 and P_6 through the following relationship

$$N_{os} = \frac{z^2 F^2 \rho_s^2 P_7}{\pi M_s^2 10^6 P_6^2} \quad [17]$$

For NiCl₂, $\rho_s = 3.55 \text{ g/cm}^3$, $M_s = 129.60 \text{ g/mol}$, and the N_{os} values are between 1×10^3 and $2.2 \times 10^4/\text{cm}^2$. These values, which are larger than those observed for the density of single pits, suggest that each large pit contains a relatively large number of overlapping sites during growth.

Bright nickel surfaces were observed during transpassive dissolution of nickel in the presence of a salt film (8). The transition from crystallographic to hemispherical pits and the change in the kinetics of pit growth at $t = t_i$ can be related to the precipitation of a layer of nickel chloride. As the total pit area at $t = t_i$ is about 0.001% of the total metal surface area, a penetration rate (v') ($v' = P_6/0.001$) of between 0.15 and 10 A/cm² results.

The pit depth (r) required to obtain the precipitation of nickel chloride can be estimated through the expression (9)

$$r = \frac{zFD_+ \Delta c_+}{2v'} \quad [18]$$

where D_+ is the cation diffusion coefficient.

By taking $D_+ = 10^{-5} \text{ cm}^2/\text{s}$ and $\Delta c_+ = 5 \times 10^{-3} \text{ mol/cm}^3$ from NiCl₂ solubility (2), the values of r are between 4.8 (10 A/cm²) and 320 μm (0.15 A/cm²). This means that deep pits are already formed when salt precipitation occurs. This conclusion is in agreement with the kinetic transition in pit growth already discussed.

In the absence of electrolyte convection, the instantaneous ion concentration at the flat metal surface dissolving at constant current density can be expressed by Sand's equation.

$$\Delta c_+ = 2v' \sqrt{t_i} / zF \sqrt{\pi D_+} \quad [19]$$

From this equation, the time (t_i) required to build up the concentration change $\Delta c_+ = 5 \times 10^{-3} \text{ mol/cm}^3$ becomes $t_i = 0.1\text{s}$ (10 A/cm²) and $t_i = 300\text{s}$ (0.15 A/cm²). These values of t_i are smaller than those resulting from the current transients (Fig. 6). The difference can be associated with the time required for salt supersaturation before precipitation (30-31).

During pitting, the pit cavity is covered by a thick layer of nickel hydroxide, which acts as a barrier to separate the pit electrolyte from bulk solution and contributes to pit stabilization (10).

The second stage of pitting occurring at $t > t_i$ is similar to the transpassive dissolution and becomes largely mass-transport controlled. In this case, Eq. [5], [12], and [13] are no longer valid (Fig. 10). The growth of salt nuclei under

diffusion control can be represented by instantaneous nucleation and tridimensional growth under diffusion control. The corresponding rate equation is (18)

$$i_s = \frac{P_8}{\sqrt{t - t_t}} [1 - \exp[-P_9(t - t_t)]] \quad [20]$$

where $P_8 = zFD_{-1/2} \Delta c_t / \pi^{1/2}$ and $P_9 = \pi N_{os}' k_s D_t$, N_{os}' denotes the number of sites available for the salt precipitation inside the pits, and k_s is a proportionality constant. When $P_9 t \rightarrow \infty$, Eq. (20) becomes

$$i_s = \frac{P_8}{\sqrt{t - t_t}} \quad [21]$$

The corresponding current transients can be simulated with Eq. [20] (Fig. 11) using the parameters assembled in Table III. Equations [20] and [21] explain the current decay observed in large artificial pits in acid solutions (31).

The cation diffusion coefficient from the bulk electrolyte can be estimated from P_8 .

Fig. 11. Current transients recorded at different E_s values in phosphate-borate + 0.5M NaCl at $t > t_t$. (x +): Experimental data. (—): Calculated using Eq. [20].

Table III. Parameters used in simulation of the potentiostatic current transients shown in Fig. 11

Phosphate-borate + 0.5M NaCl	0.275	74.9	0.021	2.55

For $\Delta c_t = 5 \times 10^{-3}$ mol/cm³, at the lowest potential $D_t = 1.2 \times 10^{-6}$ cm²/seg. This is a reasonable figure for ionic diffusion from the bulk solution.

According to the localized acidification theory, pit stabilization occurs under diffusion control (6). The critical value of ri for pit initiation for all bivalent metals is close to 5×10^{-7} A/cm (32). However, in the presence of weak acid salts, the critical conditions for pit initiation are achieved at larger values of ri . In borate-boric acid solutions, the increase in the borax concentration from 10^{-4} to 10^{-3} results in an increase of about one order of magnitude in the ri value (6). Then, for 0.15M borax concentration as used in this work, the ri value must be greater than 10^{-4} A/cm. The penetration rate (v') obtained for nickel pitting in the borate-boric acid buffer at E_s close to E_{bv} is 0.3 A/cm². Consequently, using the value of 3×10^{-4} A/cm, localized acidification seems to contribute to pit growth only when the pit depth is greater than 10 μ m. This value is close to that required for the salt layer precipitation.

From the above discussion, it can be concluded that the nucleation and growth mechanism describes the phenomenology of the initial stages of nickel pitting by chloride in nearly neutral buffered solutions and alkaline solutions containing chloride. However, the above interpretation involves the limitations of the nucleation and growth mechanism which yields a macroscopic description of the corrosion process by taking into account the nucleation of a growth center, the corresponding geometry of the growing process, and the overlapping of nuclei (33).

Electrochemical Studies of the Passive Film on 316 Stainless Steel in Chloride Media

M. G. S. Ferreira¹ and J. L. Dawson

UMIST, Corrosion and Protection Centre, Manchester, England M60 1QD

ABSTRACT

The kinetics of passive film growth on 316 stainless steel in 3% sodium chloride solution have been studied by dc and ac electrochemical measurements. The inverse logarithmic rates of current decay showed two stages of film growth, both controlled by a high field conduction mechanism. Impedance measurements were interpreted on the basis that diffusion of the metallic species through the film controlled the film growth-dissolution process. Capacitance data indicate that the film is 20–25Å thick, depending on potential, with a field strength of 6.66×10^6 V cm⁻¹.

The passivation of metals is of considerable technical importance, but, despite the considerable amount of research carried out on this topic, our understanding of the phenomena is still incomplete. The subject has been reviewed recently by Uhlig (1), and, although the present trend is to accept the formation of a film as being responsible for passivation, the important role of adsorption during the initial film formation stages should also be recognized (2).

In the case of stainless steels, many discrepancies appear to exist in the literature (3–11); the relationship between the composition of the films and the role of chromium and molybdenum on the protective properties still requires further study. Examination of publications relating to stainless steels shows that it is often difficult to compare results due to the various experimental conditions, different surface preparations, and limitation of the techniques used in the studies.

The composition, structure, and electrical properties of passivating films on austenitic stainless steels have been investigated using a range of different techniques: electron diffraction (3–6), x-ray photoelectron spectroscopy (ESCA) (7, 8), impedance measurements (7, 8), radioactive indicators (9, 10), ellipsometry (7, 8, 11), Auger electron spectroscopy (12–14), and chemical analysis of stripped films (3, 4). Of these methods, only the electrochemical and ellipsometric techniques provide *in situ* measurements.

There are also only a few publications concerned with the initiation of the film growth mechanism on iron (15) and stainless steel (7, 16), and virtually no evidence is available which indicates the mechanisms involved in the process of film growth and retention of passivity. However, recent impedance studies (19) at UMIST on 304 stainless steel in 3% sodium chloride solutions showed that a restricted diffusion process is obtained through the film, and this appeared to be a controlling factor in film stability.

The lack of quantitative data is a major problem in the development of detailed models. Nevertheless, Auger electron spectroscopy, x-ray photoelectron spectroscopy, and ellipsometry are providing semiquantitative results on the composition within the film and also on compositional changes with electrode potential.

Evaluation of the film thickness on stainless steel gave values between 5 and 60Å (3, 4, 7, 11, 17), and there is also evidence that these films possess semiconductive properties (17, 18).

The purpose of the present studies was to investigate the mechanism operating during passive film growth on 316 stainless steel and to study the changes with potential in the passive region. The ac impedance technique was the major investigative technique, since it provides *in situ* information on the mechanisms and kinetics of the processes.

DC measurements were also carried out, and the results obtained were assessed in terms of the kinetics of film growth. These were then correlated with impedance data to provide a model of the processes resulting in the formation of the passive film.

Experimental

Cell and electrodes.—A three-electrode cell consisting of a glass tube, 125 mm long and 25 mm diam, with three side arms was used in the experiments. A platinum foil and a saturated calomel electrode served as counter and reference electrodes, respectively. The working electrode was machined from bar stock of AISI 316 stainless steel with a composition

C	Si	Mn	P	S	Cr	Mo	Ni
0.04	0.23	1.65	0.030	0.016	16.87	2.49	12.72

In a preliminary series of experiments, considerable difficulties were experienced in achieving reproducibility of results due to the unpredictable onset of pitting and crevice corrosion. Electrode designs utilizing any form of masking procedure were found unsuitable; even the compression type of fitting, as used in the Makrides type of

¹ Present address: Laboratório de Electroquímica, Instituto Superior Técnico, 1096 Lisboa Codex, Portugal.

electrode (20), was not always satisfactory in eliminating crevice corrosion. It was also observed that with cylindrical electrodes, the site for pit initiation often occurred where the wall of the cylinder met the circular base. Reproducibility was only achieved by use of a truncated cone shaped electrode which was immersed to a fixed depth into the electrolyte and suspended from a leak-proof compression assembly incorporating a PTFE gasket (21). The truncated cone had an upper diameter of 10 mm, a lower diameter of 5 mm, and a height of 6 mm. The specimens were mechanically polished with emery paper to a 1000 grit silicon carbide finish under flowing water. Following this operation, the specimens were polished with a diamond paste to a 3 μm finish, degreased with acetone, and stored in a desiccator overnight prior to use.

Solutions.—Most studies were carried out in solution containing 3% sodium chloride, *i.e.*, 0.51M, with the pH adjusted to a value of 6.5 using 0.01M sodium hydroxide solution.

Comparison was also made with three solutions of pH = 0.6, but with varying chloride content: 0.5M H_2SO_4 + 0.1M NaCl, 0.5M H_2SO_4 + 0.3M NaCl, 0.5M H_2SO_4 + 0.5M NaCl, and 0.5M NaCl + 0.065M HCl.

Prior to an experiment, all solutions were deoxygenated overnight with pure nitrogen; the measurements were carried out at an ambient temperature of 291 K.

Electrochemical experiments.—Potentiokinetic measurements were carried out using an anodic sweep from the corrosion potential after the specimens had been immersed for half an hour to the depth required to give a working area of 60 mm^2 in the solution. The sweep rate was 10 mV min^{-1} , and the potential was reversed when the current density reached the value of 1 mA cm^{-2} or 400 mV . The equipment used in the experiments included a Chemical Electronics I. C. 20/05 potentiostat in conjunction with a Chemical Electronics linear sweep unit, a Sinclair DM 2 digital multimeter, and a Bryans Y-log X recorder which was used to monitor the current flowing through the cell.

Impedance measurements were made using a Solartron 1172 frequency response analyzer (FRA) over the frequency range 10 kHz–10 mHz and a 10 mV rms amplitude signal and the results were stored on a punch tape and subsequently analyzed on a Digital Equipment Corporation PDP 11/10 minicomputer. The circuitry used (21) made it possible for the experiments to be carried out at any required potential, the sweep rate from the initial corrosion potential being changed at a set rate (10 mV min^{-1}) until the desired value was reached.

Results and Interpretation

Polarization data.—The corrosion potential of the stainless steel specimens covered with the air-formed film produced by the overnight stand in the desiccator was typically $-150 \pm 20 \text{ mV vs. SCE}$. On polarization to more noble potentials, the anodic current density remained virtually unchanged at between 0.2×10^{-3} and $0.3 \times 10^{-3} \text{ mA cm}^{-2}$, the passivation current density. Above $+50 \pm 20 \text{ mV vs. SCE}$, the pitting potential, there was a rapid increase in current density with the increase in potential and pits could be seen on the metal surface. The potentiodynamic sweep was reversed at $+400 \text{ mV vs. SCE}$, and although there was an initial current increase the current decreased with the cathodic sweep until the alloy became passive again at a potential of -50 mV vs. SCE , the protection potential (see Fig. 1). These polarization results were similar to those found by previous workers (22, 23).

Film growth kinetics.—Freshly prepared electrodes, *i.e.*, ones relatively free from the air-formed film, were used to obtain the variation of current with time at a fixed potential. During these potentiostatic experiments, the current was observed to decrease progressively with time to the constant i_p value; then, by means of Faraday's law, the value of the charge passed, Q , was used to estimate the film thickness, x

Fig. 1. Potentiodynamic plot of 316 stainless steel in 3% sodium chloride solution.

$$x = \frac{QM}{nF\gamma\rho} \quad [1]$$

Two estimates of the film thickness were made by assuming that the composition was either $\gamma\text{-Fe}_2\text{O}_3$ or $\text{Fe}(\text{OH})_3$. Thus, at a potential of -120 mV vs. SCE , $Q = 3.45 \times 10^{-3} \text{ C/cm}^2$, M for $\gamma\text{-Fe}_2\text{O}_3 = 159.7 \text{ g}$, assuming a surface roughness $\gamma = 1.2$, the film density $\rho = 5.6 \text{ g/cm}^3$, and $nF = 0.579 \times 10^6 \text{ C}$, which gave a thickness of 14.2 \AA . For $\text{Fe}(\text{OH})_3$, $M = 107 \text{ g}$; $\rho = 3.5 \text{ g/cm}^3$; and $nF = 0.289 \times 10^6 \text{ C}$, *i.e.*, a thickness of 26 \AA . These values appear to be reasonable for films on stainless steel in aqueous solutions and would only be modified slightly if account were to be taken of the other alloying elements in the steel.

Figure 2 shows an $\ln i$ vs. $\ln t$ plot, suggesting an experimental relationship of the type

$$\ln i = -a \ln t + b \quad [2]$$

but with two linear regions corresponding to two different stages of film growth. Rearrangement of Eq. [2] gives

$$\ln t = -\frac{\ln i}{a} + \frac{b}{a} \quad [3]$$

But at constant potential and temperature, the film thickness, x , is also proportioned to $\ln t$ (25)

$$\frac{1}{x} = -K \ln t + K' \quad [4]$$

where K and K' are constants. Substitution of Eq. [3] into [4] gives

$$\frac{1}{x} = -K \left(-\frac{\ln i}{a} + \frac{b}{a} \right) + K' \quad [5]$$

or

$$\ln i = \frac{a}{Kx} + b - a \frac{K'}{K} \quad [6]$$

This is the inverse logarithmic law as suggested (24) by the kinetic equation

Fig. 2. Change of current with time at the potential of -120 mV

$$\ln\left(\frac{i}{i_0}\right) = B\left(\frac{E - E_0}{x}\right) \quad [7]$$

where i_0 , B , and E_0 are constants.

The correlation between $\ln i$ and $\ln t$, as predicted by the above equation, is shown to exist but involves a two-stage film growth, with the first occurring during the first 10 min of immersion. This change may be either the result of composition and structural changes within the film, as suggested for iron films (26, 27), or after 10 min the ionic current from the metal or film dissolution is no longer negligible and this is reflected in the film growth kinetics. Independent of the explanation, the inverse logarithmic law indicates that film growth occurs by a high field conduction mechanism which assists the movement of cations through the film.

AC measurements.—The ac data for the 316 stainless steel in 3% NaCl solution is presented in Fig. 3-5 for five different potentials: -130, -80, -20, +30, and +40 mV.

The three plots for the lower potential range of the passive region are shown in Fig. 3. These complex plane plots all have the same general shape which may correspond either to part of a large diameter charge-transfer semicircle or a charge-transfer-dominated region with some diffusion control, as found in other corrosion systems (28). Experimental plots were also compared with simulated plots obtained from computer-based equivalent circuit models as described later.

The data were also presented as a Bode diagram in the same figure, and it reflects the same features of the complex plane plots. Both show that the frequency responses are shifted to the left of the complex plot, indicating the large time constants for the system.

The plots shown in Fig. 4 and 5 deviate from those in Fig. 3. Since these correspond to potentials closer to the breakdown potential, they may reflect an increasing contribution from the anodic dissolution of the underlying metal through discontinuities or the weak points in the film (29-32); these processes are facilitated by the increase of potential. It can also be seen that the time constants decreased when compared to values obtained at the lower potentials, as revealed by the greater spread in the complex plane plot data.

Capacitance.—The capacity of the interface was determined as the slope of a plot of an imaginary part of the admittance Y'' , against angular frequency, ω . The results were then expressed as the reciprocal of the capacity vs. potential for the passive region as shown in Fig. 6. It can be seen that the reciprocal of capacity changes linearly with the potential from the rest potential up to +20 mV vs. SCE. Above this value, $1/C$ still increases with potential, although there is increasing scatter and a change in the slope. This is a reflection of the change in the complex plane plots with an alteration of reaction kinetics or a possible modification of the film for potentials higher than +20 mV vs. SCE or both.

The assumption is that the experimentally measured total capacitance, typically 7-10 μF , for the passive region is mainly due to the film because of the values obtained;

Fig. 3. Impedance plots between -130 mV and -20 mV

Fig. 4. Impedance plot at +30 mV

Fig. 5. Impedance plot at +40 mV

we could, therefore, neglect the contribution from the electrochemical double-layer capacity (17, 41).

A further assumption is that the surface film is homogeneous in its dielectric properties and that the thickness of the film, x , is inversely proportional to the capacity. Taking into account a surface roughness factor for the surface and the permittivity of vacuum, ϵ_0 , equal to $8.854 \times 10^{-14} \text{ F cm}^{-1}$, the capacity will be given by (17)

$$C = \frac{\epsilon\gamma}{0.113x} A \quad [8]$$

where C is the capacitance (μF), ϵ the dielectric constant, γ the surface roughness factor, and x the thickness of the film in angstroms. The constant 0.113 has the units $\text{cm}^2 \text{ F}^{-1} \text{ \AA}^{-1}$.

Using the roughness factor of 1.2 reported for an iron surface mechanically polished with 600 grit emery paper (33) [as used by Curley-Fiorino and Schmidt (17) for 304 stainless steel], a dielectric constant of 15.6, and a 2 \AA correction to account for any contribution of double-layer capacity to the measured capacity (17), the film thickness was estimated for the applied potentials, as shown in Fig. 7. It is seen that the thickness of the film increases line-

Fig. 6. Reciprocal of capacitance vs. potential

Fig. 7. Film thickness vs. potential

arly with potential from 20.5Å at -158 mV vs. SCE to 23.2Å at +20 mV vs. SCE.

The important feature of these results is the fact that the film properties were observed *in situ* in the chloride media because of the minor influence of the double-layer capacitance.

Impedance data in solutions containing sulfuric acid and hydrochloric acid.—In order to assess the influence of pH and change of chloride ion concentration, impedance plots in the passive region were obtained for the 316 stainless steel in 0.5M sulfuric acid and in mixed sulfuric, hydrochloric, and sodium chloride solutions, all of them with pH 0.6. The shape of these complex plane plots was very similar to those previously found for passive and pitting conditions, depending on the state of the metal.

For solutions containing 0.5M H₂SO₄, the metal was always passive, but in those containing 0.5M H₂SO₄ + 0.3M NaCl and 0.5M H₂SO₄ + 0.5M NaCl, the onset of pitting started for potentials around +600 and +500 mV, respectively. The value of capacitance was determined at various potentials, and the plots of capacitance vs. potential are shown in Fig. 8. It can be seen that, in general, the capacitance values were higher, indicating a thinner film, 5-10Å, in the 200-800 mV range. There was a decrease in capacity for potentials between +200 and +600 mV vs. SCE, followed by an abrupt increase. Identical results have been reported for AISI 304 stainless steel in sulfuric acid by Okamoto (7), who interpreted the increase of capacity on the basis of the adsorption of SO₄⁻ ion at potentials higher than the transition value.

A solution containing a sulfate-free chloride mixture of 0.5M NaCl + 0.065M HCl was also examined, but in a more limited potential range due to the lower onset of pitting. The capacity values of the interface when plotted against the potential are shown in Fig. 9 conjointly with an iden-

Fig. 8. Effect of sodium chloride concentration on capacitance measurements in 1N H₂SO₄.

tical plot for a 3% NaCl solution (pH 6.5). It is seen that the capacity after first increasing with potential decreased slightly once pitting had started but increased again at higher potentials. A comparison of Fig. 8 and 9 suggests that the capacitance behavior is more related to the pH than to the solution composition. For the four plots corresponding to pH 0.6, the decrease in capacity is followed by an increase at the higher potentials, whereas, for the 3% NaCl solution, the capacity diminishes with potential for the whole range of potentials studied.

Discussion

The corrosion potential for 316 stainless steel in 3% NaCl solution is typically situated in the passive region. At more anodic potentials, and after short immersion times of freshly prepared electrodes, the major contribution to the current flow should be film growth, either

or

The impedance plots for the stainless steel polarized in the range of potentials between -130 and -20 mV in the passive region and shown in Fig. 3 should reflect the behavior of the metal dissolution or film formation at the potentials investigated. These complex plane shapes appeared to be well defined and could be considered as a straight line which bends slightly; or, the plot is part of a large diameter semicircle. Almost identical shapes were found by Epelboin *et al.* (34, 35) for nickel and chromium in sulfuric acid solution, by Armstrong *et al.* (36) for chromium in sulfuric acid solution, and also by Jibara (19) for 304 stainless steel in 3% NaCl solution. The first two interpreted the "almost vertical line" as the result of purely capacitive behavior, and Armstrong (36) interpreted this as a geometric capacity arising from a film where there is little mobile charge. Jibara (19) simulated this type of plot by assuming a restricted diffusion process in the film.

The present impedance data were interpreted by means of a computer simulation which has been developed by various members of the electrochemical group at UMIST over a period of years. This program can generate a simulation of a multicomponent equivalent circuit. For the present work it was found that the Randles equivalent circuit (see Fig. 10) gave a reasonable simulation provided that depression² of the plot was also incorporated. In this interactive computing procedure, the best estimate of the values of the different elements of the equivalent circuit was first made from experimental data. These values were used in a preliminary simulation, and the parameter values were then adjusted (Table I) until the simulation plot matched the experimental data as shown in Fig. 3-5.

Quantitative comparison of the data.—The charge-transfer resistance value of $1.26 \times 10^5 \Omega \text{ cm}^2$ is large compared to those found for freely corroding systems, and this indicates a low metal dissolution rate through the film. This was expected, since the passive current was $< 3 \times 10^4 \text{ mA cm}^{-2}$. This current flows across the interface and does not change significantly with the applied potential throughout the passive region, and, therefore, it should be valid to use the Stern-Geary equation (42) to estimate the corrosion current, especially as the corrosion potential is also situated in the passive region. Under these conditions, the Stern-Geary equation can be written as

$$\frac{1}{\theta} = i_{\text{corr}} \frac{\ln 10}{b_c} \quad [11]$$

The cathodic Tafel coefficient b_c was estimated from experimental data to have a value of 0.13V (see Fig. 1). The

² Depression of the impedance semicircle is ascribed to a distribution of time constants over the reaction surface; the angle of depression is that subtended by the semicircle center to the real axis.

Fig. 9. Effect of pH on capacitance measurements

calculated value of $4.48 \times 10^{-4} \text{ mA cm}^{-2}$ for i_{corr} was found to be of a magnitude similar to that of the passive current.

The Warburg impedance was assessed as being a film diffusion process where the diffusion layer thickness, δ , was assumed to be equal to the film thickness, x . In this case, the diffusion factor (37) for the film, K_f , will be given by

$$K_f = x \left(\frac{2}{D_f} \right)^{1/2} \quad [12]$$

Thus, for a value of 21 \AA , the typical value of capacity at -130 mV , and for $K = 5$ (the value used in the simulation), a value for diffusion coefficient D_f of $3.45 \times 10^{-15} \text{ cm}^2 \text{ s}^{-1}$ is obtained for the mobile specimens in the film. This value of D_f is considered reasonable for diffusion through a film, being lower than the value corresponding to aqueous solutions, and is comparable with the values proposed by Armstrong *et al.* (38) for films on cadmium in KOH solutions.

The value of D_f was used to calculate the concentration, c_f , of the diffusing iron species in the film where the Warburg coefficient is

$$\sigma_f = \frac{RT}{\sqrt{2} n^2 F^2} \frac{1}{c_f D_f^{1/2}} \quad [13]$$

The value for the concentration of mobile species was thus found to be $c_f = 2.48 \times 10^{-5} \text{ mol liter}^{-1}$, and, since the diffusion appears to operate within the film, then Fick's law of diffusion may be written as

$$i_p = \frac{n F c_f D_f}{x} \quad [14]$$

Fig. 10. Randles equivalent circuit

where i_p is the passivation current flowing through the film. Experimentally, the passivation current was less than $3 \times 10^{-4} \text{ mA cm}^{-2}$, and using a value of $2 \times 10^{-4} \text{ mA cm}^{-2}$ ($2 \times 10^{-7} \text{ A cm}^{-2}$), the concentration of species, c_f , in the film was estimated at $6.3 \times 10^{-5} \text{ mol liter}^{-1}$, which is comparable with the value estimated from the Warburg coefficient. The discrepancy may be due to the system not being entirely controlled by diffusion, since in a thin film with a high space charge, migration may also contribute to the mass transport. These correlations justify the modeling used for the simulation and also give support to the proposal that diffusion operates through the passive film.

The impedance plot in Fig. 4 at the potential of $+30 \text{ mV}$ vs. SCE was also simulated using the same equivalent circuit and the values for the different elements shown in Table I. Values of the film diffusion coefficient, D_f , and the concentration of the mobile species were also calculated using Eq. [8] and [9] and a film thickness of 23.5 \AA (see Fig. 7). At $+30 \text{ mV}$, $D_f = 1.2 \times 10^{-14} \text{ cm}^2 \text{ s}^{-1}$ and $c_f = 2.66 \times 10^{-5} \text{ mol liter}^{-1}$, which is higher than calculated at the lower potential, suggesting an increase in mobility of the species with increase in potential.

The inverse logarithmic law observed for the film growth process, Fig. 2, showed two different stages of film growth, the initial rate occurring during the first 10 min of immersion. As indicated previously in the Results section, the change in rate is either due to an increasing contribution by the ionic current of the metal dissolution rate or is the result of a change in the composition or structure of the film. A change in structure has been considered for the film growth on iron (26, 27) and was also used by Bulman and Tseung (11) to explain their ellipsometric data on austenitic stainless steel in sulfuric acid. An increasing ionic current and a composition or structural change are not mutually exclusive. Under the steady-state conditions of a fully grown film, our present impedance data and modeling provide conclusive evidence for metallic iron diffusion, and this is consistent with the film having a p-type semiconductor defect structure (39). However, the initial stages of film growth are more speculative, since other experimental evidence is not available and even Auger analysis of a change in the film composition near metal is as yet inconclusive (21). Some indication of the process involved in the film growth can be obtained from further examination of the present data.

Table I. Data from complex plane plot simulations

Electrode condition	θ Charge transfer resistance ($\Omega \text{ cm}^2$)	τ Time constant (s)	β Depression angle	σ_f Warburg coefficient ($\Omega \text{ cm}^2 \text{ s}^{-1/2}$)	K_f Diffusion factor ($\text{s}^{1/2}$)	R_n Solution resistance ($\Omega \text{ cm}^2$)
Passive (-130 to -20 mV) Fig. 3	1.26×10^5	2.25	8	3.2×10^4	5	24
Passive (30 mV) Fig. 4	2.5×10^4	0.35	8	1.6×10^4	3	24
Passive-pitting (40 mV) Fig. 5	1.6×10^4	0.28	10	5×10^3	0.6	24

The slope of the plot of film thickness, x , against potential, E , see Fig. 7, provides an estimate of the electric-field strength in the film of $6.66 \times 10^6 \text{ V cm}^{-1}$ ($6.66 \times 10^{-2} \text{ V \AA}^{-1}$). This gives a rate of increase of film thickness of 15\AA for each volt of potential increase, which is comparable to that found on other metals, particularly aluminum, although the potential range on stainless steel before breakdown prior to the onset of localized corrosion is obviously less. The present result suggests again that similar physical processes are involved in the film growth mechanism. More significantly, an indication of the initial film composition can be provided by Eq. [7]. Extrapolation of the thickness *vs.* potential plot to the zero film thickness intercept provides a value of E_0 , the equilibrium potential of the initial film. From Fig. 7, this was found to be -1.4V vs. SCE , which is comparable to the equilibrium potential of chromium oxide (40).

The important role of chromium in the passive film on stainless steel is well known and, in particular, it is interesting to note that the chromium-rich zone, as determined by Auger spectroscopy, is next to the metal (21). Hence, it is reasonable to envisage growth proceeding outward from the initial film.

Conclusions

1. For potentials between the corrosion potential (the lower limit investigated) and $+20 \text{ mV}$, there is a linear relation for the dependence of the reciprocal of capacity on potential. The thickness of the film, as measured by impedance measurements, assuming a parallel-plate condenser model, with the passive layer as dielectric, is in the range $20\text{-}25\text{\AA}$, depending on the applied potential.

2. In the same range of potentials, the passivation current was independent of potential. This is in accordance with film growth by a high field conduction mechanism as reflected by an inverse logarithmic law of current *vs.* time. Two stages of film growth can be distinguished, one below 10 min and the other for longer times.

3. Impedance measurements and computer simulations lead to the establishment of a model for the passivated steel, which shows that diffusion of the metallic species occurs through the passive film.

4. The field strength in the film is $6.66 \times 10^6 \text{ V cm}^{-1}$, corresponding to a rate of film formation of 15\AA for each volt of potential increase.

5. The equilibrium potential of the initial oxide film formation is -1.4V (SCE) , corresponding to chromium oxide, and this indicates the important role played by chromium in the formation and constitution of the film.

Polarization of Aluminum during AC Corrosion in Sulfate Solutions

T. C. Tan^{*,1} and D-T. Chin^{*}

Department of Chemical Engineering, Clarkson University, Potsdam, New York 13676

ABSTRACT

An experimental study has been made of the effect of alternating voltage on the corrosion of aluminum in aqueous solutions of (i) 1N H₂SO₄, (ii) 1N Na₂SO₄, (iii) 1N NaOH, and (iv) 1N Na₂SO₄ containing 0-5010 ppm Cl⁻ ions. The polarization curves were measured with an alternating voltage (AV) modulation technique using sinusoidal waves, and the pitting behavior of aluminum was examined with constant potentiostatic coulometry and SEM photomicrography. The measurements were made over a range of AV magnitudes from 0 to 1500 mV rms, and AV frequencies from 20 to 600 Hz. The severity of AV effect was found to depend on the presence of an Al₂O₃ surface film. In alkaline solutions and in the sulfate solution containing a large amount of chloride ions, where no oxide was present on aluminum surface, AV exerted little or no effect on the anodic dissolution reaction of aluminum. In acidic and neutral sulfate solutions, AV enhanced the formation of oxide film at high anodic dc potentials as well as the dissolution of aluminum through the pores of the oxide film. Application of AV did not increase the pitting corrosion of aluminum in sulfate solutions.

Most published works on the corrosion of aluminum deal with its pitting potential, pit morphology, and pit mechanisms. Particular emphasis has been placed on the polarization of aluminum in chloride solutions. Some literature (1-7) is available on the corrosion of aluminum in the presence of alternating current (ac). Williams (1) reported that ac increased the corrosion rate of aluminum. French (2) suggested a critical ac current density of 0.0775 mA/cm², below which no appreciable corrosion of aluminum would occur in soil and chloride solutions. Hall and English (2) in their comments on French's work, reported that the corrosion rate of aluminum in 0.1% NaCl solution decreased to zero as the frequency of a 10V superimposed alternating voltage (AV) increased from 20 to 20,000 Hz (3). Thompson and Wood (4) studied the effect of 14V AV on the behavior of an aluminum electrode in 0.4M NaCl. Pitting was observed and the pit size and pit density increased with time. They attributed the pitting process to the positive half-cycle of the AV, and suggested that the pits were initiated by oxygen or hydrogen evolution at the flaws on the oxide film. The works by Serra and Mannheimer (5) and Chin *et al.* (6-7) indicated that ac exerted a greater influence on the corrosion of aluminum than copper and mild steel in soil.

The present project is a part of a continuing program in this laboratory looking into the ac corrosion of metals in aqueous environments (6-16). In this work, the effect of ac on the anodic and cathodic polarization curves of aluminum in sulfuric acid, sodium sulfate, sodium chloride, and sodium hydroxide solutions were measured with an AV modulation technique (13-16) using a sinusoidal wave. The corrosion behavior of aluminum under the influence of AV was also examined with constant potentiostatic coulometry and scanning electron photomicrography (SEM).

Experimental

The details of the experimental setup and electric circuit for AV modulation have been described in previous publications (10, 14-16), and will not be repeated here. The solutions used in this study were: (i) 1N H₂SO₄ (pH 0.1), (ii) 1N Na₂SO₄ (pH 7), (iii) 1N Na₂SO₄ plus 0-5010 ppm NaCl (pH 7), and (iv) 1N NaOH (pH 14). All solutions were deaerated by bubbling nitrogen gas for several hours before the experiment. During the experiment, the bubbling of nitrogen was continued at a slower rate, and the pH's of the solutions were maintained at a constant value by adding a small amount of dilute sulfuric acid or sodium hydroxide. A 1.5 liter Plexiglas cell equipped with a platinum screen counterelectrode, a silver/silver-chloride reference electrode (Ag/AgCl), and a Luggin capillary was used for the experiments. The working electrode was a stationary aluminum rod² (0.627 cm in diam), whose cylindrical side was insulated with a Teflon sheath leaving a

circular area of 0.309 cm² exposed to the electrolyte. For each experiment, the aluminum electrode was polished with 400 grit and then with 600 grit polishing paper. It was washed with alcohol, rinsed in distilled water, and soaked in concentrated nitric acid for 5 min. The electrode was again washed with distilled water and immediately placed in the cell and was positioned at approximately 2 mm from the tip of the Luggin capillary tube. To ensure good reproducibility in the polarization measurements, the electrode was further activated cathodically in the test electrolyte by polarizing at -3.0V vs. Ag/AgCl for 5 min. The electric circuit for AV modulation was then switched on, and the rest (corrosion) potential of aluminum was measured by adjusting the dc potential until no dc current flowed in the cell. The cathodic polarization curve was first obtained by incrementing the dc potential to -3.0V vs. Ag/AgCl with a step rate of 50 mV/min and a step size of 50 mV. The electrode potential was returned then to its rest potential, and the anodic polarization curve was obtained by stepping the potential toward the noble direction using the same step size and step rate until a potential of 6.0V vs. Ag/AgCl was reached. In this way, the dc polarization of the aluminum electrode under the influence of sinusoidal AV was measured in the test electrolytes for a range of AV magnitudes from 0 to 1500 mV rms, and AV frequencies from 20 to 600 Hz. Potentiostatic coulometry experiments were carried out with an aluminum stud having the same composition and exposed area as the electrode used in the polarization measurement. The aluminum samples were polarized with a constant AV in the test electrolyte at selected dc potentials in the active, passive, and transpassive regions of the polarization curve. After 5C of dc were passed, the electrode was removed from the cell and its surface was examined under a scanning electron microscope (SEM). All experiments were carried out at a room temperature of 26° ± 1°C.

Results

Polarization of aluminum without the influence of AV.—To establish a basis for comparing with AV modulation, a particular set of runs was made to determine the anodic and cathodic polarization of aluminum in the test electrolytes without any superimposed AV. The results showing the effect of pH on the behavior of aluminum in sulfuric acid, sodium sulfate, and sodium hydroxide solutions are given in Fig. 1. In neutral sodium sulfate solution, aluminum exhibited a narrow anodic active potential regime of 0-0.3V vs. Ag/AgCl with a critical current density of 0.023 mA/cm². The curve did not show a distinct passive-transpassive transitional potential. Instead, the dc current density increased slowly with increasing dc potential. At 5.6V vs. Ag/AgCl, the current rose to 0.1

² A commercial 6061-T6 aluminum was used for the experiment. Its chemical composition (w/o) was: Cu, 0.15-0.4; Si, 0.4-0.8; Mn, 0.15 max; Zn, 0.25 max; Fe, 0.7 max; Ti, 0.15 max; Mg, 0.8-1.2; Cr, 0.04-0.35; other impurities, 0.15 max; Al, remainder.

Fig. 1. DC polarization curves of aluminum in sulfate solutions at various pH values

mA/cm² as compared to 0.007 mA/cm² at 0.3 mV vs. Ag/AgCl. Although the increase was about 14 times, the dc current density was still small, and the aluminum could be considered to be passivated within the potential range investigated. As pH of the solution decreased from pH 7, the rest potential shifted to less noble values, and the dc current density in the anodic region increased. The anodic "nose," which characterized a transition from the active potential to passive potential, also diminished with decreasing pH, and completely disappeared in 1N sulfuric acid (pH 0.1). A similar trend was also observed as the pH of the solutions increased from 7.0; the anodic dc current density increased with increasing pH values. At pH 14, which corresponded to 1N sodium hydroxide, the anodic dc current density was 100 times greater than that in 1N sulfuric acid, which was again 100 times greater than that in neutral 1N sodium sulfate solution. Figure 2 shows the effect of pH on the rest potential of aluminum in sulfate solutions. The most positive rest potential was obtained for pH 7 sodium sulfate solution. As the pH values decreased or increased from this neutral value, the rest potential became more negative. Aluminum exhibited a higher corrosion tendency in alkaline environment than in acidic environment; this was indicated by a more negative rest potential of -1.4V vs. Ag/AgCl in pH 14 solution as compared to a value of -0.93V vs. Ag/AgCl at pH 0.1.

DC polarization curves of aluminum in neutral 1N sodium sulfate solutions containing various amounts of sodium chloride (0-5010 ppm) are given in Fig. 3. Chloride ions had a significant effect on the anodic polarization of aluminum. Below 38 ppm, chloride ions increased the critical current density for passivity by one order of magnitude, and shifted the active-passive transitional potential to a more positive value of 1.5V vs. Ag/AgCl. Above 100 ppm, chloride ion virtually eliminated the passivity of aluminum in neutral sulfate solution, and dc current density increased more than 1000 times on the anodic polarization curves. Pitting became visible on the specimen after the polarization measurements at chloride concentrations greater than 100 ppm. The pit size and pit density increased with increasing chloride concentrations. Figure 4 shows the rest potential of aluminum in 1N sodium sul-

fate in the presence of chloride ions. Similar to the pH effect, the rest potential became more negative with increasing chloride concentrations.

DC polarization curves with 60 Hz sinusoidal AV.—The effect of 60 Hz sinusoidal AV on the dc polarization curves of aluminum in (i) 1N Na₂SO₄, (ii) 1N H₂SO₄ or NaOH, and (iii) 1N Na₂SO₄ containing 38 ppm NaCl, respectively, are shown in Fig. 5, 6, and 7. Generally speaking, AV behaved as a depolarizer, and increased the dc current density at a given dc potential. The effect of AV increased with increasing AV magnitude. AV showed the

Fig. 2. Rest potential of aluminum in sulfate solutions at various pH values.

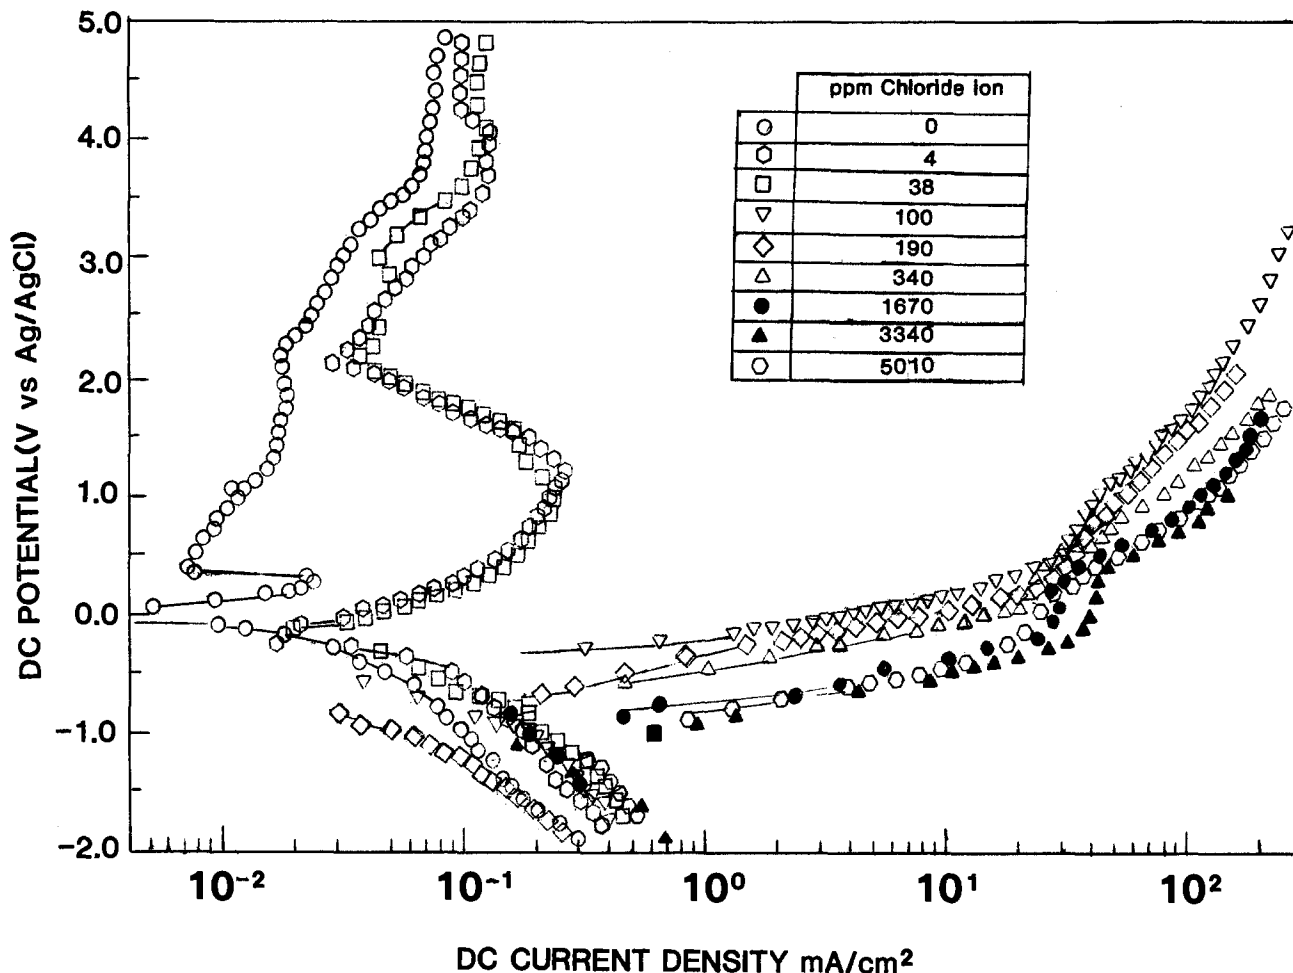

Fig. 3. DC polarization curves of aluminum in 1N sodium sulfate solution containing various amounts of chloride ions

greatest effect on the polarization of aluminum in 1N Na_2SO_4 solution, followed in turn by 1N H_2SO_4 , 1N Na_2SO_4 + 38 ppm NaCl, and 1N NaOH. For the neutral sodium sulfate solution, AV increased the critical current density and shifted the active-passive transitional potential toward the noble direction. The anodic dc current also increased with increasing AV; however, the increase was not as large as that of the pH effect or the addition of chloride ions (Fig. 1 and 3) to the sulfate solution. Application of a 1500 mV rms AV resulted in only a tenfold increase in dc current density in the anodic regime. The anodic dc current density with AV was smaller than 1 mA/cm^2 , and the polarization curves did not exhibit a dis-

tinct passive-transpassive transitional potential. This implied that the aluminum surface was still covered by an oxide layer even in the presence of AV. For 1N sulfuric acid and 1N sodium hydroxide solutions, the general characteristics of anodic polarization curves with or without AV were about the same except that AV slightly increased the dc current density. The effect of AV on the behavior of aluminum was less discernible in 1N sodium hydroxide than in 1N sulfuric acid. For the 1N sodium sulfate solution containing 38 ppm of chloride ion, application of AV appeared to eliminate the transition to passive potentials. Below the Flade potential of 1.0V vs. Ag/AgCl, AV did not affect the dc current density on the anodic curves.

Shifts in the rest potentials were observed upon the superimposition of AV. Figure 8 shows the rest potential shift for aluminum in 1N sodium sulfate, sulfuric acid, and sodium hydroxide solutions. Applications of AV caused the rest potential to shift toward the negative direction. The phenomenon agreed with an analysis of Chin *et al.* (9-10) that the shift in the rest potential resulted from an asymmetric behavior between the anodic and cathodic polarization of the corrosion system. For the present systems, the anodic polarization curves without AV possessed a Tafel slope in the active regime smaller than that on the cathodic polarization curves; according to the analysis, the rest potential would be shifted toward the negative direction.

Fig. 4. Effect of chloride ion concentration on the rest potential of aluminum in 1N sodium sulfate solution.

Effect of AV frequency.—DC polarization curves showing the effect of AV frequency on the behavior of aluminum in 1N Na_2SO_4 are shown in Fig. 9. In these runs, the applied sinusoidal AV was maintained at a constant magnitude of 750 mV rms. and the frequency varied from 20 to 600 Hz. For comparison, the polarization curve without AV is also plotted in the figure as open squares. It can be seen that the highest effect was obtained with 20 Hz AV,

Fig. 5. Effect of 60 Hz sinusoidal AV on the dc polarization curves of aluminum in 1N sodium sulfate solution

and an increase in frequency shifted both the anodic and cathodic polarization curves toward the polarization curves without AV. Apparently, at high AV frequencies,

the double-layer impedance became smaller and more current was used in the charge and discharge of the electric double layer at the electrode-solution interface.

Fig. 6. Effect of 60 Hz sinusoidal AV on the dc polarization curves of aluminum in 1N sulfuric acid and 1N sodium hydroxide solution

Fig. 7. Effect of 60 Hz sinusoidal AV on the dc polarization curves of aluminum in 1N sodium sulfate containing 38 ppm chloride ion

Fig. 8. Shift in the rest potential of aluminum by 60 Hz sinusoidal AV in 1N sodium sulfate (○), 1N sulfuric acid (△), and 1N sodium hydroxide (○).

SEM photomicrographs.—The SEM photomicrographs of aluminum samples after the potentiostatic coulometry experiments in 1N sodium sulfate solution are shown in Fig. 10. The experiments were carried out with 60 Hz sinusoidal AV. The specimens were potentiostatically held at selected anodic dc potentials, and the SEM analysis was made after 5C had passed through the cell. As a reference, Fig. 10a shows the surface with only a dc potential at 2.5V vs. Ag/AgCl, and Fig. 10b shows the effect of addition of 1670 ppm Cl⁻ ion at the same dc potential without any superimposed AV. Deep circular pits were

Fig. 9. Effect of AV frequency on the dc polarization of aluminum in 1N sodium sulfate solution. The sinusoidal AV was maintained at 750 mV rms.

Fig. 10. SEM photomicrographs of aluminum surface after potentiostatic coulometry experiments with 60 Hz sinusoidal AV in 1N sodium sulfate solution (pH 7). a(top left): 0 AV at dc potential of 2.5V vs. Ag/AgCl. b(top right): 0 AV at dc potential of 2.5V vs. Ag/AgCl with 1670 ppm Cl^- . c(bottom left): 1500 mV rms AV at dc potential of 2.5V vs. Ag/AgCl. d(bottom right): 500 mV rms AV at dc potential of 0.5V vs. Ag/AgCl.

observed for all aluminum samples polarized at anodic dc potentials. The pit size and pit density increased as the pH of sulfate solution increased or decreased from a neutral value 7.0. The severest pitting of aluminum was obtained with 1N sodium hydroxide, followed by 1N sulfuric acid, and 1N sodium sulfate. Addition of chloride ions caused a lateral expansion of the pits on the oxide film as shown in Fig. 10b. The effect of AV on the pitting of aluminum is shown in Fig. 10c and 10d. The sample shown in Fig. 10c was superimposed with 1500 mV rms AV (60 Hz), and polarized at a dc potential of 2.5V vs. Ag/AgCl. For the same amount of dc coulombs passed, no discernible effect by AV was observed on the pitting of aluminum in 1N sodium sulfate solution. The pits with AV exhibited the same circular shape, size, and distribution; only the pitting rate was higher because of a higher dc current density with AV at the same dc potentials. An interesting topography on the oxide film is shown in Fig. 10d; this particular aluminum sample was superimposed with a 500 mV rms AV (60 Hz) and was held at a dc potential of 0.5V vs. Ag/AgCl, corresponding to an active-passive transitional potential shown in Fig. 5. The oxide film on this sample exhibited the dry mud-like cracks and grain boundaries. The pit shape and size on the sample were similar to those polarized at the same dc potential without superimposition of AV.

Discussion

In this laboratory, the method of AV modulation has been used to determine the effect of alternating current

(AC) on the corrosion of mild steel (10, 14) and stainless steels (15-16) in a number of aqueous environments. AV was found to destroy the passivity of the steels in sulfate, nitrate, chloride, perchlorate, and chlorate solutions. For the systems which exhibited an instantaneous passivation upon polarization at the anodic potentials, AV diminished the passive regime by shifting the passive-transpassive transitional potential toward the negative direction. In the solution where the electrodes exhibited distinct active, passive, and transpassive anodic potential regimes, AV increased the critical current density for passivity and decreased the passive regime by shifting the transpassive potential toward the negative direction and by increasing the dc current density in the passive regime. The passive current density of mild steel in sulfate, nitrate, and perchlorate solutions and of stainless steel in sulfuric acid was increased by AV by one to two orders of magnitude; whereas in chlorate solution, AV prevented the formation of oxide film on mild steel surface, and completely eliminated the passive regime on the polarization curve. The SEM photomicrographs revealed that AV destroyed the passive film and enhanced the pitting corrosion of mild and stainless steels. The effect was similar to the addition of chloride ions to the corrosion environments.

In the present results, there are three important features which differed from those of the previous investigations.

1. The anodic polarization curves of aluminum in sulfate solutions without AV did not have a distinct passive-transpassive transitional potential over a pH range of 0-12.

A small active potential region was obtained for the neutral sodium sulfate solution, and the addition of chloride ions of less than 38 ppm extended the active-passive transitional potential to 1.5V *vs.* Ag/AgCl. However, the critical current density for passivity was of the same order of magnitude as the dc current density in the passive regime. No passivation was observed for aluminum in 1N sodium hydroxide solution and in 1N sodium sulfate solution containing more than 100 ppm of chloride ions.

2. Although AV shifted the active-passive transitional potential toward the noble direction and increased the both anodic and cathodic current densities on the dc polarization curves in the present systems, AV did not seem to destroy the passivity of aluminum in acidic and neutral sulfate solutions or in the sulfate solutions containing less than 38 ppm of chloride ions. The anodic dc current density with 1500 mV rms AV was less than 1 mA/cm² in 1N neutral sodium sulfate solution, and was less than 2 mA/cm² in 1N sulfuric acid for all the dc potentials investigated, implying that the aluminum surface was covered with a layer of oxide film even in the presence of AV. No distinct transpassive potentials were observed on the polarization curves with applied AV.

3. AV did not destroy the protective oxide film on aluminum surfaces in acidic and neutral sulfate solutions; nor did it enhance the pitting of aluminum by changing the pit shape, size, and distributions. Addition of chloride ions to the sulfate solutions caused more severe pitting of aluminum than did the application of AV.

The above features may be explained by the presence of an Al₂O₃ film on the aluminum surface. Al₂O₃ is amphoteric, and its solubility is smallest in neutral solutions (pH 6-7). It dissolves in acidic solutions to give Al³⁺ ions, and in alkaline solutions it reacts with hydroxyl ions to form soluble AlO₂⁻. Depending on the pH value, the following anodic reactions can occur during the corrosion of aluminum in aqueous solutions

in alkaline solutions

in acidic and neutral solutions

In alkaline solutions, no oxide film is present on the metal surface, and aluminum would dissolve at a high rate at anodic potentials. Application of AV would exert little or no influence on the anodic dissolution reaction of aluminum in 1N NaOH solution, as shown in Fig. 6. In acidic and neutral solutions, aluminum would first corrode according to reaction [2] at low anodic overpotentials. However, at sufficiently high anodic overpotentials, reaction [3] would start to take place, and an Al₂O₃ film formed on the aluminum surface would impede reaction [2] from continuing at a high rate. The present results seem to suggest that AV promoted both the reactions [2] and [3] for aluminum in acidic and neutral sulfate solutions. Periodically pulsating current has been used in the aluminum anodizing industry to improve the thickness of oxide film formed in sulfuric acid baths (17-18). AC was found to increase the rate of aluminum anodizing process and improve the color penetration into the oxide film. This fact agreed with the present SEM analysis shown in Fig. 10 that AV neither destroyed the oxide film nor increased the pitting corrosion of aluminum in sulfate solutions. The rates of metal dissolution and film formation processes were enhanced by AV at approximately equal magnitudes in acidic and neutral sulfate solutions.

The photomicrograph shown in Fig. 10d revealed an interesting effect of AV on the morphology of the oxide film on the aluminum surface. The experimental condition of this sample coincided with the critical current density of aluminum in 1N Na₂SO₄ when 500 mV rms si-

nusoidal AV (60 Hz) was superimposed onto the system. The photomicrograph revealed a dried mud-like matrix structure with circular pits evenly distributed on the surface. It should be noted that the cracks on the oxide film did not radiate from the pits, and some even circled around a pit in a concentric fashion. Similar morphological structure was reported by Galvele *et al.* (19) for the interior of pits on an aluminum sample polarized in deaerated sodium nitrate solution. Richardson and Wood (20) also found a similar structure for their aluminum sample after 20 days immersion in 1N KCl at pH 6 and under the influence of 14V AV. Michele (21) observed a similar oxide structure on the bottom of pits for aluminum polarized at a dc potential of -0.74V *vs.* SHE in deaerated HCl solution. The phenomenon was apparently associated with the active dissolution of aluminum near the Flade potential, where the film formation process started to compete with the metal dissolution reaction.

Conclusions

A study has been made of the effect of sinusoidal AV on the behavior of aluminum in aqueous sulfate solutions over a range of pH 0-14. The results revealed that the presence of an Al₂O₃ surface film played an important role on the corrosion of aluminum in the presence of AV. When no oxide film was present on the metal surface, such as in alkaline solutions and in the neutral sulfate solutions containing a large amount of chloride ions, AV exerted little or no influence on the anodic dissolution reaction. In acidic and neutral sulfate solutions which permitted the growth of Al₂O₃ at high anodic potentials, AV enhanced the film formation process as well as the metal dissolution reaction through the pores of the oxide film. Application of AV did not increase the pitting corrosion of aluminum in sulfate solution.

Study of Hydration Inhibitors on Aluminum Oxide Using Tunneling Spectroscopy and Molecular Electrostatic Potential Calculations

H. W. White,* C. D. Crowder, and G. P. Alldredge

Department of Physics and Astronomy, University of Missouri-Columbia, Columbia, Missouri 65211

ABSTRACT

Inelastic electron tunneling and *ab initio* molecular electrostatic potential calculations have been used to investigate the bonding of several phosphonate based hydration inhibitors adsorbed on aluminum oxide. Results are reported for phosphoric acid (PA), methylphosphonic acid (MPA), hydroxymethylphosphonic acid (HMP), and nitrotrismethylphosphonic acid (NTMP). Tunneling spectra were taken for PA, HMP, and NTMP and the observed frequencies compared to values obtained from FTIR, IR, and Raman spectra of similar compounds. Upward shifts in the P=O and P-O(H) stretch frequencies indicated that the phosphonates bond to the aluminum oxide surface through the phosphonate group. *Ab initio* quantum mechanical molecular electrostatic potentials (QMESP's) were calculated for PA, MPA, and HMP. Analysis of these results provided a means to understand on a molecular level the known variations in effectiveness for each of the inhibitors investigated.

Inelastic electron tunneling spectroscopy (IETS) and *ab initio* molecular electrostatic potential calculations have been used to investigate the bonding of several hydration inhibitors on aluminum oxide. The goal was to determine mechanisms whereby these molecules can inhibit the hydration of aluminum oxide in the presence of moisture. In this paper, results are discussed for the following phosphonate-type molecules: phosphonic acid (PA), methylphosphonic acid (MPA), hydroxymethylphosphonic acid (HMP), and nitrotrismethylphosphonic acid (NTMP).

Wedge tests of the type commonly used for adhesive bond testing have shown that NTMP in monolayer coverages on aluminum oxide can significantly increase bond strength and increase the lifetime of aluminum-aluminum oxide-polymer adhesive bonds. Similar tests on HMP and PA showed improvement but to a lesser extent. In contrast, recent tests on MPA showed that it provided no increase in performance.

IETS is a sensitive technique for measuring the vibrational frequencies of monolayer and submonolayer coverages of a molecular species adsorbed on a thin, insulating oxide surface, usually aluminum oxide.

The original intent of this work was to compare experimental and calculated IETS intensities for one or more small inhibitor molecules to obtain information on the orientation and bonding of the adsorbed species. Results for a more symmetrical, test-case molecule (thiourea) showed that the IETS intensity calculations could not be carried out because of the lack of complete vibrational analyses for the molecules of interest. However, methods developed for the model calculations have proved to be very useful for investigating variations in the molecular charge distribution for the inhibitors. Specifically, *ab initio* techniques have been used to determine the molecular structure, the quantum mechanical electrostatic potentials (QMESP's), and the charges which can be associated with each of the atoms in PA, MPA, and HMP. In this work, we exploit equipotential contour maps associated with QMESP's. This analysis is based, in part, on bonding information obtained while performing tunneling intensity calculations for thiourea (for which QMESP's were calculated as one step toward the determination of partial charges of thiourea); however, tunneling intensities were not calculated for the hydration inhibitors. Such calculations are too formidable.

Experimental

The IETS measurements were made on tunnel junctions prepared on insulating ceramic substrates. An alu-

minum electrode approximately 1000Å thick was evaporated onto the substrate at 10^{-7} - 10^{-8} torr. An oxide layer was grown on the aluminum and then doped with a water-based solution of the inhibitor. This doping process was done outside the vacuum chamber. The doped substrate was then returned to the vacuum chamber, and a top metal electrode of Pb was evaporated to complete the junction. Electrical leads were attached, the resistances were measured, and those junctions with good electrical characteristics were immersed in liquid helium for IETS measurements.

IETS spectra were obtained from 300 to 4000 cm^{-1} for PA, HMP, and NTMP. The observed frequencies and mode assignments are listed in Tables I, II, and III. The lower frequency portion of the spectrum obtained on a junction doped with a 0.3% solution of PA in water is shown in Fig. 1. Peak locations have been labeled in units of cm^{-1} . The HMP spectrum shown in Fig. 2 was taken on a junction doped with 10 mg of HMP per ml of water. The IETS spectrum for a 0.1% solution of NTMP is shown in Fig. 3.

Junctions doped by the same procedures as those used for the other molecules indicated that little, if any, MPA remained on the oxide layer. The general appearance of the oxide layer to the naked eye and also under a low power microscope suggested that the MPA did not absorb onto the oxide layer in the manner in which the other molecules did.

Results

An aluminum phonon near 320 cm⁻¹ and an aluminum oxide phonon near 945 cm⁻¹ occur in each of the spectra for PA, HMP, and NTMP. They are due to intrinsic features of the junction electrodes and will not be discussed further. All peak positions have been corrected for the presence of a superconducting top (Pb) electrode.

Weak bands appear at 475 and 455 cm⁻¹ in HMP and NTMP, respectively, whereas no peak occurs in PA in this region. Veken and Herman (1) assign a band as PO₃

in-plane motion which they observed near 480 cm⁻¹ (vw) in IR and at 498 cm⁻¹ (sh/w) in Raman spectra of dibasic methylphosphonic acid in water. The PO₃ in-plane assignment for PA near 520 cm⁻¹ is probably a PO₃ in-plane mode, but with different symmetry character. Thomas and Chittenden (2) give a possible alternative description to these peaks. They describe a weak, diffuse peak near 500 cm⁻¹ which they associate with P-O (OH) groups. Since the peaks are weak and can evidently be lost in some spectra, they cannot be considered significant.

The 545 and 585 cm⁻¹ peaks in NTMP, even though weak and broad, are of interest since FTIR results of NTMP adsorbed on aluminum oxide (3) show very strong, well-formed peaks at 547 and 585 cm⁻¹. The FTIR spectrum of dried NTMP (3) also shows a band near 554 cm⁻¹ which has been assigned as P-O motion. The IETS spectrum for HMP shows a weak peak at 550 cm⁻¹, and it is possible that the PA spectrum has a shoulder near 550 cm⁻¹, however, the results are not conclusive. These peaks are assigned as P-O deformation modes by compar-

Fig. 1. IETS spectrum from 300 to 1500 cm⁻¹ for a 0.3% solution of PA in water.

Fig. 2. IETS spectrum from 300 to 1650 cm^{-1} for a 1% solution of HMP in water.

ison with data by Veken and Herman (1). In Table I, we indicate a tentative assignment of this P-O deformation mode for the 610 cm^{-1} peak in PA.

There are several peaks in the PA spectra whose assignment is very unclear. Their locations are 629 (vw), 655 (vw), 690 (s), 800 (w), 865 (sh), and 920 (vs) cm^{-1} . Assignments of the strong peaks at 690 and 920 cm^{-1} were of special interest. No strong peaks occur in the 690 cm^{-1} region of either HMP or NTMP. There are strong peaks at 880 cm^{-1} in each; however, they are clearly associated with the CH_2 motion in HMP and NTMP. The strong

peaks at 790 cm^{-1} in HMP and at 780 cm^{-1} in NTMP can also be assigned to P-C stretch motion (1).

Peaks near 1085 (m) in PA, at 1055 (vs) in HMP, and at 1040 cm^{-1} (vs) in NTMP are undoubtedly $\nu(\text{P-O-H})$ which are known to occur near 1000 (± 100) cm^{-1} for molecules with these end groups. The FTIR data for NTMP adsorbed on aluminum oxide (3) has a very strong, broad band near 1050 cm^{-1} . FTIR on an Al-NTMP complex, formed by reacting $\text{Al}(\text{NO}_3)_3$ with NTMP (3), has a peak near 1160 cm^{-1} , both of which could have $\nu(\text{P=O})$ contributions.

Fig. 3. IETS spectrum from 300 to 1600 cm^{-1} for a 0.1% solution of NTMP in water.

Peaks at 1210 (vs) in HMP and at 1200 cm^{-1} (b) in NTMP were assigned as $\nu(\text{P}=\text{O})$, in accordance with many literature discussions of the location of the phosphoryl frequency. According to Thomas and Chittenden (4), it sometimes occurs as a doublet and, as a result, can appear as such or as a broad peak. In their extensive analyses of $\nu(\text{P}=\text{O})$ shifts as a function of attached groups to phosphorus, they found that the mean value was sufficient to provide agreement with other data. In PA, a broad peak does occur at 1170 cm^{-1} , which was assigned as $\nu(\text{P}=\text{O})$. A weak shoulder at 1215 cm^{-1} was tentatively assigned as $\nu(\text{P}=\text{O})$ for lack of reasonable alternatives. The 1235 cm^{-1} peak in HMP is in the region expected for O-H deformations.

The location of the 1200 cm^{-1} $\nu(\text{P}=\text{O})$ peak in the IETS spectrum of NTMP was initially compared with a peak located at 1256 cm^{-1} as determined in an FTIR study of NTMP adsorbed on aluminum oxide (3). We now believe that this 1256 cm^{-1} peak is not due to $\nu(\text{P}=\text{O})$ since it is quite high. The FTIR of dried NTMP had a peak near 1188 cm^{-1} , and the Al-NTMP complex (3) showed a strong peak near 1160 cm^{-1} .

The 1350 (vs) and 1430 cm^{-1} (vs) peaks in HMP and the 1315 (vs) and 1430 (vs) peaks in NTMP were assigned as CH wag and C-H deformation modes, respectively. Veken and Herman (1) found CH wag and deformation modes at 1305 and 1430 cm^{-1} in dibasic $\text{CH}_3\text{PO}_3^{2-}$. The very weak peaks at 1315, 1395, and 1458 cm^{-1} in PA are likely to be due to CH contamination as suggested by the structure near 2940 cm^{-1} in PA.

Very strong $\nu(\text{C-H})$ modes were observed near 2910 cm^{-1} in HMP and near 2935 cm^{-1} in NTMP, as would be expected for molecules containing aliphatic CH bonds (*i.e.*, below 3000 cm^{-1} in almost all cases). A medium intensity, broad band near 3550 cm^{-1} in HMP was assigned as an O-H stretch.

There were interesting IETS peaks near 2445 cm^{-1} in HMP and 2430 cm^{-1} in NTMP which did not occur in PA. Although the nature of the modes is not clear, the fact that each was so strong and occurred in a region where no strong peaks were expected suggests that they are due to a Fermi resonance (overtone or combination occurring near a fundamental of the same symmetry type). In this case, the fundamental could be associated with an OH stretch mode since these can extend to much lower frequencies than 3550 cm^{-1} for phosphonic acid groups, as discussed by Thomas and Chittenden (2).

Of particular import to this work is the behavior of the $\nu(\text{P}=\text{O})$ and of the $\nu(\text{P-O-H})$ vibrations. The locations and relative strengths of the $\nu(\text{P}=\text{O})$ and $\nu(\text{P-O-H})$ IETS frequencies among PA, HMP, and NTMP are listed in Tables I, II, and III, respectively. The FTIR frequencies in cm^{-1} for dried NTMP, NTMP adsorbed on aluminum oxide, and the Al-NTMP complex were as follows for the $\text{P}=\text{O}$ and P-O-H modes, respectively: dried, 1188-970 and 1188-970; oxide adsorbed, (1256?) and 1052; and Al-complex, 1160 and (not observed). The assignment for the 1256 cm^{-1} peak is not clear, as stated above.

The IETS spectra for HMP showed much stronger features for these two modes than did the PA and NTMP. The locations of the IETS $\nu(\text{P}=\text{O})$ modes at 1170, 1210, and 1200 cm^{-1} for PA, HMP, and NTMP, respectively, when compared with the (maximum) value from the dried NTMP and Al-complex spectra suggested that the frequency for the $\text{P}=\text{O}$ mode was increased by adsorption on the oxide.

A similar shift which might have occurred in the $\nu(\text{P-O-H})$ frequencies cannot be determined on the same basis since the location of the $\nu(\text{P-O-H})$ frequency for the dried NTMP was not well determined by the FTIR data. Some progress can be made in the analysis of the $\nu(\text{P-O-H})$ modes, however, by comparison with solution data from the literature. Veken and Herman (1) found the $\nu(\text{P}=\text{O})$ frequency near 1140 cm^{-1} for dilute solutions of H_3PO_3 in water (*i.e.*, near the 1170 cm^{-1} value for IETS PA). The P-OH_2 antisymmetric and symmetric stretch frequencies were near 1010 and 950 cm^{-1} , respectively,

and the corresponding IR frequencies were near 1005 and 960 cm^{-1} , in good agreement with the Raman values. Since IETS $\nu(\text{P-O-H})$ frequency values were 1085, 1055, and 1040 cm^{-1} , respectively, for PA, HMP, and NTMP, the official data suggested that both the $\nu(\text{P}=\text{O})$ and $\nu(\text{P-O-H})$ observed frequencies were increased by adsorption. From these upward shifts, it was concluded that the phosphonate groups were significantly perturbed by adsorption on the oxide, and that in all those molecules these groups were active in the formation of bonds to the surface.

In summary, the observed upward shifts in the $\nu(\text{P}=\text{O})$ and $\nu(\text{P-O-H})$ frequencies observed in the IETS spectra as compared to values from FTIR, IR, and Raman data taken on dried, oxide adsorbed, complexed, and solution samples strongly suggests that PA, HMP, and NTMP bond to aluminum oxide through the phosphonate group. For further analysis, it would be useful to have frequency values for PA, HMP, and NTMP in solution. The absence of IETS intensities for tunnel junctions doped with MPA indicates that it does not bond nearly as strongly as do PA, HMP, and NTMP. On this basis, it would be judged as a poor inhibitor candidate. This conjecture was found to be in agreement with results from wedge tests (5).

Molecular Charge Distributions

In the discussion thus far, IETS vibrational frequencies and their shifts from values obtained independently (*e.g.*, optically) have been used to extract information on the adsorbed species. One of the original goals of this work was to compare measured and calculated relative peak intensities in an IETS spectrum to obtain information on the orientation and structure of the inhibitor molecules—MPA in particular. This goal could not have been achieved without extensive modeling and computer resources because the molecules are complex and complete vibrational analyses have not been made. As stated earlier, and discussed later, QMEP's instead could be utilized to obtain bonding information. They are considerably more straightforward to calculate than are tunneling intensities.

In the intensity calculations for thiourea, which were done to make IETS a more quantitative tool, an improved model was developed for calculating the intensities as a function of the orientation and structure of the adsorbate. It was called the floating valence model, the basis of which is the partial charge model of Kirtley *et al.* (6). In this model, the electron-molecule interaction is approximated by a coulombic interaction between the electron and partial charges assigned for each atomic site of the molecule. One of the major difficulties associated with this model was that there was no means to reliably assign the atomic partial charges, the values of which greatly influence calculated peak intensity ratios. Also, it was known from other calculations (7) that the pseudo-dipolar potential seen by the tunneling electron is not always oriented, as would be expected from charges moving along directions of atomic motion.

The floating valence model solved the two primary problems by the use of a two-step procedure first used by Momany (8) to determine partial charges. First, *ab initio* molecular QMEP's were calculated using an atomic orbital basis set. The second step was to determine the effective charge located at each atomic site, which would give a classical electrostatic potential equal to the QMEP.

To obtain reasonable tunneling intensities, we had to modify the fitting procedure to obtain more accurate partial charge values. This was done by dividing the charge on each atomic site into two portions. A core charge was forced to follow the motion of the atom while a valence charge was allowed to "float" in both direction and displacement magnitude to best fit the QMEP. We called these potential-derived (PD) charges. The development of the floating valence model and ensuing calculations for thiourea were extensive and are being published elsewhere (9, 10). The tunneling calculations clearly showed that the PD charges were very accurate.

The complete tunneling intensity calculations for thiourea (10) and the analyses of partial charges and QMEP's reported in this study provide three significant results relevant to the utilization of QMEP's, partial atomic charges, and calculated tunneling intensities to the study of inhibitors. First, there must exist an accurate and complete vibrational mode analysis for any molecule for which accurate tunneling intensities are to be calculated. For most large molecules, the analysis is either incomplete or has not been attempted. Second, molecular electrostatic equipotential contour plots through various symmetry planes give pictorial and quantitative information on the charge distribution for the inhibitor molecules. Although such plots are not generally available in the literature, plots can be produced for quite complex molecules, such as those in this study. The charge distribution in an inhibitor molecule affects its bonding characteristics, and hence its effectiveness. As such, they are useful for deducing information about the molecular orientation and relative bond strengths for various inhibitors. Studies of the systematic variations in the charge distributions with structure and with the substitution of various groups is a powerful tool for the development of better inhibitors and understanding inhibitor mechanisms. Third, accurate atomic partial charges for inhibitor molecules can be calculated from generated QMEP's. Although partial charges were calculated for the inhibitors in this study, attempts to correlate their variation with inhibitor effectiveness were unsuccessful. Additional work is required.

It should be made clear that our justification for utilizing QMEP's, rather than a complete comparison of experimental and calculated intensities, for hydration inhibitors stems directly from information gleaned from the complete tunneling intensity comparison for thiourea on aluminum oxide. Thiourea is a corrosion inhibitor for aluminum in dilute hydrochloric acid.

In the following section, the procedure for calculating QMEP's is presented in brief form. Results for PA, MPA, and HMP are reported. The large number of atoms in NTMP made it unsuitable for the *ab initio* calculations.

The *ab initio* electrostatic potentials were calculated using self-consistent Hartree-Fock theory. The basic equation for this theory is

$$\hat{F}\Psi_i = \epsilon_i\Psi_i \quad [1]$$

where Ψ_i is the *i*th molecular orbital, ϵ_i is the *i*th energy eigenvalue, and \hat{F} is the Fock operator (the effective one-electron operator) defined by

$$\hat{F}(p) = -\frac{1}{2}\nabla^2 - \sum_a \frac{Z_a}{r_{ap}} + \sum_j (2\hat{J}_j - \hat{K}_j) \quad [2]$$

where *p* is the electron index, *a* is the atom index, Z_a is the nuclear charge for the *a*th atom, r_{ap} is the distance from the *a*th nucleus to the *p*th electron, and \hat{J}_j and \hat{K}_j are the coulomb and exchange operators, which are as follows

$$\hat{J}_j\Psi_i(p) = \int \Psi_j^*(q) \left(\frac{1}{r_{qp}} \right) \Psi_j(q) d\tau_q \Psi_i(p) \quad [3]$$

$$\hat{K}_j\Psi_i(p) = \int \Psi_j^*(q) \left(\frac{1}{r_{qp}} \right) \Psi_i(q) d\tau_q \Psi_j(p) \quad [4]$$

where *q* and *p* are electron indexes, $d\tau$ is a volume element, and r_{qp} is the distance between the *q*th and *p*th electrons.

In our calculations, the linear combination of atomic orbital (LCAO) approach was used. It assumes that the molecular orbitals $\Psi_i(\vec{r})$ can be expanded in terms of atom-centered atomic orbitals $\phi_{\mu a}(\vec{r}_a)$ as

$$\Psi_i(\vec{r}) = \sum_a \sum_{\mu} \phi_{\mu a}(\vec{r}_a) C_i^{\mu a} \quad [5]$$

where *a* is the atom index, μ reflects the *n*, *l*, and *m* quantum numbers of the orbital, \vec{r} is a position vector

relative to the origin, \vec{R}_a is the position vector of the *a*th nucleus, and $\vec{r}_a = \vec{r} - \vec{R}_a$, and $C_i^{\mu a}$ are expansion coefficients which we wish to determine.

In atomic calculations, Slater-type orbitals (STO's) are often used to represent the radial dependence of the atomic orbitals. A normalized STO with principal quantum number *n* is given by

$$\text{STO}_n(r) = N_n r^{n-1} e^{-\zeta r} \quad [6]$$

where N_n is a normalization constant, and ζ is a parameter which is optimized to give the best fit to the radial dependence of a particular atomic orbital.

Unfortunately, STO's are too unwieldy to use for molecular calculations. One approach to alleviate this difficulty is to use a linear combination of gaussians to represent the exponential dependence of the STO's. If $\phi_{\mu}(r)$ represents the exponential dependence of an STO, then it can be expanded as follows

$$\phi_{\mu}(r) = \sum_{i=1}^N d_{i\mu} \exp(-\alpha_i r^2) \quad [7]$$

where *N* is the number of gaussians used in the expansion, $d_{i\mu}$ are contraction coefficients, α_i is the gaussian exponent.

This approach as implemented by Quantum Chemistry Program Exchange (QCPE) no. 437 (Gaussian 80) (11) was used to perform the computations. The gaussian contraction scheme for each orbital is referred to as the basis set. Two different basis sets were used for PA, MPA, and HMP, designated by STO-3G and STO 4-31G (or as 4-31G).

The Fock operator of Eq. [1] depends on the set of Ψ_i chosen. Gaussian 80 uses optimized atom-centered atomic orbital $[\phi_{\mu a}(\vec{r}_a)]$ along with a set of "guessed" $C_i^{\mu a}$ to calculate an initial $\Psi_i(\vec{r})$ via Eq. [5]. (The starting $C_i^{\mu a}$ are generated from a Hückel or projected Hückel guess.) The Fock matrix was determined from the $\Psi_i(\vec{r})$ via Eq. [2], [3], and [4] and was used in Eq. [1] to solve for new Ψ_i and ϵ_i . This process is repeated until the energy eigenvalues converge. The final wave functions yielded the optimal set of $C_i^{\mu a}$ which were used to calculate the electron density, $\rho(\vec{r})$, from the relationship

$$\rho(\vec{r}) = \sum_i^{\text{occ}} |\Psi_i(\vec{r})|^2 = \sum_{\substack{\mu, a \\ \nu, a'}} \phi_{\mu a}(\vec{r}_a) \phi_{\nu a'}(\vec{r}_{a'}) \sum_i^{\text{occ}} C_i^{\mu a} C_i^{\nu a'} \quad [8]$$

where \sum_i^{occ} indicates that the sum is over occupied orbitals only.

All calculations used restricted Hartree-Fock theory which assumes that both a spin up and a spin down electron occupy each spatial orbital. Once $\rho(\vec{r})$ had been obtained, the molecular electrostatic potential, $V(\vec{r})$, could be determined since

$$V(\vec{r}) = \sum_a \frac{Z_a e}{|\vec{r} - \vec{R}_a|} - e \int \frac{\rho(\vec{r}')}{|\vec{r} - \vec{r}'|} d\vec{r}' \quad [9]$$

In its original form, Gaussian 80 did not calculate $V(\vec{r})$. The STVINT section of Gaussian 80 was modified to do the appropriate integral calculations. Once this was done, it was a simple matter to add in the nuclear contributions to the potential (the first term in Eq. [9]) to calculate the QMEP's.

Equation [9] allowed the determination of the electrostatic potential at a point \vec{r} . To accurately fit the potential around a molecule, the potential must be known for a fairly large, representative set of field points. The electrostatic potential was calculated using a rectangular array of equally spaced points with the origin at the center of nuclear charge.

In order to calculate the QMEP's for the inhibitor molecules, it was necessary to first determine their structure by suitable methods since they were not available from the literature. The approach was to begin with a reasonable structure (or structures, in the case of MPA) with best guess values for bond lengths and angles and then to util-

ize the optimization features of the Gaussian 80 QCPE program to determine bond lengths and angles. One of the two structures assumed for MPA was the eclipsed methyl group, denoted as MPA-E. The other structure, denoted as MPA-S, had a methyl group staggered with respect to the P=O bond. The minimum energies obtained for MPA-E and MPA-S were so close as to preclude a decision on which structure was more stable.

The bond angles, bond lengths, and cartesian coordinates for PA, MPA-E, MPA-S, and HMP calculated with this technique are listed in Tables IV through XI. They are in reasonable agreement with values for angles and bond lengths of various related compounds.

Molecular electrostatic potentials were obtained for each of the four structures described. Two basis sets, STO-3G and 4-31G, were used to investigate the effects of basis set selection. Plots of equipotential lines through the planes of reflection symmetry using the 4-31G basis set are shown in Fig. 4-7 for PA, MPA-E, MPA-S, and HMP. Inspection of these figures reveals significant changes in the molecular charge distributions which depend on the nature of the attached group. The effect of basis set (not shown) was also apparent; however, the 4-31G is deemed to be more accurate.

Discussion

There does appear to be some correlation of features observed in the molecular electrostatic equipotential contours and apparent bonding strength and inhibitor effectiveness as deduced from wedge tests and tunnel junction features. Analyses of peak shifts in the tunneling spectra indicate the phosphonate groups bond to the oxide layer. The bonding for MPA is very weak. The contours for PA in Fig. 4 show the existence of a large region just below the three P-O bonds which is very negative in potential. The -60 kcal/mol region which occurs just below the (single-bonded) oxygen would also appear below the other two oxygens which are out of the plane. These three oxygens would be even more negative if they were deprotonated and, as such, could form strong bonds to exposed aluminum cations in the oxide layer. The orientation and bonding arrangement for the adsorbed ion would be as schematically depicted in Fig. 8, with the P=O bond furthest from the oxide layer with its bond direction perpendicular to the layer. This bonding scheme seems quite reasonable.

Fig. 4. Electrostatic potential contour plot for PA in the plane of reflection symmetry using a 4-31G basis set. Potential values are in kilocalorie per mole and distances are in angstroms.

Likewise, the equipotential contours for HMP in Fig. 7 also reveal the presence of a large negative potential region. The region is, however, formed by two single-bonded oxygens (which are out of the plane of reflection symmetry) and the oxygen in the C-O-H group. If HMP is considered to be as PA but with one of the O-H groups replaced by a C-O-H group, then the region of negative potential can be interpreted as being tipped toward the P=O bond direction. The -60 kcal/mol contour near the oxygen in the C-O-H group is larger than that shown for PA in Fig. 4 and indicates the possibility for the formation of a stronger Al-O bond for HMP than exists for PA. A possible orientation and bonding arrangement for HMP on aluminum oxide is shown schematically in Fig. 9. The P=O bond direction is tipped with respect to the plane of the oxide. It is not known whether the P=O bond would contribute significantly to the bonding in this orientation.

The contours for MPA-E and MPA-S shown in Fig. 5 and 6 are similar to each other except for the expected

Fig. 5. MPA-E equipotential plot in the plane of reflection symmetry using the 4-31G basis set. Potential values are in kilocalorie per mole and distances are in angstroms.

Fig. 6. MPA-S equipotential plot in the plane of reflection symmetry using the 4-31G basis set. Potential values are in kilocalorie per mole and distances are in angstroms.

differences due to the two configurations of the CH_3 group. There are two single-bonded oxygens in MPA. The most negative contour in the plane of reflection symmetry between them is only -15 kcal/mol. The negative potential region for MPA-E and MPA-S is much smaller and is less negative than for either PA or HMP. The region near the P=O bond does not vary appreciably among PA, MPA, and HMP. Therefore, the molecular equipotential contour plots for PA, MPA, and HMP indicate that MPA would not adsorb as strongly as either PA or HMP and, as a consequence, would be much less effective as a hydration inhibitor. This conclusion is in agreement with results from the IETS studies discussed earlier and with wedge test results on adhesive bonds.

Conclusions

The goal of this project to use a combined experimental and theoretical approach in the application of IETS to the study of hydration inhibitors on aluminum oxide. The

value of both tunneling spectroscopy and QMEP's for understanding inhibitor bonding has been established. For PA, HMP, and NTMP, observed shifts in $\nu(\text{P}=\text{O})$ and $\nu(\text{P}-\text{O}(\text{H}))$ tunneling frequencies from optical values strongly show that these molecules bond to the oxide layer through the phosphonate group. Tunnel junctions doped with MPA indicate that the bonding of MPA to the oxide is much weaker, and on this basis would be judged as a poor inhibitor candidate. This conjecture was found to be in agreement with wedge test results. Likewise, analysis of the equipotential contours for PA, MPA, and HMP indicated that PA and HMP could form strong bonds to exposed aluminum cations through the three single-bonded oxygens in PA, and through the two

single-bonded oxygens and the oxygen in the C-O(H) group in HMP. The equipotential contours for MPA indicated that it would form a much weaker bond than did PA and HMP. Since NTMP has three phosphonate groups, these results indicate that it would also be a strong adsorber and effective inhibitor.

The calculations in this work did not include the effects of electron transfer between the inhibitors and the oxide surface. A more complete model should include the effects of chemisorption on the structure and bonding properties of the inhibitors.

In future work, it would be informative to compare adsorbed and solution spectral frequencies for several of the large, effective phosphonate inhibitors having different substituted groups in order to more effectively determine any systematic behavior of frequency shifts upon adsorption. The use of semi-empirical methods could be used to more efficiently optimize molecular structures and to calculate molecular charge distributions for inhibitor molecules with as many as 100 atoms. *Ab initio* and semi-empirical calculations can be applied to a wide range of inhibitor types, including corrosion inhibitors on various metals.

Electrochemical Behavior of Passive Iron in Acid Medium

II. The Passive Film/Solution Interface

M. Keddou and C. Pallotta

Groupe de Recherche n° 4 du CNRS, "Physique des Liquides et Electrochimie," associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

The passive film on iron in acid media is investigated by means of a rapid change of electrolyte composition, with special attention to anion content, and by redox kinetics studies with a rotating disk under steady state and nonsteady state (electrohydrodynamic impedance). These techniques, associated with classical electrochemical impedance, allow one to establish the existence at the film-electrolyte interface of a loosely structured film limiting the rate of mass transfer in the case of ferrocyanide oxidation. Dynamic exchange of anions and most of the electrolyte composition effects take place in this layer. An attempt is made to relate the behavior of the passive film on iron in acid media to basic properties of iron oxides and oxyhydroxides in their colloidal state.

As shown in the first paper of this series (1), the impedance analysis of passive iron over a wide frequency range allows one to separate the transport properties in the film both from the charge transfer at interfaces and from film growth (1). A resistance linearly dependent on the potential is found. This dependence strongly supports the mechanism of high field assisted migration across the film, as suggested by Vetter.

A partially reversible charge transfer reaction at interfaces was evidenced by nonsteady-state experiments. The low frequency behavior of the impedance in the millihertz range led to the conclusion that diffusion is not the process controlling the passive current. The capacitance observed in this range is related to film growth and allows one to estimate the ratio of the film forming current to the dissolution current under nonsteady state.

The passive current acts as a scaling factor for the most important parameters involved in the electrochemical characterization of passivity. Its value depends strongly on electrolyte composition (anions and pH), probably through the charge carrier concentration in the film. This makes it possible to describe the passive system as a chemically dependent high field assisted ion migration (1).

Most of the data available from literature on the electrochemical response of passive iron to redox couples deal with neutral or alkaline media (2-6). Usually, only steady-state polarization curves were used to investigate the kinetics of these reactions, and the results were analyzed in terms of the semiconducting properties of the film or of tunneling. Furthermore, the possible modifications of the passive film as a result of redox reactions and its dependence upon anions were disregarded.

This part of the paper is aimed at analyzing the film/solution interface. This will be carried out by investigating the role of anions on the passive current and also the response of the passive system to redox couples in order to answer the following questions. Is there any correlation between the passive current value and the ability of the film to ensure electron charge transfer? Do the anions determine the kinetics of charge transfer on the film surface? Is the passive film-anion interaction dynamic or are the anions statically bonded to the film structure? Is there only a surface effect or is there penetration of anions in the film structure?

Experimental

Experimental conditions and devices are similar to the ones described in Ref. (1). A special cell was designed for performing a quasi-instantaneous and thorough change of electrolyte composition. As shown in Fig. 1, the cell is divided in two compartments separated by a glass frit, leaving the working electrode compartment isolated. The new solution enters the working electrode compartment as an impinging jet perpendicular to the electrode surface producing a composition transient. The stopcock at the cell

bottoms allows the new electrolyte to flow from a 1 liter reservoir placed on top of the cell. A Pt counterelectrode and a mercurous sulfate electrode in saturated K_2SO_4 (SSE) complete the cell. All potentials were referred to this reference electrode.

The solutions were deaerated by Ar bubbling and maintained at 25°C. A conventional electrochemical cell was used for other types of measurements. The working electrode, a disk of 0.2 cm², was prepared as explained in Ref. (1). A rotating disk setup was used with a range of angular velocities from 0 to 8000 rpm.

Procedure

The electrode was polarized at the working potential in the passivation domain for a given time. Then the electrolyte was suddenly changed and the current transient recorded as a function of time. Impedance measurements were carried out in this initial state and after the solution change, once the current attained its steady-state value in the new solution. In some instances, after about 15h of passivation in the full passive range, ions were incorporated into the electrolyte by adding different amounts of

Fig. 1. Electrochemical cell for composition transients. Compartment A: 60 cm³. Compartment B: 10 cm³.

concentrated solutions. Care was taken in order to avoid pH changes. In the case of cation addition, the salt was chosen in order to avoid the introduction of foreign anions into the electrolyte.

Results and Discussion

Influence of the hydrodynamic conditions on the passive current.—Unexpectedly, the passive current of the Fe/H₂SO₄ and Fe/H₃PO₄ systems depends on the angular velocity of the electrode. As a consequence of an angular velocity transient, the current attains a limiting value showing an increase of between 10 and 30% of its stationary stagnant value, I_p , depending on potential. In the case of Fe/1M H₃PO₄, the I_p /time response to an angular velocity transient can be divided in two regions. The first, over a short interval of time, is characterized by a stepwise increase of the current as shown in Fig. 2. In the second region, over a long interval of time, the current tends slowly towards its limiting steady-state value following a staircase profile, as can be seen in Fig. 2. In this final state, the rotation of the electrode has practically no remaining effect on I_p . The duration of each of these two regions depends on the value of the angular velocity. For the opposite angular velocity transient, the current returns to about its initial value also following a staircase profile as shown in Fig. 3.

In the Fe/0.5M H₂SO₄ system, only the first stepwise increase of current is observed as a result of an angular velocity transient. A dependence of I_p vs. $\Omega^{-1/2}$ is found showing a limiting effect for angular velocities higher than 2200 rpm, as can be seen in Fig. 4. The electrode rotation has no effect on the passive current for the Fe/1M HClO₄ system.

The electrochemical properties of the passive iron system, and particularly its impedance behavior analyzed in Ref. (1), is not modified as a consequence of the electrode rotation.

Redox reactions on passive iron.—In order to analyze the film/solution interface from the viewpoint of its kinetic behavior, different ions were introduced into the solution after about 15h of passivation in a given electrolyte. Both Fe(II) and Fe(CN)₆⁴⁻ ions are in their oxidation domain in the full passive range (between ca. 0.2 and 1.0V). Ferrous ions were chosen with the idea of interfering with the ionics of the passive film.

Fe(CN)₆⁴⁻ to Fe(CN)₆³⁻ oxidation.—The kinetics of ferrocyanide oxidation are largely dependent on the electrolyte. In perchloric and phosphoric solutions, the reaction is diffusion controlled at moderate angular velocity ($\Omega = 110$ rpm) in the entire passive domain, while in sulfuric solutions a mixed kinetics is observed below 0.5V.

The I^{-1} vs. $\Omega^{-1/2}$ plots allow one to obtain at the same time kinetics and transport data. In the case where the electrode is coated by a solid layer, the following equation is valid (7)

$$I^{-1} = I_s^{-1} + I_{\Omega \rightarrow \infty}^{-1} + I_k^{-1} \quad [1]$$

where $I_s = nFD C^\infty / \delta$ is the Fick law, δ is the thickness of the concentration profile dependent on Ω according to the Levich equation, D the diffusion coefficient, and C^∞ is the concentration in the solution bulk, $I_{\Omega \rightarrow \infty} = nFD_L C^\infty / \delta_L$, δ_L is the thickness of the solid layer independent of Ω , and D_L the diffusion coefficient in this layer. Finally, I_k is the kinetic current. A nonzero intercept on the current axis then indicates either a kinetic limitation or a diffusion limitation originated in a diffusion layer of constant thickness.

As a comparison, the effect of the supporting electrolyte on the ferrocyanide oxidation on Pt was also analyzed. The results are shown in Fig. 5 and 6 and in Tables I and II. As expected from diffusion in the liquid phase, the same diffusion coefficient is obtained for Fe(CN)₆⁴⁻ on Pt and on passive iron electrodes. Regarding the $I_{\Omega \rightarrow \infty}$ limit, a larger dependence on the electrolyte composition is observed on passive iron in comparison with Pt.

In perchloric solutions, Pt and passive iron behave almost identically, whereas the difference between them increases in sulfuric and phosphoric solutions.

The relatively small influence of the electrolyte composition on the $I_{\Omega \rightarrow \infty}$ limit on Pt may be attributed to kinetic effects associated with a modification of the double-layer properties and/or of the active surface due to the different adsorption characteristics of anions. However, in the case of passive iron, the dependence of the $I_{\Omega \rightarrow \infty}$ limit on the electrolyte composition is so important that this interpretation hardly remains valid and a special interaction between passive iron and anions may be supposed in the case of sulfuric and phosphoric solutions. In contrast, in a perchloric solution, a metal-like behavior is observed.

For getting a deeper insight in the effect of anions on the passive film/solution interface, electrohydrodynamic impedance (EHD) was used. The method, based in the

modulation of the angular velocity of the working electrode, was introduced (7) to investigate the coupling between heterogeneous kinetics and mass transport. The angular velocity Ω is modulated thus: $\Omega = \Omega^0 + \Delta\Omega \text{Re}(\exp \sigma jt)$ with $\Delta\Omega/\Omega^0 \ll 1$, σ being the angular frequency, $j = \sqrt{-1}$, and t is time. As a consequence, the different quantities related to mass transport are modulated allowing definition of an electrohydrodynamic impedance: $\partial I/\partial \Omega|_E$ under potentiostatic conditions (7-9).

EHD data obtained for different mean velocities and plotted as reduced amplitude $A(p)/A(o)$ vs. the reduced frequency p ($p = \sigma/\Omega^0$) are shown in Fig. 7, curves B, C, D, for the ferrocyanide oxidation on passive iron in perchloric, sulfuric, and phosphoric solutions. Fig. 7A represents the theoretical curve for a diffusion-controlled electrochemical reaction (7-9). Figure 7B and 7C shows that for

perchloric and sulfuric acids the data can be reduced by the dimensionless parameter p , whatever the Ω value is, between 200 and 2000 rpm. Nevertheless, for sulfuric solution (curve B), the curves are translated from the theoretical curve (curve A) toward the low p values. In the case of phosphoric solution (curve D), in addition to the translation, a slight shift of the data is observed toward

Fig. 7. Reduced amplitude of the potentiostatic EHD impedance. Ferrocyanide concentration: 1 mM . A: Theoretical curve. B: $\text{Fe}/1 \text{ M HClO}_4$; $E = 0.65 \text{ V}$. the low p values when Ω changes from 200 to 600 rpm. However, changes of Ω from 600 to 2000 rpm produce no additional translation of the curves. Phase shift *vs.* reduced frequency plots confirm these observations.

It was shown that a translation of the data toward the low p values as Ω increases characterizes the EHD impedance of a reaction taking place on an electrode where a solid porous layer acts as a barrier between the active surface and the electrolyte (10). A new feature from the EHD impedance of the ferrocyanide oxidation on passive iron in sulfuric solutions is the reduction of the data at different Ω to a single curve translated from the theoretical one. The EHD results may be analyzed together with the observations described in Ref. (1). From the short time response of the current to an angular velocity transient (Fig. 2 and 3), it could be concluded that the electrode behaves like a usual mass-transfer-limited interface in the mixed kinetics domain. However, the long time current/time profile under constant angular velocity (staircase profile) suggests a simultaneous effect of erosion as a consequence of frictional shearing stress and/or centrifugal forces acting on a loosely structured film. A possible explanation of the EHD diagrams in the case of sulfuric solutions is also based on the presence of a loosely structured film whose thickness decreases as Ω increases. This film should attain a more solid structure, in the case of phosphoric solution, leading to a nonreducibility of the EHD experimental data for Ω values of 200 and 600 rpm. For greater angular velocities, the film thickness dependence on Ω reoccurs.

Mechanical damage to the passive iron/acid solution interface can also be induced by ultrasonic waves (11). This could be extremely relevant to erosion-corrosion processes.

The electrochemical impedance diagrams for the oxidation of ferrocyanide on passive iron in the different solutions can be analyzed as a parallel combination of the film response itself and of the electrochemical oxidation taking place on its surface. The impedance diagram characteristic of the iron passive system in acid media is shown in Fig. 8A. As discussed previously (1), it consists of three frequency domains: a capacitance loop at relatively high frequencies (HF capacitive loop), an inductive loop at medium frequencies (MF domain), and a capacitive domain at low frequencies (LF capacitive branch). The HF loop can be characterized by its real axis intercept R_{HF} .

In Fig. 8B is shown the impedance diagram for the oxidation reaction alone, calculated by subtracting the contribution of the passive electrode in the case of sulfuric acid at a potential where a mixed kinetics takes place. A fraction of a transfer reaction loop, at high frequencies, followed by a diffusion loop are observed. From the frequency spacing on the latter and the diffusivity coefficient (Table I), a δ value of 90 μm is found for $\Omega = 110$ rpm. It can be ascribed to the diffusion layer in the solution.

At low frequencies, there is an increase of the impedance in the frequency region interfering with the diffusion loop (Fig. 8B). If ferrous ions are present in the solution (from the active/passive transition), the mean current decreases during the impedance measurement in the low frequency domain ($f < 1$ mHz), changing the steady-state polarization conditions. Probably, the film growth process induces the precipitation of $(\text{Fe}(\text{CN})_6)_2\text{Fe}_3$, blocking the access of ferrocyanide to the active surface.

Fe(II) to Fe(III) oxidation.—Contrary to the observation in alkaline solutions (pH 8.4) (12, 13), the current of the passive iron/ferrous ion system in sulfuric and perchloric solutions depends on potential.

In the case of sulfuric solutions, two potential regions are distinguished, as shown in Fig. 9. In the first one, the current increases linearly with potential. In the second one, for potential more anodic than 0.7V, a Tafel relationship is verified. The presence of these two domains is independent of the polarization direction. Furthermore, the

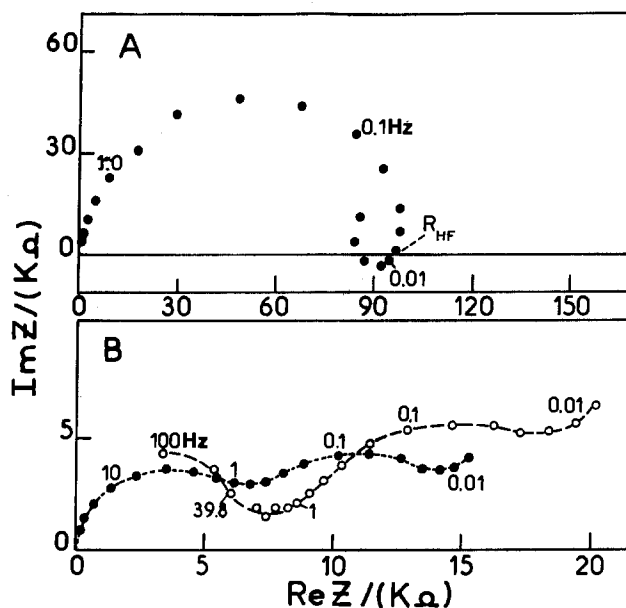

Fig. 8. A: Complex impedance diagram, Fe/0.5M H_2SO_4 ; $E = 0.3\text{V}$. B: (●●●) Experimental complex impedance diagram for the oxidation of ferrocyanide 1 mM on Fe/0.5M H_2SO_4 , $E = 0.3\text{V}$, $I = 14.6\ \mu\text{A}$, $\Omega = 112$ rpm. (○○○) Complex impedance diagram relative to the oxidation of ferrocyanide calculated by subtracting the contribution of the passive film (see text).

same results are obtained if the electrode is first passivated at each potential and then ferrous ions are added. In the case of the Fe/ HClO_4 system, only the first domain is accessible (Fig. 9) since at higher potentials a transpassive dissolution occurs.

At constant potential, the current increases linearly with the ferrous ion concentration (14). Nevertheless, the ratio of the oxidation current to the passive current is practically the same in sulfuric and perchloric media. In agreement with the passive current ratio, for the same potential and ferrous ion concentration, the oxidation current is 110 times greater in Fe/0.5M H_2SO_4 than in Fe/1M HClO_4 (Fig. 9). This behavior strongly differs from that observed in a solution containing ferrocyanide ions. The presence of ferrous ions seems to interfere with the film properties in such a way as to restrain the rate of charge transfer to a level correlated with the initial passive current. The formation of a ferrous-enriched layer is ex-

Fig. 9. Relation between potential and current for: (●●●) Fe/0.5M $\text{H}_2\text{SO}_4 + 0.14\text{M Fe(II)}$, and (○○○) Fe/1M $\text{HClO}_4 + 0.14\text{M Fe(II)}$.

pected from the cation substitution properties of iron oxides and oxyhydroxides (15). Consequently, the slow transformation of the film could lead to a change in the current. For instance, the Fe/0.5M H₂SO₄ system reacts stepwise to a ferrous ion addition. However, when the electrode is passivated in the first potential region, after the first sudden increase, the current evolves slowly. After 5 days of polarization, the current triples its initial stepwise value.

As proved by Raman spectroscopy, after 68h of polarization in the presence of ferrous ions, the layer transformation leads to pure magnetite as the potential approaches the transition domain in Fig. 9 (0.7V). Contrarily, at the same potential and polarization time, Raman spectroscopy reveals a mixture of hematite and magnetite in the absence of ferrous ions (16).

In other words, the transition observed around 0.7V may be interpreted as a critical potential at which percolation (17) gives rise to a bulk conductivity in the layer.

It is noticeable that this change in the film properties detected by redox and optical measurements is not related to any observable modification of the electrochemical behavior of passive iron. This could be easily understood by considering that optical and electronic behavior, on one hand, and ionic transport involved in passive corrosion, on the other hand, are related to the properties of the passive film material at two different scales.

As is shown in Fig. 10, the impedance diagram in this first potential domain consists of a high frequency capacitance loop and a LF domain, characterized by a 45° straight line, suggesting a diffusion limiting process. The $R_{HF}I$ product is close to 100 mV, as in the case of passive iron in absence of ferrous ions (1), in agreement with an oxidation current depending on the same process as the passive current.

In this potential domain as the current rises linearly with the potential (Fig. 9), the low frequency limit of the impedance must tend to a real constant value. From the I vs. E plot (Fig. 9), a resistance of 20 kΩ is calculated as the limiting value of the impedance for the Fe/0.5M H₂SO₄ + 0.14M Fe(II) system. For the Fe/1M HClO₄ + 0.14M Fe(II) system, a limiting resistance of 3 MΩ is obtained. Nevertheless, it is not possible to attain the low frequency limit of the impedance since at frequencies lower than 1 mHz the measuring signal by itself starts to increase the mean dc current, thus changing the polarization condition. There is an interaction, in the low frequency domain, between the film processes (film growth) and the kinetics of the oxidation reaction. This interaction is not expected from the potentiostatic polarization curves' showing little hysteresis.

Anion effect.—It is well known that the physicochemical properties of colloidal dispersions of iron oxides in aqueous solutions are strongly influenced by the counterion adsorption (18-24). Its influence depends on pH according to the point of zero charge value (pzc: pH at which the adsorbed H⁺ concentration equals the adsorbed OH⁻ concentration in the absence of specific ion adsorption). In the case of hematite, one of the possible film

Fig. 10. Complex impedance diagram for Fe/0.5M H₂SO₄ + 0.05M Fe(II); $E = 0.5V$; $I = 14.7 \mu A$.

constituents, the pzc is placed at near neutral pH (pH 8.5) (18, 19, 22-24). Then, according to the pH of the solution, anions or cations will be adsorbed. The acid domain is influenced by anion adsorption. The ion-surface interaction is strongly related to the surface properties and to the nature of the ion, principally its electrostatic field strength (charge-to-size ratio); according to this, for a given surface there are two different types of interactions. The first one occurs with ions having a high electrostatic field, which is, therefore, a structure promoter for the surrounding water molecules. The second type includes large ions with relatively weak field strength, which are less heavily hydrated and therefore act as structure breakers (28).

According to adsorption studies on colloidal hematite, chloride, sulfate, perchlorate, and phosphate anions can be classified according to their increasing interactions with the surface as follows: chloride \approx perchlorate < sulfate < phosphate (19, 21, 28). Phosphate anion adsorption is so exceptionally strong that under special conditions the phosphate becomes a potential-determining ion (19). Contrarily, the anions leading to pitting corrosion are not specifically adsorbed on the oxide surface.

Anions are also known to play an important role in the chemical synthesis of iron oxides and oxyhydroxides (25-27). They even affect the chemical nature of oxyhydroxides (26, 27). For instance, chloride is known to induce β FeOOH formation.

Anions affect the crystallization process as well in the chemical formation of magnetite (25, 27). For instance, chloride yields only exceedingly small magnetite particles. In contrast, sulfate allows magnetite particles of a broad range of diameters.

It seems that this data can be extrapolated profitably to be applied to the passive film in various environmental conditions. Additional support is provided by the fact that anion sequences are the same according to either their surface interaction with colloidal iron oxide, as stated above, or their effect on passive current, as emphasized in Ref. (1). From these observations, it is possible to predict an important influence of cations on the iron passive current at pH > 8.5. It is noteworthy that pH 8.5, boric-borate buffered solutions, in which most of passivity investigations was carried out, corresponds precisely to the pzc of hematite and magnetite (18, 19, 23, 24). At this particular pH, the solubility of the oxides attains its minimum value (23,24).

Therefore, according to these basic properties of colloidal iron oxides, two interactions with the film material are to be considered: (i) surface interactions, (ii) bulk interactions during formation modifying the chemical and crystallographical properties of the film.

In order to investigate which of these effects is more relevant to the passive iron electrode, two types of experiments were performed: (i) measurement of the steady-state passive current as a function of the composition of a binary mixture of anions, (ii) analysis of composition transients.

Binary mixture.—Once the electrode is passivated in a given electrolyte (A), increasing amounts of a different acid solution (X) were successively added to the solution under potentiostatic conditions. A steady-state value is reached after each addition. Figure 11 shows the normalized current $I_p([X]/[A])/I_p([X])$ as a function of electrolyte composition $[X]/[A]$. In both cases investigated, the binary mixture is enriched in the acid giving rise to the higher passive current in pure solutions, and an increase of the normalized current is observed. Nevertheless, perchlorate is more easily displaced by sulfate than sulfate is by phosphate. Unfortunately, in contrast with colloid studies (21, 29), we have no access to the surface concentration of anions, making the analysis impossible in terms of adsorption isotherms.

Composition transients.—To study how anions influence the passive film to lead to a current strongly dependent on the solution composition (1), the effect of composition

Fig. 11. Normalized current as a function of the composition of a binary acid mixture at constant pH.

transients was investigated. After 15h of passivation at 0.35V in 1M $H_2SO_4 + Na_2SO_4$, pH 0.95 solution, the electrolyte was changed to 1M H_3PO_4 under polarization using the electrochemical cell described in the Experimental section (Fig. 1). The current/time curve observed in Fig. 12A shows that the I_p value characteristic of the Fe/1M H_3PO_4 system is attained after about 30 min. The same type of curve is observed when 1M $HClO_4$ is replaced by 1M H_2SO_4 , i.e., when the replacement is in the direction of increasing I_p . However, when this sequence was inverted in the direction of diminishing I_p , the current/time profile strongly changes. The major part of the current change is recorded in the first minutes following the composition transient. Finally, a slow process lasting several hours leads to the steady-state I_p value characteristic of the passive iron in the new solution. As shown in Fig. 12B, 80% of the current change occurs in the first minute. The first region of the current/time curve is not influenced by the angular velocity of the electrode. Contrarily, the second region depends on the angular velocity: if the same experiment as shown in Fig. 12B is repeated with a rotating electrode ($\Omega = 2.800$ rpm), the second domain of the transient is reduced by about 4h.

These results clearly establish the dynamic behavior of the passive iron/acid solution interface with respect to an-

Fig. 12. Passive current/time response to a composition transient. A: From 1M $H_2SO_4 + Na_2SO_4$, pH = 0.95 to 1M H_3PO_4 . B: Opposite direction.

ions. However, both types of transients cannot be expressed as a unique analytical function in the full time range, which reveals the complexity of the process. Nevertheless, the transient toward lower passive current (Fig. 12B) clearly shows at least two types of interactions. The first one may be related to a fast anion bonding to the film surface which blocks the passive dissolution. The second slow part of the transient, affected by the angular velocity, may be related to anion penetration in the film itself. As supported by the effect of the angular velocity, the part of the film under hydrodynamic influence is involved to some extent in this bulk process. A change in the film composition induced by anions can be also considered (30).

Conclusion

A large amount of experimental data relevant to the properties of the film electrolyte interphase have been obtained, allowing one to define a transition region of appreciable thickness and cohesion. This view lies in the sensitivity of the electrochemical behavior to the angular velocity of the disk electrode under the following conditions: (i) dissolution in the passive state, (ii) redox kinetics for which the steady state and nonsteady state (EHD impedance) in the laminar flow regime show the existence of a loosely structured boundary layer, (iii) long-term response of the passive current to transients of electrolyte composition.

It is noticeable that the dependence of the layer on the electrolyte composition defined in terms of its transport and hydrodynamic behavior obeys the same sequence as the passive current densities. Hardly detectable in the perchloric solution, it reaches its maximum effect in the phosphoric medium. Anions penetrate this layer, contributing to its properties. They are incorporated into its structure in such a way that they are exchanged with anions in solution. Furthermore, redox reactions allowed by the good electronic conductivity of the internal film, are controlled by mass transfer across this region. An intricate situation is found in the case of ferrous anions, a possible constituent of the layer, probably inducing modifications of its ionic and electronic properties.

In this paper, a clear attempt is made to establish a connection between passive iron and some basic properties of iron oxides, especially in their colloidal state. It seems that this approach of passivity, even though straightforward in the framework of the oxide theory, was not explored in the literature. The main features of anion interaction with passive film have been related to their adsorbability on the surface of micelles. A conclusion regarding the existence of a transition layer on top of the passive film is not entirely original since the possible existence of a gel-like or polymeric structure in neutral media was invoked by other authors (31-33). A consideration of colloidal iron oxides also strongly supports this description and may provide some kind of new approach to passivity studies. It is known that hematite particles in aqueous solutions consist of a bulk anhydrous oxide surrounded by a hydrated interface (23). Goethite ($\alpha FeOOH$) is proposed (23) for the hydrated layer since it is a more stable oxyhydroxide and it has a structure related to hematite with a lower symmetry. The $\alpha FeOOH$ lattice is characterized by two FeO layers between OH planes, giving an alternate sequence as: OH—FeO—FeO—OH · OH—FeO. This lamellar structure, including H-bonds between OH neighbors, allows water molecules and ions to be intercalated, resulting in a material of a highly flexible composition (15). Protection conferred by some elements such as Mo may be attributed to their accommodation in this structure by cation substitution (34).

The resulting picture of the passive film is that of a two-layer structure: an inner region [dealt with in Ref. (1)], nearly independent of the solution composition, in which most of the electrical field is located; and an outer transition region accommodating the composition effects and defining a local environment in which growth and dissolution of the underlying layer take place.

Ellipsometric Study of Anodic Oxide Films on Titanium in Hydrochloric Acid, Sulfuric Acid, and Phosphate Solution

Toshiaki Ohtsuka, Minoru Masuda, and Norio Sato*

Electrochemistry Laboratory, Faculty of Engineering, Hokkaido University, Sapporo 060, Japan

ABSTRACT

The anodic oxide film on titanium has been studied by ellipsometry and SEM observation. *Ex situ* multiple-angle-of-incidence and *in situ* ellipsometric measurements allow the complex refractive index to be estimated at $\bar{n} = 2.3 - 2.9i$ for the titanium substrate and at $\bar{n} = 2.1 - 0.03i$ for the anodic oxide film at wavelength 546.1 nm. The anodic oxide film thickness increases linearly with potential in a range from -0.55 to 7.5 V (RHE) at the rate of 2.8 nm V^{-1} in phosphate solutions of pH 1.6-12.1, 2.5 nm V^{-1} in $0.1M$ HCl solution, and 2.4 nm V^{-1} in $0.1M$ H₂SO₄ solution. At potentials more positive than 7.5 V, the film breaks down, leading to the formation of a thick oxide film probably due to an increased ionic current through the breakdown sites. The film composition is estimated to be TiO₂(H₂O)_{1.4} or TiO_{0.6}(OH)_{2.8}, which suggests the presence of hydroxyl bridge in its bonding structure.

The physicochemical properties of anodic oxide films formed on titanium are of importance in understanding the corrosion stability and photoelectrochemical activity of titanium oxide and oxide-covered titanium, which have attracted interest in recent years in the field of photoelectrode materials.

There has been a number of studies on the passivation of titanium dealing with the mechanism of active dissolution and active-passive transition in acidic aqueous media from electrochemical and impedance measurements (1-6). Armstrong *et al.* (1) and Harrison *et al.* (7) found that titanium dissolves producing Ti (III) ion in the active potential region and Ti (IV) ion in the passive potential region. Impedance measurements have shown that the electrode capacitance of titanium decreases when the passivation

manifests itself on the polarization curve (1, 7). The film formation accompanying passivation was investigated in aqueous and anhydrous solutions by Laser *et al.* (8) and Smith *et al.* (9) using ellipsometry.

Many attempts have also been made to produce thick oxide films by anodization at high current efficiency. In some respects, titanium behaves as a typical valve metal, but the anodic oxide film is electrochemically less stable than the barrier films formed on Al, Ta, and Nb (10). McAleer *et al.* (10) investigated by optical interferometry the breakdown phenomenon during potentiostatic anodization of titanium at high scan rate and found that both oxygen evolution and rapid film thickening take place when the film breaks down. Yahalom *et al.* (11) investigated by use of TEM the anodic oxide film of titanium stripped from the metal substrate and detected the anatase type of diffraction pattern for the anodized oxide

*Electrochemical Society Active Member.

film subjected to breakdown and crystallization. Dyer *et al.* (12) employed ellipsometry to study the film growth on titanium during galvanostatic oxidation and obtained the relationship between film thickness, cell voltage, weight gain, and anodic charge passed.

In this work, the relation between potential and film thickness is examined for the anodic oxide films formed on titanium in aqueous solution of various pH values in a wide range of potential from 0 to 15V, including the passivation and anodization regions. Furthermore, the film breakdown is discussed on the basis of the thickness measurements and electron microscopic observation of the film.

Experimental

A titanium sheet of 99.85 weight percent (w/o) purity (impurity: C = 0.009, N = 0.004, O = 0.101, H = 0.0013, and Fe = 0.036%) was cut to specimens 10 × 15 mm with a small handle. The specimens were mechanically polished through to 2000 grid emery paper, degreased with acetone in an ultrasonic cleaner, and annealed in vacuum at 1030 K for 3h. They were further polished by alumina abrasives through to 0.5 μm and finally etched in an aqueous mixture of HF (2 volume percent [v/o]) and HNO₃ (4 v/o) for 2s at room temperature. After polishing, the small handle of the specimen connected with a lead wire was covered with silicon rubber sealant.

Electrolytes used are aqueous solutions of 0.1M (mol dm⁻³) H₂SO₄ (pH 0.9), 0.1M HCl (pH 1.1), and four mixtures of 0.1M H₃PO₄ and 0.1M Na₃PO₄ (pH 1.6, 4.6, 6.9, and 12.1). The solutions were prepared from doubly distilled water and analytical-grade reagents. Before transfer into the cell, the solutions were deoxygenated by injecting purified nitrogen gas for more than 24h in solution reservoirs, each of which is connected with the cell through a stopcock.

The electrolytic cell was a Pyrex vessel 100 cm³ in capacity with two optical quartz windows fixed at an angle of 140.64°.

Titanium ion dissolved into the solution during anodic oxidation was analyzed by a colorimetric method using hydrogen peroxide. All measurements were carried out at 298.3 ± 0.5 K. The electrode potential of titanium was measured in reference to a Ag/AgCl electrode and converted into the reversible hydrogen electrode potential scale in the same solution at P_{H₂} = 1 atm (RHE).

Two types of manual ellipsometers were used, one of which was a vertical type of ellipsometer (Rudolf Company Type 43702-200E) for *ex situ* measurements in air by the multiple-angle-of-incidence (MAI) method (13) and the other a horizontal type of ellipsometer (Mizojiri Company Type DV 36) for *in situ* measurements in the electrolytic cell. For these ellipsometers, filters were used to isolate a 546.1 nm light beam for mercury lamps. The polarizer and compensator were placed in the incidence light path, and the analyzer and detector in the reflected light path. The *ex situ* MAI method was adopted to determine the optical unknown parameters of the oxide-covered titanium; *i.e.*, the complex refractive index of titanium substrate $\bar{n}_3 = n_3 - ik_3$, complex refractive index of oxide film $\bar{n}_2 = n_2 - ik_2$, and film thickness d . The MAI measurement was carried out at four different angles of incidence, $\phi_1 = 45.0^\circ, 55.0^\circ, 65.0^\circ,$ and 75.0° , for the electrode which had been anodically oxidized, rinsed with doubly distilled water, and then stored in a desiccator at room temperature. Calculation of five unknown parameters ($n_3, k_3, n_2, k_2,$ and d) or three unknown parameters ($n_2, k_2,$ and d) was made to minimize the standard deviation

$$\text{std dev} = \left[\frac{\sum_{i=1}^N (2\Psi_i^M - 2\Psi_i^T)^2 + (\Delta_i^M - \Delta_i^T)^2}{2N-1} \right]^{1/2} \quad [1]$$

where Ψ_i^M and Δ_i^M are, respectively, experimental values of the relative amplitude ratio and the relative phase difference at an angle of incidence $\phi_{1,i}$, and Ψ_i^T and Δ_i^T are the theoretical values. The reason for the use of a factor of

two for Ψ in Eq. [1] is that Ψ must have an error limit one-half as large as that of Δ , because the Ψ and Δ have been obtained from the azimuths of polarizer, P , and analyzer, A , under the extinction condition in what is known as the first zone: $\Psi = A$ and $\Delta = 2P + 90^\circ$, where A and P have been measured at a similar degree of error limit. The *in situ* measurement was conducted at an angle of incidence $\phi_1 = 70.32^\circ$, and analysis was made by making experimental loci of Ψ and Δ fit theoretical curves computed using the optical parameters estimated by the MAI method. All the ellipsometric analysis calculations were carried out at Hokkaido University Computing Center (14).

Results

Polarization curve.—Figure 1 shows the anodic current density (c.d.) measured after 1h polarization of the original specimen at every designated potential in 0.1M HCl solution and in 0.1M H₂SO₄ solution. The average dissolution current c.d., i_{diss} , is also plotted, which was determined from the amount of Ti(IV) ion dissolved into solution during 1h polarization in 0.1M H₂SO₄ solution. In 0.1M H₂SO₄ solution, the active-passive transition is observed to occur at -0.2V. In 0.1M HCl solution, however, no active dissolution is observed. The passivation manifests itself in a potential range from -0.2 to 3.0V, beyond which oxygen evolution takes place. In the oxygen evolution potential region the polarization curve exhibits the Tafel slope as large as 2.3 V decade⁻¹, which is much greater than that of other transition metals, such as iron, nickel, and cobalt. Such a large Tafel slope is probably due to the large bandgap energy of semiconductive oxide films formed on titanium. In 0.1M HCl solution, pitting corrosion was observed at potentials more positive than 11V, and the anodic current greater than 1×10^{-3} A cm⁻² produced white corrosion precipitates speckling the specimen surface slightly colored dark blue due to interference of light. The average dissolution c.d. measured for 1h polarization in 0.1M H₂SO₄ solution increases slightly with potential, reaching 1×10^{-6} A cm⁻² at 12V. In 0.1M H₂SO₄ solution, the amount of Ti dissolved in the active potential region was found to be equivalent to Ti(III) dissolution. The polarization curve was also measured in phosphate solutions, which was similar to that obtained in 0.1M HCl solution (see Fig. 6).

Fig. 1. Anodic current and average dissolution current as functions of potential for titanium electrode in 0.1M hydrochloric and 0.1M sulfuric acid solutions. The anodic current was measured at the end of 1h potentiostatic oxidation of the original specimen, and the average dissolution current was estimated from the amount of Ti(IV) ion dissolved into solution during 1h oxidation.

Ellipsometry.—To analyze the surface oxide film by ellipsometry, the complex refractive index, $\bar{n}_3 = n_3 - ik_3$, of the substrate metal must be known. In this work, the *ex situ* MAI method was applied to estimate the optical parameters of titanium metal and a thin air-formed oxide layer on the polished specimen surface. The result is shown in Fig. 2, where comparison is made between the measured values and the theoretical curves estimated by the least squares method. The optical parameters thus estimated with a mirror-like titanium surface provide the complex refractive index $\bar{n}_3 = 2.3(\pm 0.1) - 2.9(\pm 0.1)i$ for titanium metal, $\bar{n}_2 = 2.0(\pm 0.1) - 0.03(\pm 0.015)i$ for an air-formed oxide layer, and the film thickness $d = 2.9(\pm 0.5)$ nm. Figure 2 also shows the result obtained with a titanium electrode anodically oxidized at 7.35V in pH 6.9 phosphate solution, from which the values of $\bar{n} = 2.13 - 0.03i$ and $d = 25.3$ nm are determined with the above complex refractive index of titanium metal. Similar *ex situ* measurements by the MAI method were performed for a number of titanium electrodes anodically oxidized at various potentials in pH 6.9 phosphate solution and in sulfuric acid solution, and the average value of the complex refractive index of the anodic oxide film is found from the measurements to be $\bar{n}_2 = 2.2(\pm 0.1) - 0.03(\pm 0.005)i$.

Figure 3 shows the experimental loci of Ψ vs. Δ obtained from *in situ* ellipsometric measurements for a number of anodically oxidized titanium electrodes in a potential region from 1 to 10V in 0.1M HCl and 0.1M H₂SO₄ solutions. The solid line in Fig. 3 indicates a theoretical line along which a film with $\bar{n}_2 = 2.10 - 0.030i$ grows on the substrate with $\bar{n}_3 = 2.3 - 2.9i$. Similar loci of Ψ vs. Δ were obtained also in phosphate solutions at various pH values. The results are given in Fig. 4 along a theoretical line corresponding to the complex refractive index of the film formed in 0.1M H₂SO₄ and 0.1M HCl solution. As shown in Fig. 3 and 4, there is a fairly good agreement between the experimental loci and the theoretical line for the range of film thickness thinner than 30 nm. A slight deviation of the experimental loci from the theoretical line is observed for the film thicker than 30 nm, which may be attributed to the surface roughening described later. This deviation, however, appears to exert only a

Fig. 2. Comparison between experimental Ψ and Δ at multiple angles of incidence and theoretical curves calculated from the optimum values of thickness and complex refractive index for the titanium substrate and the oxide film.

Fig. 3. Comparison between experimental Ψ and Δ measured *in situ* in 0.1M hydrochloric and 0.1M sulfuric acid solutions at an angle of incidence $\phi_1 = 70.32^\circ$ and a theoretical Ψ vs. Δ curve calculated for a growing film with $\bar{n}_2 = 2.1 - 0.03i$ on a substrate with $\bar{n}_3 = 2.3 - 2.9i$.

slight influence on the thickness estimation so that the same complex refractive index is used to evaluate the film thicker than 30 nm. The optical parameters estimated under this *in situ* condition is in agreement with the optical parameters obtained from the *ex situ* MAI measurement, except for a small difference in the refractive index of the oxide film, \bar{n}_2 . The change of the oxide film that might occur during storage was checked by MAI ellipsometry after removal of the specimen from the electrochemical cell and found to be inappreciable after 5 days of storage in desiccator.

Film thickness.—From the results shown in Fig. 3 and 4, the film thickness can be estimated. Figure 5 and 6 show the film thickness as a function of potential in 0.1M HCl, and 0.1M H₂SO₄, and phosphate solutions. Figure 6 also shows the anodic c.d. measured after 1h polarization at constant potential. The film thickness is observed to increase almost linearly with increasing potential up to 7.5V. At potentials higher than 7.5V, the thickness increases more steeply with potential and the reproducible results of thickness measurements are hardly obtained.

In the nearly linear thickness-potential curves a slight break is observed at about 3V, showing the film thickness/potential ratio 2.6 nm V⁻¹ at 0.0-3.0V, and 2.4 nm V⁻¹ at 3.0-7.5V in 0.1M HCl solution, and 2.5 nm V⁻¹ at 0.0-3.0V and 2.3 nm V⁻¹ at 3.0-7.5V in 0.1M H₂SO₄. No such break is seen in phosphate solutions, showing the thickness/potential ratio 2.8 nm V⁻¹ at 0.0-7.5V.

Fig. 4. Comparison between experimental Ψ and Δ measured *in situ* in phosphate solutions and a theoretical Ψ vs. Δ curve.

Fig. 5. Film thickness as a function of potential for the anodic oxide film formed on titanium by 1h potentiostatic oxidation in 0.1M hydrochloric and 0.1M sulfuric acid solutions.

The ratio of thickness to anodic charge passed was also measured by stepwise potential increase with a time interval of 1h. The result is shown in Fig. 7, from which the ratio is found to be $0.85 \text{ nm cm}^2 \text{ mC}^{-1}$ in pH 6.9 phosphate solutions. A slight scatter observed at 4.60V is due to the oxygen evolution reaction which consumes a part of anodic charge.

The galvanostatic film growth was also studied in pH 6.9 phosphate solution. Figure 8 shows the potential rise and film growth at constant anodic current. The thickness/charge ratio is $(d/Q) = 0.68 \text{ nm cm}^2 \text{ mC}^{-1}$ at $20 \mu\text{A cm}^{-2}$ and $(d/Q) = 0.71 \text{ nm cm}^2 \text{ mC}^{-1}$ at $5 \mu\text{A cm}^{-2}$, which are smaller than the $(d/Q) = 0.85 \text{ nm cm}^2 \text{ mC}^{-1}$ obtained for the potentiostatic film. This difference is probably caused by the film dissolution whose rate is dependent on the anodic c.d. (15). The linear potential rise and film growth are seen to level off at potentials more positive than 3V, where the oxygen evolution is taking place. The

Fig. 6. Film thickness as a function of potential for the anodic oxide film formed on titanium by 1h potentiostatic oxidation in phosphate solutions at pH 1.6, 4.6, 6.9, and 12.1

Fig. 7. Relationship between film thickness and anodic charge for the anodic oxide film on titanium by potentiostatic oxidation in pH 6.9 phosphate solution. The potential was increased stepwise at a time interval of 1h.

complex refractive index estimated for the galvanostatic film was found to be $n_2 = 2.10 - 0.03i$, which is consistent with the index obtained for the potentiostatic film.

Discussion

Complex refractive index.—The conventional ellipsometry at a fixed angle of incidence requires the oxide-free metal surface to estimate the complex refractive index of the metal. Smith *et al.* attempted to estimate by conventional ellipsometry the optical constant of a titanium electrode in HF solution where any surface oxide

Fig. 8. Electrode potential and film thickness as functions of anodic charge passed during constant current oxidation of titanium in pH 6.9 phosphate solution.

layer would dissolve, leading to surface roughening. The electrochemical reduction of surface oxides, usually employed for iron and other metals, is incapable of producing the oxide-free bare titanium surface because of formation of surface hydride layer during cathodic reduction.

In this work, MAI ellipsometry has been employed to estimate the complex refractive index of titanium substrate covered with a surface oxide layer. This method is, in contrast with the conventional ellipsometry, capable of determining the five unknowns, n_2 , k_2 , d , n_3 , and k_3 , of a film-covered metal from a number of measurable parameters, Ψ and Δ , at different angles of incidence.

The complex refractive index of titanium at wavelength 546.1 nm found in the literature, shows some scatter ($n_3 = 2.0$ -3.1, $k_3 = 2.0$ -3.7), as listed in Table I. The index obtained in this work is relatively small compared with the reported values except by Andreeva (16) and Dyer *et al.* (12). It is known that the index measured by ellipsometry is sensitive to the specimen surface. In this work, the titanium specimen was slightly etched to remove a superficial polishing layer without roughening the surface.

The refractive index, n_2 , of the oxide film listed in Table I shows almost no scatter except for a value reported by Laser *et al.* (8). The anodic oxide film is found to possess the refractive index smaller than that of crystalline TiO_2 whose refractive index is larger than 2.5 for anatase, rutile, and brookite (21). The small refractive index may be attributed to the hydrated structure of the anodic oxide film.

The extinction index, k_2 , of the anodic oxide film obtained in this work indicates that the film is slightly light absorptive at wavelength 546.1 nm, though the film has been claimed to be transparent in literature. The slightly light absorptive nature may be explained by assuming the presence of ionic and electronic defects in the film.

Film growth.—The film growth of anodic oxide on titanium has been reported to obey the high field ion migration mechanism (22-24)

$$i = i_0 \exp(B\bar{E}) \quad [2]$$

where i_0 is ionic self-diffusion c.d. at zero field, \bar{E} electric field strength, and B a constant given as follows

$$B = zaF/RT \quad [3]$$

In Eq. [3], z and a indicate, respectively, the ionic valency and the half-jump distance (or the activation distance) of migrating ion. The validity of Eq. [2] can be examined on the results of galvanostatic oxidation (Fig. 8), where the electric field is calculated from the values of $(\partial E/\partial t)$ and $(\partial d/\partial t)$.

$$\bar{E} = \left(\frac{\partial E}{\partial d} \right) = \left(\frac{\partial E}{\partial t} \right) \left(\frac{\partial d}{\partial t} \right)^{-1} \quad [4]$$

The \bar{E} vs. i relationship is given in Fig. 9, where the closed symbol indicates the result of potentiostatic 1h oxidation. From the plot in Fig. 9, the parameters of i_0 and B in Eq. [2] are found; $i_0 = 7.7 (\pm 2.0) \times 10^{-11}$ A cm⁻² and $B = 24 (\pm 5)$ nm V⁻¹. The value of i_0 is 100 times as large as that estimated by Johansen *et al.* (22) in aqueous ammonium borate solution and by Nishimura *et al.* (23) in aqueous chloride solution. Mizushima (24) reported a larger value of i_0 in anhydrous ethylene glycol. The value of B is fairly close to that obtained by other workers (22-24). From the value of B , the half-jump distance is found to be 0.16 nm for the migration of Ti(IV) ion, which is close to one-half of the distance between neighboring Ti ions in the lattice.

Film breakdown.—The linear relationship between film thickness and potential obtained under potentiostatic conditions has been shown to break at potentials more positive than 7.5V (Fig. 5 and 6). The abrupt thickening of the film above 7.5V may be attributed to the creation of lattice defects which increase the ionic leakage current. Observation with a scanning electron microscope (SEM; JEOL JSM-255) shows nearly the same surface morphology before and after oxidation at potentials more negative than 5V. At potentials more positive than 5.5V, a crater-conglomerate morphology with a single-crater diameter of about 3 μm is observed. Such a crater-like morphology was also reported by Yahalom *et al.* (11). At potentials more positive than 7.5V, the surface becomes rough, with a ripple-like appearance. From the surface observation described above, it appears that the breakdown of the anodic oxide film commences at 5.5V, producing a number of crater-like cracks, which will provide leakage paths for ionic current. The internal compressive stress induced by high field electrostriction will play an important role in the film breakdown, as proposed in a paper by Sato (25). At potentials more positive than 7.5V, the ionic current concentrates at the cracks, forming a thick oxide layer, whose thickness for unit voltage becomes greater than that of the film formed at more negative potentials.

Film composition.—Different models for the passive film on titanium have been proposed in literature, which assume either a unilayered or a multilayered structure. In this work, the unilayered model has been adopted, since the film was found to grow up along the theoretical curve

Fig. 9. Relationship between anodic current density and electric field strength for an anodic oxide film growing on titanium in pH 6.9 phosphate solution.

of the ellipsometric parameters drawn from a single-layer model.

The potential at zero film thickness is found to be $E = -0.55 \pm 0.10\text{V}$ from the linear thickness-potential plot shown in Fig. 5 and 6. This potential is very close to the transition potential from Ti_2O_3 to TiO_2 (26), suggesting that the passivation film is composed primarily of TiO_2 structure. From the large value of thickness-to-charge ratio and the small refractive index, it is suggested that the anodic oxide film contains some amount of water. Yahalom *et al.* (11) and Blondeau *et al.* (27) have observed electron diffraction patterns corresponding to anatase TiO_2 for the anodic films formed at potentials more positive than 50V, where the film breakdown takes place. Blondeau *et al.* (27) have also observed a quasiamorphous structure for the anodic oxide film formed at more negative potentials.

The thickness-to-charge ratio, $d/Q = 0.85 \text{ nm cm}^2 \text{ mC}^{-1}$, in a potential region less positive than 3.6V is 1.5 times as large as the theoretical value, $d/Q = 0.54 \text{ nm cm}^2 \text{ mC}^{-1}$, calculated from the density of crystalline anatase (21), $\rho = 3.84 \text{ g cm}^{-3}$, assuming the roughness factor, r , to be unity. This indicates that the anodic oxide film is hydrated. If we write the composition of the film as $\text{TiO}_2(\text{H}_2\text{O})_y$, the content of water, y , may be calculated by Eq. [5]

$$y = \left[\left(\frac{d}{Q} \right) \left(\frac{4F\rho}{r} \right) - M_{\text{TiO}_2} \right] \frac{1}{M_{\text{H}_2\text{O}}} \quad [5]$$

where M_{TiO_2} and $M_{\text{H}_2\text{O}}$ are the molecular weights of TiO_2 and H_2O , respectively. By use of $(d/Q) = 0.85 \text{ nm cm}^2 \text{ mC}^{-1}$ obtained above and $\rho = 3.2 \text{ g cm}^3$ measured by Dyer *et al.* (12), we obtain $y = 1.4$ and hence the composition of the anodic oxide film to be represented by $\text{TiO}_2(\text{H}_2\text{O})_{1.4}$ or $\text{TiO}_{0.6}(\text{OH})_{2.8}$. From the composition estimated above, it is evident that the film contains a large number of hydroxyl bridges in its bond structure. The presence of hydroxyl bridge may be confirmed by reversible absorption and desorption of hydrogen ions in the film observed by Dyer *et al.* (28).

Conclusion

The following conclusions may be drawn.

1. The complex refractive index at wavelength 546.1 nm is found to be $\bar{n} = 2.3-2.9i$ for the titanium substrate and $\bar{n} = 2.1-0.03i$ for the anodic oxide film formed on titanium in aqueous solution.

2. The anodic oxide film thickens linearly with increasing potential in a potential region from -0.55 to $+7.5 \text{ vs. RHE}$ under the condition of potentiostatic oxidation for 1h. The rate of thickness increase with potential is 2.8 nm V^{-1} in phosphate solutions (pH 1.6-11.5), 2.5 nm V^{-1} in 0.1M HCl solution, and 2.4 nm V^{-1} in 0.1M H_2SO_4 solution.

3. Breakdown of the anodic oxide film occurs at potentials more positive than 7.5V, beyond which a thick film

is formed. The thickening of the broken film is attributed to an increased ionic leakage current at breakdown sites.

4. The anodic oxide film is represented by $\text{TiO}_2(\text{H}_2\text{O})_{1.4}$ or $\text{TiO}_{0.6}(\text{OH})_{2.8}$, which contains a large density of hydroxyl bridge in its bonding structure.

Analysis of Passive Films on Stainless Steel by Cyclic Voltammetry and Auger Spectroscopy

N. Ramasubramanian,* N. Preocanin, and R. D. Davidson

Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada K0J 1J0

ABSTRACT

Anodic passivation of Type 316L stainless steel in a borate-boric acid buffer solution was studied using cyclic voltammetry and Auger spectroscopy. Based on a comparison with the results obtained on the metals (iron, chromium, and nickel), the reduction peaks appearing in the voltammograms for the steel were attributed to the reductive dissolution of a ferric oxide and to valence transitions associated with chromium and nickel in the oxide. It is shown that cyclic voltammetry in the buffer solution provides a qualitative and semiquantitative analysis of the passive film growth. Okamoto's model of formation of two types of films, determined by the anodization potential, is found to be applicable; the mechanism of oxide growth is related to selective enrichment of iron or chromium, which is based on solubility relationships predicted by thermodynamic considerations.

In our catalyst development work, stainless steel (AISI 316L), in the passivated or oxidized condition, is used as a support material. Subsequent to the deposition of the catalytically active material on the oxidized steel, the catalyst is subjected to cyclic voltammetry and the surface area of the catalyst is evaluated from the hydrogen and oxygen adsorption/desorption peaks appearing in the voltammograms. In order to avoid the dissolution of the oxide film on stainless steel, a borate-boric acid buffer solution of pH 8.6 was selected, instead of the normally used 1N sulfuric acid solution, for the voltammetry measurements. Information on the passive film growth and its reduction characteristics in the borate-boric acid buffer solution was, therefore, essential to facilitate interpretation of the electrochemical data obtained with the catalyst.

Studies on passivity are primarily oriented toward understanding the corrosion behavior of metals and alloys. Detailed investigations on the electrochemical behavior of iron in the buffer solution are reported in the literature (1). In the case of stainless steels, however, a major part of the reported work is devoted to their behavior in acid and chloride solutions (2-5). Recently, surface analytical techniques, such as Auger spectroscopy and x-ray photoelectron spectroscopy, have been used extensively to elucidate the compositional changes in the passive film (3-7). For example, the enrichment or depletion of an alloying element in the passive film has been shown to depend on the pH of the anodizing solution (5). It has been proposed that the passive film is a duplex oxide (4); another conclusion is that two kinds of passive films are formed on the steel depending upon their formation potentials (3). If the passive film itself or a part of it is a reducible oxide and more than one type of oxide is present, then their cathodic reduction potentials could be expected to be different. Therefore, cyclic voltammetry in combination with a surface analytical technique, Auger spectroscopy, could provide information on the composition of the passive film.

The work reported here was undertaken to study the anodic oxidation of stainless steel and cathodic reduction of the oxides formed in a borate-boric acid buffer solution, characterize the oxide using cyclic voltammetry in the buffer solution, determine the composition of the oxide by Auger spectroscopy, and correlate the electrochemical and Auger results. For the sake of comparison, passive films grown in sulfuric acid and sodium hydroxide solutions were also tested in the buffer solution.

Experimental

The material was AISI Type 316L stainless steel. It was supplied by Sulzer Canada, Incorporated, (Sulzer packing BX) in the form of a corrugated sheet, 0.2 mm thick, having fine channels or grooves on the surface so as to provide a large exposed area. Samples 3-4 cm² in area were

* Electrochemical Society Active Member.

cut from these sheets, degreased, washed, and dried. A conventional glass cell with three compartments housing the working electrode, a saturated calomel reference electrode, and a platinum gauze counterelectrode was used for the electrochemical studies. The solution used was a buffer solution of pH 8.6 obtained by mixing required volumes of 0.15M boric acid and sodium borate solutions. Argon was kept bubbling through the solution in all the three compartments of the cell. All measurements were made at room temperature.

Prior to an experiment, the sample was reduced at a cathodic current of 1 mA cm⁻² for 1 min. It is expected that such a treatment would reductively dissolve any ferric oxide present on the as-received material; chromium-rich oxide, if present, is unlikely to be removed by this procedure. Anodic oxidation was done potentiostatically by holding the sample at the desired potential for 1h; galvanostatic reduction of the passive film was carried out at a constant current of 10 μ A cm⁻²; a scanning rate of 100 mV s⁻¹ was used for cyclic voltammetry measurements. Subsequent to the anodic oxidation, the sample was lifted up above the solution, the electrical connections were rearranged for cathodic reduction or cyclic voltammetry, and the sample was reimmersed in the solution. A potentiostat, Model 173, and a Universal programmer, Model 175, supplied by Princeton Applied Research, and a current source, Model 225, and electrometers, Model 600B, supplied by Keithley, formed part of the electrochemical system.

Auger analysis was carried out using a Physical Electronics Model 595 scanning Auger microprobe (SAM) equipped with a cylindrical mirror analyzer and a coaxial electron gun. Samples were mounted on holders so that the surface normals made an angle of 60° to the electron beam, and 30° to the ion beam.

Survey spectra and depth profile data were taken using a 5 keV, 50 nA electron beam rastered over a 100 μ m² area. Smooth regions on the sample surfaces were chosen in order to minimize any topographical effects. Depth profiles were obtained in the alternating sputter mode (10s cycles) using digital data acquisition. A 4 keV Ar⁺ ion beam rastered over a 4 mm² area yielded a current density of $\sim 20 \mu$ A/cm² (measured with an unbiased Faraday cup). Under these conditions, a sputter rate of $2.6 \pm 15\%$ nm/min was obtained. Calibration of sputter rate was based on an oxide film grown on 304 stainless steel, and its thickness determined by nuclear microanalysis (8). The base chamber pressure was 5×10^{-10} torr, and during sputtering the main chamber pressure rose to 2×10^{-8} torr.

For each profile, the elements C, O, Cr, Fe, and Ni were monitored at 273, 512, 529, 651, and 848 eV kinetic energy, respectively. The Auger peaks were computer differentiated and the peak-to-peak (p-p) height values for each element were normalized by dividing by the sum of the p-p values for Cr, Fe, and Ni.

Results

All the potentials were measured and are quoted relative to the saturated calomel electrode. Subsequent to the initial cathodic reduction of the air-formed oxide film, at 1 mA cm^{-2} and -1.4 V , the rest potential attained by the sample was usually at $\sim -0.7 \text{ V}$. After anodic oxidation, if the sample was left immersed in the solution, the open-circuit potential shifted steadily in the cathodic direction; for example, in the case of films grown at 0 and $+0.6 \text{ V}$, the potentials were at -0.45 and -0.25 V , respectively, in $\frac{1}{2} \text{ h}$. Thus, the possibility existed for the passive film to undergo autoreduction. Therefore, it was necessary to lift the sample up above the solution temporarily till the appropriate changes in the connections were made for the reduction of the passive films. Such changes were made within 1 min, and reduction was carried out immediately following reimmersion of the sample in the solution. The potential measured on reimmersion was cathodic to the anodization potential by about 0.2 V . In some experiments, after anodization, changes in the connections were made quickly without lifting the sample above the solution. The open-circuit potential measured and the voltammogram traced were quite similar to those obtained in the usual experiments, for the same anodizing conditions, where the sample was lifted above the solution for a short time.

In Fig. 1, the voltammograms obtained with the samples anodized at various potentials are compared. Initial scan was in the cathodic direction from the potential measured on reimmersion in the solution to -1.1 V , which was followed by the anodic scan to 0 V . The result ob-

Fig. 1. Voltammograms obtained in a borate-boric acid buffer solution for stainless steel, Type 316L, anodized 1h in the buffer solution; specimen areas in cm^2 and anodizing potential in volts, respectively, are as follows: a: 3.4, 0. b: 3.8, 0.3. c: 3.9, 0.6. d: 4, 0.75. e: 3.8, 0.9. f: Specimen 3.8 cm^2 in area exposed to air for 4h following initial cathodic reduction step.

tained for a sample that was exposed to air for 4h following the initial cathodic reduction step is also included in the figure. A reduction peak located at -0.64 V is observed with the film formed at 0 V ; this peak becomes more pronounced with the sample anodized at 0.3 V . Increasing the anodizing potential to 0.6 V leads to the appearance of a second reduction peak at 0 V and an increase in the current for the initial peak; the latter has shifted to -0.75 V . With further increase in the anodizing potential to 0.9 V , the peak currents increase and the reduction peaks show a shift toward more cathodic potentials; they are located at -0.2 and -0.8 V . All the passive films showed a broad anodic peak at $\sim -0.3 \text{ V}$, and this peak current increased with increase in the passive film thickness.

The variation in the thickness of the passive film, expressed as the equivalent amount of charge passed during anodization, with applied potential is shown in Fig. 2A. The amount of charge consumed in forming the film increases more rapidly at $\geq 0.5 \text{ V}$ than at lower potentials. In Fig. 2B are shown the galvanostatic reduction curves for the passive films formed at various potentials. The films formed at $\leq 0.3 \text{ V}$ show a single reduction wave at $\sim -0.55 \text{ V}$, whereas those formed at $\geq 0.3 \text{ V}$ show an additional wave at $\sim 0 \text{ V}$. In the case of the latter films, the final reduction potential attained is more cathodic by 200 mV when compared to the films formed at low potentials.

In Fig. 3, a selected set of voltammograms, obtained with a sample cycled several times in a range of potentials and over various ranges of potentials, is shown. The cathodic limit was set at -1.1 V , and the anodic limit was increased from 0 to 1.2 V in steps of 0.3 V during the scans. The results are quite similar to those shown in Fig. 1 for the passive films. With increasing anodic potential, the reduction peak currents at 0 and -0.6 V increase and the

B: Galvanostatic reduction curves obtained in the buffer solution for the passive films; specimen areas in cm^2 and passivation potentials in volts are as follows: a: 3.8, 0. b: 4.2, 0.3. c: 3.8, 0.6. d: 3.6, 0.9. e: Specimen 3.9 cm^2 in area exposed to air for 4h after initial cathodic reduction step. f: As-received sample, 4.2 cm^2 in area.

Fig. 3. Cyclic voltammograms obtained for 316L stainless steel, 4 cm² in area, in borate-boric acid buffer solution.

peaks shift slightly toward cathodic values; the reduction peak at 0 V is observed when the anodic scan limit is set at ≥ 0.6 V; all the curves show a broad anodic peak at -0.3 V. An anodic oxidation peak and also a cathodic reduction peak at $+0.75$ V become obvious when the potential is set at > 0.9 V during the anodic scans.

The results of the Auger analysis for passive films formed at 0 V, before and after the galvanostatic reduction, are shown in Fig. 4 and 5. Referring to the galvanostatic reduction curves shown in Fig. 2B, the reduction was followed just up to the knee (marked by an

Fig. 4. Normalized Auger peak heights vs. sputtering time for passive films grown on 316L stainless steel at 0.9V for 1h in borate-boric acid solution. A: Passive film as grown. B: Passive film reduced galvanostatically in the buffer solution to a potential marked by an asterisk as shown in Fig. 2B.

Fig. 5. Auger results for passive films grown on 316L stainless steel in borate-boric acid buffer solution; anodized at 0V for 1h. A: Passive film. B: Passive film reduced galvanostatically, following anodization, to a potential marked by an asterisk as shown in Fig. 2B.

asterisk), in the curves. In the case of the films grown at 0.9V, the oxygen profiles shown in Fig. 4A and 4B clearly indicate that a part of the oxide has been removed by the galvanostatic reduction step. Enrichment of chromium with a corresponding depletion of iron occurs in the oxide close to the steel-oxide interface; the relative levels of chromium and iron then gradually attain their values in the bulk of the steel at close to the oxide-solution interface. A slight enrichment of nickel is noticed in the outer layers of the oxide. The galvanostatic reduction has removed the outer oxide layers to a depth where the enrichment of chromium and depletion of iron had occurred; i.e., iron had been the major constituent of the part of the passive film that was reductively dissolved. In the case of films formed at 0 V, the galvanostatic reduction curve, Fig. 2B, shows that the charge equivalent to the reducible oxide is quite small when compared to the 0.9V film. This is also confirmed by the oxygen profiles shown in Fig. 5A and 5B. Chromium enrichment with the corresponding iron depletion occur in the oxide, and this region extends from one interface to the other.

Auger results for a sample cycled several times between -1.1 and $+1.2$ V are shown in Fig. 6; the sample was examined after a final scan in the anodic direction when the potential applied was 1.2V. Profiles for iron and chromium are quite similar to those for the 0.9V film in Fig. 4. Subsequent to an enrichment of chromium and depletion of iron close to the steel-oxide interface, the chromium level decreases and that of iron increases toward the oxide-solution interface. It is interesting to note that, even after a number of passivation and oxide reduction steps during the repeated cycling, the profiles are quite similar to a passive film formed at 0.9V in a single step. The profiles obtained for the air-formed oxide films, one existing on the as-received sample and that formed in 4h of exposure after the initial cathodic reduction step, are shown in Fig. 7; the latter were quite similar to those obtained for the 0 V film following the galvanostatic reduction step (cf. Fig. 7B and 5B). Chromium enrichment and iron depletion at the steel-oxide interface are seen to be common for both of the air-formed films. But, in the as-received condition, there is a reversal in the composition of the surface layers relative to the steel-oxide interface; they are enriched in iron and depleted in chromium. It must be pointed out that the oxide formed, even after 4h of exposure to air, following the initial cathodic reduction step did not show an arrest or a wave at -0.6 V during the galvanostatic reduction, whereas the oxide existing on the sample in the as-received condition always showed a distinct arrest (Fig. 2B, curve f) at -0.6 V, comparable to that obtained for a film formed at $+0.3$ V.

The voltammograms for the metals iron, chromium, and nickel and the alloy Nichrome are shown in Fig. 8. A

Fig. 6. Composition of the passive film formed on 316L stainless steel in borate-boric acid solution after repeated cycling as shown in Fig. 3; Auger analysis done after a final anodic scan when the potential was 1.2V.

composite of the curves of the three metals matches quite well with the voltammograms shown in Fig. 1 and 3 for the steel. Reduction peaks observed at -0.6V for iron, 0V for chromium, and $+0.7\text{V}$ for nickel and the anodic peaks (indicating the transition from an active to a passive state) at $\sim -0.3\text{V}$ obtained for all the three compare well with similar peaks obtained in the case of the steel. The galvanostatic reduction curves for the metals anodized to various potentials revealed a well-defined arrest at -0.6V , only in the case of iron; in the case of nickel and chromium, the potentials rapidly decreased to -1.4V ; a small inflection at 0V was noticed in the case of chromium.

Discussion

Auger analysis.—The mechanism of passive film formation on stainless steels is governed by the thermodynamic stability of the oxidation products, oxides and/or hydroxides, at the pH and the potential (3, 5); this conclusion is amply confirmed by the results presented here. When the equilibrium diagrams for iron, chromium, and nickel are compared, it is seen that at pH 8.6 and a potential of -1.35V (for the sake of consistency, potentials are

Fig. 7. Auger results for an air-formed oxide film on 316L stainless steel; A: As-received sample. B: Specimen reduced at -1.4V and 1 mA cm^{-2} and exposed to air for 4h.

Fig. 8. Cyclic voltammograms for (a) iron 1.3 cm^2 , (b) chromium 2.4 cm^2 , (c) nickel 2 cm^2 , and (d) Nichrome, 1 cm^2 obtained in borate-boric acid buffer solution.

all referred to SCE), Cr_2O_3 is a stable oxide phase (9, 12). The Auger results obtained for the air-formed film (Fig. 7B) indicate a zone of chromium enrichment and iron depletion in the thin oxide layer. The profiles for the oxide that existed prior to the initial cathodic reduction step in the as-received condition (Fig. 7A) show a reversal in composition through the thickness of the film; the surface layers are rich in iron and depleted in chromium, relative to the inner interface, where the opposite is true. Cathodic reduction at 1 mA cm^{-2} and -1.4V , the initial surface preparation step, has thus selectively dissolved an oxide that was rich in iron. Galvanostatic reduction of the as-received sample indeed shows a distinct potential arrest at -0.6V , the characteristic reductive dissolution potential of a hydrated ferric oxide film (10, 11). Thus, the initial surface is not film free; passive film growth occurs on the surface carrying a thin ($\sim 1\text{ nm}$ thick) layer of chromium-rich oxide. From the equilibrium diagrams it is expected that at potentials anodic to 0V , chromium would dissolve preferentially in the buffer solution. The Auger results confirm this prediction; when the steel is passivated at potentials $\geq 0\text{V}$, the zone of chromium enrichment and iron depletion stays closer to the steel-oxide interface and the chromium level decreases and that of iron increases toward the oxide-solution interface (Fig. 4). When a sample was repeatedly passivated and the oxides formed were successively reduced, the final step of passivation still left the chromium-enriched and iron-depleted zone close to the steel-oxide interface (cf. Auger data in Fig. 6). During the passivation, half of a cycle chromium has preferentially dissolved, leaving an oxide richer in iron in the outer layers; this iron oxide has dissolved during the subsequent reduction half of the cycle. The final repassivation, which occurred between -0.3 and 1.2V (cf. Fig. 3 and 8; transpassive region for chromium) over a period of 15s, has led to the increase in iron

and decrease in the chromium levels toward the outer interface. The similarity in the composition of this passive film to that grown by a single-step anodization at +0.9V for 1h lends support to the proposal that passive film growth on the steel involves a selective dissolution process (3). The potential arrest at -0.6V observed during the galvanostatic reduction is characteristic of the reductive dissolution of Fe_2O_3 as Fe^{2+} in the solution (10, 11). The removal of outer oxide layers, rich in iron, during the galvanostatic reduction is also evidenced by the Auger results; the profiles obtained for a passive film, before and after the galvanostatic reduction, indicate reductive dissolution of outer oxide layers right up to the zone of chromium enrichment, near the steel-oxide interface, in the passive film.

Cyclic voltammetry.—The reduction peak appearing at -0.6 and -0.8V in the voltammograms of the passive films has to be attributed to the reductive dissolution of an oxide in the outer layers that is mostly of iron. A similar peak is observed in the voltammograms for pure iron; it corresponds to the potential arrest at -0.5 to -0.7V during the galvanostatic reduction; in the case of iron, this potential arrest is identified with the reduction of Fe_2O_3 and dissolution as Fe^{2+} (10, 11). With increasing anodic potential and, hence, the passive film thickness on the steel, the reduction peak current in the voltammogram increases; the galvanostatic reduction at this potential also corresponds to an increase in the amount of the reducible oxide. From the previous discussion based on solubility considerations, and confirmed by the Auger results, it is seen that thickening of the passive film with applied potential proceeds by the depletion of chromium and enrichment of iron in the outer oxide layers relative to the zone of chromium enrichment and iron depletion at the steel-oxide interface. The outer oxide layers of the passive film, reducible at -0.5 to -0.8V, are thus mostly ferric oxide (Fe_2O_3).

By comparison of the peaks obtained on the steel and pure chromium, the reduction peaks observed in the voltammograms at 0 to -0.2V are ascribed to chromium oxide in the passive film. In the galvanostatic reduction curves, a potential arrest at ~ 0 V is observed for both passivated chromium and the steel. Referring to the equilibrium diagram, it is seen that Cr_2O_3 is a stable oxide phase in the buffer solution at these potentials (9). Therefore, the reduction peak is not likely to be due to the reductive dissolution of the chromic oxide. However, the fact that this peak is observed only when passivation is done at $\geq 0.6\text{V}$ and that at these anodic potentials trivalent chromium can be oxidized to the hexavalent state (cf. equilibrium diagram) implies that this reduction peak is associated with the Cr^{6+} to Cr^{3+} transition occurring in the oxide. It is unlikely to be due to the reduction of Cr^{6+} species in the solution because samples passivated at $\geq 0.6\text{V}$ in a separate cell, washed in running water, and transferred to another cell containing a fresh quantity of the buffer solution still produced the same type of voltammograms showing the reduction peaks at 0 to -0.2V and -0.6 to -0.8V.

There were other interesting observations associated with this reduction peak at 0 to -0.2V. Samples anodized in 1M sulfuric acid solution, to various potentials up to 1V, when tested in the buffer solution, showed only the presence of a reduction peak at -0.7V, whereas voltammograms obtained with samples anodized in 0.1M sodium hydroxide solution of pH 12.8 and tested in the buffer solution revealed the presence of both reduction peaks, at -0.2 and -0.78V. With the samples anodized in the buffer solution and washed, dried, and tested immediately, the voltammograms showed both reduction peaks; however, after drying when aged for $\geq 1\text{h}$, the immersion potential of the sample in the buffer solution was cathodic at ~ -0.15V and only the reduction peak due to Fe_2O_3 at -0.6V was observed in the voltammogram. The passive film is believed to be a hydrated oxide (3); the hexavalent chromium species may be part of the bound water in the passive film and it undergoes autoreduction with aging.

When tracing cyclic voltammograms, anodic scans to potentials $> 0.9\text{V}$ led to the appearance of a reduction peak at +0.75V; this peak is very pronounced when thin oxide films, ~ 50 nm thick, grown thermally at 773 K on the steel are tested in the buffer solution. A reduction peak at about this potential is observed with pure nickel and Nichrome; these materials also show a corresponding anodic oxidation peak at +0.9V (cf. Fig. 8). The cathodic peak at +0.75V, therefore, reflects the reduction of nickel from a high to a lower valence state in the oxide; the equilibrium diagram suggests several oxidation states for nickel, stable as oxides, in the range of potentials from 0.4 to 0.8V at pH 8.6 (12).

In the case of passive films on the stainless steel, the oxides formed may not be identified individually as the oxides of the metals constituting the steel. For example, the shift in the cathodic direction of the reduction peak potentials in the voltammograms could be associated with compositional changes in the oxides making up the passive film. As a result, the efficiency of reduction of the hydrated ferric oxide on the steel could be different from that on iron. However, the sum of the heights of the two reduction peaks, attributed to chromium and iron oxides in the voltammograms, is seen to increase with the anodizing potential. This variation, shown in Fig. 2A, is similar to that of the charge passed in forming the passive film. This increase in the charge passed corresponds to an increase in the thickness of the total oxide, and reducible oxide is clearly evidenced by the Auger data (Fig. 4 and 5) and the galvanostatic reductions (Fig. 2B). The peak currents at 0 to -0.2V and -0.6 to -0.8V could thus be related to the relative amounts of the two oxides (chromium rich and iron rich) in the passive film. Additional work is necessary to relate quantitatively the peaks in the voltammograms with the composition of the passive film.

Structure of the passive film.—Anodic passivation of the stainless steel in the buffer solution bears a close analogy to that in acid solutions, and the results reported here support the model put forward by Okamoto for the structure of the passive film (3). In our study, steel carrying a thin film of chromium-rich oxide (nonreducible under the surface preparation conditions employed) is passivated. Depending on the anodization potential, two types of film are formed: at low potentials, $< 0\text{V}$, the oxide (hydrated) is mostly of chromium and, at high potentials, the outer oxide layers are mainly of iron. A zone of chromium enrichment and iron depletion is maintained close to the steel-oxide interface and film thickening with the applied potential proceeds by an increase in the level of iron and a decrease in the level of chromium toward the oxide-solution interface. The films formed at potentials $\geq 0\text{V}$ consist of at least two parts: outer layers of mainly ferric oxide, which could be reductively dissolved at ~ -0.6V, and inner layers rich in chromium oxide. The mechanism of growth of the passive films is governed by the solubility relationships of the oxides to the potential applied and pH of the solution.

Conclusions

Passivation behavior of 316L stainless steel in a borate-boric acid buffer solution of pH 8.6 was investigated by electrochemical means and Auger spectroscopy. Cyclic voltammograms obtained in the buffer solution showed characteristic reduction peaks. Similar peaks were also observed when the metals iron, chromium, and nickel were tested in the buffer solution. The reduction peak heights increased (proportionately) with increase in film thickness. A peak at -0.6 to -0.8V is identified with the reductive dissolution of a hydrated ferric oxide; reduction peaks at 0 to -0.2V and +0.75V are attributed to valence transitions, occurring in the solid state, associated with chromium and nickel, respectively, in the oxide.

Auger composition depth profiles revealed a zone of chromium enrichment and iron depletion close to the steel-oxide interface. Away from this zone and toward the oxide-solution interface, the level of iron increased and

that of chromium decreased with increase in passive film thickness. Auger data also confirmed the reductive dissolution of outer oxide layers occurring during the galvanostatic reduction at -0.6 to -0.8 V.

At potentials < 0 V, the passive film consisted mainly of chromium oxide; with increase in anodization potential, the outer layers were rich in the reductively dissolvable ferric oxide. Compositional changes in the passive film can be explained on the basis of selective solubility of the oxides at the applied potentials.

Cyclic voltammetry in the buffer solution, in combination with other surface analytical techniques, offers a qualitative and at least a semiquantitative analysis of passive film growth on stainless steels.

Fluoride-Based Catalysts for the Electrodeposition of Chromium

J. P. Hoare and M. A. LaBoda*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090-9055

ABSTRACT

Steady-state polarization and transient cyclic voltammetric studies were carried out on bright Pt microelectrodes in chromic acid solutions catalyzed by NaF and Na_2SiF_6 . These data indicate that HF is the active agent in these plating baths and that it acts as both a blocking agent and a catalyst for the electrodeposition of Cr. Current efficiency studies in the high speed plating machine support these conclusions.

According to the model of Cr electrodeposition from chromic acid solution (1, 2), most of the Cr in solution exists as the trichromate ion, $\text{HCr}_3\text{O}_{10}^-$. Sulfuric acid is added to the bath in a regulated amount. The sulfate exists as bisulfate ions, HSO_4^- , which complex one end of the trichromate ion so that electrons are transferred from the cathode to the other end of the complex in the outer Helmholtz plane. In addition to this role as a blocking agent, the HSO_4^- ion acts as a catalyst by complexing with the decomposition product of the trichromate complex to form a dipolar chromous complex. This chromous species is adsorbed on the cathode surface where two electrons are transferred to produce a deposit of metallic Cr and the release of the HSO_4^- to solution.

It is known (3-6) that additions of fluoride ion, whether in the form of HF, a salt of an indifferent metal, or a fluorosilicate, to chromic acid will catalyze the conventional electrodeposition of metallic Cr. In an effort to understand the mechanism of fluoride-catalyzed chromic acid plating baths, an investigation was made of the polarization characteristics of Pt cathodes in various solutions of chromic acid to which small amounts of NaF or Na_2SiF_6 were added.

Experimental

The cathodes were made by melting small beads (~ 0.04 cm^2 in area) at the ends of Pt wires (99.99% pure) in an oxygen torch and were cleaned by the repeated heating in a burning hydrogen jet following by quenching in concentrated HNO_3 , as described earlier (1). The mounting of the test electrodes (three for duplicate runs) in the Teflon cell has been detailed previously (1, 7). After the cell was filled with 2.5M chromic acid (250g CrO_3 /liter), the required amount of NaF was added to the solution, which was stirred with purified N_2 (~ 150 cm^3 /min). In this series of runs, the cyclic voltammograms were obtained as a function of sweep rate as before (7). The cell was opened, another portion of NaF was added, and the cyclic

voltammogram was taken once more. This procedure was repeated until measurements were made in 2.5M chromic acid catalyzed by making the solution 0.04, 0.08, 0.12, 0.20, 0.28, and 0.36M in NaF.

In another series of experiments, the ratio of CrO_3 /NaF was maintained at about 10/1 while the concentration of chromic acid was varied. The solutions investigated were 0.1, 0.5, 1.0, 1.75, and 2.5M in CrO_3 . For each solution, the cyclic voltammogram was obtained on the Pt-bead electrode in N_2 -stirred solution, followed by the galvanostatic and potentiostatic steady-state polarization measurements. The details of such measurements have also been presented elsewhere (1, 7).

All potentials are recorded against the saturated calomel reference electrode (SCE), and all experiments were carried out at ambient temperature ($24^\circ \pm 1^\circ\text{C}$).

The steel-tube samples (length, 7.6 cm; od, 3.8 cm; wall thickness, 0.17 cm) were plated in the high speed plating (HSP) system (8) for 1 min in a sulfate-catalyzed solution [CrO_3 , 50 g/liter, H_2SO_4 , 0.5 g/liter, and boric acid, 10 g/liter as a brightness extender (9)] and in a sulfate-silico-fluoride solution (CrO_3 , 50 g/liter; H_2SO_4 , 0.4 g/liter; Na_2SiF_6 , 0.5 g/liter; boric acid, 10 g/liter). The electrolyte was pumped through the anode-cathode gap space of 3.8 mm by an air pressure range of 2.76-5.51 kPa, which yielded flow velocities of 2 and 4 m/s. The temperature range was 68° - 85°C and the voltage range was 5-15V. The cathode area was 83.6 cm^2 and the anode area was 89.7 cm^2 . All samples were weighed before and after plating to obtain the weight of deposit, and from a knowledge of the quantity of charge passed, the cathode efficiency for Cr plating was determined.

Results

The identification of the electrode processes responsible for the peaks observed on the cyclic voltammograms is aided by a knowledge of the electrode reactions determining the rest potential and the formation of the adsorbed films on the electrode surface (steady-state po-

larization studies), and by surface analysis measurements (AES, XPS, SEM, etc.). The steady-state polarization curves at constant current on a Pt-bead cathode are plotted in Fig. 1 for five concentrations of chromic acid, all catalyzed by NaF such that the CrO_3/NaF ratio was close to 10/1. In general, the curves consist of three plateaus separated by limiting current regions. As suggested before (7), the first plateau at A corresponds to polarization of the local cell generated by the oxidation of Pt

and the reduction of Cr VI to Cr III at low current densities.

At higher current densities, the local cell is eliminated and the current falls to B through a limiting current where the current is consumed in the reduction of Cr VI to Cr III. With a high enough current density, the reduction of Cr VI can no longer support the demanded current and the current falls to C where the reduction of H^+ ions to H_2 gas supports the current. Finally, for the higher CrO_3 concentrations at D, a deposit is laid down on the Pt surface, shown by the bending upward of the curve in a so-called negative resistance region.

This negative resistance region produced by a change in surface area is more evident in the polarization curves obtained at constant potential in Fig. 2. These curves have the same general appearance as those in Fig. 1 with three plateaus, except that they are separated by negative resistance regions corresponding to the limiting current regions in Fig. 1. These area changes arise from the changes in the surface area produced by the reduction of the platinum oxides generated by the oxidizing power of

Fig. 2. Steady-state potentiostatic polarization curves obtained on Pt in the same solutions studied in Fig. 1.

the chromic acid. At D, the area changes are caused by the deposition of the Cr layer.

As the CrO_3 concentration increases, the length of the A plateau increases because more oxide is present in the more oxidizing environment. In the weak solution of 0.1M CrO_3 + 0.0096M NaF, the Cr VI concentration is so low that the system goes to H_2 evolution at low currents and a Cr metal deposit is not obtained (lack of negative resistance at D). A very thin porous deposit is obtained in the solution of 0.5M CrO_3 + 0.05M NaF as noted by the hump at D in Fig. 1. For the solutions of 1.0M CrO_3 + 0.096M NaF and stronger concentrations, good deposits of Cr metal are obtained at D but the area change or surface roughness increases with increasing concentration.

The surfaces of Pt-bead electrodes which had been cathodized in NaF-catalyzed chromic acid electrolyte were removed from the test cell, washed, dried, and analyzed with Auger electron spectroscopy (AES). The deposits obtained from 2.5M CrO_3 + 0.24M NaF, 1.75M CrO_3 + 0.168M NaF, and 0.5M CrO_3 + 0.05M NaF were investigated. The oxygen content of these Cr coatings range between 5 and 7 atomic percent (a/o). Although fluorine was detected in relatively very small amounts in the deposit, the height of the fluorine peak in AES spectra increased with increasing concentration of the electrolyte. From depth profiles obtained with argon sputtering, the thickness of these Cr deposits ranged between 20 and 50Å.

In Fig. 3, the cyclic voltammograms obtained on a Pt cathode in uncatalyzed 2.5M chromic acid are reproduced as a function of the sweep rate between -200 and 1500 mV. The two hydrogen desorption peaks, I_H and II_H on the anodic going sweep, the three complex polychromate reduction peaks, I'_O , II'_O , and III'_O on the cathodic going sweep, and the fact that the height of the major peaks indicated by Roman numerals are a linear function of the sweep rate indicate as before (7, 10) that the system is free of impurities. The large background current observed on the cathodic going sweep but not on the anodic going sweep arises from the reduction of Cr VI to Cr III. At a Pt anode, Cr III cannot be oxidized to Cr VI because the Cr III ions form a very stable hexaquo complex with water (7).

The cyclic voltammograms on Pt in 2.5M chromic acid containing 0.04M NaF as a function of sweep rate between -200 and 1500 mV are presented in Fig. 4. Here, at potentials below 0V, the current falls to very negative values where a thin layer of Cr metal is deposited on the Pt surface. This Cr layer, which does not exhibit the hydrogen reduction peaks, is removed at anodic potentials in peak V_O . Since the peak heights in Fig. 4 are a linear function of the sweep rate, the electrode processes which generate the peaks are surface reactions and do not arise from diffusion processes from solution.

Fig. 3. A family of cyclic voltammograms obtained on Pt in 2.5M CrO_3 solution as a function of sweep rate (100, 83, 67, 50, 33, and 17 mV/s) between -200 and 1500 mV. The 100 mV/s curve is the outside curve. Roman numerals identify major peaks.

Fig. 4. Family of cyclic voltammograms obtained on Pt in 2.5M CrO₃ + 0.04M NaF solution as a function of the sweep rate (100, 83, 67, 50, 33, and 17 mv/s) between -200 and 1500 mV. The 100 mv/s curve is the outside curve. Roman numerals identify major peaks.

When the concentration of NaF was raised to 0.8M, the V₀ peak became more pronounced, but with further additions of NaF, little or no change in the peak area could be detected, even when the NaF concentration was raised to 0.24M shown in Fig. 5. In fact, at a NaF concentration of 0.45M, no change in V₀ was detected. The area under V₀ corresponds to the amount of Cr deposited on the Pt surface and appears to be virtually independent of the NaF concentration above about 0.1M. This observation is in agreement with that in the high speed plating machine where the rate of deposition is independent of the fluoride concentration above a given threshold value. In other words, one does not overcatalyze a Cr plating bath with F⁻ ion additions.

The presence of I₀' , II₀' , and III₀' in Fig. 4 and 5 and the negative resistance region at D in Fig. 1 and 2 give evidence that a cathodic film is formed in NaF-catalyzed chromic acid baths at the cathode. It is from this cathodic film that the Cr coating is deposited.

Figure 6 contains the cyclic voltammograms obtained on Pt-bead electrodes in 2.5M chromic acid (curve A) and in chromic acid catalyzed with Na₂SiF₆ addition (0.25M Na₂SiF₆) (curve B). Since the shape of curve B in Fig. 6 and that in Fig. 4 are highly similar, it is not critical to the quality of the product whether the fluoride catalyst is added as a salt of an indifferent cation or as a silicofluoride. A choice may be determined by the greater ease with which the silicofluorides can be handled and stored and by the greater solubility of the silicofluorides.

The high speed plating data of steel-tube samples in Na₂SiF₆-catalyzed chromic acid are plotted at two electro-

lyte flow rates (2 and 4 m/s) at 68°, 80°, and 85°C in Fig. 7 as the current efficiency for Cr plating as a function of the apparent current density. The current efficiency increases with the current density, decreases with the temperature, and is virtually independent of the flow rate.

Discussion

For metallic Cr to be deposited from the trichromate ion, a blocking agent must be present so that electrons will be transferred to only one end of the HCr₃O₁₀⁻ ion. In the case of sulfate-catalyzed CrO₃ electrolytes, the transfer of electrons to one end of the trichromate ion is hindered by the hydrogen bonding of HSO₄⁻ ion to the double-bonded oxygens at that end (1, 2). Since it makes little difference to the electrodeposition process how the fluoride is added (3-6) (see Fig. 2 and 6), a hydrogen containing species common to all the fluoride addition agents is HF and is considered to be the active catalyst for the electrodeposition of Cr. Fluoride ion hydrolyzes to HF according to Eq. [3]

Fig. 7. Cathode current efficiency as a function of the apparent current density for Cr deposition on steel-tube samples in the mixed catalyst electrolyte at 68°C, circles; 80°C, triangles; and 85°C, squares. Open symbols, 2 m/s and filled, 4 m/s flow rate; (A) sulfate catalyst tank plating envelope; (b) mixed catalyst tank plating envelope.

and in the very strong acid medium of 2.5M chromic acid Eq. [3] is shifted to the right. In the case of the silicofluoride, it has been found (11) that metal silicofluorides are decomposed in concentrated H_2SO_4 to SiF_4 and HF. Possibly, in the strong acid environment of 2.5M chromic acid, Na_2SiF_6 disintegrates to HF by Eq. [4]

It is suggested, as in the case of sulfate-catalyzed chromic acid (2), that an equilibrium exists between all possible complexes formed by hydrogen bonding between HF and the polychromate ions where the distribution of complexes is determined by the ratio of CrO_3 to the catalyst concentrations. For sulfate-catalyzed systems, the greatest probability of obtaining a complex with one end blocked occurs at a CrO_3/H_2SO_4 ratio of 100/1. In the fluoride-catalyzed case, the ideal complex is

where the double-headed arrows indicate hydrogen bonding and the δ^- is the average negative charge resulting from resonance between the two hydrogen-bonded forms.

Electrons are transferred to the unblocked end of the complex in the outer Helmholtz plane by quantum mechanical tunneling through the potential energy barrier of the double layer. With the transfer of $4e$ and the reaction with $4H^+$ in six steps, one obtains a chromous complex

Decomposition of this complex takes place by an acid-catalyzed hydrolysis by reaction with H_3O^+ ions to give

Since $Cr(OH)_2$ is in equilibrium with $Cr=O + H_2O$, the HF may hydrogen bond to $Cr=O$ to form the dipolar complex

The positive end of this complex can be specifically adsorbed on the cathode surface. With the transfer of two electrons and the reaction with $2H^+$ ions, Cr metal is deposited and H_2O and HF are liberated. In this role, the HF acts as a catalyst.

In solutions containing F^- ions and HF, these species can combine to form the complex ion FHF^-

with a pK of 0.7 (12). As F^- ion is added to the system, the equilibrium (Eq. [9]) shifts to the left to form the HF_2^- ion. Since the hydrogen is tied up in the $F-H-F$ linkage, it cannot hydrogen bond with polychromate double-bonded oxygens. This behavior can account for the observed fact that a fluoride-catalyzed, chromic acid, plating bath resists overcatalyzation as in Fig. 4 and 5, in contrast to sulfate-catalyzed baths (2). The equilibrium constants for the ionization of HF (12)

and the ionization of HF_2^- , Eq. [9], maintains the CrO_3 /catalyst ratio in the range for acceptable Cr plating ($\sim 30/1$ from Fig. 4 and 5). Such a bath is self-regulated.

In the HSP machine, it was observed that an acceptable deposit of Cr was not obtained on steel-tube samples in fluoride-catalyzed chromic acid electrolytes at $68^\circ-85^\circ C$ and a flow rate of 2-4 m/s. Misplates such as patches and discolored smuts were deposited. In conventional plating from a fluoride-catalyzed bath, a viscous cathodic film could not be detected at the cathode surface, in contrast to that observed in sulfate-catalyzed baths (2). It is believed that the cathodic film is composed of a mixture of all possible complexes between HF, polychromates, and H_2O molecules. These HF-polychromate-complex films are much less viscous than the HSO_4^- -polychromate-complex films. As a result, the HF-polychromate films are relatively much thinner and can be swept from the cathode-electrolyte interface by the high flow rates used in the HSP system. Under these conditions, a poor deposit of metallic Cr would be expected, in agreement with the experimental observations, because Cr is deposited from the cathodic film (1).

When sulfuric acid was added to the fluoride-catalyzed chromic acid, excellent, bright, hard deposits of Cr were obtained on steel with this mixed-catalyst system in the HSP machine (see Fig. 7). In this case, the H_2SO_4 can form the more viscous cathodic film which is not easily swept from the cathodic surface by the high solution flow rates in the HSP machine.

It is concluded from these data that in fluoride-catalyzed Cr plating baths, HF acts as a blocking agent as well as a catalyst for the electrodeposition process. Although HF is a poorer blocking agent than HSO_4^- ion, it is a better catalyst for the reduction of the chromous complex (Eq. [8]) because of the higher electronegativity of the F atom. Since HF reacts with F^- ion to form the indifferent complex HF_2^- , a fluoride-catalyzed bath resists overcatalyzation, with further additions of fluoride producing a self-regulating bath.

The Electrorefinement of Indium Through an Aluminum Alkyl Complex Electrolyte

M. S. Su, J. S. Gentry, C. B. Boss, C. G. Moreland, and K. J. Bachmann*

Department of Chemistry, North Carolina State University, Raleigh, North Carolina 27695-8204

ABSTRACT

High purity indium metal has been prepared by electrolysis at constant potential from a mixed Al + In complex electrolyte that contains typically 2 mol $\text{Al}(\text{C}_2\text{H}_5)_3$ and 0.06 mol $\text{In}(\text{C}_2\text{H}_5)_3$ per mol $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3\text{F}$. Based on the results of cyclic voltammetry applied to the pure Al complex electrolyte and to the mixed electrolyte, a mechanism for the cathodic and anodic steps in the electrorefinement process is proposed. This mechanism is described by the following net electrode reactions

It is the opinion of the authors that the $[\text{Al}_2\text{F}(\text{C}_2\text{H}_5)_6]^\ominus$ and $[\text{Al}_3\text{F}(\text{C}_2\text{H}_5)_9]^\ominus$ ions that are shown by NMR studies to exist in equilibrium with uncomplexed $\text{Al}(\text{C}_2\text{H}_5)_3$ and $\text{Al}_2(\text{C}_2\text{H}_5)_6$, respectively, serve merely as supporting electrolyte. The indium metal obtained by electrorefinement in a mixed Al + In alkyl electrolyte is suitable for the synthesis and bulk crystal growth of In containing compound semiconductors. However, a further reduction of the ~ 2 ppm Al contamination level is required for making the electrorefined In a useful source material for epitaxial growth processes.

The ability of aluminum alkyl compounds, AlR_3 , to form complex electrolytes with alkali halides was discovered in 1955 by Ziegler *et al.* (1, 2), who recognized the potential of these electrolytes for the electrorefinement of aluminum (3). In subsequent patent applications, the replacement of the alkali halides by quaternary ammonium halides (4) and the extension of the electrorefinement to other Group IIIA metals (4) and Group IIB and Group IVA-VIA elements (5) have been disclosed.

Two series of complexes of the form $\text{M}^+[\text{AlR}_3\text{X}]^-$ and $\text{M}^+[\text{Al}_2\text{R}_6\text{X}]^-$, termed 1:1 and 1:2 complexes, respectively, have been reported with generally higher conductivity of the halide to aluminum ratio 1:2 complexes (6-9). For the $\text{K}^+[(\text{C}_2\text{H}_5)_3\text{Al-F-Al}(\text{C}_2\text{H}_5)_3]^-$ complex salt, x-ray diffraction studies show colinearity for the Al-F-Al atoms and tetrahedral coordination about the Al atoms (10). This result was interpreted in Ref. (10) in terms of a partial π character of the F-Al bond and an sp hybridization of the fluorine atom, which was supported by a subsequent NMR study of the electroneutral isoelectronic compound $(\text{CH}_3)_3\text{Si-F-Al}(\text{C}_2\text{H}_5)_3$ (11).

Ultraclean Group IIIA metals and metal alkyl compounds are presently of considerable technological interest for fabricating III-V compound semiconductors. In view of the advanced state of III-V compound bulk-crystal growth and epitaxy, the controlled reduction of the impurity background in the source materials is a key issue for the improvement of both optoelectronic devices and FET structures. The indium containing III-V compounds and alloys are currently of particular interest in the context of light sources and detectors for optical communications (12), thus motivating our work on the purification of this metal.

Experimental

The aluminum alkyl electrolyte was prepared according to the procedures of Dotzer (14). An excess of trimethylamine gas was passed over a 57g charge of triethylaluminum in a 1 liter flask. The triethylamine:triethylaluminum one-to-one adduct, obtained in a considerably exothermic reaction, was distilled under vacuum at 120°C . The clear, colorless distillate was heated to 50°C and stirred. A 55g sample of benzyl fluoride was added, dropwise. The mixture was then heated to 100°C and stirred for 30 min and served as a stock for the preparation of complex solutions by further additions of triethylaluminum. The electrolyte used for electrorefinement experiments consists of at least 2 mol $\text{Al}(\text{C}_2\text{H}_5)_3$ and 6 mol toluene per mol $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3\text{F}$. In some cases, $\text{In}(\text{C}_2\text{H}_5)_3$

was added to this electrolyte. For the NMR studies described below, we prepared, also, complex solutions of NaF in triethylaluminum. The NMR spectra were taken on a EM-390 NMR spectrometer. Where not stated, the spectra shown in Fig. 1-6 were recorded at room temperature. All sample preparations and solution transfers were performed in an atmosphere of dry nitrogen.

A two-electrode galvanostatic or a three-electrode potentiostatic configuration was used for deposition of indium onto a platinum sheet cathode. The anode was either a pure aluminum wire or a block of indium metal. For the three-electrode potentiostatic experiments, the reference electrode was an aluminum wire in a pure triethylaluminum electrolyte. The electrolytes in the electrorefinement cell and in the reference electrode compartment contact in a sintered Vycor plug.

Samples of the electrolyte and deposited metal were analyzed by plasma-emission methods. Aliquots of the electrolyte, representing less than 0.05% of the total mass of the electrolyte in the cell, were removed and immediately weighed under an N_2 atmosphere. The samples were then hydrolyzed, similar to previously described procedures (13), by the addition of aqueous HCl, extracted from the toluene phase, and reweighed.

Samples of the deposited metal were taken by removing the Pt cathode from the cell, rinsing thoroughly with toluene followed by benzene, mechanically removing the metal from the electrode, melting under decahydronaphthalene, etching with 6M HCl, and weighing. The samples were then dissolved in concentrate HCl and diluted with deionized water.

The hydrolyzed electrolyte and dissolved metal samples were analyzed utilizing a Beckman spectraspan IV direct current argon plasma spectrometer.

Identification of the Complex Equilibria by NMR

Figure 1 shows the $^1\text{H-NMR}$ spectra for (a) triethylaluminum and (b) molar ratio of NaF to $\text{Al}(\text{C}_2\text{H}_5)_3 = 1:m$ solution, where $m = 2.5$, and further dilution of this solution with $\text{Al}(\text{C}_2\text{H}_5)_3$ to (c) $m = 3$ and (d) $m = 4$. Note that spectra b, c, and d were recorded at -10°C and these solutions also contained 3 mol toluene per mol NaF. This is important since in the absence of toluene a phase separation occurs at $m = 2$ (7). This phase separation is prevented in toluene containing solutions. Also, the phase separation established at $m \geq 2$ in the absence of toluene is reversed upon addition of toluene. Therefore, the toluene diluted solutions are thermodynamically stable to at least $m = 4$. Due to the influence of the electropositive Al atom, the CH_2 quartet is shifted upfield from the position of the CH_3

*Electrochemical Society Active Member.

Fig. 1. $^1\text{H-NMR}$ spectra of $\text{NaF} + \text{Al}(\text{C}_2\text{H}_5)_3 + \text{toluene}$ solutions

triplet. At dilution $m = 2.5$, the upfield shift of the CH_2 signal is enhanced as expected from the F-Al interaction. Dilution beyond $m = 2.5$ results in the appearance of two CH_2 signals at fields that are characteristic for the complex and the pure triethylaluminum, respectively.

Figure 2 shows the $^1\text{H-NMR}$ spectra of molar ratio of trimethylbenzyl ammonium fluoride to triethylaluminum = $1:m$ solutions for various values $1 \leq m \leq 3$. As in the spectra for the Na^+ complex, the quartet associated with the CH_2 group of the ethyl groups in the anion complex is shifted upfield as compared to this position for pure $\text{Al}(\text{C}_2\text{H}_5)_3$. However, for $m \geq 3$, the fine structure due to the interaction of the CH_2 protons with the protons of the methyl group in the C_6H_5 group is reduced and a broadening occurs in the single line associated with the protons of the aromatic ring in the benzyl group. This phenomenon may be due to signal averaging and/or Al-proton coupling, but coincides, also, with the onset of a phase separation that is observed upon replacing Na^+ by $[\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3]^+$ for dilutions $m \geq 3$.

Figure 3 shows the $^{19}\text{F-NMR}$ spectra for molar ratio of toluene to NaF to $\text{Al}(\text{C}_2\text{H}_5)_3 = 3:1:m$ solutions with (a) $m = 2$, (b) $m = 2$, (c) $m = 2.5$, and (d) $m = 4$. A single peak at $\phi = 183$ ppm is observed for the $m = 1$ solution and is associated with the 1:1 complex $\text{Na}[\text{FAl}(\text{C}_2\text{H}_5)_3]$ reported previously (1-3, 5). For the $m = 2$ solution, a predominant peak at 172 ppm and a weak second peak at 166 ppm are recorded. The peak at 166 ppm increases relative to the peak at 172 ppm upon further dilution of the solution by $\text{Al}(\text{C}_2\text{H}_5)_3$. As pointed out in the above discussion of the ^1H spectra up to $m = 2.5$, no excess of uncomplexed $\text{Al}(\text{C}_2\text{H}_5)_3$ is detectable. Using this fact and the integrated intensities of the ^{19}F signals at 166 and 172 ppm for a solution with $m = 2.5$, we conclude that the signal at 172 ppm is associated with the previously reported 1:2 complex

Fig. 2. $^1\text{H-NMR}$ spectra of $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3\text{F} + \text{Al}(\text{C}_2\text{H}_5)_3$ solutions

(1-3, 5, 9) and the signal at 166 ppm is associated with a heretofore not recognized 1:3 complex.

Figure 4 shows a plot of the ratio of the integrated ^{19}F signals for the 1:2 and 1:3 complexes as a function of the molar ratio of $\text{Al}(\text{C}_2\text{H}_5)_3$ to $\text{NaF} = n$. As expected from the mass action law, the concentration of 1:3 complex increases as the concentration of free $\text{Al}(\text{C}_2\text{H}_5)_3$ increases (cf. discussion of Fig. 1).

Figure 5 shows the $^{19}\text{F-NMR}$ spectra for molar ratio of trimethylbenzyl ammonium fluoride to triethylaluminum = $1:m$ solutions where (a) $m = 1$, (b) $m = 1.5$, (c) $m = 2$, and (d) $m = 3$. The spectrum Fig. 5a was measured at -10°C . For the most diluted solution, $m = 3$, two dominant peaks at 172 and 166 ppm are observed that, in analogy to the NaF complex solutions, are associated with the 1:2 and 1:3 complexes, respectively. Also, a small additional peak at 162 ppm is observed, indicating the possible formation of higher-order complexes in the trimethylbenzyl ammonium fluoride solutions. In the $m = 2$ solution, this signal is absent and the signal associated with the 1:2 complex is dominant. However surprisingly, the signal at 162 ppm appears as a broadened significant feature in Fig. 5a, which shows an additional sharp peak at 153 ppm plus a broad peak at 175 ppm. The stoichiometry of the F compounds associated with the signals at 162 and 153 ppm is presently unknown. The broad signal at 175 ppm we interpret as an average between the signals associated with the lower order complexes.

Figure 6 shows the change in the $^{19}\text{F-NMR}$ spectra of $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3\text{F} + \text{Al}(\text{C}_2\text{H}_5)_3$ complex electrolyte at constant $m \approx 3$ upon dilution by toluene. Clearly, the ratio of the 1:2 to 1:3 complex concentrations increases with dilu-

Fig. 3. ^{19}F -NMR spectra of $\text{NaF} + \text{Al}(\text{C}_2\text{H}_5)_3 + \text{toluene}$ solutions

tion. Assuming maximum conductivity for the 1:2 complex, this observation accounts for the previously unexplained increase in the conductivity of the halide:aluminum alkyl = 1:2 electrolytes upon dilution with toluene. Also, the shift of the equilibrium between 1:2 and 1:3 complex in toluene towards higher 1:2 complex concentration combined with a segregation coefficient $k \ll 1$ for 1:3 complex incorporation during crystal growth from such toluene solutions reconciles our results with the x-ray data of Natta *et al.* (6), which refer to pure

Electrorefinement Studies

Figure 7 shows the cyclic voltammograms for trimethylbenzyl ammonium triethylaluminum fluoride electrolyte using an Al anode for various dilutions m in the range $2.00 \leq m \leq 2.13$. The peak anodic and cathodic current densities for Al dissolution and Al deposition, respectively, are proportional to the amount of $\text{Al}(\text{C}_2\text{H}_5)_3$ added. According to the above NMR study, at $m = 2$ most of the $\text{Al}(\text{C}_2\text{H}_5)_3$ is complexed, but the concentration of free $\text{Al}(\text{C}_2\text{H}_5)_3$ increases substantially with increasing m , suggesting that the peak anodic and cathodic current densities for Al dissolution and Al deposition, respectively, are related to the concentration of excess $\text{Al}(\text{C}_2\text{H}_5)_3$ that is coupled to the following equilibria

We propose the following overall anodic and cathodic partial reactions.

For the anodic reaction

The formation of ethyl radicals in the anodic step, as assumed in Eq. [3], is a proven experimental fact and leads, in the case of inert metal anode, to the formation of the disproportionation products ethane and ethylene, as previously reported (9).

For the cathodic reaction

Since a replacement of the Al anode by an In anode leads to the chemical dissolution of In according to Eq. [8]

the overall anodic reaction is in this case

Consequently, upon electrolysis under galvanostatic conditions, the initially pure aluminum complex electrolyte becomes enriched in triethylindium, which, according to the equilibrium

is coupled to net cathodic reaction

This suggests the possibility of In deposition from an initially pure Al complex electrolyte, which has been verified previously (9) and has been explored here in more detail.

Table I shows the increase of the In concentration in the electrolyte during a typical galvanostatic experiment at a current density of 20 mA/cm² at the cathode which corresponds to ~5 mA/cm² at the In anode. The following features were observed: (i) the indium concentration increased very slowly to a steady-state value of $\sim 9 \times 10^{-3}M$, (ii) there were considerable fluctuations in the In concentration close to the cathode particularly during the initial period of the electrolysis. These fluctuations may have been related to changes in the flow conditions in the cell.

Figure 8 shows the cyclic voltammograms of $m = 2.4$ aluminum electrolyte with various additions of triethylindium. Two cathodic and two anodic peaks were observed, corresponding to the deposition of In and Al and the reoxidation of the reduced species, respectively. In view of the small In:Al ratio in the electrolyte, the height of the Al peaks were far less sensitive to changes in the In concentration than were the In peak heights, which increased linearly with the In concentration.

The peak separation between Al and In deposition was ~0.8V, offering thus an excellent opportunity for separation by electrolysis at controlled potential. Analyses of deposits obtained at the In-peak potential revealed an Al level of, typically, 2 ppm, which we believe is primarily due to difficulties in completely cleaning the Al electrolyte off the surface of the cathodic deposit. No other impurities were detected. In particular, Ga that was found as a trace metal impurity in the commercial 5N and 6N pure In metal available to us was absent in the electrorefined In. This material is well suited for the growth of bulk single crystals of the indium containing III-V compounds where small levels of isoelectronic impurities do not significantly affect the lattice constant and the band structure. In fact, currently, the deliberate addition of isoelectronic impurities as a means for increasing the yield stress of III-V substrate crystals is being explored in several laboratories with the aim at reducing the density of dislocations due to thermal stress during crystal growth. However, for the purpose of epitaxial growth, further work on the reduction of the Al impurity level is required because of its relatively large distribution coefficient and sticking coefficient under the conditions of liquid phase epitaxy and molecular beam epitaxy, respectively. Of

2058	—	9.3

Fig. 8. Cyclic voltammograms at 25°C of $\text{Al}(\text{C}_2\text{H}_5)_3$ to $\text{In}(\text{C}_2\text{H}_5)_3$ to $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3\text{F}$ to toluene = 2.40x:1:3 solutions. Traces (A) $x = 0.003$, (B) $x = 0.010$, and (C) $x = 0.017$.

course, this restriction does not apply to the growth of Al and In containing III-V alloy epilayers, where In electrorefined through the above described mixed Al + In alkyl electrolyte is a potentially useful source material.

Summary

High purity indium metal has been prepared by electrolysis at constant potential from a mixed Al + In complex electrolyte that contains typically 2 mol $\text{Al}(\text{C}_2\text{H}_5)_3$ and 0.06 mol $\text{In}(\text{C}_2\text{H}_5)_3$ per mol $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3\text{F}$. Based on the results of NMR measurements that provide insight into the complex equilibria and of cyclic voltammetry applied to the pure Al complex electrolyte and to the mixed electrolyte, a mechanism for the cathodic and anodic steps in the electrorefinement process is proposed. This

mechanism is described by the following net electrode reactions

It is the opinion of the authors that the $\text{C}_6\text{H}_5\text{CH}_2\text{N}(\text{CH}_3)_3^+$, $[\text{Al}_2\text{F}(\text{C}_2\text{H}_5)_6]^-$, and $[\text{Al}_3\text{F}(\text{C}_2\text{H}_5)_9]^-$ ions that exist in equilibrium with uncomplexed $\text{Al}(\text{C}_2\text{H}_5)_3$ serve merely as supporting electrolyte. The indium metal obtained by electrolysis in a mixed Al + In alkyl electrolyte is suitable for the synthesis and bulk crystal growth of III-V compounds and other In containing compound semiconductors. However, a further reduction of the ~2 ppm Al contamination level is required for making the electrorefined In a useful source material for epitaxial growth processes.

Cyclic Voltammogram of Formaldehyde and Its Related Species in Electroless Copper Solution

Thomas M. Tam*

Lockheed Missiles and Space Company, Incorporated, Sunnyvale, California 94086

ABSTRACT

The cyclic voltammetric method that allows the evaluation of formaldehyde concentrations in electroless copper solution is described. In this study, evidence is provided to show that methylene glycolate anion and its copper (II) complex are electroactive species in the solution. These species give a peak centered around $-0.25\text{V vs. Ag/AgCl}$. It is also proposed that this technique can easily be integrated into a remote monitoring system.

Electroless copper plating solutions are widely used in the fabrication of printed circuit boards. This solution has three critical chemical components requiring control: the copper concentration, the formaldehyde concentration, and the alkalinity of the solution. The goal of this study is

* Electrochemical Society Active Member.

to identify chemical probes that will allow monitoring of these parameters via a computer control system. The ideal probes are those that can measure the process solution *in situ*. For an electroless copper solution, it was found that the concentration of copper and alkalinity can be conveniently measured by color and pH probes. How-

ever, no probe is available to measure formaldehyde in this solution.

Recently, there have been a few publications discussing the cyclic voltammetric method for studying the chemistry of electroless copper plating solution (1-4). These authors were able to identify voltammetric peaks that could be assigned to formaldehyde. Some of these voltammograms were either too complicated or lacking in quantitative data and therefore unsuitable for our purpose. It was found that by using a rotating platinum working electrode and scanning the voltage within a narrow range (i.e., -0.60 to $+0.8V$), an anodic peak is obtained and can be assigned to formaldehyde. Data are presented in this paper that validate assignments of this peak to formaldehyde and related species.

Experimental

Solutions.—The sample solution used in this study was a one-month-old Shipley electroless copper solution obtained from the plating shop. This was originally prepared by using Shipley's Cuposit 328A, S, and Y solutions² (Shipley Company, Incorporated). The purpose in using this solution is that the results can be directly applied to a production solution.

For experiments where the formaldehyde was the variable, 80 ml of the process solution was diluted to 100 ml by using varying amounts of Shipley 328S and deionized water.

For experiments where copper (II) is the variable, copper sulfate (2-10 g/l) and a constant weight of Rochelle salt (25 g/l) were added to 20 ml process solution. An appropriate amount of Cuposit 328S was added to adjust the concentration of formaldehyde to 0.1-0.2M. These solutions were then diluted to 100 ml.

The pH of these solutions was adjusted using either concentrated H_2SO_4 or NaOH solutions.

Analysis of the solution.—The total concentration of formaldehyde, $[\Sigma CH_2O]$, was obtained using a procedure recommended by Shipley (5). The total copper concentration was obtained by iodometric titration (6) and is represented by $[\Sigma Cu(II)]$.

The pH of these solutions was adjusted using either concentrated H_2SO_4 or NaOH solutions.

Cyclic voltammetric measurements.—A 200 ml Brinkmann titration vessel was used to hold the working, auxiliary, and reference electrodes. The working electrode was prepared by pressing a 1/8 in. diam platinum rod into a 3/8 in. diam stainless steel rod. The electrode body was sealed using Microstop (Michigan Chrome and Chemical Corporation). The exposed platinum surface was polished with 600 grit silicon carbide grinding paper. A Dietzen motor equipped with a rotating mercury contact (Mercotac Incorporated) was used to rotate the electrode. The auxiliary electrode used was a piece of 1/6 in. diam copper wire, and the reference electrode was a gel-type double junction Ag/AgCl electrode (Graphic Control). The potential was driven by a cyclic voltammetric unit. A Soltec X-Y recorder (UP6432S) was used to record the voltage and current change, and the potential was scanned between -0.6 and $+0.8V$ at a rate of 40 mV/s.

Curve analysis.—Intensity of the peak at $-0.25V$ was obtained by integrating the area under the recorded curve. If the scan rate in obtaining the voltammogram is known, the time element (seconds) along the X-axis can be determined. The current at a given time gives the total number of coulombs, Σq , which is proportional to the concentration of electroactive species of interest. The cyclic voltammetric system currently used does not have an integrator. To obtain the area, the voltammogram obtained from the X-Y chart recorder is photocopied. On the photocopied voltammogram, a base line was drawn to

connect the minima at -0.15 to $-0.45V$. The peak was then cut out along the trace and weighed. Using a proportionality factor, the weight was then converted to Σq .

Results

Separate voltammograms of electroless copper solutions have been published (1, 2, 4). The peaks of these voltammograms are due to the plating of copper onto the electrode surface during cathodic scan, and to the reduction of copper to its oxide during anodic scan (7, 8). In addition, there are peaks that can be assigned to formaldehyde. These formaldehyde peaks seem to be affected by copper plated on the electrode surface; therefore, they are difficult to use for quantitative data. It was found by using a platinum electrode and scanning the voltage in a narrower range ($-0.6-0.8V$) that copper will not deposit on the electrode surface. As a result, a relatively clean voltammogram, as shown in Fig. 1, was obtained. When the voltage is scanned in a cathodic direction, a single sharp peak centered at -0.20 to $-0.25V$ is observed, and will be designated as peak A. If the voltage is scanned beyond the mixed potential ($-0.70V$), copper deposition will result (9, 10).

On the anodic scan, a different broad-band centered around $+0.2V$ is also observed. For a freshly prepared solution, this broad-band's intensity is rather high. As the solution is left to stand for a period of time (e.g., overnight), the intensity of the band decreases significantly. This band could be due to oxidation of formaldehyde and is inhibited by the formation of platinum oxide (3, 11). This change has no effect on peak A. The intensity of peak A depends upon the total concentration of formaldehyde, $[\Sigma CH_2O]$, copper, $[\Sigma Cu(II)]$, and the pH of the solution. By varying one of these parameters at a time, a series of quantitative data have been obtained. With this data, we attempt to assign peak A to specific electroactive species that are related to formaldehyde.

Intensity of peak A vs. $[\Sigma CH_2O]$ and pH.—In this study, the sample solution was a one-month-old electroless solution obtained from the plating shop. Peak intensity, Σq , can be obtained by keeping the pH and $[\Sigma Cu(II)]$ of the solution constant. The $[\Sigma CH_2O]$ can be varied by adding concentrated CH_2O solution (Cuposit 328S) to the electroless copper solution. The intensity of the peak increases linearly with respect to $[\Sigma CH_2O]$. Figure 2 shows three examples where the pH of the solutions were maintained at 11.82, 12.28, and 12.51. When pH of the solution is changed, the linear relationship of the two parameters still exists, but the slope of the straight line, S , changes. Also note that none of the straight lines can be extrapolated to a zero intercept. The intercepts, I , are dependent upon the change in pH of the solution. The values of I and S at different $[OH^-]$ (calculated from pH measurements) are shown in Table I. By plotting S^{-1} vs. $[OH^-]^{-1}$,

Fig. 1. Cyclic voltammogram of methylene glycolate and related copper (II) species in electroless copper solution. $[\Sigma Cu(II)] = 0.039M$; $[\Sigma CH_2O] = 0.23$; pH = 12.30. Sweep rate = 40 mV/s; rotational speed = 3000 rpm; temperature = $23^\circ \pm 1^\circ C$.

¹All voltages reported herein are with respect to Ag/AgCl reference electrode.

²Cuposit 328: (A) concentrated copper and formaldehyde solution; (S) concentrated formaldehyde solution; (Y) concentrated alkaline solution.

Fig. 2. Dependence of peak A's intensity of $[\Sigma \text{CH}_2\text{O}]$ and pH. Experimental conditions are given in Fig. 1.

a linear relationship is observed (see Fig. 3). These results can be represented by a general equation

$$\Sigma q = \frac{C_a Q_1 [\text{OH}^-]}{1 + Q_1 [\text{OH}^-]} [\Sigma \text{CH}_2\text{O}] + I \quad [1]$$

The principal species of formaldehyde dissolved in aqueous medium is methylene glycol, $\text{CH}_2\text{O}_2\text{H}_2$. In alkaline medium, methylene glycol will dissociate to methylene glycolate, (a) (12)

$$Q_1 = \frac{[\text{CH}_2\text{O}_2\text{H}^-]}{[\text{CH}_2\text{O}_2\text{H}_2][\text{OH}^-]} \quad [2]$$

$$[\Sigma \text{CH}_2\text{O}] = [\text{CH}_2\text{O}_2\text{H}_2] + [\text{CH}_2\text{O}_2\text{H}^-] \quad [3]$$

The value Q_1 is the equilibrium quotient for reaction [A]. Equation [3] is the mass balance equation for $[\Sigma \text{CH}_2\text{O}]$. The other terms in Eq. [2] and [3] are the equilibrium concentration of methylene glycol and methylene glycolate (a) that exist in the solution described by reaction [A]. Species a has been proposed as the electroactive

species in several other studies (4, 13). In this case, it is also proposed as one of the electroactive species that give rise to peak A. The Σq value measured can therefore be expressed by Eq. [4]

$$\Sigma q = C_a(a) + I \quad [4]$$

where C_a is the apparent proportionality constant describing the sensor parameters (*e.g.*, stirring and scan rate, surface area, etc.) and other solution matrix properties (14). In this study, these parameters were held constant. Equations [2], [3], and [4] can be used to derive Eq. [1], which describes the linear relation of Σq vs. $[\Sigma \text{CH}_2\text{O}]$ (Fig. 2) at constant $[\Sigma \text{Cu(II)}]$ and pH. The slope of the plot, $S = C_a Q_1 [\text{OH}^-] (1 + [\text{OH}^-]^{-1})^{-1}$, is pH dependent. The inverse of S gives Eq. [5], which can be used to describe the plot shown in Fig. 3

$$\frac{1}{S} = \frac{1}{C_a Q_1 [\text{OH}^-]} + \frac{1}{C_a} \quad [5]$$

From this plot, the slope $(C_a Q_1)^{-1}$ and intercept C_a^{-1} are $0.48 \text{ C}^{-1}\text{M}^2$ and $2.39 \text{ C}^{-1}\text{M}$, respectively. From these two values, the equilibrium quotients, Q_1 for reaction [A] can be calculated to be 50M^{-1} at 23°C . By using this value, the dissociation quotient for $\text{CH}_2\text{O}_2\text{H}_2$ is found to be $5.0 \times 10^{-13}\text{M}^{-1}$. Table II shows the same quotient determined by different workers.

The intercept I , from Eq. [1], first increases and passes through a maximum (pH = 12.53), then decreases as a function of pH. The change in the estimated surface concentration of formaldehyde (17) and the plating rate of electroless copper solution (18-20) with respect to pH behave in a similar fashion.

Intensity of peak A vs. $[\Sigma \text{Cu(II)}]$.—The dependence of Σq upon $[\Sigma \text{Cu(II)}]$ has also been studied. To isolate the ef-

fect of $[\Sigma \text{Cu(II)}]$, Eq. [6] as used to correct the effect of $[\text{OH}^-]$, $[\Sigma \text{CH}_2\text{O}]$, and residual I value

$$C_a = (\Sigma q - 1) \frac{1 + Q_1 [\text{OH}^-]}{Q_1 [\text{OH}^-] [\Sigma \text{CH}_2\text{O}]} \quad [6]$$

The values for C_a were determined with $[\Sigma \text{CH}_2\text{O}]$ maintained at 0.1M, 0.2M, and pH 12.5. The copper concentration, $[\Sigma \text{Cu(II)}]$, was varied from 0.01M to 0.10M by adding CuSO_4 and sodium tartrate salt to diluted electroless copper solutions. The value C_a decreases as $[\Sigma \text{Cu(II)}]$ increases and levels off at high $[\Sigma \text{Cu(II)}]$. A straight line is obtained by plotting $C [\Sigma \text{Cu(II)}]^{-1}$ vs. $[\Sigma \text{Cu(II)}]^{-1}$, as shown in Fig. 4. The equation that describes the plot is

$$\frac{C_a}{[\Sigma \text{Cu(II)}]} = \frac{C_1}{[\Sigma \text{Cu(II)}]} - C_2 \quad [7]$$

where $C_1 = 5.2 \times 10^{-2} \text{ C} \cdot \text{M}^{-1}$ and $C_2 = 4.6 \times 10^{-1} \text{ C} \cdot \text{M}^{-2}$. The change in shape of peak A with respect to $[\Sigma \text{Cu(II)}]$ is shown in Fig. 5. Notice that at low copper concentration, peak A is an asymmetric peak [Fig. 5(a)], which is similar to that of CH_2O in basic tartaric salt solution. But when $[\Sigma \text{Cu(II)}]$ is increased, peak A becomes more of a symmetric peak [Fig. 5(c)].

These results can be explained as follows. When copper (II) is dissolved in alkaline solution containing tartrate ion ($\text{C}_4\text{H}_2\text{O}_6^{-2} = \text{L}$), monomeric and dimeric species will form, e.g. $\text{L}_2\text{Cu(II)}$, LCu(II)(OH)_2 , and $\text{L}_2\text{Cu(II)}_2$ (21, 22). Within the pH range (11.4-12.9) of this study, the principal species is LCu(II)(OH)_2 (4, 18). The LCu(II)(OH)_2 species can react with methylene glycolate to give complex (b)

Schoenberg (18) has shown by using EPR and spectrophotometric techniques that (b) is a stable complex in the solution. Byerly has also proposed this complex as a reaction intermediate for the reduction of Cu(II) by formaldehyde (23). We are proposing that species (b) is also an electroactive species. At low $[\Sigma \text{Cu(II)}]$, the principal electroactive species is methylene glycolate, (a). As $[\Sigma \text{Cu(II)}]$ increases, (a) is being replaced by (b). The proportional constant of species (b) is smaller than that of (a). This will cause the apparent proportional constant, C_a , to decrease (Eq. [7]). This rationale is consistent with the change in shape of peak A observed Fig. 5.

Conclusion

In this report, the cyclic voltammetric technique was used to study the electroless copper solution. Quantita-

Fig. 5. Change in the shape of peak A with respect to $[\Sigma \text{Cu(II)}]$. (a) $[\Sigma \text{Cu(II)}] = 0.016\text{M}$; (b) 0.029M ; (c) 0.069M . $\text{pH} = 12.51 \pm 0.04$.

tive data have been obtained to show that the peak at -0.25V depends upon $[\Sigma \text{CH}_2\text{O}]$, $[\Sigma \text{Cu(II)}]$, and pH of the solution. For the present moment, peak A is assigned to methylene glycolate, a, and its copper (II) adduct, b. This proposal most likely is oversimplified, but, nevertheless, it is consistent with the data presented thus far.

Use of different types of electrochemical measuring systems as remote sensors have been suggested elsewhere (17, 24). The cyclic voltammetric technique used in this work is easy to operate and can be integrated into a remote monitoring system. The apparatus described has been used to measure the formaldehyde concentration in the shop solutions for more than 2 months. The only precaution required was to rinse and soak the electrodes in deionized water after they were used. The accuracy of the data is estimated to be $\pm 13\%$. Because of these advantages, this technique offers another possibility of measurements *in situ*.

ABSTRACT

Recently, an experimental method was introduced which allows photoelectrochemical studies of nearly intrinsic semiconductors. In this simple technique, subbandgap illumination is used to make the bulk material photoconductive. A corresponding model explains this behavior in terms of a potential distribution which is similar to that of a doped semiconductor. The method allows one to predict whether the time consuming process of chemical doping, for applications such as photoelectrolysis, is worth undertaking. The model proposed relies heavily on the photoconductivity of the insulator. We have now been able to observe the effect even on a number of very poor photoconductors, such as layered chalcogenides SnS_2 , $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$, MnPS_3 ($M = \text{Cd}, \text{Mn}$). In the case of SnS_2 , we can compare the photoelectrochemical studies of undoped semiconductors with chemically doped semiconductors. Furthermore, we find that the response at high photon energies caused by the subbandgap illumination scales indeed with the photoconductivity of the high resistivity semiconductors, lending additional support for the model.

Photoelectrochemical investigations of undoped semiconductor electrodes are often hampered by extremely low quantum yields. The photocurrent response to monochromatic light is usually limited to a narrow spectral region near the absorption edge. For charge carriers created in the vicinity of the electrode surface by strongly absorbed photons, the internal electric fields are not sufficiently strong to provide an efficient separation of the electron-hole pairs. Recently, it has been shown (1, 2) that irradiation of the electrode with a light source providing photon energies in the range of the bandgap may drastically change the properties of the insulator-electrolyte interface. This subbandgap illumination can enlarge the spectral response due to a second monochromatic light source by several orders of magnitude, even for wavelengths much shorter than the absorption edge. A simple model (1, 2) explains this behavior as a change of the potential distribution in the electrode: the bulk of the insulator electrode gets photoconductive by irradiation with weakly absorbed light and the resulting potential distribution resembles that of a doped semiconductor.

The effect of a background illumination which induces a higher injection rate of carriers has been used for more than 10 years (3, 4). But usually only relatively highly doped semiconductors were examined.

In this paper, we show that this double-beam technique can be applied to rather poor photoconductors such as SnS_2 , $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$, MnPS_3 , and CdPS_3 . These materials crystallize in a layered crystal structure of hexagonal (SnS_2 , $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$) or rhombohedral (CdPS_3 , MnPS_3) symmetry, respectively (5, 6). The bonding between layers is weak compared to the intralayer forces, the latter being predominantly of covalent character.

Taking SnS_2 as an example, we demonstrate a close relationship between the photocurrent spectra of doubly illuminated high resistivity electrodes and chemically doped electrodes.

In addition to the photoelectrochemical measurements the bandgaps were determined by standard optical techniques.

Crystal Growth

Single crystals have been grown from the elements or from the prereacted compounds by the chemical vapor

transport reactions, with iodine as transport agent and in presence of excess chalcogen. The growth temperatures of the crystals were between 590° and 680°C and the temperature of the source material between 620° and 710°C. The temperature difference between the two ends of the crucible about 15 cm in length did not exceed 30°C. In the case of the doped sample $\text{SnS}_2\text{:Ga}$, the compound was sublimated several times from one end of the ampulla to the other before the last growth transport, in order to homogenize the impurity distribution in the crystals. Typical samples were checked by x-ray diffraction tests.

Electrode Preparation, Photoelectrochemical Cell, and Experimental Setup

All crystals were mounted on brass in Teflon cylinders with conducting silver paint. The edges of the crystal plates were protected with epoxy. In all cases, the surface perpendicular to the c-axis was exposed to the solution. The aqueous electrolytes used were 1M HCl, 1N H_2SO_4 , 1M NaOH, or 1M Na_2S , as indicated in the figure captions. The photoresponse for all electrodes was measured using a standard three-electrode cell: a working electrode, a saturated calomel electrode (SCE) as a reference, and a platinum wire as counterelectrode. For the potential control of the highly resistive electrodes an ordinary power supply was used. The doped SnS_2 electrodes were controlled potentiostatically with the disk circuit of a Tacussel bipotentiostat. The working electrode was arranged in such a way that simultaneous irradiation by two light sources was possible. Monochromatic illumination was provided by a tungsten-halogen lamp (12V, 55W) filtered through a Zeiss M4G II single prism monochromator. This radiation was chopped at 150 Hz and the photocurrent response was measured with standard lock-in techniques. Subbandgap illumination was achieved with unchopped radiation using a 150W Xe lamp and a Schott filter with an absorption edge just below that of the crystals.

Results and Discussion

Solid-state properties.—All undoped crystals have resistivities larger than $10^7 \Omega \text{ cm}$ at room temperature (7). In Table I are given the approximate values of the bandgap energies ($E_{\text{gap}} + E_{\text{phonon}}$), obtained by plotting the

Table I. Approximate value of the bandgap energy derived from optical measurements

	$E_{\text{gap}} + E_{\text{phonon}}$ (eV)
SnS_2	2.14 ± 0.02
$\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$	1.98 ± 0.02
CdPSe_3	2.27 ± 0.03
MnPSe_3	1.87 ± 0.03
$\text{Sn}_{1-x}\text{Ga}_x\text{S}_2$ ($x = 0.001$ nom.)	2.19 ± 0.02

square root of the absorption coefficient α vs. the photon energy (all transitions are indirect). The expected kink in the $\sqrt{\alpha}$ curve could not be observed because all investigated layered crystals were too thin. Therefore, the phonon energy E_{phonon} could not be determined.

Photoelectrochemical measurements.—It is a characteristic feature of high resistivity semiconductor electrodes that the response to monochromatic illumination is usually limited to a small spectral region near the absorption edge.

The magnitude of the photoresponse strongly depends on the photoconductivity of a sample. In fact, it will be shown below that the photoconductivity of all our samples is rather poor. As an example, for a ternary compound exhibiting all the salient features of such a poor photoconductor we show in Fig. 1, the photocurrent-potential curves for a cathodically polarized CdPSe_3 electrode in 1M HCl. For strongly absorbed monochromatic illumination, i.e., $E_{\text{photon}} = 2.70$ eV, which is far above the adsorption edge ($E_{\text{gap}} \sim 2.27$ eV), the photocurrent remains extremely small up to the highest electrode potential (Fig. 1, lower curve). When the electrode is in addition illuminated with subbandgap light (Xe radiation, Schott filter OG530, corresponding to a cutoff around of 2.3 eV) the photocurrent increases dramatically (Fig. 1, upper curve). The magnitude of the enhancement strongly depends on the ratio of the intensities of subbandgap to monochromatic illumination. Towards high values of this ratio, a saturation of the enhancement is commonly observed (see also Fig. 4 below). The dark current was much smaller than 1 nA, just as for all other cases considered below.

With and without subbandgap illumination the photocurrent-potential curves are practically linear up to the highest applied potential (Fig. 1). The same has been found for all high resistivity materials investigated in this work. Furthermore, the photocurrent-potential curves are symmetrical for anodic and cathodic polarization. The infrared part of the subbandgap spectrum affects the enhancement very little. This is revealed most clearly by the strong dependence of the enhancement on the cutoff

Fig. 1. Photocurrent-potential curves for a CdPSe_3 -electrode in 1M HCl, cathodic polarization. For the lower curve, the electrode was illuminated with chopped monochromatic light ($E_{\text{photon}} = 2.64$ eV) alone, whereas for the upper one both light sources (steady-state subbandgap radiation with a cutoff energy of about 2.3 eV) were used. The dark current was negligible.

Fig. 2. Spectral dependence of the quantum yield for a CdPSe_3 electrode in 1M HCl with monochromatic illumination alone (curve a) and with additional subbandgap radiation ($E_{\text{photon}} < 2.34$ eV, curves b and c). Curve b corresponds to an anodic ($+100$ V_{SCE}) and curve c to a cathodic bias (-100 V_{SCE}). In the case of monochromatic illumination alone, the quantum yields for anodic and cathodic polarization coincide (curve a, ± 100 V_{SCE}).

filter. The use of filters with cutoff energies far below the absorption edge of the electrode does not lead to an increase of the response at high energy.

The quantum yield spectra for CdPSe_3 are shown in Fig. 2 with monochromatic illumination alone (curve a) and with additional subbandgap illumination (curves b and c). In the latter case curve b is for anodic polarization ($+100$ V_{SCE}) while curve c represents cathodic polarization (-100 V_{SCE}). For monochromatic illumination alone the curves for anodic and cathodic polarization coincide. The most remarkable feature of Fig. 2 is the huge increase of the blue response ($E_{\text{photon}} > 2.6$ eV) upon illumination of the electrode by subbandgap radiation (compare Fig. 1). In addition the photoconductivity is enhanced by roughly a factor of two at 2.4 eV. Qualitatively the behavior of CdPSe_3 is thus similar to that one of the much better photoconductor HgI_2 apart from the asymmetry between anodic and cathodic polarization for the latter (2). In fact for CdPSe_3 the symmetry is not completely achieved either when subbandgap irradiation is employed (Fig. 2, curve b and c). This might be due to increased surface recombination for short wavelengths in the cathodic case. For all other high resistivity materials considered below the symmetry is even more pronounced. This indicates that electron and hole mobilities parallel to the c-axes are of the same order of magnitude in these compounds. As an example we show the quantum yield spectra of pure SnS_2 in 1M HCl (Fig. 3). The curves are labeled in the

Fig. 3. Quantum yield spectra of SnS_2 in 1M HCl with monochromatic illumination alone (curve a, ± 10 V_{SCE}) and with subbandgap radiation (cutoff energy of about 2.18 eV) for anodic polarization ($+10$ V_{SCE}, curve b) and cathodic polarization (-10 V_{SCE}, curve c), respectively.

Fig. 4. Spectral dependence of the quantum yield for an $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$ electrode for various intensities of the subbandgap illumination (cutoff energy ~ 2.03 eV). Electrode potential $2 V_{\text{SCE}}$, electrolyte $1M \text{Na}_2\text{S}$. Curve 1: Monochromatic illumination alone. Curve 2: Subbandgap radiation filtered with 0.001 neutral-density filter. Curve 3: Subbandgap radiation filtered with 0.01 neutral-density filter. Curve 4: Subbandgap radiation filtered with 0.05 neutral-density filter. Curve 5: Subbandgap radiation filtered with 0.1 neutral-density filter. Curve 6: Subbandgap radiation filtered with 0.5 neutral-density filter. Curve 7: Subbandgap radiation filtered with 0.708 neutral-density filter. Curve 8: Subbandgap radiation with full Xe-lamp intensity.

same way as in Fig. 2. In contrast to the quantum yield spectra of CdPSe_3 however, the electrode potential was only $\pm 10 V_{\text{SCE}}$. It has to be borne in mind that neither Fig. 2 nor Fig. 3 represent limiting quantum yields since no saturation of the photocurrent-potential curves is observed. We believe that the lack of saturation in the photocurrent *vs.* potential is a direct consequence of the small photoconductivity encountered in these materials. The high bulk recombination rate thus prevents the establishment of a sufficient space-charge layer which would in turn lead to an efficient carrier separation. Nevertheless, it appears that the generation of charge carriers by subbandgap illumination is high enough to yield a substantial increase of the blue response, even in the poor photoconductors considered in this work. This is true only for sufficient intensities of the subbandgap radiation. Taking as an example an $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$ electrode in $1M \text{Na}_2\text{S}$, the dependence of the quantum yield spectra on the intensity of the subbandgap radiation is plotted in Fig. 4. Qualitatively, the behavior is the same as for pure SnS_2 . Intensities are given in arbitrary units. The blue response becomes larger the larger the intensity, showing saturation for the highest values of the latter. This can be seen more clearly in Fig. 5, in which the quantum yield is plotted against the intensity of the subbandgap illumination (for various photon energies of the monochromatic radiation) on a double logarithmic scale.

The behavior of MnPSe_3 is entirely similar to that one of the other materials described above.

In order to show that the spectral response of doubly illuminated high resistivity semiconductor electrodes resembles that one of chemically doped semiconductor electrodes, we compare the behavior of pure SnS_2 with that one of gallium-doped SnS_2 . Surprisingly, Ga doping (nominal 0.1%) leads to an increase of the bandgap by 0.05 eV (Table I) compared to pure SnS_2 . Furthermore, the n-type behavior (Fig. 6) indicates that Ga is not incorporated into Sn sites as a trivalent dopant. The actual donor concentration, which is not known at present, will be determined in a forthcoming publication.

In Fig. 6, the current-potential curves are represented for an SnS_2 photoanode in the dark and with monochromatic illumination ($E_{\text{photon}} = 3.1$ eV) of approximately $60 \mu\text{W}/\text{cm}^2$. The reverse dark current is negligible up to $3 V_{\text{SCE}}$. Photocurrent onset is around $0.4 V_{\text{SCE}}$. The saturation of the photocurrent for anodic potentials is relatively

Fig. 5. $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$: Quantum yield *vs.* intensity of the dc subbandgap illumination (cutoff energy ~ 2.03 eV) for various photon energies of the chopped monochromatic beam. Intensities are given in units of the full Xe-lamp intensity I_0 . Curve a: 2.15 eV. Curve b: 2.3 eV. Curve c: 2.5 eV. Curve d: 2.9 eV. Electrode potential $2 V_{\text{SCE}}$, electrolyte: $1M \text{Na}_2\text{S}$. Plotted lines are a guide for the eye.

slow indicating a rather low doping. The quantum yield spectrum (uncorrected for reflection) of a Ga-doped SnS_2 electrode is shown in Fig. 7. The shape of the photoresponse is virtually identical to that one of the undoped electrode in Fig. 3. The absolute magnitude of the response, however, is much larger, approaching 100% at 3.1 eV if reflection losses are taken into account. The electrolyte was $1M \text{Na}_2\text{S}$ in this case. The use of this electrolyte resulted in a much better output stability for the higher photocurrent densities at the doped electrodes (see also below). The indirect nature as well as the value of the bandgap are nicely confirmed in Fig. 8, in which both $\sqrt{\Phi \cdot h\nu}$ and $\sqrt{\alpha \cdot h\nu}$ are plotted against the photon energy. Φ and α are the quantum yield and adsorption coefficient, respectively. It should be remarked that, in accordance with Ref. (8), our data do not permit an unambiguous distinction between an indirect allowed and an indirect forbidden transition. In the latter case, a plot of the cube root of the absorption coefficient *vs.* photon energy should yield a straight line. The square root fit shown in Fig. 8 does represent our data somewhat better.

Photocorrosion.—In the dark the investigated materials were stable in all used electrolytes. The photocurrent of all investigated semiconductors was accompanied by obvious decomposition of the electrode, particularly at high irradiation intensities. For the high resistivity semiconductors [SnS_2 , $\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$, CdPSe_3 , MnPSe_3] and for

Fig. 7. Quantum yield spectrum of a doped SnS_2 electrode. Electrode potential 2 V_{SCE} . Electrolyte: $1 \text{ M Na}_2\text{S}$.

Fig. 8. Ga-doped SnS_2 : Dependence of $\sqrt{\Phi \cdot h\nu}$ (Φ = quantum yield, $h\nu$ = photon energy) and $\sqrt{\alpha \cdot h\nu}$ (α = absorption coefficient) on the photon energy. The linear behavior indicates an indirect bandgap [i.e., $\sqrt{\alpha} \propto (h\nu - E_{\text{gap}} - E_{\text{phonon}})$]. Same electrolyte and potential as in Fig. 7.

chemically doped SnS_2 the light induced decomposition was very rapid.

In the case of SnS_2 , an anodic photocurrent leads to the formation of a yellow layer (probably sulfur), accompanied by a decrease of the photocurrent. For this compound the thermodynamic data are available (9-12), assuming the reaction

the anodic decomposition potential is calculated to be $V_{\text{dec}}^{\text{an}} \approx 0.14 \text{ V}_{\text{SCE}}$. For cathodic decomposition, we obtain $V_{\text{dec}}^{\text{cath}} \approx -0.005 \text{ V}_{\text{SCE}}$ from

at pH 0.

For anodic polarization addition of Na_2S to the electrolyte leads to a stable photocurrent for small light intensity

whereas the elemental sulfur is dissolved by the polysulfide electrolyte.

Discussion.—All high resistivity semiconductors investigated to date, appear to have the following common photoelectrochemical characteristics: (i) for monochromatic illumination alone, the photocurrent response is limited to weakly absorbed radiation, (ii) for photon energies far above the absorption edge, a significant photocurrent is obtained only when the electrode is simultaneously illuminated with a second light source,

Table II. Relation between the photoconductivity and the enhancement of the blue response due to additional subbandgap irradiation

	Φ/Φ'
SnS_2	0.1
$\text{Sn}(\text{Se}_{0.1}\text{S}_{0.9})_2$	0.1
CdPSe_3	0.3
MnPSe_3	0.1
HgI_2 (2)	0.5
GaS (1)	0.1

Φ : Maximum quantum yield at the photoconductivity peak (see, e.g., curves a and b in Fig. 2 and 3).

Φ' : Maximum quantum yield in the presence of subbandgap illumination. Average values of up to five samples were used. Individual measurements may differ by as much as a factor of 10 without a change of Φ/Φ' .

providing photon energies in the range of the bandgap, (iii) for an optimum enhancement of the blue response, a high enough intensity of the subbandgap illumination is necessary. Furthermore, the correct choice of the high energy cutoff of the latter may be crucial.

All these features are well explained by the model outlined in detail in Ref. (2). The model explains the observed enhancement of the photoresponse in terms of a change of the potential distribution in the electrode by photoexcited bulk carriers. As a consequence, the model predicts a strong dependence of the effect on the photoconductivity of a sample. This can be verified indeed by comparing the materials investigated in this work with the much better photoconductors GaS , CdS (1), and HgI_2 (2). Qualitatively, the effect of the subbandgap illumination on the photocurrent spectra is quite similar in all these cases. This has to be contrasted with the much lower absolute quantum yields of our materials, even at a bias short of electric breakdown (see, e.g., Fig. 2). There is thus an obvious correlation between the height of the photoconductivity peak Φ (curve a in Fig. 2 and 3) and the maximum quantum yield Φ' , which can be obtained for photon energies far above the absorption edge in the presence of suitable subbandgap illumination (curves b and c in Fig. 2 and 3, as well as top curves in Fig. 4). In order to put this statement in a more quantitative form, the ratio between these two quantities, Φ/Φ' , is given in Table II for several different semi-insulating electrode materials. Evidently, this number is very nearly the same for all materials. In particular, it is practically independent of the shape of the photocurrent-potential curves. However, the absolute magnitude of the quantum yields Φ' , taken at the same bias,¹ differs by as much as a factor of 2000!

These results thus give conclusive evidence that the induced photoresponse far above the absorption edge indeed scales with the photoconductivity. Another important result is the striking similarity of the photoresponse spectra for undoped, doubly illuminated SnS_2 (Fig. 3) and Ga doped SnS_2 (Fig. 7). Apart from the differences in scale, the spectra are virtually identical. This then leads to the conclusion, that the double-beam technique described above can be used to extract valuable information, such as bandgaps and spectral response curves from high resistivity electrodes, which is relevant for the doped counterparts as well. In other words, the method can be applied for a rapid scan of materials properties which are important for photoelectrochemical applications. It has been demonstrated that while the materials do have to show some photoconductive response, the method is by no means limited to good photoconductors.

¹ The quantum yields Φ' are difficult to compare in view of the gross differences of the photocurrent-potential curves for different materials. For HgI_2 (2) and CdS (1), the photocurrent-potential curves saturate at moderate potentials, while, e.g., for CdPSe_3 , a linear behavior is observed up to 100V. There is no doubt, however, that the quantum yields for the compounds listed in Table II differ enormously in the bias range accessible to the experiment.

Influence of Electrolyte Concentration on the Anodization and Breakdown Characteristics of Ta₂O₅ Films

I. Montero, J. M. Albella, and J. M. Martínez-Duart

Instituto de Física del Estado Sólido, CSIC and Departamento Física Aplicada, Universidad Autónoma Cantoblanco, 28049 Madrid, Spain

ABSTRACT

Voltage-time anodization curves, breakdown voltages, and I-V characteristics have been measured in Ta₂O₅ films grown in oxalic and phosphoric acid electrolytes. The results have been interpreted in terms of a simple avalanche model for the electronic current. The origin of the primary electrons of the avalanche is attributed to the electrolyte species incorporated into the oxide during the anodization process.

The anion incorporation from the electrolyte into the oxide during the anodization process is known to exert a strong influence on the physical and chemical properties of the films. Among others, increasing the concentration of phosphate ions into the Ta₂O₅ films lowers its density (1), permittivity (2), refractive index, and ionic conductivity (3), and, on the contrary, it increases the rate of growth and the electric field present during the anodization (4). Similarly, it is well known that the concentration of the anodization electrolyte plays a significant role in determining the breakdown voltage during the anodic oxidation (5).

In a previous paper (6), we applied a simple avalanche model, proposed by Ikonopisov (7), to explain the breakdown characteristics of the Ta₂O₅ films grown in a H₃PO₄ electrolyte at different current densities. From the results of that work, we concluded that the primary electron current of the avalanche is most likely originated in the anions incorporated into the oxide. Within the framework of this hypothesis, it was assumed that the anions act as donor levels in the oxide energy gap releasing electrons to the conduction band as a consequence of the strong anodization field. Once in the conduction band, the electrons can be accelerated and multiplied in an avalanche mechanism along the oxide thickness. The breakdown then occurs when the avalanche, and hence the thickness, reaches a critical size. Thus, in this picture, the breakdown characteristics are directly associated with the electrolyte anions incorporated into the oxide during the anodization process.

In this paper, we further investigate the influence of the incorporated anions in the electrical properties of the resulting oxide by anodizing the tantalum in electrolytes with different concentrations. We have used two kinds of electrolytes, phosphoric acid, which is known to result in a high anion incorporation into the oxide (8), and oxalic acid, which produces a negligible anion incorporation (9).

*Electrochemical Society Active Member.

Experimental

Tantalum samples of 99.96% nominal purity, supplied by Reframet Hoboken, were anodized in different electrolytes at a constant current density ($j_t = 0.85 \text{ mA cm}^{-2}$). The samples were previously cleaned and chemically polished following standard treatments (10). During the anodization, the samples were mounted in a special holder which only exposed to the electrolyte a circular area of $1.18 \pm 0.04 \text{ cm}^2$ of the sample (6). The temperature of the cell was kept constant at $20^\circ \pm 0.2^\circ\text{C}$ by means of a thermostatic bath.

The voltage-time curves during anodization, $V = V(t)$, as well as their derivatives, dV/dt , were recorded by means of a data acquisition system based on the HP 3497A digital voltmeter (input impedance $> 10^9 \Omega$) and the HP 85 microcomputer. The leakage current after anodization and the current-voltage (j-V) characteristics were measured by means of an electrometer with an input impedance of $10^9 \Omega$. Other experimental details can be found elsewhere (6).

Results

Figure 1 shows the values of the time derivative of the voltage per unit current density, j_t , as a function of the anodization voltage for different molar concentrations of the H₃PO₄ electrolyte. A slight decrease in the value of $(1/j_t)(dV/dt)$ is observed as the anodization voltage V increases. However, when the breakdown voltage is reached, the derivative abruptly decreases approaching zero (not shown in the figure). Increasing the electrolyte concentration produces a shift of the curves towards higher values of the derivative in agreement with previous observations by Amsel *et al.* (11) and Randall (2). Anodization in oxalic acid gives similar results, although in this case the influence of the electrolyte concentration on the derivative curves is much smaller than in phosphoric acid. Figure 2 presents the results of the breakdown voltage—defined by the voltage in which the anod-

Fig. 1. Anodization rate per unit current density as a function of the anodization voltage for different molar concentrations of the H₃PO₄ electrolyte.

Fig. 2. Breakdown voltage during anodization as a function of the electrolyte concentration for both the oxalic acid and phosphoric acid.

ization curves of Fig. 1 abruptly change their slope—as a function of concentration of the electrolyte. It is observed that the oxalic acid, the electrolyte which incorporates the least, gives higher breakdown voltages than the phosphoric acid.

The residual leakage current after anodization, *i.e.*, the final current in the constant voltage stage at the end of the anodization, was also recorded. For this purpose, the samples were held in the electrolyte at the formation voltage, until the rate of current decrease was less than 1% in a 10 min interval. This procedure generally took more than 1h. The measured residual currents are given in Fig. 3 as a function of the formation voltage, *V_F*, for two phosphoric based electrolytes of different molarities, 1.0×10^{-2} and 2.2×10^{-3} M. Several aspects can be pointed out from these results. First, the more concentrated electrolyte gives higher currents in the whole range of the anodization voltages. Second, both curves show a linear stage in the logarithmic variation of the leakage current *vs.* the formation voltage.

The conduction mechanism dominating in these films was also investigated by measuring the *j*-*V* characteristics of the system Ta/Ta₂O₅/electrolyte. Only the more resistive samples grown in the 2.2×10^{-3} M H₃PO₄ electrolyte were studied, the measuring electrolyte and cell being the same as those used in the anodization. In that way, polarization and history effects were minimized. In the whole range of the applied fields, *E*, the current decay with time followed a law of the type $j \propto t^{-n}$ with *n* constant ($n \leq 1$), until a stationary value was reached. These values are represented in Fig. 4 in the form of a log (*j*/*E*) *vs.* *E*^{1/2} plot, for several samples grown at different formation voltages.

Fig. 3. Leakage current after anodization *vs.* formation voltage for samples anodized in two H₃PO₄ electrolytes of different concentrations.

Discussion

The analysis of the results has been carried out on the basis of the avalanche model proposed in a previous paper (6). According to this model, during anodization at a constant current density, *j_t*, there exists an avalanche electronic current, *j_e*, which increases exponentially along the oxide thickness, *d*, due to an impact ionization mechanism. Thus, the electronic current at the anode is

$$j_e = j_0 \exp(\alpha d) = j_0 \exp(\alpha \beta V) \quad [1]$$

where α is the impact ionization coefficient and *j₀* is the primary electron current. β is the anodization constant, *i.e.*, the angstrom per volt ratio, and it is equal to the inverse of the anodization field, *E*.

Taking into account the presence of the electronic current, the anodization ionic current, *j_i*, is given by

$$j_i = j_t - j_e = j_t - j_0 \exp(\alpha \beta V) \quad [2]$$

and the rate of voltage growth by

$$\frac{dV}{dt} = K j_i = K [j_t - j_0 \exp(\alpha \beta V)] \quad [3]$$

Fig. 4. Leakage current *vs.* applied field, represented in a Poole-Frenkel plot, for samples grown in a H₃PO₄ electrolyte at different formation voltages.

with K , the unitary anodization rate, expressed by

$$K = \frac{M}{10F\rho} E \quad [4]$$

M being the molecular weight, F the Faraday constant, and ρ the oxide density. By a least squares analysis, we have obtained the parameters K , j_0 , and α which best fit the experimental results of Fig. 1 to the theoretical Eq. [3]. In this way, the solid lines in Fig. 2 represent the theoretical curves obtained by this method.

The relative magnitude of the primary electron current at low voltages, j_0/j_1 , corresponding to each curve of Fig. 1, is presented in Fig. 5 as a function of the electrolyte concentration for both electrolytes, phosphoric and oxalic acids. In the above quotient, j_1 is the extrapolated ionic current density at 0 volts, *i.e.*, from the Eq. [2]: $j_1 = j_i - j_0$. It is observed in Fig. 5 that for the phosphoric acid, j_0/j_1 steadily increases with the mole concentration of the electrolyte, but, for the oxalic acid, j_0/j_1 is nearly constant. Along with these results, Fig. 5 also contains (broken line) the ratio mol P/mol Ta⁵⁺, *i.e.*, the relative phosphorous concentration in the oxide, obtained by Randall *et al.* (8) using radiotracer techniques.¹ It is evident that there exists a strong correlation between the j_0/j_1 curve for the phosphoric acid and the phosphorous concentration, which is consistent with our previous hypothesis of considering the incorporated anions as a source of the primary electrons of the avalanche. According to this mechanism, the anions act as donor levels in the forbidden band of the oxide. In contrast to the phosphoric acid, the oxalic acid is known to produce a negligible incorporation even at high electrolyte concentrations, as measured by ESCA and AES techniques (9). This fact explains the low constant value of j_0/j_1 in the whole range of the oxalic concentration (see Fig. 5).

The impact ionization coefficient of the avalanche is given in Fig. 6 for both electrolytes as a function of their mole concentration. It is observed that α is nearly constant for the oxalic acid except in the high concentration side, where the solution is near saturation. As for the phosphoric acid, the ionization coefficient slightly increases with the electrolyte concentration. Two effects can contribute to this increase in the α values. First is the anion incorporation itself, which can modify the oxide lattice, adding foreign atoms or molecules with a lower ionization potential. Second is the increase in the anodization electric field, which arises as a consequence of the electrolyte incorporation. The larger incorporation of the phosphate, as compared with the oxalate, anions also explains the differences between the corresponding values of the ionization coefficient.

The increase in the anodization field due to the electrolyte incorporation is apparent from the results of Fig. 7, where the electric field, E , has been plotted as a function of the concentration of the electrolyte for both the phosphoric acid and the oxalic acid. Here, the electric field has been obtained from the constant K in Eq. [4]. Owing to the lack of data on the variation of the oxide density with the electrolyte incorporation, it is not possible to give an accurate value of the anodization field. Therefore, a value of $\rho = 8.03 \text{ g cm}^{-3}$ has been used, which corresponds to nearly pure Ta₂O₅ films (1). However, lower values of E would be expected (within about 2% or 3% in the case of the phosphoric electrolyte) if the decrease in ρ for the films grown in the more concentrated electrolytes had been taken into account (1). The influence of the incorporated anions on the anodization electric field has been discussed in another paper and it has been attributed to increase of the energy barrier for ionic transport (12).

The results on the residual leakage current during the constant voltage stage can also be interpreted in the lines of the model, which takes into account the avalanche

¹The ratio mol P/mol Ta⁵⁺ for the whole oxide has been calculated from the reported values of the phosphorous concentration in the outer layer of the oxide.

Fig. 5. Ratio of the primary electron current to the ionic current as a function of the electrolyte concentration for both the oxalic acid and the phosphoric acid. The values of the relative phosphorous concentration for films grown in H₃PO₄ electrolytes, measured by Randall *et al.* (8), are also represented.

Fig. 6. Impact ionization coefficient vs. electrolyte concentration for Ta₂O₅ films grown in phosphoric and oxalic acid electrolytes.

electronic current originated at the incorporated anions. It is reasonable to expect higher electronic currents for the more concentrated electrolyte due both to a higher level of oxide doping and the higher value of the electric field found in this electrolyte. The presence of a linear stage in the curves of Fig. 3 is also in agreement with the exponential increase of the electronic current predicted by the avalanche model. In addition, the nonlinear dependence can be explained by the lower fields found in the low voltage region, as discussed by Young (13), and by the onset of breakdown processes at the side of the high voltages.

The exponential increase of the residual current, j_1 , found in the intermediate region of Fig. 3 follows the equation

$$j_1 = j_0' \exp(\alpha' V_F) \quad [5]$$

where j_0' and α' have the same meaning as the parameters of the avalanche of Eq. [1], *i.e.*, $\alpha' = \alpha\beta$. In fact, the values of j_0' and α' found from Fig. 3 are lower than the corresponding ones in the stage of constant current. Nevertheless, this is not surprising considering that, as pointed out, during the constant voltage stage the value of the electric field is much smaller than during the previous anodization at constant current.

The results of the conduction through the system Ta/Ta₂O₅/electrolyte (Fig. 4) yield straight lines in a log(j/E) vs. $E^{1/2}$ plot, which suggests a Poole-Frenkel mechanism of conduction. Other mechanisms gave a worse fitting of the results. As it can be appreciated, the experimental points follow straight parallel lines in a wide range of applied fields, E . From the slopes of these straight

Fig. 7. Anodization electric field vs. electrolyte concentration for Ta₂O₅ films grown in phosphoric and oxalic acid electrolytes.

lines, the relative permittivity $\epsilon_r = 4.98$ (average value) has been obtained by using the well-known expression for the current density

$$j = j_c \exp(\beta_{PF} E^{1/2} / kT)$$

where $j_c = \sigma_c E$ (σ_c constant), k is Boltzmann's constant, T the absolute temperature, and β_{PF} is given by

$$\beta_{PF} = \left(\frac{e^3}{\pi \epsilon_0 \epsilon_r} \right)^{1/2}$$

e being the electronic charge and ϵ_0 the vacuum permittivity. It is worth noting that the value of ϵ_r agrees closely with that resulting from the refractive index $n = 2.2$ (2), applying the Maxwell relation, $n^2 = \epsilon_r$, thus supporting the Poole-Frenkel mechanism (14). There is a great controversy about the dominant conduction mechanism in Ta₂O₅ films (15). The majority of papers refer to the system Ta/Ta₂O₅/metal; the system Ta/Ta₂O₅/electrolyte has received comparably less attention. The general agreement is that the control of the conduction mechanism is in the bulk, while the contacting electrolyte may play a less important role (16). Taking into account the presence of the phosphate anions in the oxide, it is reasonable to associate them to the Coulomb traps of the Poole-Frenkel mechanism.

It may be observed in Fig. 4 a shift of the straight lines towards higher values of the current as the formation voltage increases. This behavior has also been displayed by samples of anodic Al₂O₃ (16) and was attributed to an avalanche mechanism of multiplication of the free carriers. This is, in turn, in agreement with our model of anodization and breakdown of the anodic Ta₂O₅ films. This view is further supported by the fact that the electronic current, j , measured at a constant field grows exponentially with the formation voltage, as is illustrated in Fig. 8. According to the results of this figure, the current j can be expressed by an equation similar to Eq. [5], with the parameters now given by $\alpha' = 0.006 \text{ V}^{-1}$ and $j_0' = 3.8 \times 10^{-7} \text{ A cm}^{-2}$, in good agreement with those obtained from Fig. 5 and 6.

In the light of the avalanche model, a lower breakdown voltage for the phosphoric acid is expected compared with the oxalic acid, as can be observed in Fig. 2. In fact, it is possible to make an estimation of the variation of the breakdown voltage V_B with the electrolyte concentration, if one assumes that the breakdown appears when the avalanche current j_e reaches a certain fraction z of the total anodization current j_t . A similar hypothesis was introduced by Ikonopisov (7). Under this condition, the breakdown voltage will satisfy the equation

$$j_0 \exp(\alpha \beta V_B) = z j_t \quad [6]$$

and hence

Fig. 8. Variation of the quotient j/E as a function of the formation voltage (Values taken from Fig. 4, for a value of the applied electric field of $E = 6.25 \text{ MV cm}^{-1}$).

$$V_B = \frac{1}{\alpha \beta} \ln \left(z \frac{j_t}{j_0} \right) = \frac{E}{\alpha} \ln \left(z \frac{j_t}{j_0} \right) \quad [7]$$

The parameter z is unknown; therefore, the absolute value of V_B cannot be calculated. Anyhow, Eq. [7] gives the dependence of V_B with the anodization parameters E , α , and j_0 . Thus, as it can be observed in Fig. 5, 6, and 7 for the oxalic acid, E and j_0 are nearly constant and α increases by a factor of two in the high concentration side. Probably, this is the main factor contributing to the observed decrease of V_B for the oxalic acid in this region. On the contrary, in the case of the phosphoric acid, the major contribution of the decrease of V_B comes from the increase of j_0 with the electrolyte concentration, as can be deduced from the results of Fig. 5. The differences in the values of j_0 found in the phosphoric and oxalic acid electrolytes also explain the lower breakdown voltages observed in the first electrolyte.

Conclusions

From the results presented in this paper, it can be concluded that the avalanche model is able to explain the main characteristics of the anodization curves and breakdown of anodic tantalum oxide grown in phosphoric and oxalic electrolytes at different concentrations. The close correlation between j_0/j_t and the mole concentration of incorporated phosphorous in the oxide firmly supports the hypothesis that the incorporated phosphate anions act as a source of primary electrons for the avalanche. The residual leakage current measurements as well as the j - V characteristics seem to indicate that the primary electrons are released from the impurity centers in a Poole-Frenkel mechanism. The presence of phosphorous in the anodic oxide also gives rise to an increase of the anodization electric field needed to maintain a definite current density. In contrast to the previous theories of the breakdown during anodization (8, 17) which speculate about the injecting properties of the electrolyte/oxide interface, in the present model the direct control of the breakdown is mainly attributed to the electrolyte anions incorporated into the oxide and to their ability to release electrons to the conduction band.

Using Parameter Estimation Techniques with a Simple Model of a Diaphragm-Type Electrolyzer to Predict the Electrical Energy Cost for NaOH Production

John Van Zee*

Department of Chemical Engineering, University of South Carolina, Columbia, South Carolina 29208

R. E. White*

ABSTRACT

Predictions of the electrical energy cost for NaOH production are determined as a function of the independent operating variables and diaphragm characterizing properties. The predictions are based on data from a statistically designed experiment, a simple model of a diaphragm-type electrolyzer, a simple model of the cell voltage losses, and parameter estimation techniques. The data were obtained over a sufficiently large range of operating conditions so that the resulting design equation may be industrially useful. The simple model of the diaphragm is based on the mass transport of the hydroxyl ion, a linear potential gradient, and is presented in terms of measurable diaphragm properties. These properties are the thickness of the diaphragm (t) and a resistivity-ratio, ρ/ρ_0 , where ρ is the resistivity of the diaphragm filled with electrolyte and ρ_0 is the resistivity of the electrolyte (this ratio may come to be known as the MacMullin number, N_M). It is shown that, according to the model of the cell, the caustic yield or current efficiency of the diaphragm cell depends on the product of N_M and t and not on each separately. The simple model of the cell voltage considers the diaphragm voltage drop, anode and cathode kinetics, and the bubble-filled brine-gap voltage drop. Parameter estimation techniques are used to determine the best values of the diffusion coefficient, average specific conductivity, exchange current densities, and transfer coefficients; these parameters and the simple models provide a design equation for the electrical energy cost of NaOH production using a diaphragm cell. The design equation is used to predict a minimum electrical-energy cost at a particular $N_M t$.

In a diaphragm-type chlorine/caustic cell (see Fig.1), hydroxyl ions are produced at the cathode according to the electrochemical reaction

The energy cost for the production of hydroxyl ions depends upon the diaphragm characteristics and the operating conditions of current density and percolation velocity. That is, to prevent the loss of OH^- ions due to migration and diffusion, cell electrolyte percolates through the diaphragm from the anolyte as shown in Fig. 1. This percolation rate must not be too large, however, because the concentration of OH^- in the catholyte decreases as the percolation rate increases, which leads to a larger steam requirement if the catholyte is to be concentrated to the typical 50% by weight solution. Increasing the current density increases the concentration of OH^- ions in the catholyte, but also increases the voltage drop through the diaphragm, which increases the electrical energy cost. Also, the diaphragm characteristics affect the diffusion and migration of hydroxyl ion and the voltage drop through the diaphragm. It is desirable, therefore, to have a simple model which is consistent with industrial production cells and which can be used to predict the con-

centration of OH^- ions in the catholyte and the diaphragm voltage drop as a function of the percolation velocity, current density, and diaphragm characterizing properties. It is also desirable to combine this simple diaphragm model with a simple model of the cell voltage losses which include the thermodynamics, kinetics, and ohmic losses so that predictions of the electrical energy cost for NaOH production can be made. (A more quantitative definition of electrical energy cost is given below in the "Energy Cost" section).

These predictions are highly dependent on the transport and kinetic parameters used in the model. Consequently, it is necessary to use a set of parameters which (i) is consistent with experimental data over a large range of operating conditions and (ii) has reasonably small confidence intervals for the parameters. Here, we use the theory of nonlinear least squares regression (1-4) to obtain a suitable set of parameters for a simple model. In this sense, we do not test various models to determine the most reasonable, but, rather, we assume that the simple model presented here is reasonable and then determine the parameters which give the "best fit" of the data. In the same sense, it is not the purpose of this paper to compare the model predictions with experimental data that were not used to obtain the parameters. [See Lee (5) for a general discussion of the use of parameter estimation in electrochemical reactor design.]

* Electrochemical Society Active Member.

Fig. 1. A diaphragm-type chlorine/caustic cell schematic

Simple models of the diaphragm¹ have been presented before (6-10), but none have included measurable diaphragm properties as independent variables, which is required for the determination of diaphragm-independent transport parameters by regression. Also, none of the previous workers have shown the effects of these diaphragm properties and the operating conditions on the energy cost for the production of NaOH in a diaphragm-type electrolyzer. Consequently, the diaphragm characterizing properties used here will be discussed, and the previously published models will be reviewed. Then, a simple model of the diaphragm-type chlorine/caustic cell which considers OH⁻ ion only will be developed and discussed in terms of dimensionless groups. The model then will be compared in more detail to previously published models and then to experimental data using nonlinear regression to estimate the transport and kinetic parameters. Finally, predictions of the electrical energy cost per metric ton of NaOH will be discussed as a function of the independent diaphragm properties and operating conditions.

Literature Review

In a recently reported, factorially designed experiment (11), two quantities were used to characterize the diaphragm in a metal anode chlorine/NaOH electrolyzer. These two properties are the MacMullin number, N_M , and the diaphragm thickness, t . The MacMullin number is defined (12, 13) as follows

$$N_M = \frac{\tau}{\epsilon} = \frac{\rho}{\rho_0} \quad [2]$$

where ρ/ρ_0 is the ratio of the electrical resistivity of an electrolyte-saturated porous medium to the resistivity of the same thickness of electrolyte. An experimental procedure is available for measuring independently both the MacMullin number and the thickness of a diaphragm (11). It should be noted that N_M has also been referred to as the formation factor (14) and the labyrinth factor (15).

Of the simple models of the diaphragm that have been proposed (6-10), only Koh (9, 10) and Mukaibo (7) included diaphragm characterizing properties, but neither recognized that N_M can be measured directly from relatively simple experiments. Koh (9, 10) used a diaphragm characterizing parameter which was obtained from an assumed value for τ or the product τ and a presumably measured value for ϵ . Mukaibo (7) [see also Hine (14, 16, 17)] used the ratio of the diaphragm area to the area of the dia-

¹ Throughout this paper, the phrase "simple model of the diaphragm" is used to indicate a model with a linear potential gradient that can be solved by analytical integration of the governing differential equations.

phragm pores, which is not measurable directly, and, hence, this ratio was an assumed quantity when the model was compared with experimental data (16). The often-used model of Stender *et al.* (6) does not include a parameter such as N_M , but some recent modifications of this model (17, 18) have recognized the need to include diaphragm properties which are independent of the transport parameters; again, these recent modifications use assumed values for ϵ or τ , and therefore they cannot be used to determine the best values of the transport parameters for use with the model. Kubasov *et al.* (19) include the thickness of the diaphragm multiplied by a "sinuosity coefficient" as the characterizing parameter, but this coefficient was not reported as a measurable quantity.

In addition to the lack of measurable diaphragm properties, other differences exist between the previously published diaphragm models and the model presented here. For example, Gallone and Rubino (8) neglected the effect of ionic migration. Hine (14, 16, 17) does not show the difference between the solution conductivity and the effective solution conductivity in the diaphragm. Mukaibo (7) assumed that the ratio of the transference number to the concentration of hydroxyl ion is constant throughout the diaphragm.

Also, the model presented here differs from the previously reported models in the specification of the boundary condition at the catholyte/diaphragm interface. That is, the model of Stender *et al.* (6), for example, is developed with a physically unrealistic boundary condition, a fixed catholyte concentration. Consideration of Fig. 1 reveals that the concentration in the catholyte depends on the velocity and the current density as well as the diaphragm properties and therefore cannot be specified *a priori* as an independent, fixed quantity. Thus, Stender's expression for the concentration profile of hydroxyl ion {Eq [13] in Ref. (6)} does not show the correct dependence on velocity and current density because it includes the concentration at the interface.

The previously reported simple diaphragm models (6-10) have not been used to analyze the combined effects of diaphragm properties and operating conditions on the energy cost for NaOH production. That is, although Koh (9, 10) showed the effect of his diaphragm effectiveness parameter on electrolyzer energy consumption, the interaction between current density, velocity, and diaphragm properties (e.g., N_M and t) was not discussed. The contribution of the diaphragm voltage drop to energy cost and the effect of diaphragm parameters on the voltage drop were not discussed by Koh or the authors of the other simple models. Hine (14) showed diaphragm IR data for a stagnant laboratory-scale diaphragm cell, but comparison of this data to model predictions was not reported. Also, the contributions of electrode kinetics to the energy consumption have not been reported previously but are included here. A more complicated model (12) of chlorine/NaOH metal anode electrolyzer has shown the effect of the product of N_M and t on specific energy consumption; however, only the essence of the model was presented, and the details were avoided for proprietary reasons.

Model

The assumptions of the simple models are as follows.

1. Dilute solution theory (20) applies.
2. The hydroxyl ion is the only species of interest within the diaphragm, and all reactions of OH⁻ with other species (e.g., H⁺ and Cl₂) occur at the anolyte/diaphragm interface. (This assumption is reasonable because the concentrations of the other species in the diaphragm are relatively small, on the order of 2% of that of the OH⁻ ion.)
3. The spatial dimension in the direction parallel to the velocity (see Fig. 1) is the only important dimension for material balances.
4. The effective diffusion coefficient for hydroxyl ion in the porous diaphragm can be written in terms of the MacMullin number (12)

$$D_e = \frac{D_1}{N_M} \quad [3]$$

5. The current density through the diaphragm is simply related to the potential gradient through the diaphragm by an effective average specific conductivity

$$i = -\frac{\kappa_{\text{avg}}}{N_M} \frac{d\Phi}{dx} \quad [4]$$

6. Water vapor loss from the catholyte is negligible, and the generated H_2 gas mixes the catholyte so that the hydroxyl ion concentration at the diaphragm/catholyte interface equals the hydroxyl ion concentration in the electrolyzer effluent.

7. The electrochemical kinetics at the anode and cathode can be approximated by a Tafel approximation

$$\Delta V_{\text{kin},i} = \frac{RT}{\alpha_i F} \ln \left| \frac{i}{i_{0,i}} \right| \quad [5]$$

where $i = 1$ and 2 for cathode and anode, respectively.

8. The effect of temperature on ΔU^θ is negligible.

9. The Nernst concentration correction to the open-circuit or thermodynamic voltage of the electrolyzer is negligible.

10. The voltage drop between the anode and the diaphragm is given by

$$\Delta V_{\text{anolyte}} = \frac{is}{(1 - \epsilon_b)^{1.5} \kappa_{\text{anolyte}}} \quad [6]$$

where $(1 - \epsilon_b)^{1.5}$ is the Bruggeman correction for the effect of bubbles in the anolyte (21, 22) and ϵ_b is assumed to be independent of current density.

With these assumptions, the steady-state material balance for hydroxyl ion in the diaphragm is

$$\frac{dN_1}{dx} = 0 \quad [7]$$

where the expression for the flux of hydroxyl ion in the porous diaphragm can be written (12) as

$$N_1 = -\frac{D_1}{N_M} \frac{dC_1}{dx} + \frac{D_1}{N_M} \frac{F}{RT} C_1 \frac{d\Phi}{dx} + vC_1 \quad [8]$$

The boundary conditions can be obtained from the second and sixth assumptions above and by recognizing that the anolyte and catholyte approximate completely mixed reactors. That is, for a typical anolyte pH of 2, the OH^- concentration is

$$\text{at } x = 0, \quad C_1 = 0 \quad [9]$$

Since OH^- is produced at the diaphragm/catholyte interface, and since the flux in the catholyte chamber consists of only convection (*i.e.*, vC_1), the material balance is

$$\text{at } x = t \quad N_1(x = t) + \frac{i}{F} = vC_1(x = t) \quad [10]$$

Substituting Eq. [4] into Eq. [8] yields

$$N_1 = -\frac{D_1}{N_M} \frac{dC_1}{dx} - \frac{D_1}{\kappa_{\text{avg}}} \frac{Fi}{RT} C_1 + vC_1 \quad [11]$$

Substituting Eq. [11] into Eq. [7] yields the second-order differential equation which governs the concentration of hydroxyl ion throughout the diaphragm

$$\frac{D_1}{N_M} \frac{d^2C_1}{dx^2} + \left(\frac{D_1 Fi}{\kappa_{\text{avg}} RT} - v \right) \frac{dC_1}{dx} = 0 \quad [12]$$

Integration of Eq. [12] subject to the boundary conditions (Eq. [9] and [10]) is readily accomplished [see Ref. (23), for example], and the result can be written as

$$C_1(x) = \frac{\frac{i}{vF} \{1 - \exp(A_1 x)\}}{\left[\frac{FiD_1}{RT\kappa_{\text{avg}}v} - \exp(A_1 t) \right]} \quad [13]$$

where

$$A_1 = \left(\frac{-FiN_M}{RT\kappa_{\text{avg}}} + \frac{vN_M}{D_1} \right)$$

Equation [13] is plotted in Fig. 12 and 13 of Ref. (23) and can be used to obtain an expression for the hydroxyl ion concentration in the effluent

$$C_1(t) = \frac{\frac{i}{vF} \{1 - \exp(A_1 t)\}}{\left[\frac{FiD_1}{RT\kappa_{\text{avg}}v} - \exp(A_1 t) \right]} \quad [14]$$

Equation [14] shows that the effluent concentration is a dependent variable when the velocity and current density are considered independent variables. An expression for the caustic yield, η , can be obtained by using the following definition

$$\eta = \frac{vC_{1,\text{effluent}}}{i/F} = \frac{vC_1(t) F}{i} \quad [15]$$

where by the sixth assumption above, $C_{1,\text{effluent}} = C_1(t)$.

Substituting Eq. [14] into Eq. [15] yields

$$\eta = \frac{\{1 - \exp(A_1 t)\}}{\left[\frac{FiD_1}{RT\kappa_{\text{avg}}v} - \exp(A_1 t) \right]} \quad [16]$$

Note that Eq. [14] and [16] show that $C_1(t)$ and η depend on the product of N_M and t and not on either quantity separately. This should be expected, since $N_M t$ is simply the effective thickness of the diaphragm. Also, it should be emphasized that η is a derived quantity, not a parameter. That is, η is calculated according to Eq. [15] after the governing equation for $C_1(x)$ (Eq. [12]) has been solved subject to the boundary conditions (Eq. [9] and [10]). Also, note that none of Eq. [7]-[12] contain η and that this is different from the formation of Caldwell *et al.* (12) and Stender *et al.* (6).

Energy Cost

The specific electrolyzer energy cost for NaOH, EC_{el} , can be formulated as the ratio of the energy consumption rate to the mass production rate of NaOH multiplied by the electrical energy cost, CE

$$EC_{\text{el}} = \frac{iV_T}{M_1 C_1(t)v} \text{CE} \quad [17]$$

In Eq. [17], the current density, i , and the velocity, v , are considered as independent variables, while $C_1(t)$ is deter-

Fig. 2. Effluent concentration dependence on $A_1 t$ and N_H .

mined by Eq. [14] as a dependent variable. Also, the sum of the cell voltage drops, V_T , is a dependent variable and includes the kinetic voltage drops at each electrode, the thermodynamic voltage required for the sum of the cathodic and anodic reactions, the voltage drop in the anolyte, and the diaphragm voltage drop. The diaphragm is typically deposited onto the cathode and, hence, any voltage drop in the catholyte is negligible. Using the fifth and seventh through tenth assumptions above gives

$$V_T = \frac{iN_M t}{\kappa_{\text{avg}}} + \frac{RT}{F} \left[\left(\frac{1}{\alpha_1} + \frac{1}{\alpha_2} \right) \ln |i| - \frac{\ln(i_{0,1})}{\alpha_1} - \frac{\ln(i_{0,2})}{\alpha_2} \right] + \Delta U^\theta + \frac{iS}{(1 - \epsilon_b)^{1.5} \kappa_{\text{anolyte}}} \quad [18]$$

Other Dimensionless Groups

It is, perhaps, worth mentioning that dimensionless groups other than the ones shown in Eq. [16] can be formulated. For example, Eq. [16] can be rewritten as

$$\eta = \frac{1 - \exp(\text{Pe} + \Delta\phi)}{-\frac{\Delta\phi}{\text{Pe}} - \exp(\text{Pe} + \Delta\phi)} \quad [19]$$

where Pe is the Peclet number

$$\text{Pe} = \frac{vN_M t}{D_1} \quad [20]$$

and $-\Delta\phi$ is the dimensionless diaphragm IR drop

$$-\Delta\phi = -\frac{F}{RT} [\Phi(x=t) - \Phi(x=0)] = \frac{FiN_M t}{RT\kappa_{\text{avg}}} \quad [21]$$

The Peclet number is a measure of the effect of convection relative to diffusion and is used routinely by chemical engineers. The dimensionless diaphragm IR drop, $-\Delta\phi$, can be thought of as a measure of the importance of the effect of ionic migration.

These dimensionless groups can also be used to write in dimensionless form an expression for the concentration distribution for OH^- ions

$$\theta_1(\zeta) = \frac{C_1(x)}{F_1} = \frac{N_H \{1 - \exp[(\text{Pe} + \Delta\phi)\zeta]\}}{-\frac{\Delta\phi}{\text{Pe}} - \exp(\text{Pe} + \Delta\phi)} \quad [22]$$

where F_1 is the concentration of the NaCl in the brine feed (a constant) and N_H is the Hine number defined as

$$N_H = \frac{i}{FF_1 v} \quad [23]$$

since Hine and Yasuda (24) were apparently the first to recognize the significance of i/Fv .

Comparison of Diaphragm Model to Existing Models

Expressions similar to those given above for $C_1(x)$, $C_1(t)$, and η have been presented by Stender *et al.* (6), Koh (9), and Mukaibo (7) which with modifications or definitions of effective thickness can be shown to be consistent with the model presented here. The expressions presented by Stender *et al.* (6) for $C_1(x)$ and η are not correct because they do not contain N_M or a similar quantity. Their equations are written in terms of δ (defined to be the thickness of the diaphragm), but their expression for η can be seen to be equivalent to Eq. [16] by defining δ in terms of measurable diaphragm properties

$$\delta = N_M t \quad [24]$$

Thus, their δ should be the effective thickness and not the measured diaphragm thickness. Using Eq. [24], their dimensionless parameter $U\delta/D_1$ can be shown to be equal to $A_1 t$ of Eq. [13], [14], and [16]. In addition, their equation for $C_1(x)$ is not complete because it depends on the concentration of OH^- in the catholyte, which also depends on other variables in their expression for $C_{\text{OH}^-}(x)$. That is,

for example, both v and $C_1(t)$ cannot be set while holding i fixed because only two independent operating variables exist for the isothermal case. This point is easily overlooked when $C_1(x)$ is made dimensionless by $C_1(t)$ and the resulting expression (*i.e.*, divide Eq. [13] by Eq. [14]) is graphed as a function of distance, x , as is shown by Hine *et al.* [14] in their Fig. 12. The resulting expression, and hence Fig. 12 of Ref. (14), appears as a function of only one dimensionless variable, $U\delta/D_1$, which is misleading because the dimensionless concentration profile is described by three dimensionless groups (divide both sides of Eq. [13] by F_1 or see Eq. [22]). Furthermore, if $C_1(t)/F_1$ is held constant, then i/vFF_1 must be changed as $A_1 t$ is changed; this point is illustrated in Fig. 2, which shows that $C_1(t)/F_1$ depends on both $A_1 t$ and i/vFF_1 . Two exceptions to this dependence occur as follows

$$A_1 t < -20; \quad C_1(t) = \frac{RT\kappa_{\text{avg}}}{F^2 D_1} \quad [25]$$

$$A_1 t > 20; \quad C_1(t) = \frac{i}{vF} \quad [26]$$

Also, when $A_1 t = 0$, Eq. [13], [14], and [16] become indeterminate forms because the quantity $FiD_1/RT\kappa_{\text{avg}}v$ equals 1.0. For these indeterminate forms, application of l'Hopital's rule results in the following limit

$$C_1(x) = \frac{1.0}{\left(\frac{D_1 F}{iN_M t} + \frac{vF}{i} \right)} \quad [27]$$

when

$$A_1 t = 0$$

Next, consider the equation for η presented by Koh (9). His equation for η contains a length parameter, EL , which can be shown to be equal to $N_M t$ by considering Koh's definition of EL

$$EL = l/\epsilon \quad [28]$$

and the definitions of l (average pore length) and N_M (12)

$$l = \tau t \quad [29]$$

$$N_M = \tau/\epsilon \quad [30]$$

where τ is the tortuosity and ϵ is the porosity of the diaphragm.² Substitution of Eq. [29] and [30] into Eq. [28] shows that

$$EL = N_M t \quad [31]$$

However, even though Koh's equation for η does contain an effective thickness parameter, he did not recognize that it can be determined by measuring N_M and t . Instead, he used an assumed value for τ and a presumably measured value for ϵ to obtain $N_M t$ (his EL). Unfortunately, his $N_M t$ values are scaled for proprietary reasons, and his equation for η is difficult to use because it contains a parameter (his A) which is incorrect as written.

Mukaibo's (6, 16) expression for η is also similar to Eq. [16]; however, his equation is based on a different approach. He defined a transference number for OH^- as follows

$$n_1 = \frac{t_1(x)}{C_1(x)} \quad [32]$$

and assumed that n_1 (not t_1) is constant throughout the diaphragm. He then defined the flux of OH^- through the diaphragm to be

$$N_1 = \frac{-D_1}{A_d/A_p} \frac{dC_1}{dx} - n_1 C_1 \frac{i}{F} + vC_1 \quad [33]$$

and integrated Eq. [7] with N_1 given by Eq. [33] in a man-

² Actually, Caldwell *et al.* (12) define N_M as τ^2/ϵ , but it is immaterial whether τ is squared or not, since it is not a quantity that can be measured directly.

ner similar to that shown in Ref. (23). The equations he obtained for $C_i(t)$ and η do have the correct dependence on N_M , since N_M is related simply to his area ratio

$$N_M = A_d/A_p \quad [34]$$

as can be seen by defining (10) the porosity of the diaphragm as

$$\epsilon = lA_p/tA_d \quad [35]$$

and using Eq. [29] and [30]

$$N_M = \tau/\epsilon = \frac{l}{t} \frac{A_d/A_p}{l/t} = \frac{A_d}{A_p} \quad [36]$$

Even though Mukaibo presented equations that do have the correct dependence on N_M , he did not recognize that N_M can be measured directly and he did not present an equation for $C_i(x)$. Also, his concept of a constant transference number (n_i) is perhaps less appealing than the concept of a constant, average specific conductivity. This may be so because κ_{avg} can be measured directly by assuming that κ_{avg} is equal to the specific conductivity of an aqueous solution of NaCl and NaOH at their average concentrations over the range of effluent concentrations of interest (e.g., 2.5M of each), whereas n_i cannot. However, it is interesting to note that an average value for n_i can be obtained from κ_{avg} , if D_1 is known.

This can be seen by considering the definitions of t_i and κ . That is, according to Newman (20), the transport number for species j in an electrolyte solution is given by

$$t_j = \frac{z_j^2 u_j C_j}{\sum_i z_i^2 u_i C_i} \quad [37]$$

and the specific conductivity is given by

$$\kappa = F^2 \sum_i z_i^2 u_i C_i \quad [38]$$

Substitution of Eq. [38] into Eq. [37] written for OH⁻ yields

$$t_1 = \frac{u_1 C_1 F^2}{\kappa} \quad [39]$$

which, by assuming that the Nernst-Einstein equation (20) is valid

$$u_1 = \frac{D_1}{RT} \quad [40]$$

shows that

$$n_1 = \frac{t_1}{C_1} = \frac{F^2 D_1}{RT \kappa} \quad [41]$$

Thus, once values for D_1 and κ_{avg} are known, an average value for n_1 could be calculated according to Eq. [41].

Parameter Estimation

Diaphragm model.—The diaphragm model presented above is formulated in terms of two transport properties of the electrolyte solution within the diaphragm, D_1 and κ_{avg} . Both D_1 and κ_{avg} are average quantities which depend on temperature and the average concentration within the diaphragm. Values for these average quantities are not available in the literature.

Their values can be estimated by nonlinear least squares (LS) regression of Eq. [14] or [16] against measured values of $C_i(t)$ or η , respectively. Note that η is derived from a combination of dependent and independent variables.³ With this regression approach, the model is "fitted" to the data, and statistical theory (1-4) states that the estimates of D_1 and κ_{avg} are the best values for the data

³ For the model presented here, i and v are considered independent variables and, hence, one should obtain the same estimates for D_1 and κ_{avg} by using either $C_i(t)$ or η as the dependent variable in the regression model. That is, statistical theory specifies that the independent variables are known precisely or at least within very small error limits (2) so that all of the error in η can be attributed to $C_i(t)$.

in the sense that the estimates result in the minimum difference between the observed and predicted values of η . Then the model with these estimates can be used for interpolation. Confidence is gained in the model if the parameter estimates obtained by LS are physically realistic. If the parameter estimates are physically realistic, extrapolations beyond the experimental range could be made within the limits of the assumptions of the model. Also, if the number of data points is large, confidence intervals on the parameter estimates can be obtained in the same manner as in linear regression (3).

The estimation of D_1 and κ_{avg} by LS requires experimental data in which both N_M and t are measured quantities. The factorially designed experiments of Ref. (11) provide data in which N_M was varied from 3.3 to 7.5 and t was varied from 0.17 to 0.33 cm. Also, the current density and velocity were measured precisely and cell temperature was controlled at $70^\circ \pm 0.5^\circ\text{C}$. In addition, the brine feed concentration was set with either a high or low acid and a constant salt concentration. The diaphragm voltage drop and the concentration of OH⁻ ion in the effluent were measured simultaneously as dependent variables. Note that D_1 and κ_{avg} are independent of the diaphragm properties and, therefore, are free stream parameters rather than effective parameters of the particular diaphragm. Thus, by fixing the values of N_M and t and the independent operating variables, i and v , the only parameters of the model which can account for an inadequate model are the values of D_1 and κ_{avg} .

It should be noted that the experimental cells of Ref. (11) consisted of laboratory cells which were designed by scaling down industrial-size electrolyzers so that geometric similarity was maintained. These cells contained a diaphragm which was placed in contact with a perforated steel cathode as shown in Fig. 1. The experimental cells were therefore consistent with the majority of industrial, metal anode cells which have the diaphragm vacuum deposited on the cathode.

Also, the model presented above was formulated to be consistent with the laboratory cells of Ref. (11). These cells were run for a period of 35 days. The replicate steady-state data were obtained over the entire period (26).

The predictions of the caustic yield and the diaphragm voltage drop are coupled through the average conductivity, κ_{avg} , and thus an appropriate LS objective function is

$$G(\beta) = \sum_{l=1}^N \frac{(\eta_l^o - \eta_l^p)^2}{\hat{\sigma}_1^2} + \sum_{k=1}^M \frac{(\Delta\Phi_k^o - \Delta\Phi_k^p)^2}{\hat{\sigma}_2^2} \quad [42]$$

where η_l^p is predicted by Eq. [16] at the experimental conditions corresponding to the l th datum, $\Delta\Phi_k^p$ is predicted by integration of Eq. [4] at the experimental conditions corresponding to the k th datum, and $\hat{\sigma}_1^2$ and $\hat{\sigma}_2^2$ correspond to the estimated variance of η and $\Delta\Phi$, respectively.

The nonlinearity of Eq. [42] results from the nonlinear model equation for η , but it does not affect the theory behind LS regression (3, 4). The computations necessary to minimize this objective function become more complicated with a nonlinear function, but many computers have subroutine libraries which can perform the necessary calculations. In this work, minimization subroutines of the International Mathematical and Statistical Library (25) were used (26).

Each of the estimated variance ($\hat{\sigma}_1^2$ and $\hat{\sigma}_2^2$) in Eq. [42] correspond to the sum of the variance associated with the measurement error and the variance associated with the model error. That is, we assume (in accordance with the assumptions of LS theory) any difference between the observed and predicted values is a lumped error which is distributed randomly. Thus, $\hat{\sigma}_1^2$, for example, was calculated by dividing the minimum value of $G(\beta)$ when $\hat{\sigma}_2^2 = \infty$ by the degrees of freedom [in this case, $N - 2$, since two parameters are adjusted to minimize $G(\beta)$]. Similarly, $\hat{\sigma}_2^2$ was calculated by dividing the minimum value of $G(\beta)$ when $\hat{\sigma}_1^2 = \infty$ by $(M - 1)$ (only one parameter, κ_{avg} , is adjusted to minimize $G(\beta)$ when $\hat{\sigma}_1^2 = \infty$).

Table I. Parameter estimates for diaphragm model

Case A. Parameter estimates with $\hat{\sigma}_2^2 = \infty$; $N = 84$					
Parameter	Estimate	\pm	95% Confidence interval	Units	^a t-statistic
D_1	3.352×10^{-5}	\pm	0.275×10^{-5}	cm ² /s	24.3
κ_{avg}	0.422	\pm	0.060	$\Omega^{-1} \text{cm}^{-1}$	14.7
$\hat{\sigma}_1^2$	1.118×10^{-3}		—	none	—
Case B. Parameter estimates with $\hat{\sigma}_1^2 = \infty$; $M = 64$					
Parameter	Estimate	\pm	95% Confidence interval	Units	^a t-statistic
κ_{avg}	0.3261	+	0.0154	$\Omega^{-1} \text{cm}^{-1}$	42.3
$\hat{\sigma}_2^2$	2.688×10^{-3}		—	V ²	—
Case C. Parameter estimates with $\hat{\sigma}_1^2 = 1.118 \times 10^{-3}$ and $\hat{\sigma}_2^2 = 2.688 \times 10^{-3}$ V					
Parameter	Estimate	\pm	95% Confidence interval	Units	^a t-statistic
D_1	2.826×10^{-5}	\pm	0.112×10^{-5}	cm ² /s	49.7
κ_{avg}	0.338	\pm	0.016	$\Omega^{-1} \text{cm}^{-1}$	41.6
$G(\beta)$	1.627×10^{-2}		—	none	—

^a See Ref. (26).

The weighting of the dependent variables in the LS objective function in this fashion gives the "best values" of the parameters for Eq. [16] and [21] and the data (27). These estimated variances are shown in cases A and B of Table I. Note that $\hat{\sigma}_1$ is dimensionless, since η is dimensionless, whereas $\hat{\sigma}_2$ has the dimensions of $\Delta\Phi$. The parameter estimates for D_1 and κ_{avg} shown for cases A and B can be compared with the parameters of case C, which were estimated with the objective function weighted as described above. That is, including the data on the voltage drop through the diaphragm lowers the estimates of D_1 and κ_{avg} and narrows the confidence intervals. The narrow confidence intervals indicate a greater sensitivity of the case C objective function to changes in the parameter values.

Figures 3 and 4 compare the predicted and observed values of η and $\Delta\Phi$ at the estimates of case C in Table I. The slopes and intercepts shown on Fig. 3 and 4 indicate that the diaphragm model agrees well enough with the experimental data to be useful for approximate design purposes. The large dispersion of observed voltage drops for a given predicted voltage drop may be a result of the fifth assumption made above; that is, the potential drop is probably a nonlinear function of the operating variables.

Figures 5 and 6 show that the residuals (*i.e.*, the difference between the predicted and observed values) are independent of the dependent variables as required by LS regression theory (2, 3, 27). Similar plots of the residuals and effective thickness ($N_M t$), current density, and velocity indicate no correlation between these independent variables and residuals (26). Thus, it can be concluded that the model with the LS parameter estimates of case C in Table I can be used to predict both the caustic yield and the diaphragm voltage drop.

Also, if the diaphragm effective thickness, $N_M t$, was known to change with time (due to plugging of the diaphragm, for example), the model could be adapted for interpolation purposes by minimizing Eq. [42] by adjusting $N_M t$ with the values of D_1 and κ_{avg} held constant at the specified values of case C. This adjusting of $N_M t$ was not necessary for the experimental data used here because both the values of N_M and t were not significantly different before and after the experiments (11).

Electrode kinetics.—Calculation of the cell voltage, V_T , by Eq. [18] requires knowledge of the kinetic parameters corresponding to the Tafel equations for the anode and

Fig. 5. Dependence of residuals on caustic yield predictions using LS parameters of case C, Table I.

cathode. The kinetic data obtained in Ref. (11) are proprietary, but for purposes of illustration, the data of Caldwell (28) can be used to estimate these kinetic parameters. That is, Caldwell reports hydrogen and chlorine overpotentials as functions of temperature and current density. By assuming that these overpotentials are independent of NaOH and NaCl concentrations, estimates of α_i and $i_{0,i}$ can be obtained by LS for use in Eq. [18] and then in Eq. [17] for prediction of the specific energy cost.

Since the overpotential data for hydrogen on low-carbon steel in 2.5M NaOH/3.01M NaCl electrolyte are large negative numbers, the Butler-Volmer expression can be inverted to give an explicit expression for V_1 , the dependent variable

$$V_1 = \frac{RT}{\alpha_1 F} \ln(i_{0,1}) - \frac{RT}{\alpha_1 F} \ln i \quad [43]$$

Thus an appropriate objective function for this data is

$$H_1(\alpha_1, i_{0,1}) = \sum_{i=1}^N (V_{1,i}^o - V_{1,i}^p)^2 \quad [44]$$

Equation [44] can be minimized easily with a hand calculator or statistical subroutines (25, 26). Unfortunately, the residuals of Eq. [44] exhibit a large correlation with temperature when all of the data (28) are used to estimate the parameters (26). Consequently, the parameter esti-

Fig. 6. Dependence of residuals on diaphragm voltage-drop predictions using LS parameters of case C, Table I.

mates (α_1 and $i_{0,1}$) were determined using only the data (28) for 343 K (*i.e.*, $N = 5$) as shown in Table II. The confidence intervals on $i_{0,1}$ and α_1 are small, even though the number of data points is small. It should be noted that even though the determination of values for α_1 and $i_{0,1}$ is simple, the determination of their confidence intervals is complicated because the Tafel equation confidence intervals correspond to $1/\alpha_1$ and $[\ln(i_{0,1})]/\alpha_1$. The confidence intervals of Table II were determined from nonlinear regression routines (26). Figure 7 compares the predictions of Eq. [43] with the data of Caldwell (28). Residual plots (26) did not show a correlation of predicted overpotentials with current density.

The overpotential data for production of chlorine on RuO₂-TiO₂ on titanium (28) should not be analyzed with a Tafel expression similar to Eq. [43] because the cathodic part of the Butler-Volmer expression is significant at small overpotentials. Instead, an implicit calculation should be performed to determine the dependent variable V_2 . This calculation is performed by forming the function, f_1

$$f_{1,j} = 0 = i_{2,j} - i_{0,2} \left\{ \exp\left(\frac{\alpha_2 F}{RT_1} V_{2,j}\right) - \exp\left[\frac{(\alpha_2 - 2) F V_{2,j}}{RT_1}\right] \right\} \quad [45]$$

Then for the given independent variables, $i_{2,j}$ and T_1 , and assumed values of α_2 and $i_{0,2}$, values of $V_{2,j}$ can be determined (by Newton's method, for example) such that $f_{1,j}$ is

approximately zero. The assumed values of α_2 and $i_{0,2}$ can be adjusted to obtain a minimized objective function which can be defined

$$H_2(\alpha_2, i_{0,2}) = \sum_{i=1}^{24} (V_{2,i}^0 - V_{2,i}^p)^2 \quad [46]$$

Nonlinear regression techniques (26) must be used to minimize Eq. [46]. It should be noted that Eq. [45] assumes that the apparent transfer coefficients sum to the number of electrons evolved in the overall oxidation of choride to chlorine (two here).

The estimated parameters using this implicit formulation for the chlorine reaction are shown in case B of Table II. The confidence intervals for these parameters are large, which indicates the need for more data at larger current densities. Figure 7 compares the experimental and predicted values at these parameter estimates. Residual plots (26) did not indicate significant correlations of the residuals with either current density or temperature, and, therefore, all of the data reported by Caldwell (28) was used.

Electrical Energy Cost Predictions

The specific electrolyzer energy cost for NaOH production (*i.e.*, Eq. [17]) can be predicted with confidence for the range of industrial conditions covered by the factorial experiment by using the parameter estimates of Tables I and II. An example of these energy cost predictions is shown in Fig. 8. The physical properties and parameters used for the calculations are shown in Table III. It should

be noted that the only assumed value in Table III is the void fraction of bubbles in the anolyte; all other values correspond to either parameter estimates, physically measurable properties (*i.e.*, diaphragm, electrolyte, or cell geometry properties), or operating conditions. Consideration of Fig. 8 shows that an $N_M t$ can be selected which minimizes the specific electrical energy cost for NaOH production at a specified current density and caustic effluent concentration (or effluent velocity as shown in Fig. 9). However, it is important to note that this minimum occurs at a value of $N_M t$ beyond that used in the experimental work and may, consequently, be invalid.

Conclusion

Development of a simple model of the diaphragm in terms of measurable diaphragm properties has provided a design equation which allows direct comparison of experimental data and theoretical predictions. This comparison, accomplished with parameter estimation techniques, shows that the models of the caustic yield and the voltage drop through the diaphragm are reasonable; changing the assumption of a linear potential gradient through the diaphragm may provide an improvement. The parameter estimates and the simple model provide a design equation which can be used to predict the minimum specific electrical energy required for NaOH production as a function of the effective thickness, $N_M t$, the current density, and the caustic concentration in the effluent (or the effluent velocity).

LIST OF SYMBOLS

A_1	see Eq. [13] (cm^{-1})
A_d	area of diaphragm (cm^2)
A_p	area of pores within the diaphragm (cm^2)
$C_1, C_1(x)$	position dependent concentration of OH^- ion (mol/cm^3)
$C_1(x = t), C(t)$	concentration of OH^- ion at diaphragm/catholyte interface (mol/cm^3)
$C_{1,\text{effluent}}$	concentration of OH^- ion in catholyte effluent (mol/cm^3)
CE	cost of electrical energy ($\$/J$)
D_1	free stream diffusion coefficient of OH^- ion (cm^2/s)
D_e	effective diffusion coefficient of OH^- ion (cm^2/s)
EC_{e1}	specific electrical energy cost for NaOH production ($\$/g$)
EL	length parameter (see Eq. [28]) (cm)
F	Faraday's constant (96,487 C/mol)
F_1	feed concentration of NaCl (mol/cm^3)
$f_{1,l}$	functional representation of Butler-Volmer equation equal to zero at l th datum (see Eq. [45])
$G(\beta)$	least squares objective function with parameter vector β , see Eq. [42]
H_1, H_2	least squares objective function for hydrogen and chlorine electrode kinetics, respectively, see Eq. [44] and [46]
i	current density through the diaphragm (A/cm^2)
$i_{2,l}$	current density on anode corresponding to l th datum (A/cm^2)
$i_{0,1}, i_{0,2}$	exchange current density of hydrogen and chlorine electrodes, respectively (A/cm^2)
l	average pore length, see Eq. [29] (cm)
M	number of data points for diaphragm voltage drop
M_1	molecular weight of NaOH (39.99 g/mol)
N	number of data points for caustic yield or hydrogen overpotential
N_1	flux of OH^- ion in diaphragm ($\text{mol}/\text{cm}^2 \text{ s}$)
N_M	MacMullin number, see Eq. [2], dimensionless
N_H	Hine number, see Eq. [23], dimensionless
n_1	transference number of OH^- ion (cm^2/mol)
Pe	Peclet number, see Eq. [20], dimensionless
R	gas constant (8.3143 J/mol K)
s	distance between anode and diaphragm anolyte face (cm)
T	temperature (K)
t	diaphragm thickness (cm)
t_j, t_1	transport number of species j , $j = 1$ for OH^- ion
u_j, u_1	mobility of species j , $j = 1$ for OH^- ion ($\text{cm}^2 \cdot \text{mol}/J \cdot \text{s}$)
U	relative velocity expression of Stender <i>et al.</i> (6) (cm/s)
ΔU^θ	open-circuit potential for chlorine/caustic cell (2.188V)
V_T	total cell voltage, see Eq. [18] (V)
V_1, V_2	hydrogen and chlorine overpotential, respectively (V)
$V_{1,l}^o, V_{2,l}^o$	observed hydrogen and chlorine kinetic overpotential, respectively, at l th datum
$V_{1,l}^p, V_{2,l}^p$	predicted hydrogen and chlorine kinetic overpotential, respectively, at independent variables corresponding to l th datum
v	percolation velocity through the diaphragm (cm/s)
x	diaphragm dimensional coordinate (cm)
z_j, z_1	ionic charge for species j , $j = 1$ for OH^- ion

Greek

α_1, α_2	apparent transfer coefficients for hydrogen and chlorine reactions, respectively
β	vector of parameters for LS ($\beta = [D_{1,\kappa_{\text{avg}}}]^T$)

Influence of Operating Conditions on the Selectivity Factor of the Nickel/Sodium Electrodialysis Separation

Claudio Fabiani, Luigi Bimbi, Massimo De Francesco, and Bernardino Scuppa

ENEA, Divisione Chimica, Laboratorio Chimica Applicata CRE-Casaccia, Rome, Italy

ABSTRACT

The NiCl₂/NaCl separation by electrodialysis is studied as a function of several operating conditions such as current density, Na/Ni concentration ratio, and temperature. The experimental $T(\text{Ni}/\text{Na})$ separation factors are discussed, assuming a membrane-controlled process, in terms of Hittorf transport numbers and electro-osmotic coefficients for the electrically driven transport of both cations through the cationic membrane (Nafion 125 from du Pont) which is assumed to be the selective component in the cell stack. Activation energy for the separation is calculated and the obtained data are compared with the values derived from membrane resistance measurements.

Electrodialysis is a well-assessed technology in desalination and is still considered an interesting possibility in the field of valuable metal recovery and nuclear waste treatment (1-3). In this last field, the electrical power availability makes the energy requirements and costs for electrodialysis less conditioning parameters. In this work, the Ni/Na separation by electrodialysis in chloride media has been considered. Two commercially available membranes, the cation-selective Nafion 125 (from du Pont) and the anion-selective R-5035 (from RAI Corporation) were used. The former membrane was chosen because of its high performance in many electrochemical applications (fuel cells, batteries, electrolysis) and the latter because it is specifically tailored for electrodialysis.

Experimental

Membranes.—Nafion 125 membranes are homogeneous perfluorosulfonic acid polymeric films from du Pont. They have an equivalent weight of 1,200 and are 5 mil thick. Membrane specimens were treated with 0.1M HCl for 48h and boiled in bidistilled water for 72h to convert the membranes to the H⁺ form, completely wet. Membrane specimens of 37 cm² in H⁺ form were then equilibrated with the electrolyte solution until cation exchange was complete. The R-5035 Raipore membrane (from RAI Corporation) is a quaternized vinylbenzylamine-grafted anion exchange membrane 8 mil thick. Membrane specimens were equilibrated in the electrolyte solution for 72h after 48h in boiling water.

Transport parameter measurements.—The Hittorf transport numbers (t_{\pm}), the electro-osmotic coefficient (β)

(cm²F⁻¹), and the membrane area resistance ($R \Omega \text{ cm}^2$) were simultaneously measured for both membranes. The results are collected in Table I. A three-chamber plastic cell formed by a cathodic compartment bounded by two ion-exchange membranes of opposite charge and two measuring compartments separated by the membrane to be characterized (Fig. 1) was used. The current delivering electrodes were a Pt cathode and a Ag/AgCl anode, because in the anode compartment, volume changes were measured and, therefore, evolution of gaseous species should be avoided. Solutions were recirculated through a thermostated bath or, in the anode compartment, for the same reasons already mentioned, magnetically stirred. The experimental procedures used to perform such measurements are reported elsewhere (4, 5). A known electrical current, I (mA), was passed for a given time interval, Δt , across the cell, and ionic and water transports across the membrane were measured. The transport of water in the anode half-cell where the reversible Ag/AgCl electrode was placed was obtained from the change in vol-

ume solution ΔV ($\Delta V = V_f - V_i$, where V_f and V_i are the final and initial volume in cubic centimeters, respectively) observed in the capillary K (Fig. 1). This figure was corrected for the volume changes related to electrode reactions and ionic species transport. Similarly, the ionic transport used to calculate the ionic transport number was measured through the change in the electrolyte concentration ΔC (mol cm^{-3}) corrected for the contribution of the volume flow due to electro-osmosis. The electrolyte concentration changes were obtained from conductivity data (Cond, Fig. 1) by using a specific calibration curve. A two-equation system was then needed to correctly calculate the Hittorf transport number (t_+ or t_-) and the electro-osmotic coefficients β . These equations are (for the case of Ni^{2+}) (4-6)

$$2t_- = \frac{10^3 V_i}{F} (C_i - C_f) - 10^3 C_f \beta \quad [1]$$

$$\beta = \frac{\Delta V}{F} = \frac{1}{F} (V_1 + 1/2 t_+ \bar{V}_{\text{NiCl}_2} + \bar{V}_{\text{Ag}} - \bar{V}_{\text{AgCl}}) \quad [2]$$

where C_i and C_f are, respectively, the initial and final electrolyte concentrations (mol cm^{-3}), F is the number of Faraday used in the Δt time interval of the experiment, and \bar{V} are the partial molar volumes of NiCl_2 (contribution from the ionic transport), Ag , and AgCl (contributions from the electrode reaction).

The electric potential drop across the membrane was measured by means of two Luggin capillaries connected to the e' and e'' (Fig. 1) electrodes and used to calculate the membrane resistance at a given electric current.

The water content of Nafion 125 [weight percent (w/o) dry polymer] in both NaCl and NiCl_2 solutions was measured according to reported procedures (5). Membrane specimens equilibrated in a given solution were dried under vacuum in an air oven at $120^\circ\text{--}150^\circ\text{C}$ after blotting their surfaces with filter paper. Membrane dryness was checked by means of IR spectroscopy and water amount was calculated as the difference between wet and dry specimens.

Electrodialysis experiments.—A laboratory stack with five cell units 2 mm wide filled with a plastic net as turbulence promoter and delimited by membranes of 37 cm^2 area was operated with an electro dialyzer Bell II supplied by Berghof (Tubingen, Germany). The usual three solutions (200 cm^3 of electrode washing, 400 cm^3 of concentrate, and feed) were thermostated and circulated at $1400 \text{ cm}^3/\text{min}$ flow rate. For washing the electrode, a solution of the same composition as the feed solution was used in each experiment. The pH of concentrate and feed were continuously measured and recorded by using two glass electrodes inserted in the solution reservoirs. From these reservoirs, small aliquots of solutions were taken at fixed times and analyzed for Cl^- and Ni^{2+} . Chloride ions were measured potentiometrically with an Ag/AgCl electrode by using AgNO_3 for titration. The nickel concentration was obtained spectrophotometrically through the dimethylglyoxime complex. The Na^- concentration was obtained with a mass balance.

The stack resistance was also continuously measured and recorded.

Results

The loss of selectivity of charged membranes due to an increase in the concentration of the external electrolyte is a well-known effect which mainly depends on the salt uptake and decreased membrane water content (5). The first effect is a consequence of the saturation of ion-exchange sites of the membrane which reduces the Donnan coion exclusion and determines the salt invasion (with coion transport) of the membrane phase. The second effect is due to the increased osmotic pressure difference between the bathing solution and the membrane phase, which reduces the water content of the latter. The loss of selectivity can be observed from the decrease of the counterion transport number as the electrolyte con-

Fig. 2. Hittorf's transport numbers for Cl^- (RAI R-5035 membrane) and Na^+ , Ni^{2+} (Nafion 125) as a function of the electrolyte molar concentration.

centration increases, as shown in Fig. 2. This effect occurs at a concentration which is lower the higher the counterion valency is, as is shown from a comparison between NaCl and NiCl_2 . This is an important effect, as the decreased membrane selectivity can compensate the higher electromobility of multivalent cations. Similar effects are observed in the membrane resistance (4) and electro-osmotic coefficient which is related to the hydration of the transported ion (5). In fact, the counterion hydration also affects the membrane selectivity. It has been observed with Nafion 125 membranes exposed to alkali hydroxide (4) and chloride (7) solutions that at a given concentration in the region of low selectivity, the cation transport number decreases by increasing the hydration according to the series $\text{Cs} > \text{K} > \text{Na} > \text{Li}$. The data reported in Table I show the corresponding effect on electro-osmotic coefficients and membrane resistance. These parameters are important in determining the selective separation factor of an electro dialysis experiment. In fact, defining $T(\text{Ni}/\text{Na})$ as

$$T(\text{Ni}/\text{Na}) = [(J_{\text{Ni}}/C_{\text{Ni}})/(J_{\text{Na}}/C_{\text{Na}})] \quad [3]$$

It can be shown with some simplifying assumptions (overall membrane control, linear steady-state concentration profiles, negligible back-diffusion, ideal behavior of anion membranes, etc.) (8) that

$$T(\text{Ni}/\text{Na}) = \frac{[(t_{\text{Ni}}/C_{\text{Ni}}^0) + t_w^{\text{Ni}}]}{[(t_{\text{Na}}/C_{\text{Na}}^0) + t_w^{\text{Na}}]} \quad [4]$$

where $t_w = \beta/18$ is the water transport number. Equation [4] assumes that the separation process for the $\text{NaCl}/\text{NiCl}_2$ mixture is mainly due to the cationic membrane and that polarization effects can be disregarded. This last condition was tested, in the current density range $5\text{--}80 \text{ mA cm}^{-2}$ we have used, by measuring the pH of feed and concentrate solutions during electro dialysis. The pH values remain practically constant after a small initial decrease.

For high current densities, when the electromigration is the predominant transport effect, Eq. [4] should reduce to (8)

$$T(\text{Ni}/\text{Na}) = [(t_{\text{Ni}}/C_{\text{Ni}}^0)/(t_{\text{Na}}/C_{\text{Na}}^0)] (I \rightarrow \infty) \quad [5]$$

This limiting law has been tested by measuring the $T(\text{Ni}/\text{Na})$ dependence on the current density. The $T(\text{Ni}/\text{Na})$ values were obtained for NiCl_2 ($\sim 0.1 \text{ M}$) - NaCl ($\sim 0.1 \text{ M}$) mixtures from the relation (8)

Fig. 3. $T(\text{Ni}/\text{Na})$ dependence on the current density I (mA/cm^2)

$$\log [C_{\text{Ni}}^{\circ}(t)/C_{\text{Ni}}^{\circ}(0)] = T(\text{Ni}/\text{Na}) \log [C_{\text{Na}}^{\circ}(t)/C_{\text{Na}}^{\circ}(0)] \quad [6]$$

which is derived by inserting into the definition for T (Eq. [1]) the expression for the ionic fluxes and by assuming T as a constant. In Eq. [6], $C_i^{\circ}(0)$ and $C_i^{\circ}(t)$ ($i = \text{Ni}, \text{Na}$) are the bulk initial and final concentrations in the feed or concentrate solutions. The plots of $\log [C_{\text{Ni}}^{\circ}(t)/C_{\text{Ni}}^{\circ}(0)]$ vs. $\log [C_{\text{Na}}^{\circ}(t)/C_{\text{Na}}^{\circ}(0)]$ are straight lines (T constant), and from their slopes the selectivity factors can be computed. The current density was varied from 5 to 80 mA/cm^2 (Fig. 3). Equation [3] predicts a limiting value for the selectivity $T(\text{Ni}/\text{Na})$ factor, at high current densities, which is reached when the ionic transport is essentially a function of the mobilities (transport numbers) of the ionic species at a given concentration (8). From the transport numbers of Ni^{2+} and Na^+ at 0.1M concentration across a Nafion membrane (Table I), a limiting value of 0.88 is obtained.

$T(\text{Ni}/\text{Na})$ dependence on the Na/Ni ratio.—The separation factors measured at different Na/Ni ratios but at a fixed current density (10 mA/cm^2) are shown in Fig. 4. A substantial constancy is experimentally observed around a value of two corresponding to the Ni/Na valency ratio. According to the $T(\text{Ni}/\text{Na})$ definition (Eq. [1]), this result means that the Ni flux decreases by increasing the Na concentration. As a consequence, the separation yield and the current efficiency decrease. The observed constant value for $T(\text{Ni}/\text{Na})$ as the Na/Ni ratio changes may depend on the nature of the ionic couple considered, since different results have been reported for the Mg/Na couple (8). An important factor in determining the constant T value is the ion exchange constant of monovalent and divalent ions with a given membrane. The results of the hydrogen ion-divalent ion-exchange experiments reported by Steck *et al.* (9) show that the exchange selectivity is almost

Fig. 4. $T(\text{Ni}/\text{Na})$ dependence on the Na/Ni equivalent ratio at a fixed current density 10 mA/cm^2 . C (equiv/ cm^3).Fig. 5. Experimental and calculated $T(\text{Ni}/\text{Na})$ values as a function of temperature in an Arrhenius-like plot.

equal for Na and Co, while for Mg the exchange is higher by a factor of two.

$T(\text{Ni}/\text{Na})$ temperature dependence.—The possibility of changing the separation factor with the temperature has been considered by measuring $T(\text{Ni}/\text{Na})$ at different temperatures in the 30°–60°C range. A complete equation for ionic and water transport in electrodialysis includes diffusion terms both for ions and water through the membrane couple (8). In this case, Eq. [4] does not hold any more. However, at high current densities the ionic and water transport due to the applied electrical field are predominant over diffusion and osmotic effects. Therefore, by assuming membrane control—that is, reduced film effects (polarization) at the membrane-solution interface—the simple Eq. [4] can be used. Under these conditions, the function $\tau_e = [(t_i/C^{\circ}) + t_w]$ can be considered as the “effective” transport number for the ionic species and an Arrhenius-type plot can be used to calculate the transport activation energy (Fig. 5)

$$d[\log T(\text{Ni}/\text{Na})]/d(1/T) = -(1/R)(E_{\text{Ni}} - E_{\text{Na}}) = -(1/R) \Delta E \quad [7]$$

where E_i is the activation energy for the transport of the i th ($i = \text{Ni}, \text{Na}$) cation. The experimental data in Fig. 5, however, do not allow one to reach a clear conclusion about the difference in behavior of Ni and Na fluxes with temperature. In fact, two hypotheses are possible: (i) the $T(\text{Ni}/\text{Na})$ vs. $1/T$ plot is a straight line with zero slope, which means that both Ni and Na transport processes have the same activation energy; (ii) the $t(\text{Ni}/\text{Na})$ vs. $1/T$ plot shows a discontinuity which separates two different transport conditions, $E_{\text{Ni}} \geq E_{\text{Na}}$ for $T \leq 40^{\circ}\text{C}$. In the first

Fig. 6. Evaluation of the desalting rate α of feed solutions for NaCl and NiCl_2 .

Fig. 7. Arrhenius-type plots for the α functions for NaCl and NiCl₂.

case, the overall activation energy is $\Delta E = 11.9$ kJ/mol, and in the second case $\Delta E = -9.6$ kJ/mol. In both cases, it should be possible to select a useful temperature range to optimize the separation process. A more extended investigation is needed possibly over an increased temperature range. However, a limit to this possibility is set by the thermal stability of the membranes. It is interesting to note that the reported values for the activation energies are comparable to those obtained from membrane resistance measurements on Nafion 125 membranes in alkali hydroxide solutions ($E_{Na} = 10$ -30 kJ/mol in the 0.02-10M range) (10).

Figure 5 shows also $T(Ni/Na)$ data calculated from the rate of desalting of binary NiCl₂/NaCl (feed) solutions at different temperatures. If the $C_i^{\circ}(0) - C_i^{\circ}(t)$ functions for both cations are plotted vs. time t (s), the slopes $\alpha = (nA/V)J_i$ (mol cm⁻³ s⁻¹) can be calculated (Fig. 6). According to the assumptions made to obtain Eq. [4]

$$\alpha = (nA/V)(t_i + C_i^{\circ}t_w) I/F \quad [8]$$

(where n is the number of pair units in the cell stack, A is the membrane area, and V is the solution volume) and both τ_i and $T(Ni/Na)$ values can be calculated from the desalting rate of the feed solution. The results of such calculations are given in Table II. From the Arrhenius plots of α for both counterions (Fig. 7), the activation energies for NaCl and NiCl₂ transport are obtained: $E_{NaCl} = 8.2$ kJ/mol and $E_{NiCl_2} = 4.8$ kJ/mol ($\Delta E = -3.5$ kJ/mol). This last value is very close to the figure for the activation energy, which can be calculated from the best linear plot of the experimental $T(Ni/Na)$ data reported in Fig. 5: $\Delta E = -4.2$ kJ/mol.

Table II. Evaluation of the desalting rate, α (mol cm⁻³ s⁻¹), effective transport number, τ , and separation factor $T(Ni/Na)$ for single NaCl/NiCl₂ from electrodiagnosis separation experiments. Feed solution 0.1M; NiCl₂ 0.1M.

$T(^{\circ}C)$	α_{Na} (mol cm ⁻³ s ⁻¹)	α_{Ni} (mol cm ⁻³ s ⁻¹)	τ_{Na}	τ_{Ni}	T (Ni/Na)
30	1.17×10^{-5}	2.13×10^{-5}	0.24	0.45	1.82
40	1.33×10^{-5}	2.30×10^{-5}	0.28	0.48	1.73
50	1.40×10^{-5}	2.43×10^{-5}	0.29	0.51	1.74
60	1.57×10^{-5}	2.53×10^{-5}	0.33	0.53	1.61

Conclusion

The use of Nafion 125 and RAI R-5035 membranes for electrodiagnosis of Na/Ni chloride binary solutions depends on the absolute Ni concentration because the Nafion selectivity in NiCl₂ solutions falls very sharply above 0.2M concentration. The $T(Ni/Na)$ separation factor does not substantially depend on the Na/Ni concentration ratio, and this constancy, at a given current density, shows that the current efficiency for Ni separation decreases as the Na concentration increases. The temperature effect on the $T(Ni/Na)$ separation factor is not very relevant in the 30°-60°C temperature range. However, some data indicate the possibility that the Ni yield decreases with temperature above a discontinuity point around 40°C.

Cyclic Pulse Voltammetric Stripping Analysis of Acid Copper Plating Baths

Dennis Tench* and John White

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

A pulse voltammetric stripping method is described for determining the absolute concentration of proprietary additive in acid copper baths containing contaminants derived from circuit board plating. Results are presented for both freshly prepared and production baths, and a comparison is made between the pulse and linear sweep voltammetric stripping analysis techniques.

Previous work (1, 2) has shown that the cyclic voltammetric stripping (CVS) method (3) yields the concentrations of proprietary additives and chloride ion in acid copper plating systems, but organic contaminants generated in circuit board production baths are found to interfere with the analyses. In spite of such interference, the CVS rate parameter has been demonstrated to correlate well with the deposit tensile properties (4), and, recently, improved circuit board yields attained via CVS control of acid copper baths have been documented (5). On the other hand, control of acid copper baths would be simplified if the absolute concentration of the additive were provided. One procedure is to generate a series of standard curves for each bath contaminant level, but this is tedious and valid only if the contaminants are always sufficiently similar so that their effect is constant for a given overall concentration.

In the present paper, a modification of CVS, *i.e.*, cyclic pulse voltammetric stripping (CPVS), is shown to yield the absolute additive concentration in at least one proprietary acid copper system in the presence of contaminants derived from circuit board plating.

Experimental Details

Acid copper baths used in the present work were air saturated and generally contained 75 g/liter copper sulfate pentahydrate, 10% by volume concentrated sulfuric acid, 75 mg/liter chloride, and various amounts of proprietary additive (Lea Ronal Copper Gleam PCM). The electrochemical cell was Pyrex (250 ml) with a Teflon top. Bath temperature was maintained constant ($\pm 0.1^\circ\text{C}$) via water circulated through a cell jacket.

The indicator electrode was a platinum rotating disk (0.46 cm^2) obtained commercially (Pine Instrument Company). Unless otherwise noted, the electrode rotation rate was always 500 rpm. A double-junction saturated calomel electrode (SCE) was used as the reference, and a platinum wire (99.0%) dipped directly in the cell served as the counterelectrode.

Voltammetric analyses were performed under computer control (Hewlett-Packard Model 9825). The electrode potential was controlled via a digital/analog converter and a potentiostat (Princeton Applied Research Corporation Model 173). Copper stripping charge was measured by current integration via a digital coulometer (Princeton Applied Research Corporation Model 179).

Pulse Voltammetric Method

Linear sweep cyclic voltammograms for a platinum rotating disk electrode in freshly prepared and production acid copper baths are shown in Fig. 1. Cathodic current corresponding to copper deposition is evident at potentials negative of about 0.0V, whereas the copper deposit is stripped from the inert electrode between about 0.0 and 0.2V, producing an anodic current peak. Since the sweep rate is constant (100 mV/s), the stripping peak area is proportional to the average copper deposition rate for a given voltage cycle. In conventional CVS

analysis of acid copper baths of this type, the stripping peak area determined with electrode rotation, A_T , is used as a measure of the concentration of brightening/leveling additives in the bath (2). As mentioned above, however contaminants that build up in circuit board production baths with use also affect the copper deposition rate and thus interfere with the additive analysis. Oxidation of such contaminants on platinum occurs positive of about 0.5V *vs.* SCE (Fig. 1), producing a well-defined current wave (4). Note that, for Fig. 1, data obtained at a higher electrode rotation rate (2500 rpm) than used for the analyses discussed below (500 rpm) are reported in order to accent the contaminant wave (which is partially mass-transport limited). A second anodic wave, corresponding to chloride oxidation (2), is observed positive of 1.2V; the plateau current is proportional to chloride concentration in freshly prepared baths but is generally less at the same chloride level in production baths, indicating that contaminants effectively compete with chloride for adsorption sites on the electrode in this potential region.

In the CPVS method, the effect of the contaminants, which apparently interfere with conventional CVS analysis by absorbing on the platinum electrode, is greatly mitigated by sequentially pulsing the electrode between appropriate plating, stripping, cleaning,¹ and equilibration potentials² (see Fig. 1) so that the electrode surface is maintained in a relatively clean and reproducible state. The steady-state charge density corresponding to stripping the copper deposit, plated at constant potential for a given length of time, is then proportional to the additive concentration and is unaffected by bath contaminants.

¹Note that the cleaning potential is in the oxygen evolution region, where organic contaminants are presumably oxidized or displaced by oxygen species on the platinum surface.

²Equilibration at a relatively negative potential is apparently necessary to reduce platinum oxides and to condition the electrode surface so that reproducible results are obtained.

Fig. 1. Linear sweep cyclic voltammograms at 100 mV/s for a rotating platinum disk electrode (2500 rpm) in freshly prepared and production acid copper baths (22°C). Note that the current scale is an order of magnitude more sensitive positive of 0.5V.

*Electrochemical Society Active Member

The pulse sequence used in the present work was

$$V_{\text{plate}} \rightarrow V_{\text{strip}} \rightarrow V_{\text{clean}} \rightarrow V_{\text{equilibrate}}$$

This sequence was repeated (under computer control) until a steady-state copper stripping charge was obtained, *i.e.*, until two sequential values agreed within $\pm 2\%$. Steady state was generally attained within two to three cycles. It should be mentioned that the plating current also varies appreciably within a given cycle; this, coupled with the inherently greater sensitivity provided by averaging, suggests that the stripping charge should be a more reliable measure of the deposition rate than the cathodic current itself. Also, as pointed out for conventional CVS analysis (3), the copper stripping charge reflects only the copper deposition rate, whereas the cathodic current may include contributions from other reduction processes.

Results and Discussion

Preliminary studies were directed toward optimization of the measurement parameters, *i.e.*, the plating, cleaning, and equilibration potentials and times were varied to establish conditions providing good sensitivity and reproducibility. The stripping potential was always 0.2V, at which copper appears to be completely stripped from the electrode. Of course, the time required for stripping varies depending on the amount of copper previously deposited. The stripping step was terminated by the computer when the current decreased by 99.95% *i.e.*, to 0.05% of its previous value (with sampling every 100 ms).

Figure 2 shows plots of the copper stripping charge density *vs.* additive concentration for 10.0s of plating at various voltages, with cleaning at 1.6V for 5.0s and equilibration at 0.425V for 5.0s. The shape of these curves results from the opposing effects of two additive components, as discussed previously (4). Essentially, the sharp decrease at low additive levels results from high molecular weight polymeric surfactants, *e.g.*, polyethylene glycols, which suppress copper deposition by blanketing the electrode surface with polymeric film, whereas the linear increase at higher concentrations is produced by the brightener component. Since the effect of the surfactants saturates at very low additive levels (4), voltammetric stripping analysis of the undiluted bath generally reflects only the concentration of the brightener component. It should be kept in mind that additive concentrations reported here are in terms of milliliters per liter of the proprietary additive solution, which also contains the other components. Apparently, as the deposition potential is

made more negative (Fig. 2), this polymeric cathode film is broken down (presumably by reduction and/or inclusion in the deposit) so that the brightener component is increasingly effective at enhancing the copper deposition rate (slope of linear portion of curve increases). A plating voltage of -0.25V was chosen for further work because adequate sensitivity is obtained and the average current density at an intermediate additive concentration (2 ml/liter) in this case approximates that typically used for production plating processes (20 mA/cm^2), so that the data might be expected to yield more relevant mechanistic information. Also, the data for -0.3V appear to deviate slightly from linearity at the highest additive concentrations investigated.

Figure 3 shows plots of the copper stripping charge density at various additive concentrations *vs.* plating time at -0.25V , with cleaning at 1.6V for 5.0s and equilibration at 0.425V for 5.0s. The expected linearity is observed, but there is an apparent change in slope at about 5s. Since the reason for this slope change is unknown,³ it is not clear which plating time should be used. A short plating time, *i.e.*, 2s, was chosen because data scatter in this case seems to be less than observed for 10s of plating.

Note that temperature is an extremely important variable to both plating performance and voltammetric analysis of acid copper baths and should be closely controlled. For the present work, a value of 25°C was originally chosen, but it proved difficult to maintain under the prevailing ambient conditions, so the later experiments were performed at 26°C . This minor difference should not significantly affect the choice of analysis conditions, but it does appreciably affect the absolute stripping charge values.

Variations in either equilibration voltage or time were found to exert a significant effect on the stripping charge obtained under otherwise equivalent conditions, presumably because of changes in the state of the platinum surface. This suggests that complete equilibrium is not attained during the short equilibration times investigated, *i.e.*, 1-20s. Thus, it is important that the equilibration voltage and time be maintained constant; 0.425V and 5.0s were chosen for the present work because they seemed to yield somewhat more reproducible results. On the other hand, variations in the cleaning time from 1 to 10s had no discernible effect; cleaning voltage was not varied.

³Possibilities include substrate effects or residual suppression of copper deposition by the polymeric additive component at shorter plating times, or an increase in deposit surface roughness at longer times.

Fig. 2. Plots of CPVS copper stripping charge density for a platinum rotating disk electrode (500 rpm) at various plating voltages *vs.* additive concentration in an acid copper bath (25°C). Plating time = 10.0s; $V_{\text{clean}} = 1.6\text{V}$ (5.0s); $V_{\text{equilibrate}} = 0.425\text{V}$ (5.0s).

Fig. 3. Plots of CPVS copper stripping charge density for a platinum rotating disk electrode (500 rpm) *vs.* plating time (-0.25V) at various additive concentrations in an acid copper plating bath (26°C). $V_{\text{clean}} = 1.6\text{V}$ (5.0s); $V_{\text{equilibrate}} = 0.425\text{V}$ (5.0s).

It should be mentioned that one might expect the equilibration time of 5s to be sufficiently long to permit bath contaminants to reabsorb on the electrode surface and affect the additive analysis. Results presented below indicate that this is not the case, suggesting that contaminant adsorption does not occur at the equilibration voltage used (0.425V). This would be consistent with the onset of contamination oxidation at about 0.5V (Fig. 1) coinciding with contaminant adsorption, the latter not occurring at more negative voltages.

CPVS results obtained at 26°C by standard addition of a proprietary additive to a freshly prepared acid copper bath and a well-used production bath are shown in Fig. 4. Note that the production data are offset by 0.25 ml/liter to account for additive presumably already present in the bath. The data points are seen to practically coincide in the two cases, indicating that the effect of bath contaminants on the results is minimal.

For comparison, conventional linear sweep (100 mV/s) CVS results (2) for the same batch of additive are shown in Fig. 5. It is evident that contaminants in the production bath also tend to increase the stripping charge density in this case, interfering with the additive analysis.

Fig. 4. CPVS results for analysis of a proprietary additive in a freshly prepared acid copper bath and a circuit board production bath (26°C).

Fig. 5. Linear sweep CVS results for the same system (26°C) as for Fig. 4 (voltage swept at 100 mV/s between -0.2 and 1.6V vs. SCE; electrode rotation = 500 rpm).

Fig. 6. CPVS results for analysis of a proprietary additive in freshly prepared acid copper bath and a circuit board production bath (26°C) from a second circuit board facility.

CPVS results obtained for a freshly prepared acid copper bath and a production bath from a different circuit board facility are given in Fig. 6. Note that the production data are offset by 0.5 ml/liter to account for additive presumably already present in the bath. Again, the data points are seen to practically coincide in the two cases. These results demonstrate decisively the effectiveness of the cyclic pulse technique in mitigating the effects of bath contaminants, at least of the types and concentrations encountered in two typical circuit board production facilities, on voltammetric stripping additive analysis.

It should be emphasized at this point that although the brightener additive component is apparently stable in freshly prepared acid copper baths, it decomposes slowly in used production baths, the decomposition rate being faster at higher additive concentrations. This phenomenon has also been observed by other workers (6). In the present case, a decrease of about 10% over one day was observed (via CPVS analysis) for additive concentrations in the 5 ml/liter range. To avoid errors associated with such effects, our analyses were always performed within a few minutes after additive additions.

Summary and Conclusions

The cyclic pulse voltammetric stripping (CPVS) method described here apparently eliminates interference of contaminants derived from circuit board plating on voltammetric analysis for additives in acid copper baths. This method involves pulsing a rotating platinum disk electrode sequentially between plating, stripping, cleaning, and equilibration voltages, and measuring the steady-state charge associated with stripping the copper deposit. Conditions used for the present work, which involved one proprietary system, were 500 rpm electrode rotation and plating at -0.25V vs. SCE for 2.0s, stripping at 0.20V until the current decreased by 99.95%, cleaning at 1.6V (oxygen evolution region) for 5.0s, and equilibration at 0.425V for 5.0s. The voltage pulse technique could most probably be used to minimize the effects of contaminants on other voltammetric analyses, e.g., chloride analyses in acid copper baths.

Electro-Oxidation of Substituted Silane High Polymers

A. Diaz* and R. D. Miller

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

We report here the first electrochemical data on substituted silane high polymer films deposited on a Pt electrode. The oxidation peak potentials were measured for a series of substituted silane high polymers. The polymers oxidize irreversibly and produce soluble products which are removed from the electrode. The ease of oxidation of the polymer depends on the substituents, and polymers with the aryl groups attached directly to the silicon backbone are more easily oxidized.

The conjugative ability of the Si-Si covalent bond is well established (1, 2). The importance of this interaction is reflected in both the redox characteristics and the optical properties of a series of permethylated silane oligomers (Si₂ through Si₆) (3). These compounds have low oxidation potentials (in the range 1-2V vs. SCE) and optical excitation energies which decrease with increased catenation. In this regard, the energies for both oxidation and the electronic absorption have been shown to scale with the number of silane atoms in the chain, as may be anticipated from Huckel theory (3, 4). The cations generated by the oxidation of the silane oligomers are unstable intermediates which react to produce soluble products; for example, the oxidation of permethyldisilane leads to the formation of trimethylsilyl carbonium ions, which react further to yield solvolysis products (3).

While electro-oxidation data for high molecular weight polysilanes have not been reported, extrapolation of the solution data obtained for the permethylated oligomers indicates that they should oxidize ca. 1.0V anodic of SCE. Recent substituent studies on the electronic spectra of silane polymers suggest that the oxidation potentials might also be sensitive to the nature and the position of the substituents on the chain (9). Furthermore, these spectroscopic observations imply that the electron-transfer/chain-length correlations may not be as simple in the presence of large substituent groups as with the compact permethylsilane derivatives (see Table I).

The oxidation characteristics and the spectral properties of the oligomeric permethylsilanes resemble those properties of certain linearly coupled aromatic oligomeric materials such as the derivatives of pyrrole, thiophene, and benzene, which are also a function of the number of aromatic units in the linear chain (6). The oxidation reactions of both series are irreversible, but in the case of the aromatic oligomers polymeric films are produced which coat the electrode surface. It is the nature of the products of the oxidation that provides the biggest difference between the silane polymers and the aromatic or heteroaromatic oligomers. Whereas the permethylsilanes produce lower molecular weight soluble products when oxidized, the aromatic derivatives generate films which are electroactive and can be switched repeatedly between the neutral and the oxidized form (7, 8).

We have electrochemically oxidized a series of substituted polysilanes deposited as thin films (400-700Å) on a

platinum electrode, and find that the relative ease of oxidation is sensitive to the nature and position of the backbone substituents. In every case, the oxidation is irreversible, as with the lower molecular weight oligomers, and the reaction proceeds with the eventual removal of the polymer film from the electrode surface. The results of this electrochemical study are described in this paper.

Experimental

The polymers used in this study were prepared as described (*vide infra*). Thin films were cast on the platinum electrode (0.5 cm²) by spin coating a solution of the polymer. Those polymers containing aromatic substituents were spun from toluene or xylene, while a 3:1 mixture of xylene-ethylcyclohexane was found to be a more suitable solvent for the alkyl polysilane derivatives. The electrochemical measurements were carried out in a single-compartment cell equipped with the film-coated platinum working electrode, a gold counterelectrode, and a calomel reference electrode. Tetraethylammonium tetrafluoroborate/acetonitrile electrolyte solutions were employed. All ESCA analyses were performed using a Hewlett Packard 5959B ESCA spectrometer. The energy reference for the instrument is set for Au at 84.0 eV. The density of the poly(methylphenyl)silane film was determined from the weight and the thickness which was measured using a Talystep instrument.

Results and Discussion

We have prepared (9) a large number of soluble, high molecular weight polysilane homopolymers by the con-

Table I. Electrochemical and absorption data for some substituted silane high polymers

denation of substituted dihalosilanes with sodium as shown below. These materials were purified and spectrally characterized as previously described (9). Most of these high polymers are thermally stable in nitrogen to at least 350°C, and many, particularly, but not exclusively, those with aromatic substituents, are high melting solids with glass transition temperatures in excess of 75°C. The polymers were quite soluble in aromatic solvents such as toluene but were insoluble in acetonitrile or the electrolyte solution.

The spectral properties of these polymers were quite unusual relative to related carbon polymers [see Ref. (5) and (9) for a more complete discussion of the spectral properties]. All of the sterically unencumbered alkyl derivatives display very strong electronic absorption maxima around 303-309 nm. On the other hand, those materials having aryl substituents directly bonded to the silicon backbone are characterized by a red-shifted absorption maximum in the 335-345 nm region. This strong absorption and the dramatic substituent effects are consistent with a delocalized sigma backbone, which also agrees with earlier observations made on low molecular weight model compounds (10). The response, however, is not systematic with the structural variation, indicating that the conformation of the backbone and/or the pendant groups may be a factor in determining the ultimate electronic spectrum of the polymer.

The polymers are readily oxidized in the potential range 0.7-1.6V vs. SCE. The oxidation peak potentials for the various polymeric films are summarized in Table I. Shown in Fig. 1 is the cyclic voltammogram for a thin film (420Å) of poly(methylphenyl)silane, on a platinum surface, measured in acetonitrile. The oxidation reaction is irreversible, and the shape of the peak at 1.00V is consistent with a surface localized reaction which does not involve diffusion. There is some residual oxidation on the anodic side of the peak which distorts the symmetry of the peak. For this polymer, the peak is surprisingly nar-

Fig. 1. Cyclic voltammogram of a poly(methylphenyl)silane film on platinum measured in acetonitrile. First (bottom) and second (top) scan.

row, with a peak width at half-height of only 100 mV. The area under the curve corresponds to 0.34 mC/cm² or 3.6 × 10⁻⁹ F/cm². For comparison, the calculated molar equivalent of the monomer units on the electrode (420Å film thickness and the film density of 1.174 g/cm³) is 40 × 10⁻⁹ mol/cm². Comparison of these numbers suggests that one electron is removed from polymer segments containing ca. 11 monomer units. With thinner films, ~120Å thick, the same symmetrical peak is observed, but at a slightly less anodic peak potential, 0.92V. The small shift in these potentials may be due to a difference in solvation of the film. The peak is also narrower, with a peak width at half-height of 90 mV. The comparison of the amount of charge involved in the oxidation reaction with the amount of polymer on the electrode indicates that one electron is removed for ca. every ten monomer units. The small change produced in the electrochemical stoichiometry by the threefold change in film thickness suggests that this number must be a close approximation of the actual value for the reaction. This stoichiometry is in the range, one electron/8-10 monomer units, which was suggested as the oligomer size range where the oxidation potentials could be used to approximate those of the corresponding high molecular weight polymer (3, 6). This stoichiometry may be an average value, and more information is needed in order to establish the precise stoichiometry.

The electrochemical stoichiometry of linear polymers, where the backbone of the chain is electroactive, is a subject which is poorly understood. This topic first emerged with the electrochemical characterization of polypyrrole, which is a linear chain of α, α' -coupled aromatic units (7). The electrochemical stoichiometry for the oxidation of this polymer is 0.25-0.30 charge/aromatic unit. Since polypyrrole, other electroactive polymers have become available and are found to have comparable stoichiometries. For example, polythiophene has 0.06 (8) to 0.25 (11) charge/aromatic unit, polypyrene has 0.31 (12), and polyazulene has 0.25 (12) charge/aromatic unit. For these polymers, the stoichiometry must reflect the length of polymer segments along the polymer chain with coplanar aromatic units which are disrupted by kinks and bends in the chain. The length of these segments must reflect a balance of the chemical stability of the delocalized cation center plus entropy considerations associated with keeping the aromatic rings coplanar.

In the case of the polysilanes, entropic considerations may be less important, since the backbone does not contain aromatic rings. For these polymers, the stoichiometry will be determined by the intrinsic coulombic interactions, which may in turn be influenced by conformational variations along the polymer backbone.

With every film, the peak is observed in the first scan only, since the integrity of the film is destroyed by the chemical irreversibility of the reaction. The electrochemical reaction produces a soluble electroactive product which is oxidized around 1.0V. Although the products of the reaction have not been identified, the reversible nature of redox reaction displayed by the electroactive product suggests that it is not simply a lower molecular weight segment of the polymer. This conclusion is based on the fact that all of the polysilane compounds studied thus far undergo chemically irreversible oxidation. Qualitatively, similar results were obtained with the films of the other polymers, except that the peaks are not so narrow and the symmetry is not as obvious because the background current anodic of the peak is significant. This can be seen with the voltammogram for poly(methyl- β -phenethyl) silane film (Fig. 2).

The films are evenly coated and featureless with no visible cracks or defects (Fig. 3). They are, however, somewhat permeable. The permeability of a poly(methylphenyl)silane film (600Å thick) coated on a platinum electrode (0.5 cm²) was estimated by measuring the cyclic voltammogram of ferrocene (10⁻⁶ mol/cm³). For this measurement, the voltage was swept between 0 and 0.7V in order to preserve the integrity of the film. With the

Fig. 2. Cyclic voltammogram of a poly(methyl- β -phenethyl)silane film on platinum measured in acetonitrile. First (bottom) and second (top) scan.

coated electrode, the current density for the oxidation of ferrocene is 40 times smaller than with bare platinum, and no change was observed in the E° . The shape of the resulting curve resembles a step, as is observed for reactions limited by diffusion across the film, and the size of the signal is not sensitive to sweep rate between 10 and 50 mV/s. The diffusion of ferrocene across the film was calculated using the expression, $j = nFCD/\sigma$, where D is the diffusion of ferrocene across the film and σ is the thick-

Fig. 3. Scanning electron micrograph of a thin film (2000Å) of poly(methylphenyl)silane cast on a silicon substrate.

ness of the film. The calculated values of j , D/σ , and D are 8×10^{-6} A/cm², 8×10^{-5} cm/s, and 0.5×10^{-9} cm²/s, respectively. These values are slightly lower than the values usually observed for other representative thin films. For comparison, the parameters for the diffusion of ferrocene across other thin film coatings on platinum electrodes are listed in Table II. As can be seen, the permeability of ferrocene across the polysilane film is less than for the other three films. It should be noted, however, that the method of preparation for the other films, except for the poly(vinylchloride), was different. Poly(vinylchloride) was prepared by spin coating (13), poly(2,6-dimethyl)phenol by electropolymerization (14), and polytrifluorotoluene by plasma polymerization (15).

The film is stable on the electrode in the potential range 0-0.7V; however, sweeping the potential up to 1.5V removes the film, and the size and the shape of the voltammogram for the ferrocene oxidation reaction approaches that with a clean platinum surface. For example, after three sweeps, the original size of the peak is recovered.

ESCA analysis of the platinum electrode surface indicated that the polymer film was completely removed from the surface during the brief electrolysis. These results are consistent with the electrochemical results described above. Analysis of a freshly cast film of poly(methylphenyl)silane revealed peaks for carbon 1s, silicon 2s, and oxygen 1s. The relative amounts of the elements calculated from the peak areas and corrected for the photoionization cross sections (1.0 for carbon, 0.955 for silicon, and 2.93 for oxygen) are 6.94 to 1.0 to 0.167, respectively. The carbon to silicon ratio is correct for the C_7H_9Si unit of the polymer; however, the small amount of oxygen present (ca. 2%) may be due either to moisture on the surface of the film or perhaps to the presence of small quantities of oxygen in the polymer itself. No platinum was detected. Analysis of the same electrode after electrolysis showed the presence of a small amount of residual carbon and oxygen only, in the ratio of 2.54, plus a large platinum signal. No silicon was detected on the electrode.

In the case of the aryl-substituted polysilanes, the oxidation reaction must involve the polysilane chain and not simply the aryl group because the oxidation potential of aryl groups are much more anodic. For example, the oxidation peak for alkyl- and silyl-substituted benzene derivatives appears at 2.3 and 2.5V, respectively, and that of anisole at 1.80V (16). As can be seen, aryl substituents on the polymer backbone greatly facilitate the oxidation of the polysilane polymer (Table I) and of tetramethylsilane. For example, with the introduction of a phenyl or a benzyl substituent, the oxidation peak for tetramethylsilane is shifted cathodically by 0.5 and 1.2V, respectively. This effect may be due partly to a stabilizing resonance interaction between the aryl group and the incipient silyl cation. The magnitude of this stabilizing interaction must, however, be sensitive to conformational effects in the backbone and of the aryl ring, since phenyl substituents do not facilitate the oxidation of the persubstituted cyclopentasilane derivatives listed in Table III. Thus, the conformational freedom of the phenyl ring, especially the rotational freedom, appears to be a critical factor. The stabilizing effect of the phenyl group is observed to some extent even when the phenyl group is not directly bonded to the silicon atom. In this regard, the phenyl substituent in the polysilane 3 shifts the oxidation peak cathodic of the cyclohexyl-substituted polymer by 0.1V.

Particularly striking is the large substituent effect of the methoxy group. The oxidation peak for poly(p-meth-

oxyphenylmethyl)silane (0.69V) is 0.31V less anodic than the peak for poly(methylphenyl)silane (1.00V). Although substituent effects can be large for small molecules—for example, the oxidation peak for anisole (1.80V) in acetonitrile solution is 0.5-0.7V less anodic than the peak for alkylbenzene derivatives (2.3-2.5V) (16)—they are usually small for polymers. For example, the effect of a p-methoxy group on the oxidation peak potential of N-phenylpyrrole polymer is only 0.06-0.15V (17).

The oxidation of the polymers is also somewhat sensitive to the nature of the alkyl substituents. In this regard, the permethyl-substituted polymers are more easily oxidized than the hexyl-substituted polymers. The oxidation peak for poly(dimethyl)silane (extrapolated value using the data from Table III) is shifted anodically by 0.4 and 0.6V compared to the polymer with one or two hexyl groups per silicon in the polymer. These voltage differences are only estimates because the comparison involves an extrapolated value using data from another laboratory. Nevertheless, the effect is large and in the opposite direction from what is normally observed for alkyl substituent effects. For example, simple alkyl groups shift the oxidation potential of polypyrrole (18) and thiophene (8) cathodically by 0.1-0.2V. Therefore, the effect is not electronic and may result from kinetic limitations caused by the bulky hexyl groups which provide some separation between the platinum surface and the polysilane backbone. This effect is probably not important with the poly(methylphenyl)silane because the phenyl groups provide a channel for electron transfer.

In conclusion, the substituted silane polymers which have already attracted attention because their photochemical and lithographic properties also appear to have the potential for interesting electrochemistry. Because of

the sensitivity of the oxidation potentials to the substituents, the choice of appropriate substituents may generate an interesting new class of redox polymers (19).

Energy Density, Power Density, and Polarization Studies of the Partially Oxidized ("p-Doped") Polyacetylene Cathode

M. Maxfield,*¹ S. L. Mu,² and A. G. MacDiarmid*

Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Films of polyacetylene, $(\text{CH})_x$, partially oxidized ("p-doped") to 2% and 7% having compositions $[(\text{CH})^{+0.02}(\text{ClO}_4)_{0.02}^-]_x$ and $[(\text{CH})^{+0.07}(\text{ClO}_4)_{0.07}^-]_x$, respectively, were employed as the cathode in electrochemical cells of the type $\text{Li}/1.0\text{M LiClO}_4$ (propylene carbonate)/ $[(\text{CH})^{+y}(\text{ClO}_4)_y^-]_x$. They were charged and discharged (both immediately and after a 16h delay) at constant currents ranging from 0.01 to 20.00 mA/cm² of $(\text{CH})_x$ film, and their capacities, energy densities, and average power densities were measured. The average cell voltage and coulombs released during discharges of a cell using a 7% oxidized polyacetylene cathode were relatively insensitive to an increase in discharge current of from 0.01 to 1.00 mA/cm².

Reversible electrochemical oxidation or reduction has been observed for a variety of organic polymers such as polypyrrole (1), polythiophene (2), polyazulene (3), polyparaphenylene (4), poly 2,6-(4-phenyl)quinoline (5), and polyacetylene (6-9). These polymers exhibit conductivities in the metallic regime of 10^1 - $10^3 \Omega^{-1} \text{cm}^{-1}$ when they are partly oxidized or reduced to form species such as $(\text{polymer})^{+y}\text{A}_y^-$ or $\text{M}_y^+(\text{polymer})^{-y}$, respectively, A^- and M^+ being inert monovalent counterions introduced during the electrochemical redox reactions. Experimental laboratory scale batteries have been fabricated from the oxidized and reduced forms of polyparaphenylene and polyacetylene, $(\text{CH})_x$, the most extensively studied being those using polyacetylene in its oxidized form, $[(\text{CH})^{+y}\text{A}_y^-]_x$ (6-8) or reduced form, $[\text{M}_y^+(\text{CH})^{-y}]_x$ (9). Electrochemical oxidation of polyacetylene has been reported in electrolytes consisting of salts of $(\text{ClO}_4)^-$ (6-8), $(\text{AsF}_6)^-$ (10, 11), $(\text{PF}_6)^-$ (10), $(\text{BF}_4)^-$ (10), and $(\text{CF}_3\text{SO}_3)^-$ (10) dissolved in propylene carbonate (PC) or sulfolane.

In the present study, a specific configuration of the $\text{Li}/\text{LiClO}_4(\text{PC})/[(\text{CH})^{+y}(\text{ClO}_4)_y^-]_x$ cell is further characterized by determining the dependence of the discharge voltage, V_d , average discharge voltage, \bar{V}_d , and capacity on the value of selected constant current discharge rates expressed in milliamperes per square centimeter of the $(\text{CH})_x$ film.

In order to examine the effect of different levels of oxidation (charge density) of the $(\text{CH})_x$ on its discharge characteristics, the maximum charge level of the $[(\text{CH})^{+y}(\text{ClO}_4)_y^-]_x$ electrode was varied from $y = 0.02$ to $y = 0.07$. The effect of possible nonhomogeneity of the dopant anion distribution within the $(\text{CH})_x$ film and/or fibrils was studied by varying the delay between the termination of a charge cycle and the beginning of a discharge cycle from 0 to 16h.

Experimental

The cells were constructed by pressing lithium metal foil (Alfa Ventron) onto a nickel grid (Delker Corporation, 189 mesh) and covering it with a separator, followed by a single layer of polyacetylene film, and finally by platinum gauze (A. H. Thomas, 52 mesh). Some stainless steels and nickel corrode in contact with oxidized polyacetylene; however, graphite has been shown to be a suitable current collector (11). The separator for the cell containing 2% oxidized $(\text{CH})_x$ was kiln-dried glass filter paper and that for the cell containing 7% oxidized $(\text{CH})_x$ was hydrophilic porous polypropylene (Celanese Celgard, K-5511) which had previously been treated with a plasma discharge (12). Anhydrous LiClO_4 (Alfa Ventron) was dried by melting under a dynamic vacuum.

For each cell, the assembly of current collectors (spot welded to Pt wire leads), electrodes, and separator were

squeezed into rectangular glass tubing ($3 \times 9 \times 50$ mm) to which was added 0.5 ml of 1.0M LiClO_4 in propylene carbonate (Aldrich) which had been distilled in a spinning band column. No analysis of water content was made. The cell was evacuated and sealed by melting the glass around the protruding electrode leads.

The polymer electrode in both cells was free standing polyacetylene film prepared as described by Shirakawa (13), except that the catalyst was aged for only 15 min at 25°C in order to produce thinner fibrils (14). Prior to the initial electrochemical oxidation of the film, the $(\text{CH})_x$ was present as the *cis*-rich isomer having been stored at -78°C under vacuum since its preparation. The film thickness was 0.1-0.2 mm, and, according to electron micrographs of samples from the same preparation, the polymer fibrils ranged from 100 to 200Å in diameter. Since the density of the $(\text{CH})_x$ fibrils is 1.2 g/cm³ (15), and since the density of the films used in this study was 0.25 g/cm³, 80% of the undoped $(\text{CH})_x$ film was void space. The effective surface area of the $(\text{CH})_x$ fibrils in $(\text{CH})_x$ films before doping has been reported to fall in the range 60-100 m²/g (15). Before recording any electrochemical data on the cells, they were twice charged and discharged in order to convert the *cis*-rich $(\text{CH})_x$ to the more thermodynamically stable *trans*-rich isomer (16).

The amounts of film used as electrodes were 19.7 mg (4.3 cm²) for the cell in which the polyacetylene was oxidized to 2% and 6.9 mg (1.15 cm²) for the cell in which the polyacetylene was oxidized to 7%. In every charge/discharge cycle, the former cell was charged at a constant current of 0.812 mA corresponding to 2% oxidation/h of the $(\text{CH})_x$. The latter cell was always charged at a constant current of 0.142 mA, corresponding to 1% oxidation/h of the $(\text{CH})_x$. Each cell was then either immediately discharged or was permitted to stand for 16h before discharging to allow the charge distribution to reach 80% equilibrium based on a diffusion constant of 4×10^{-18} cm²/s (17) and a fibril diameter of 100-200Å. The discharges were performed at constant currents in the range of 0.01-20.00 mA/cm² of film. The discharge voltage, V_d , was recorded as a function of the coulombs released until it dropped to 2.50V, the approximate midgap potential of pristine *trans* $(\text{CH})_x$, a direct bandgap semiconductor. Because of the minute density of states in the bandgap, the reduction potential of neutral $(\text{CH})_x$ can fall anywhere between 1.75 and 3.10V vs. Li/Li^+ (18). Hence, the remaining available positive charge could be released in a 16h discharge at a constant applied potential of 2.50V without injection of negative charge.

Table I is a compilation of data for each charge/discharge cycle. It includes (i) the extent of charging expressed as a percent oxidation of the $(\text{CH})_x$ and also as the number of coulombs, $Q(\text{in})$, involved in the charge process; (ii) the average discharge voltage, \bar{V}_d ; (iii) the constant discharge current, i_d , employed; (iv) the discharge time at the applied constant current; (v) the coulombs liberated during the constant current discharge, $Q(\text{out})$; (vi)

^a 2 or 7 indicates percent oxidation of the polyacetylene at the end of a charge cycle; "immediate" indicates discharge of the cell immediately after the charging cycle was completed; "delayed" indicates discharge of the cell 16h after the charge cycle was completed.

^b Average voltage during the constant current discharge.

^c Coulombs involved in a charge cycle.

^d Constant current discharge (mA/cm²) of (CH)_x film.

^e Duration of the constant current portion of the discharge.

^f Charge released during the constant current portion of the discharge cycle.

^g Sum of the charges released during the constant current and constant applied potential portions of the discharge cycles.

^h Q_{eff} = [(Q(out), total)/Q(in)]100.

ⁱ 35.75h.

^j 27.50h.

the total number of coulombs liberated Q(out, total) during the constant current and constant applied potential discharge steps; and (vii) the coulomb efficiency, Q_{eff} = 100 [Q(out, total)/Q(in)]. The \bar{V}_d values were calculated from the area under each discharge curve divided by the number of coulombs released during the discharge.

The effective resistance, R_{eff}, of a cell was determined periodically by (i) measuring the charge or discharge voltage, V; (ii) interrupting the charge or discharge cycle; (iii) measuring the open-circuit voltage, V_{oc}, within 1s; and (iv) calculating R_{eff}, by the relationship R_{eff} = (V - V_{oc})/i, where i is the constant charge or discharge current. It should be noted the R_{eff} will be larger than the internal resistance, R_i, of the cell because of charge-transfer and diffusion impedance effects; however, R_{eff} gives a qualitative indication of the change in the effective resistance of the cell at various stages during its charging and discharging.

Results and Discussion

A charge cycle of a cell from the initial uncharged open-circuit voltage of 2.75 (18) to 3.78V is given in Fig. 1. According to the value of Q(in), the polyacetylene was oxidized to 2%, i.e., to a composition of [(CH)^{+0.02}(ClO₄)_{0.02}]_x. After a 16h stand period, it was discharged at a constant current of 0.43 mA (0.10 mA/cm² of film) during 78 min. The residual charge remaining in the polyacetylene was then released by a constant potential discharge at 2.50V during ~16h, as described above. This returned the cell to its initial uncharged state. Processes occurring at the electrodes during charging are given by

resulting in the net reaction

The discharge reactions are the reverse of the above.

At the charge rate of 2%/h, the charging potential rose rapidly to 3.4V, at which stage the effective resistance of

Fig. 1. Comparison of charge and discharge potentials and quasi-equilibrium cell potentials of a Li/LiClO₄(PC)/[(CH)^{+x}(ClO₄)_{0.02}]_x cell as a function of extent of charging (percent oxidation of polyacetylene).

the cell was several thousand ohms. By the time the polyacetylene was charged to 0.05%, the effective resistance was less than 200Ω and by the end of the charging process it was ~20Ω. During the following 16h stand period, the cell potential dropped from 3.78 to 3.55V (7), indicating that a quasi-equilibrium distribution of ClO₄⁻ ions throughout the (CH)_x fibrils had taken place. The dashed line gives the relationship reported previously (7) between the quasi-equilibrium values of the open-circuit voltage observed following a 24h stand period after charging, i.e., V_{oc(24h)} and the extent of charge. It can be seen that this curve and the discharge curve lie very close to each other. The rate of discharge employed was, therefore, sufficiently small to cause only very little polarization. The discharge voltage fell sharply as the charge level dropped below 0.2% based on the residual charge removed during the 16h constant potential discharge, after which only negligible charge could be recovered.

Constant current discharge cycles for the cell containing 2% oxidized polyacetylene are given in Fig. 2 for immediate and delayed discharges together with the corresponding current densities expressed as milliamperes per square centimeter of polyacetylene and as milliamperes per gram of the combined weight of the [(CH)^{+0.02}(ClO₄)_{0.02}]_x and the weight of lithium actually consumed in the discharge reaction. For the delayed discharges at 0.10 and 1.00 mA/cm², the discharge potential showed a "plateau" region before it dropped abruptly.

Fig. 2. Discharge characteristics of a Li/LiClO₄(PC)/[(CH)^{+0.02}(ClO₄)_{0.02}]_x cell. Upper figure: discharge immediately after a charge cycle. Lower figure: discharge following a 16h stand period after completion of the charge cycle.

The plateau regions were more apparent in the discharges performed immediately after charging. With increasing current, these plateau regions were slightly offset to lower voltage, as expected, and the number of coulombs released progressively diminished. However, both of these trends became less pronounced when the oxidation level of the polyacetylene was raised to 7%, as shown in Fig. 3. Each time the cell was discharged at currents ranging from 0.01 to 1.00 mA/cm², most of the charge was released at a discharge voltage greater than 3.0V. In fact, the plateau regions of the top three curves in the upper figure of Fig. 3 all fell at 3.4V and the charge released was only modestly affected by increasing current. It can be seen that currents as high as 10.00 mA/cm² were possible with substantial coulomb release even after the cell had been permitted to stand for 16h.

The cause of the less-than-ideal coulombic efficiency of the $[(CH)^{+y}(ClO_4)_y]_x$ cathode (see Table I) is not clear at the present time. The loss in efficiency observed immediately after the termination of a discharge cycle is undoubtedly due in large part to the diffusion of the $(ClO_4)^-$ ions from the interior to the exterior of the $(CH)_x$ fibrils (8, 19, 20). Particularly on standing or during slow charge/discharge cycles, loss of charge is also probably caused by some type of self-discharge process which regenerates undoped $(CH)_x$ and/or to irreversible chemical destruction of the cathode material by its slow reaction with the electrolyte or with impurities in the electrolyte. In addition, it has recently been shown that $[CH^{+y}(ClO_4)_y]_x$ is itself intrinsically unstable, slowly losing its conductivity on storage in an inert environment (21). The fact that the accumulated charge loss for the cell containing 7% oxidized $(CH)_x$ during the cycling experiments summarized in Table I amounts to 1 electron per 4.4 carbons without significant deterioration of the cell performance suggests that self-discharge may be the principal mechanism causing coulombic loss. Subsequent transmission infrared spectra of a similar $[CH^{+y}(ClO_4)_y]_x$ electrode revealed essentially no change in the spectrum after ten cycles to ca. 6% in 1M LiClO₄ in PC. Recent work has shown that the coulomb efficiency for immediate discharges can be at least 91%-95% for cells employing $(CH)_x$ cathodes oxidized up to 7%-10% levels (8, 11, 20).

In order to compare the discharge characteristics of the cells, the average discharge voltage, \bar{V}_d , was plotted vs. its associated current density in Fig. 4 for all the immediate and the delayed discharge cycles given in Table I and Fig. 3. The \bar{V}_d for immediate discharges of the cell containing 7% oxidized polyacetylene did not change significantly for an increase in discharge current of two orders of magnitude. At 1.00 mA/cm², it had dropped only to 3.37V. After ~80% $(ClO_4)^-$ ion equilibration had occurred within

Fig. 3. Discharge characteristics of a Li/LiClO₄(PC)/[(CH)^{0.07}(ClO₄)_{0.07}]_x cell. Upper figure: discharge immediately after a charge cycle. Lower figure: discharge following a 16h stand period after completion of the charge cycle.

Fig. 4. Polarization curves for Li/LiClO₄(PC)/[(CH)^{0.07}(ClO₄)_{0.07}]_x cells containing cathodes consisting of polyacetylene oxidized to 2% and 7%.

the polymer fibrils as promoted by the 16h delay in discharging the cell, \bar{V}_d still decreased by only 0.5V over a current increase of three orders of magnitude. Electronic conductivity depends on the charge density within the polymer, ranging from 10⁻⁷ at zero charge density to 10² for $[CH(ClO_4)_y]_x$ at 7 charges per 100 carbons ($y = 0.07$) (16). Similarly, the rate of charge transfer increases with increasing charge density (23). The polarization at a polymer electrode might therefore be expected to depend on the overall charge density and its distribution throughout the electrode. For example, a resistive layer between the polymer bulk and the current collector could form as the charge density is depleted in that region. Replenishing the charge density at the current collector would be limited by the small diffusion coefficient of anions in the polymer [estimates as low as 4×10^{-18} cm²/s (17) and as high as 6×10^{-12} cm²/s (19) have been reported].

Since the cell voltage falls rapidly at the end of the constant current discharges, except for the higher rate discharges, the charge released, to 2.50V, $Q(\text{out})$ (see Table I), is taken to be the usable capacity of the cell for a given drain rate. Changing the voltage to which $Q(\text{out})$ was measured from 2.5 to 3.0V would substantially reduce the usable capacity at discharge rates higher than 2.0 mA/cm² but would leave the lower rate capacities essentially the same (see Fig. 5).

Energy densities are calculated using the charge released on discharge to 2.5V. Energy densities and average power densities are based on the weight of the $[(CH)^{+0.07}(ClO_4)_{0.07}]_x$ employed and the weight of the Li metal consumed in the discharge reaction.

The energy released in watt-hours (Wh) during a discharge was measured by dividing the area under the

Fig. 5. Discharge characteristics of Li/LiClO₄(PC)/[(CH)^{0.07}(ClO₄)_{0.07}]_x cell. The discharge studies were performed immediately after a charge cycle was completed.

curve (volts times coulombs) by 3600 s/h. The average power in watts was calculated as the product of \bar{V}_d in volts and the current in amperes. The higher discharge rates and their associated higher average power densities result, as expected, in a decline in the energy density. The energy densities of the cell containing 2% oxidized polyacetylene are, as expected, less than those containing the 7% oxidized film; however, the average power densities are nearly the same. It might be noted that recent studies using a $\text{Li}_{0.2}\text{TiS}_2/\text{LiAsF}_6$ (acetonitrile)/ $[(\text{CH})^{+0.08}(\text{AsF}_6)_{0.08}^-]_x$ cell (24) have given 80% coulombic efficiencies at discharge currents of 5.0 mA/cm² (overall $Q_{\text{eff}} = 95\%$) (11). If similar results were attained using a Li anode instead of the $\text{Li}_{0.2}\text{TiS}_2$ anode, the energy densities and capacities would be approximately twice those given above. An increase in average power density would also be expected.

Conclusions

These studies demonstrate that cells containing 7% oxidized polyacetylene cathodes and perchlorate dopant ions, $[(\text{CH})^{+0.07}(\text{ClO}_4)_{0.07}^-]_x$, can release 40% of their charge at discharge rates up to 10.0 mA/cm² with less than a 0.5V decrease in cell potential. The effect of the nature of perchlorate dopant anion on the cell characteristics can be only determined after similar studies using other dopants have been performed. These results show that an organic polymer can act as a cathode in a rechargeable cell and that the stored charge can be delivered on demand at a surprisingly high rate.

Electrochemiluminescence of Osmium Complexes

Spectral, Electrochemical, and Mechanistic Studies

Héctor D. Abruña*

Department of Chemistry, Cornell University, Ithaca, New York 14853

ABSTRACT

Electrochemical, spectral, and electrochemiluminescent (ECL) studies of bipyridine and phenanthroline complexes of osmium are presented. ECL was observed for a large number of complexes, but the emission intensity in some cases proved to be much lower than anticipated. For $[\text{Os}(\text{bpy})_2(\text{dmsO})_2]^{2+}$, this was determined to be due to an EC process taking place after oxidation of the complex to give rise to $[\text{Os}(\text{bpy})_2(\text{CH}_3\text{CN})_2]^{3+}$. Surface ECL was demonstrated for electropolymerized films of $[\text{Os}(\text{dstyr-bpy})_2 \text{diphos}]^{2+}$ (dstyr-bpy is 4,4'-distyryl 2,2' bipyridine). The phenomenon of intramolecular ECL was probed by studies on $[\text{Os}(\text{bpy})_2 \text{Fc-p}]^{2+}$ (Fc-p is 1,1' bis diphenyl phosphino ferrocene). It was found that instead of intramolecular ECL being operative, a quenching mechanism was responsible for the observed behavior. For complexes that do not exhibit complications, there was a linear correlation between the solution luminescence quantum yield and the ECL emission intensity, consistent with the direct formation of the excited state via the redox process without any intervening steps or additional relaxation pathways.

Electrogenerated chemiluminescence (ECL) is the study of the generation of emitting excited states via the electron-transfer reaction of electrogenerated reactants (1). There have been extensive studies carried out on both organic systems (1) and transition metal complexes (2, 3). In the latter category, $\text{Ru}(\text{bpy})_3^{2+}$ (bpy is 2,2'-bipyridine) has received a great deal of attention due to its high emission quantum yield and favorable electrochemical properties (3). Furthermore, ECL studies can be used to gain a better understanding of the photophysical properties of the system involved (1).

A recent report from this laboratory (4) presented a new family of electrochemiluminescent materials based on bipyridine and phenanthroline complexes of osmium. These complexes, first described by Meyer and co-workers (5), are notable in that in contrast to $\text{Os}(\text{bpy})_3^{2+}$ they exhibit high emission quantum yields. Furthermore, this new family allows for a broad range of synthetic variations.

This paper presents further electrochemical and electrochemiluminescent characterization of phenanthroline and bipyridine complexes of osmium. It is found that a large number of these complexes will give rise to ECL emission, although, in some cases, the observed ECL intensity was much lower than had been anticipated.

It is also demonstrated that surface ECL can also be observed from the films of electropolymerized complexes. Though the emission arising from these films is not as intense as that observed from electropolymerized $\text{Ru}(\text{vinylbipyridine})_3^{2+}$ films, it is much longer lived.

The phenomenon of intramolecular ECL (that is, generation of emitting excited states through intramolecular electron transfer) was addressed, and two complexes were synthesized to ascertain the feasibility of having this process take place.

Finally, in a comparison of the relative ECL intensities for a number of complexes having different solution luminescence quantum yields, it was found that, for cases with no complications, there was a linear correlation between ECL intensity and solution luminescence quantum yield, indicating the direct formation of the excited state via the redox process.

Experimental

Synthesis.— $[\text{Os}(\text{L})_2](\text{PF}_6)_2$.—L = bpy, phen (phen is 1,10 phenanthroline), v-bpy (v-bpy is 4-vinyl,4' methyl, 2,2' bipyridine). These complexes were prepared according to the procedure of Buckingham *et al.* (6).

$[\text{Os}(\text{L})_2\text{Cl}_2]$.—L = bpy, dmbpy (dmbpy is 4,4' dimethyl 2,2' bipyridine), dstyr-bpy (dstyr-bpy is 4,4'-distyryl, 2,2' bipyridine), phen. These complexes were prepared according to the procedure of Sullivan (7). Briefly, $(\text{NH}_4)_2\text{OsCl}_6$ (typically 1 mM) was heated at reflux in thoroughly

deaired ethylene glycol for 3h with 2 equivalents of L. The solution was allowed to cool, and an equivalent volume of water was added. A very large excess of sodium dithionite was added and the solution was stirred for 3h. The solution was refrigerated overnight, and $[\text{Os}(\text{L})_2\text{Cl}_2]$ precipitated. The material was collected, washed with cold water and ether, and dried under vacuum.

$[\text{Os}(\text{L})_2\text{L}'](\text{PF}_6)_2$.—L = bpy, dmbpy, dstyr-bpy, phen. L' = diphos (diphos is bis 1,2 diphenyl phosphino ethane), dpmm (dpmm is bis 1,2 diphenyl phosphino methane), dpae (dpae is bis 1,2 diphenylarsino ethane), Fc-p (Fc-p is 1,1' bis diphenylphosphino ferrocene), phen-dione (phen-dione is phenanthroline 5,6 dione). These complexes were prepared according to the procedure of Meyer *et al.* (5). Except for $[\text{Os}(\text{phen})_2(\text{phen-dione})]^{2+}$, all of the complexes were purified by recrystallization from acetonitrile/ether and by chromatography on neutral alumina. The $[\text{Os}(\text{phen})_2(\text{phen-dione})]^{2+}$ complex adhered so strongly to alumina that it could not be eluted. It, therefore, was purified by repeated (three times) recrystallizations from acetonitrile/ether.

$[\text{Os}(\text{bpy})_2(\text{CH}_3\text{CN})_2](\text{PF}_6)_2$.—This complex was synthesized by heating at reflux $[\text{Os}(\text{bpy})_2\text{Cl}_2]$ (typically, 100 mg) in thoroughly deaired ethylene glycol (15 ml) for 8h in the presence of a 100 times excess of acetonitrile. The solution was allowed to cool, and the excess acetonitrile was eliminated by evaporation. An equal volume of water was added, and the complex was precipitated with saturated aqueous NH_4PF_6 . The precipitate was collected, washed with water and ether, and dried under vacuum. The complex was purified by recrystallization from acetonitrile/ether and by chromatography on neutral alumina.

$[\text{Os}(\text{bpy})_2(\text{dmsO})_2](\text{PF}_6)_2$ (dmsO is dimethyl sulfoxide).—The dimethyl sulfoxide complex was synthesized by heating at reflux $[\text{Os}(\text{bpy})_2\text{Cl}_2]$ in thoroughly deaired dimethyl sulfoxide for 24h. The solution was allowed to cool, and the complex was precipitated with saturated aqueous NH_4PF_6 . The precipitate (brownish at this point) was collected and washed with water and ether and dried under vacuum. Purification by recrystallization proved ineffective. The complex was purified by chromatography on neutral alumina. By eluting with methanol, a brownish-green band was separated, leaving a canary yellow band at the top of the column. This material (the desired complex) was eluted with acetone. The complex was isolated by evaporating the acetone.

Except for $[\text{Os}(\text{bpy})_2(\text{Fc-P})]^{2+}$ and $[\text{Os}(\text{phen})_2(\text{phen-dione})]^{2+}$, the preparations followed literature procedures or simple extensions of these. Since the above two compounds had not been previously reported, they were characterized by elemental microanalysis. The results are consistent with the formulations $[\text{Os}(\text{bpy})_2(\text{Fc-P})]^{2+}(\text{PF}_6)_2 \cdot \text{CH}_3\text{CN}$ (calculated: 48.44% C, 5.04% N, 3.39% H, 4.02% Fe;

* Electrochemical Society Active Member.

found: 48.53% C, 4.49% N, 3.69% H, 3.83% Fe) and $[\text{Os}(\text{phen})_2(\text{phen-dione})]^{2+}(\text{PF}_6)_2 \cdot 2\text{H}_2\text{O}$ (calculated: 39.77% C, 7.74% N, 2.39% H; found: 39.82% C, 7.73% N, 2.24% H). Analyses were performed by Galbraith Laboratories, Knoxville, Tennessee.

Reagents.—Tetra-*n*-butyl ammonium perchlorate (G. F. Smith) was recrystallized three times from ethylacetate, dried *in vacuo* at 90°C for 72h, and stored in a dry box. Phen-dione was obtained from G. F. Smith Company, and Fc-p was obtained from Aldrich; all other ligands were obtained from Strem Chemical Company and were used as received. Acetonitrile (Burdick and Jackson distilled in glass) was stirred over calcium hydride for two days and distilled from it under nitrogen. It was degassed on a vacuum line and stored inside a dry box (Vacuum Atmospheres Corporation) over 4Å molecular sieves which had been previously deaerated on a vacuum line at 150°C for one week. All other reagents were of at least reagent-grade quality and were used without further purification.

Instrumentation.—Electrochemical experiments were performed with a Princeton Applied Research Model 173 Potentiostat-Galvanostat, Model 179 Digital Coulometer, and Model 175 Universal Programmer. Data were recorded on a Hewlett-Packard Model 7045-B X-Y Recorder or on a Nicolet Model 4094 Digital Oscilloscope.

ECL was detected using an Oriel Model 7240 monochromator with either an Oriel Model 7060 photomultiplier tube (operated at -700V), or a Hamamatsu Model R758 photomultiplier tube (operated at -1200V) and a Pacific Instruments Model 124 Digital Laboratory Photometer. In some cases, ECL was detected using an EG&G Electrooptics Model 450-1 Radiometer Photometer with a 550-2 Multiprobe.

Luminescence spectra were obtained on a Hitachi Perkin-Elmer Model MPF-3 Spectrofluorimeter. Neither ECL nor solution luminescence spectra were corrected for the photomultiplier response.

Procedure.—To prevent any contamination from either water or oxygen, all solutions were prepared inside the dry box. The cell used for ECL consisted of a single compartment cell with three standard tapered joints for the electrodes and provided with an optical Pyrex window. The working electrode was a platinum disk sealed in glass which was bent so as to have the surface of the electrode facing the optical window at a distance of 2-3 mm. The counterelectrode was a large area (~ 10 cm²) platinum mesh, and the reference electrode was a silver wire. Both the counter and reference electrodes were sealed through uranium glass to standard tapered joints. The working electrode was mounted on a standard tapered vacuum Teflon holder (Kontes). All solutions were prepared fresh just prior to use, and the cell was charged and sealed inside the dry box.

For obtaining ECL spectra, the potential of the working electrode was pulsed (at a frequency of 0.5 Hz) between values 100 mV positive and negative of the formal potentials for oxidation and reduction, respectively.

Obtaining reproducible ECL intensities was somewhat more complicated. However, a procedure was developed that yielded data that were reproducible to ± 6%. This deviation could arise in part from small variations in the cell positioning. In order to obtain a reproducible geometry, the same cell was used in all of the experiments, with the working electrode being aligned through markings. In addition the optical window of the cell was positioned flush with the entrance slit (fixed 10 nm bandpass) of the monochromator. For intensity measurements, the procedure used was as follows. The cell was prepared as previously described. A cyclic voltammogram at 0.2 V/s was run, and the formal potentials for oxidation and reduction were determined (in order to account for any drifts in the reference potential of the silver wire used as a reference electrode). The potential limits were set 100 mV positive and negative of the formal potentials for oxidation and reduction, respectively. Resistance compensation was used in all intensity measurements. Data were recorded on the digital oscilloscope, and both the peak value and inte-

grated intensities were recorded. The measurements presented represent averages of three different preparations with ten individual transients being averaged every time.

Other experimental conditions for ECL intensity measurements were as follows: (i) concentration of complex was $1.0 \pm 0.01 \times 10^{-3}\text{M}$, (ii) supporting electrolyte $0.100 \pm 0.005\text{M}$, (iii) pulse width of 2s, (iv) cell geometry and electrode area were strictly the same.

Electropolymerization

Two of the complexes synthesized (*i.e.*, $[\text{Os}(\text{v-bpy})_3]^{2+}$ and $[\text{Os}(\text{dstyr-bpy})_2\text{diphos}]^{2+}$) bear electropolymerizable ligands, these being vinylbipyridine and distyrylbipyridine, respectively. Electropolymerization was accomplished according to a previously reported procedure (8) where the potential of a platinum electrode in contact with a 0.5 mM solution of the complex in acetonitrile was scanned in the negative region (typically between -0.5 and -1.6V), whereupon polymerization took place. This procedure was continued until the desired coverage of electroactive material was obtained. The electrode was removed from solution, rinsed with acetone, and placed in electrolyte solution containing no dissolved complex. A cyclic voltammogram was obtained, and, from integration of the area under the voltammetric wave, surface coverages were determined. ECL spectra were determined in acetonitrile containing only supporting electrolyte.

Results and Discussion

Electrochemistry.—As mentioned in a preliminary communication (4), the electrochemical behavior of these complexes of osmium can be broadly divided into metal-localized oxidations and ligand-localized reductions. The oxidative electrochemistry of these complexes is largely metal based and as such represent formally the oxidation of Os^{II} to Os^{III}. As such, the formal potentials for oxidation are very strongly dependent on the coordination environment of the osmium. As Os(II), the complexes have a spin paired d⁶ configuration [d⁵ as Os(III)]. The presence of good sigma donors would, to a first approximation, stabilize the Os(III) oxidation state to a much higher degree than Os(II). Similarly, the presence of good π accepting ligands would stabilize the d⁶ center (through backbonding) much more than the d⁵Os(III) (10). Shifts in the formal potentials for a metal ion complex depend on the relative magnitude of the formation constants for the oxidized and reduced species. From the arguments presented above, good sigma donors would stabilize the oxidized [Os(III)] form of the complex to a greater extent than the reduced form [Os(II)] with π acceptors having the opposite effect. As such one would anticipate that good sigma donors would move the formal potentials in a negative direction, whereas good π acceptors would move them in a positive direction, consistent with the data presented.

As far as the reductive electrochemistry is concerned, a number of reduction waves, largely ligand localized, can be observed. Since the reduction is formally on the ligands, the presence of other ligands in the coordination sphere of the metal exerts only a secondary effect. As such, the formal potentials for reductions are only slightly shifted with changes in the coordination sphere of the metal. Values for the formal potentials for oxidation and reduction are presented in Table I.

Some of the complexes synthesized, however, exhibit electrochemical responses that deviate from the general trends outlined above. As such, these will be considered individually.

$[\text{Os}(\text{bpy})_2\text{Fc-p}](\text{PF}_6)_2$.—The electrochemical behavior of this complex differs from that of the others in that it exhibits two oxidation waves (Fig. 1A, 1B) in the region from 0.0 to +2.0V *vs.* SSCE. This behavior can be understood by considering the nature of the ligand and its own electrochemical characteristics. The ligand, shown structurally as an inset of Fig. 1C, consists of two diphenyl phosphino units attached to the 1,1' positions of ferrocene. Its coordinating properties are those of a

ⁿ Luminescence not detected.

^o Very weak luminescence detected but could not be specifically characterized.

^p Extensive adsorption precludes determination.

Note: For ECL experiments, applied voltages were 100 mV past the formal potentials for the redox processes involved, e.g., for [Os(dmbpy)₂diphos]²⁺ the potentials were +1.32 and -1.46V, respectively.

diphos-like ligand. This is evidenced by the fact that the complex [Os(bpy)₂Fc-p]²⁺ has a λ_{max} for absorption (484 nm) that is very similar to that of [Os(bpy)₂diphos]²⁺ (473 nm). The electrochemistry of the ligand [Fig. 1C, 1D (in methylene chloride solvent)] shows two oxidation waves, at +0.58 and +1.21V, respectively. The wave at +0.58V can be ascribed to oxidation of the ferrocene unit, and the one at +1.21V to oxidation of the phosphine sites. These potentials are consistent with values for substituted ferrocenes on the one hand (9) and triphenyl phosphine on the other.¹ The fact that the first oxidation wave is chemically irreversible is surprising since ferrocene derivatives generally show reversible electrochemistry. One could speculate that this irreversibility might be due in part to the presence of the phosphine groups since ferrocene derivatives with strong electron withdrawing substituents show reversible electrochemistry (e.g., diacetyl ferrocene). In fact, a cyclic voltammogram of diacetyl ferrocene in the presence of triphenyl phosphine also shows signs of chemical irreversibility. This might be due to nucleophilic attack of the phosphine on the ferricenium cation.

The complex shows a reversible oxidation at +0.87V. This wave is ascribed to oxidation of the ferrocene unit where the formal potential has been shifted, presumably by donating electron density to the osmium center through coordination. In addition, one would expect the Os^{III/II} oxidation wave to appear at more positive potentials on the basis of the ligands involved. It also appears that coordination of the diphenylphosphino units (of the ligand) to the osmium center stabilizes the ferrocene group, since once coordinated they cannot undergo the nucleophilic attack mentioned above.

Controlled potential electrolysis at +1.1V reveals that this oxidation process involves the transfer of one electron ($N \approx 0.97$) and that the process is reversible on the time scale of controlled potential electrolysis. Spectral changes upon oxidation are relatively modest (Fig. 2A, 2B) when compared to the corresponding results for [Os(bpy)₂diphos]²⁺ (Fig. 2C, 2D). Furthermore, there is the appearance of a weak absorption at about 650 nm ascribed to a ferricenium center (see Fig. 2A', 2B'), again consistent with the fact that this oxidation wave is largely localized on the ferrocene center.

¹ Triphenyl phosphine oxidizes with an E_p of about +1.3V.

A second, multiple electron (by comparing the height of this wave with that for the first oxidation) irreversible wave is observed at a peak potential value of $E_p = +1.46V$. This could represent a composite wave including not only the oxidation of Os^{II} to Os^{III}, but also the oxidation of the phosphine ligand. This again is consistent with the electrochemical behavior of the free ligand.

[Os(phen)₂(phen-dione)](PF₆)₂.—As done for the case of the Fc-p ligand, the electrochemistry of this complex (Figs. 3A, 3B) can be interpreted by considering the electrochemical behavior of the phen-dione ligand (Fig. 3C). The ligand shows reductive waves at potentials of -0.45 and -1.25V vs. SSCE (11, 12), consistent with the presence of the orthoquinone structure. The electrochemistry of the complex is, however, quite complex. On an initially positive going scan, a wave at +0.96V vs. SSCE is observed. Upon scan reversal, a wave at +0.89V vs. SSCE is observed, this being the counterpart to the wave at 0.96V. We ascribe this redox process to the Os^{III/II} couple due to the similarity in potential with [Os(phen)₃]²⁺. On continuing the negative going sweep, a second wave at $E_p = 0.27V$ vs. SSCE is observed. Further reductions are observed at $E_p = -0.2V$ and at -1.26 and -1.52V. On a second, positive going sweep, a wave at $E_p = 0.37V$ is observed. This is the anodic counterpart to the wave at $E_p = 0.27$ observed on the negative sweep. It was also found that upon scanning between 0 → -1.8V vs. SSCE the complex undergoes some type of coupling process so as to give rise to an adherent electrochemically active film of the complex on the surface of the electrode (Fig. 3B).

As mentioned before, the oxidation wave for [Os(phen)₂(phen-dione)]²⁺ (Fig. 2A) observed at $E^{o'} = +0.92V$ is ascribed to the Os^{III/II} process due to the similarity of this potential to that observed for [Os(phen)₃]²⁺ ($E^{o'} = 0.86$). Similarly, the waves at $E^{o'} = -1.26$ and $-1.52V$ are ascribed to the reduction of the phenanthroline ligands, again due to similarities in $E^{o'}$ values for [Os(phen)₃]²⁺. The fact that [Os(phen)₃]²⁺ does not exhibit any electrochemical activity between +0.70 and -1.2V indicates that the observed waves for [Os(phen)₂(phen-dione)]²⁺ in this potential region are due to the presence of the quinone center in the phen-dione ligand. The shifting of the waves in a positive direction is consistent with the effect of metal coordination to the phen-dione ligand.

Fig. 1. A and B: Cyclic voltammograms for $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{2+}$ in acetonitrile solution containing 0.1M TBAP. Sweep rate was 0.2 V/s. In A, the anodic limit was +1.3V, in B, +1.8V. C and D: Cyclic voltammograms for 1,1'-diphenyl phosphino ferrocene in methylene chloride solution containing 0.1M TBAP. Sweep rate was 0.2 V/s. In C, the anodic limit was +0.8V, in D, +1.6V.

Fig. 2. Spectra in acetonitrile for $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{2+}$ (A), $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{3+}$ (B), (A' and B' are the spectra for the same complexes in the region from 600 to 750 nm under expanded scale to emphasize the band at 650 nm), $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ (C), and $[\text{Os}(\text{bpy})_2\text{diphos}]^{3+}$ (D).

$[\text{Os}(\text{bpy})_2(\text{dmsO})_2](\text{PF}_6)_2$.—A cyclic voltammogram for this complex at 0.2 V/s is shown in Fig. 4. On an initially negative going sweep, four one-electron reversible reductions can be observed (see Table I for E^0 values). As with other complexes, these reductions are ascribed to the sequential reduction of the bipyridine ligands by one and two electrons, respectively.

The oxidative electrochemistry is somewhat more complex. On an initially positive going sweep, a wave at $E_p = +1.82\text{V}$ is observed. Upon scan reversal, only a very small current is observed, indicative of decomposition of the oxidation product. Upon scanning the potential further in the negative direction, a new wave appears at $E_p = 0.89\text{V}$. Scan reversal (back in the positive direction) shows that there is an anodic counterpart to this wave and that the

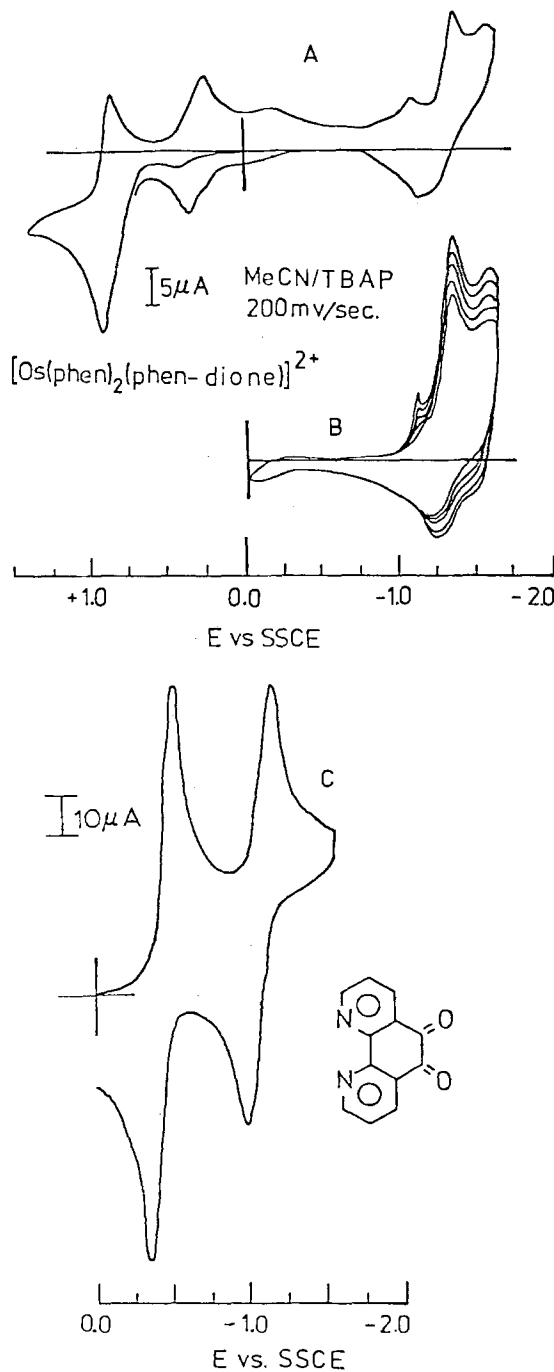

Fig. 3. A: Cyclic voltammogram for $[\text{Os}(\text{phen})_2(\text{phen-dione})]^{2+}$ in acetonitrile solution containing 0.1M TBAP. Sweep rate was 0.2 V/s. B: Consecutive voltammograms depicting surface deposition. C: Cyclic voltammogram on a glassy carbon electrode for phenanthroline 5-6 dione in acetonitrile solution containing 0.1M TBAP. Sweep rate: 0.25 V/s.

process represents a system that is both chemically and electrochemically reversible. As the rate of potential sweep is increased, the cathodic counterpart of the wave at +1.82V increases with a concomitant decrease of the wave at $E_p = +0.89V$. At sweep rates higher than 50 V/s, no decomposition is noted, and the voltammogram is that of a chemically and electrochemically reversible system with an E^0 of +1.79V. The behavior outlined is that typical of an EC-type process. In essence, upon oxidation, $[\text{Os}(\text{bpy})_2(\text{dmsO})_2]^{2+}$ undergoes rapid loss of dmsO with incorporation of 2 mol of acetonitrile (solvent) into the coordination sphere of the osmium. That the product is $[\text{Os}(\text{bpy})_2(\text{CH}_3\text{CN})_2]^{2+}$ is indicated by the fact that the additional wave that appears at slow scan rates has an E^0 value that is virtually identical to that of $[\text{Os}(\text{bpy})_2(\text{CH}_3\text{CN})_2]^{2+}$ ($E^0 = +0.91V$). Furthermore, controlled potential electrolysis at 1.9V yields an n value of 0.96. Spectral characterization of the product again confirms the fact that $[\text{Os}(\text{bpy})_2(\text{CH}_3\text{CN})_2]^{2+}$ is the reaction product.

ECL.—As reported previously (4), intense ECL could be observed from a number of these complexes (see Table I) when the potential of an electrode was pulsed between values corresponding to the oxidation and reduction plateaus of the complex. In general, the observed ECL spectrum was virtually identical to the solution luminescence spectrum obtained in acetonitrile solution.

Of particular interest was the $[\text{Os}(\text{bpy})_2(\text{dmsO})_2]^{2+}$ complex, because of its very high solution luminescence quantum yield ($\phi_2 = 0.38$). On this basis, it was expected that it would show a correspondingly high ECL intensity. This, however, did not turn out to be the case. Even though ECL was observed, and the ECL spectrum coincided with the solution luminescence spectrum in acetonitrile (Fig. 5A), the observed ECL intensity was much lower than had been anticipated. From the electrochemical study of the complex (*vide supra*), it was concluded that the low ECL intensity was due to the decomposition of the complex (loss of dmsO and solvolysis of the complex) when present in its oxidized form. In retrospect, it is not surprising that the complex is unstable in the oxidized form, particularly in light of the coordination sphere and the formal potential for oxidation. In essence, the presence of very strong π acceptors (10) such as dimethylsulfoxide shifts the value of the metal based oxidation to about 1.80V. Upon oxidation to Os^{III} , the degree of π backbonding decreases dramatically, and since the bonding of the dmsO's depends largely on this, the bonding interaction is severely weakened and there is loss of dmsO. From the electrochemical study, it was found that the decomposition could be suppressed at high sweep rates (> 50 V/s). As such, it was thought that having a short pulse width in the ECL experiment would enhance stability and increase the emission intensity. Therefore, a variety of pulse widths were examined. Though it was indeed found that shorter pulse widths

Fig. 4. Cyclic voltammogram for $[\text{Os}(\text{bpy})_2(\text{dmsO})_2]^{2+}$ in acetonitrile solution containing 0.1M TBAP. Sweep rate was 0.2 V/s, and the initial scan direction was cathodic.

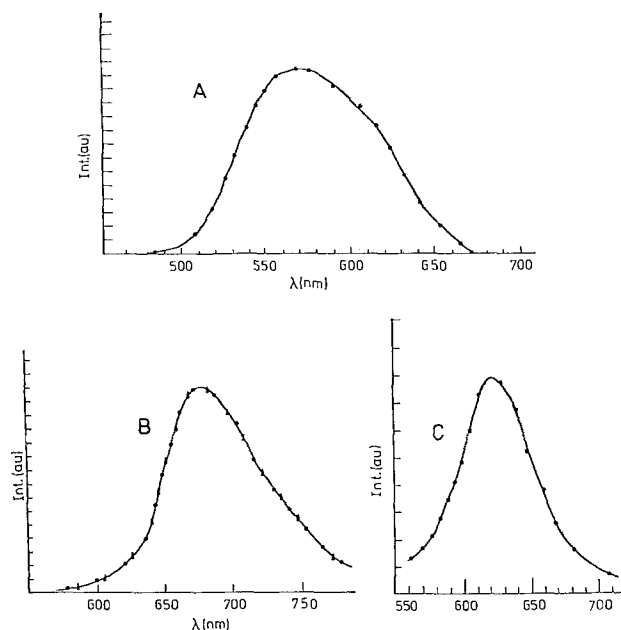

Fig. 5. A: ECL (—) and solution (·) luminescence spectra for $[\text{Os}(\text{bpy})_2(\text{dmsO})_2]^{2+}$. B: Solution luminescence (·), solution ECL (—), and surface ECL (Δ) spectra for $[\text{Os}(\text{dstyr-bpy})_2\text{diphos}]^{2+}$. C: ECL (—) and solution (·) luminescence spectra for $[\text{Os}(\text{bpy})_2\text{Fc-p}]^{2+}$.

would enhance the overall stability of the system, it was also found that ECL emission intensities did not increase to any great extent. This essentially reflects the fact that at short pulse widths the amount of electrogenerated products is small and, as such, ECL intensities are low. We are currently trying to circumvent the problem by synthesizing a chelating disulfoxide

which, by virtue of being a chelate, might impart an enhanced stability to the oxidized complex.

Intense ECL was, however, observed for a number of complexes (Table I). In conjunction with our previously reported results, this represents a very extensive series of electrochemiluminescent materials based on a transition metal.

Surface ECL.—It has been previously reported (14) that ECL can be observed from electrodes modified with electropolymerized layers of $\text{Ru}(\text{v-bpy})_3^{2+}$. The mechanism for light generation is again believed to be due to electron-transfer recombination between oxidized and reduced species within the electropolymerized film to give rise to light emission. As such, surface ECL is conceptually identical to conventional solution ECL.

The phenomenon of surface ECL was also investigated for some of the osmium complexes. Specifically, two complexes that are capable of undergoing electropolymerization were synthesized: $[\text{Os}(\text{dstyr-bpy})_2\text{diphos}]^{2+}$ and $[\text{Os}(\text{v-bpy})_3]^{2+}$. The distyryl-bipyridine and vinyl bipyridine groups can undergo electroreductive polymerization to give rise to strongly adherent and electrochemically active layers of the metal complexes. Electropolymerization was carried out from 0.5 mM solution of the monomers (further details are given in the Experimental section). After modification, the electrodes were rinsed and placed in supporting electrolyte containing no complex in solution. The electrochemical behavior of these electrodes was typical (Fig. 6) of surface immobilized redox reagents (15) with the waves being symmetrical about the potential axis, exhibiting small ΔE_p , and having peak currents that were directly proportional to the rate of potential sweep.

The conditions necessary for the observation of ECL were established by pulsing the potential of the electrode between values that were 100 mV past the formal poten-

Fig. 6. Cyclic voltammogram in acetonitrile containing 0.1M TBAP for an electrode modified with an electropolymerized layer of $[\text{Os}(\text{dstyr-bpy})_2\text{diphos}]^{2+}$. Sweep rate was 0.5 V/s.

tials for oxidation and reduction. In the case of $[\text{Os}(\text{dstyr-bpy})_2\text{diphos}]^{2+}$, ECL emission was detected. The observed surface ECL spectrum corresponded closely to that obtained for homogeneous solution ECL as well as the solution luminescence spectrum (Fig. 5B). While the surface ECL intensity for $[\text{Os}(\text{dstyr-bpy})_2\text{diphos}]^{2+}$ was not as high as that for films of $[\text{Ru}(\text{v-bpy})_3]^{2+}$, it was much longer lived (~ 2 h). This material may be useful for display devices based on surface ECL. In the case of $\text{Os}(\text{v-bpy})_3^{2+}$, no surface ECL could be detected with the instrumentation available. From the value of the homogeneous solution luminescence quantum yield for $\text{Os}(\text{bpy})_3^{2+}$, one would anticipate a very weak luminescence for the immobilized layer so that the inability to detect ECL should not be very surprising.

Intramolecular quenching of ECL.—As mentioned previously, the phenomenon of ECL is generally believed to arise from the intermolecular electron-transfer recombination of electrogenerated reactants. Usually, this involves the oxidation and reduction of a single species (metal complexes in the present case). Intense ECL can be obtained with the use of external redox reagents that can serve as either oxidants or reductants. In fact, we previously reported (4) that intense ECL could also be observed for $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ when [n-methy phenothiazine] $^+$ or anthraquinone $^-$ were used as oxidant or reductant, respectively. The fact that external redox agents could be used suggested that it might be possible to achieve this (but in an intramolecular fashion). That is, to incorporate a second redox center into the metal complex and to try to obtain ECL by stepping the potential between this additional redox center and the appropriate redox process for the metal complex. In order to be able to demonstrate this, first one must be able to incorporate a second redox center and, second, the redox potential of this process must be such that it is straddled by the formal potentials for oxidation and reduction of the metal complex itself. Furthermore, the potential of this secondary redox center must be such that the energetic difference in formal potentials between this couple and the appropriate redox process for the metal complex is sufficient to populate the excited state. With these constraints in mind, two ligands that bear electroactive centers were identified. These are 1,1'-bis diphenylphosphino ferrocene and phenanthroline-5,6 dione.

In the first case, the ferricenium would serve as the oxidant, and, in the second, the reduced ortho-quinone group on the phenanthroline would serve as the reductant. Both of these materials fulfill the requirements outlined previously concerning the value of their redox potentials.

These systems are now considered in detail.

$[\text{Os}(\text{bpy})_2\text{Fc-p}]^{2+}$.—As mentioned previously, this complex exhibits two oxidation waves at $E_{0'} = +0.87\text{V}$ and at $E_p = +1.46\text{V}$, with the first oxidation being ascribed to the

ferrocene center. Upon pulsing the potential of an electrode, in contact with a 0.5 mM solution of the complex between +0.97 and -1.32V vs. SSCE , a weak yet perceptible luminescence is detected. More intense luminescence is obtained when the potential of the electrode is pulsed between +1.6 (corresponding to a potential past the second oxidation) and -1.32V . In both cases, the ECL spectrum was virtually identical to the solution luminescence spectrum in acetonitrile (Fig. 5C). At first, it might appear that these results are consistent with "intramolecular ECL", that is, electron transfer within the complex to yield an excited state. However, further experiments demonstrated that this was not the case. Specifically, studies on the potential dependence of the ECL intensity for $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ proved particularly valuable. It should first of all be mentioned that under usual ECL conditions (that is, pulsing the potential of the electrode between values that are 100 mV past the formal potentials for oxidation and reduction) the ECL intensity for $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ is two to three orders of magnitude higher than that for $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{2+}$. This is somewhat surprising, since the solution luminescence quantum yields for these complexes do not differ by such a large factor. In addition, quite intense ECL could be observed for the $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ complex when the positive pulse was to only +0.9V. (This corresponds to the first oxidation wave for the $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{2+}$ complex.) In fact, the ECL intensity for $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ under these conditions was more intense than that for $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{2+}$ when pulsing between the same potential limits. These results gave an indication that perhaps what was taking place was a quenching of luminescence and not intramolecular ECL. In order to test this, both ECL and solution luminescence studies were performed in the presence of diacetyl ferrocene in its reduced and oxidized forms. Diacetyl ferrocene was chosen because its formal potential for oxidation is nearly identical to that of the first oxidation of $[\text{Os}(\text{bpy})_2\text{Fc-P}]^{2+}$.

In Fig. 7A is shown a transient of the ECL emission for $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ when the potential is pulsed between +1.44 and -1.33V . Figure 7B represents the experiment under identical conditions except that diacetyl ferrocene (about 0.8 eq) has been added. (It should be mentioned that the intensity scale for part A is 100 times less sensitive than that for B and C, which are on the same scale.) Also shown in Fig. 7C is an ECL transient for $[\text{Os}(\text{bpy})_2(\text{Fc-P})]^{2+}$ when the potential was pulsed between +1.6 and -1.3V . Notice that the intensity of the ECL signal is of the same order of magnitude as that for $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ in the presence of diacetyl ferrocene. Clearly, there is very efficient quenching by the added diacetyl ferrocene. That the quenching was due to the oxidized form (ferricenium) was demonstrated by looking at the solution luminescence of $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ in the absence of diacetyl ferrocene as well as in its presence in either the oxidized or reduced form. The solution emission intensity in the absence of diacetyl ferrocene as well as in its presence in the reduced form were quite comparable (a decrease of less than 10%). In the presence of ferricenium, however, the solution luminescence was almost entirely quenched. These results, then point to the fact that what is taking place in the case of $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ is not intramolecular ECL but rather a very effective quenching of the excited state by the ferricenium centers.

$[\text{Os}(\text{phen})_2(\text{phen-dione})]^{2+}$.—As mentioned previously, the electrochemical behavior of this material is quite complex, especially due to the fact that it undergoes some type of coupling reaction to give electrodes covered with a film of polymeric nature. Though an ECL signal was observed when pulsing between +1.4 and -1.8V , it was so weak that a spectrum could not be obtained with our current equipment. As such, the ECL behavior of the material was not pursued any further.

Correlation of ECL intensity with solution luminescence quantum yield.—It was previously reported (4) that, even though $[\text{Ru}(\text{bpy})_3]^{2+}$ and $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ have very sim-

Fig. 7. A: ECL transient for $[\text{Os}(\text{bpy})_2(\text{diphos})]^{2+}$ by pulsing the potential of the platinum electrode, in contact with a 1 mM acetonitrile solution of the complex, containing 0.1M TBAP, between +1.44 and -1.23V. B: Same as in A except diacetyl ferrocene (0.8 eq) has been added. (Scale is 100 times that of A.) C: ECL transient for $[\text{Os}(\text{bpy})_2\text{Fc-p}]^{2+}$ by pulsing the potential of a platinum electrode in contact with a 1 mM acetonitrile solution of the complex containing 0.1M TBAP between +1.6 and -1.3V. (Scale is same as in B.)

ilar solution luminescence quantum yields, the ECL intensity for the osmium complex is about 30% lower than that for $[\text{Ru}(\text{bpy})_3]^{2+}$, after taking into account the differences in solution luminescence quantum yields. Two different mechanisms could be postulated as being responsible for this effect. The first is a quenching mechanism, and the second corresponds to an activation process where the energy of activation for the electron-transfer event leading to the formation of the excited state is high for the osmium complex relative to $[\text{Ru}(\text{bpy})_3]^{2+}$. Since in the experiments performed there were no intentionally added quenchers, it was speculated that the activation mechanism was perhaps responsible for the differences in ECL intensities. If this were to be the case, and if the osmium complexes follow a common mechanism giving rise to the formation of an emitting excited state, then there should be a linear correlation between solution luminescence quantum yield and ECL intensity for the osmium complexes. As such, the measurement of relative ECL intensities was pursued. These measurements, however, proved to be more difficult to perform than had been anticipated. In essence, there are a number of factors that can affect ECL intensities, and these must be recognized and reproducibly controlled.

First of all, in order to eliminate interferences from impurities, the strictest care must be exercised in the purification of the complexes, solvent, and supporting electrolyte as well as in the cleaning of the cell (see Experimental section). Since ECL intensities are known to be very sensitive to the presence of water and oxygen, a

silver wire reference electrode was used (to eliminate water contamination from an SCE) and all manipulations in the preparation of the cell were carried out inside a dry box.

Since ECL is due to the electron-transfer recombination of electrogenerated species, then the amount of oxidized and reduced material generated at the electrode surface will have a dramatic effect on the observed ECL intensity. As such, in order to be able to compare ECL intensities for different complexes, one must insure that the amount of oxidized and reduced material generated at the electrode surface is constant for all of the complexes studied. This was accomplished by measuring the formal potentials for oxidation and reduction prior to performing ECL (to account for any drifts in the silver wire reference electrode) and adjusting the pulse limits to be 100 mV past these values. Since all of the redox processes involved are electrochemically reversible and if one assumes that variations in diffusion coefficients are insignificant, then by providing the same electrode surface conditions, a constant amount of oxidized and reduced material should be generated at the electrode surface assuming a constant bulk concentration for all the complexes. This, however, presupposes that ohmic losses are small or accounted for. In fact, it was found that, in order to obtain reproducible results, the cells could not have compartments separated by sintered glass disks (frits) and iR compensation had to be employed. Under these conditions, and using the experimental procedure outlined beforehand, very reproducible ($\pm 5\text{-}7\%$) ECL intensities could be obtained. The

Fig. 8. Plot of relative ECL intensity vs. solution luminescence quantum yield for: $[\text{Os}(\text{bpy})_3]^{2+}$ (a), $[\text{Os}(\text{phen})_3]^{2+}$ (b), $[\text{Os}(\text{bpy})_2(\text{CH}_3\text{CN})_2]^{2+}$ (c), $[\text{Os}(\text{bpy})_2(\text{diphos})]^{2+}$ (d), $[\text{Os}(\text{bpy})_2(\text{Fc-P})]^{2+}$ (e), and $[\text{Os}(\text{bpy})_2(\text{dmsO})_2]^{2+}$ (f). Note: The quantum yield for this complex is not on scale, $\phi_e = 0.38$.

results obtained for a number of complexes are presented in Fig. 8, where relative ECL intensity is plotted against solution luminescence quantum yield. As can be seen, there is a very good correlation, and, in fact, a linear regression analysis of the data yields a correlation coefficient of 0.99. This would, then, imply the direct formation of the excited state from the redox process without other intervening pathways. ECL intensities for $[\text{Os}(\text{bpy})_2\text{Fc-p}]^{2+}$ and $[\text{Os}(\text{bpy})_2(\text{dmso})_2]^{2+}$ fall drastically off the line, consistent with these arguments and the results presented previously.

Furthermore, the ECL intensity for $[\text{Ru}(\text{bpy})_3]^{2+}$ would fall significantly above the line. These results would thus seem to indicate that $[\text{Ru}(\text{bpy})_3]^{2+}$ and $[\text{Os}(\text{bpy})_2\text{diphos}]^{2+}$ follow different pathways, leading to the formation of the emitting excited state, and that this might be reflected as a higher energy of activation in the electron-transfer event leading to the formation of the excited state.

Conclusions

Intense ECL can be observed for a large number of bipyridine and phenanthroline complexes of osmium. Surface ECL can also be observed when the complex is immobilized on the surface of the electrode. It was found that there was a good correlation between the observed ECL intensity and the solution luminescence quantum yield, implying the direct formation of the excited state via the redox process without the intervening deactivation pathways. The complexes that did not follow this correlation were shown to do so because of complicating factors such as an EC process, in the case of $[\text{Os}(\text{bpy})_2(\text{dmso})_2]^{2+}$, and intramolecular quenching, in $[\text{Os}(\text{bpy})_2(\text{Fc-P})]^{2+}$. In the last case, it had been postulated that it might exhibit intramolecular ECL, but it was shown that the observed behavior was due to the presence of intramolecular quenching.

A Theoretical Calculation of the Hydrogen Evolution Reaction Velocity at the Mercury Electrode

Zhang Lin-Shao

Department of Chemistry, Jilin University, Changchun, China

ABSTRACT

The theoretically derived expressions of the current density, the height and width of the potential barrier are presented based on the thermal activation model and Schottky effect. These expressions are suitable to the compact layer of a near-ideal polarized electrode.

On the basis of the thermal activation model the expression of the hydrogen evolution reaction velocity for compact double layer can be written as follows (1)

$$i = e \int W(E)G(E)d\nu_e \quad [1]$$

where $d\nu_e$ is the number of electrons in metal with energy between E and $E + dE$ which impinge on unit area of the metal surface in unit time. According to Fermi distribution, it is given by

$$d\nu_e = \frac{4\pi kTm}{h^3} \cdot \ln \left[1 + \exp \left(-\frac{E - E_f}{kT} \right) \right] dE \quad [2]$$

The $G(E)$ (in Eq. [1]) is the probability of having the acceptor state with energy equal to that of the electron in the metal electrode, as in the case of other workers, it can be described by using a classical distribution function (1)

$$G(E) = \exp \left(-\frac{\Delta E}{kT} \right) \quad [3]$$

Derivation of the Current Density Expression

The $W(E)$ (in Eq. [1]) is the probability of tunneling through barrier. Taking the Schottky effect into account, the potential barrier may be described by

Table I. Comparison of experimental and calculated values of current density for mercury electrode in contact with 0.1M HCl solution

Potential difference (V vs. RHE)	Electrode charge density $q^M/10^{-2}$ (cm^{-2})	H^+ - H_2O bond extension (\AA)	Current density ($\mu\text{A cm}^{-2}$)			
			Calculated	Post (2)	Bockris (1)	Conway (3)
-0.80	-11.5	2.48	5.44	5.48	5.22	3.63
-0.75	-10.7	2.67	2.20	2.19	1.90	1.40
-0.70	-10.0	2.85	0.34		0.69	0.54

$$U(x) = -\frac{e^2}{16\pi\epsilon_0\epsilon_\gamma x} - \frac{eq^M x}{\epsilon_0\epsilon_\gamma} \quad [4]$$

where q^M is the electrode charge density. This equation is suitable for the compact double layer of a near-ideal polarized electrode. Using the WKB approximation, the expression of the tunneling probability can be written as follows

$$W(E) \doteq \exp \left\{ -2\sqrt{\frac{8\pi^2 m}{h^2}} \int_{x_1}^{x_2} \sqrt{\left(|E| - \frac{e^2}{16\pi\epsilon_0\epsilon_\gamma x} - \frac{eq^M x}{\epsilon_0\epsilon_\gamma} \right)} dx \right\} \quad [5]$$

If

$$x = \frac{\epsilon_0\epsilon_\gamma E t}{eq^M}$$

Eq. [5] becomes

$$W(E) \doteq \exp \left[-\frac{8\pi\epsilon_0\epsilon_\gamma\sqrt{2m}}{3eq^M h} |E|^{3/2} \cdot \theta(E) \right] \quad [6]$$

where

$$\theta(E) = \frac{3}{2} \int_{t_1}^{t_2} \sqrt{1 - \frac{e^3 q^M}{16\pi\epsilon_0^2\epsilon_\gamma^2 E^2 t}} - t dt$$

Substituting Eq. [2], [3], and [6] into Eq. [1], we get

$$i = \frac{4\pi k T m e}{h^3} \int_{E_0}^{E_F} \exp \left(-\frac{8\pi\epsilon_0\epsilon_\gamma\sqrt{2m}}{3eq^M h} |E|^{3/2} \cdot \theta(E) \right) \cdot \exp \left(-\frac{E - E_0}{kT} \right) \cdot \ln \left[1 + \exp \left(-\frac{E - E_F}{kT} \right) \right] dE \quad [7]$$

where $E_0 = E_F - \Delta E_0 + |e\eta| + |e\Delta\phi_c|$ and ΔE_0 is the activation energy. Since the first exponential term behind the integration symbol (in Eq. [7]) is a function of E and the electrons of tunneling barrier are mainly the electrons of the level in the neighborhood of Fermi level, one may expand the exponential term into the series at $(E - E_F)$. We get

$$\frac{-8\pi\epsilon_0\epsilon_\gamma\sqrt{2m}}{3eq^M h} |E|^{3/2} \cdot \theta(E) \doteq -S + \frac{E - E_F}{P} \quad [8]$$

where

$$S = \frac{8\pi\epsilon_0\epsilon_\gamma\sqrt{2mE_F^3}}{3eq^M h} \theta(E_F)$$

and

$$\frac{1}{P} = \frac{-4\pi\epsilon_0\epsilon_\gamma\sqrt{2mE_F}}{eq^M h} \cdot \left[\theta(E_F) + \frac{2}{3} E_F \left(\frac{d\theta(E)}{dE} \right)_{E_F} \right]$$

and

$$\theta(E_F) = \frac{3}{2} \int_{t_1}^{t_2} \sqrt{1 - \frac{e^3 q^M}{16\pi\epsilon_0^2\epsilon_\gamma^2 E_F^2 t}} - t dt \quad [9]$$

The integrated limits t_1 and t_2 can be obtained by solving the equation

$$1 - \frac{e^3 q^M}{16\pi\epsilon_0^2\epsilon_\gamma^2 E_F^2 t} - t = 0 \quad [10]$$

Substituting Eq. [8] into Eq. [7] and integrating it, we get the expression of the current density

$$i = \frac{4\pi k T m e}{\left(\frac{1}{P} - \frac{1}{kT} \right) h^3} \exp \left(-S + \frac{E_0 - E_F}{kT} \right) \cdot \left\{ \ln 2 - \exp \left[\left(\frac{1}{P} - \frac{1}{kT} \right) (E_0 - E_F) \right] \cdot \ln \left[1 + \exp \left(-\frac{E_0 - E_F}{kT} \right) \right] + \int_{\exp \frac{(E_0 - E_F)}{kT}}^1 \frac{Z^{(kT/P) - 2}}{(1 + Z)} dZ \right\} \quad [11]$$

The Expressions of the Height and Width of the Potential Barrier

The barrier height (H) is defined as

$$H = \omega - |U(x_m)|$$

where ω is the work function of the metal and $U(x_m)$ is the electron energy corresponding to barrier maximum, the x_m can be obtained from Eq. [4]

$$x_m = \sqrt{\frac{e}{16\pi q^M}}$$

therefore

$$U(x_m) = -\sqrt{\frac{e^3 q^M}{4\pi\epsilon_0^2\epsilon_\gamma^2}}$$

The barrier width (d) is equal to the difference between integrating limits in Eq. [5], i.e.

$$d = x_2 - x_1 = \frac{\epsilon_0\epsilon_\gamma\omega}{eq^M} (t_2 - t_1)$$

Application of the Expression of the Current Density

We can now calculate the current density using Eq. [11] on the assumptions that Eq. [4] is suitable approximately for a mercury electrode in contact with 0.1M HCl solution (the potential difference is in the range -0.70 to -0.80V) and that the Fermi level of the metal and dielectric constant ϵ_γ are independent of the potential difference in this range. The calculated values of the current density as a function of the potential difference for the case of $\epsilon_\gamma = 6.48$ are obtained. In order that the calculated values are consistent with the experimental results, the extension of the $\text{H}^+ = \text{H}_2\text{O}$ bond ($d_{\text{H}^+ = \text{H}_2\text{O}}$) must be dependent on the electrode charge density, this relationship can be described by

$$d_{\text{H}^+ = \text{H}_2\text{O}} = \frac{0.1106115435 t_2 d}{t_2 - t_1}$$

Computed in this way, Table I gives the current density and extended values of the $\text{H}^+ = \text{H}_2\text{O}$ bond for different potentials. Table II gives the calculated values of the barrier height, barrier width, and the field strength for different potentials. The calculated formulas are in this paper.

The calculated results show that the calculated values of the height and width of the potential barrier decrease

Table II. Calculated values of barrier height, barrier width, and field strength

Potential difference (V)	Current density ($\mu\text{A cm}^{-2}$)	Field strength (V m^{-1})	X_M (Å)	Barrier height (eV)	Barrier width (Å)
-0.80	5.44	2.01×10^9	1.66	3.85	22.29
-0.75	2.20	1.87×10^9	1.73	3.88	23.98
-0.70	0.34	1.74×10^9	1.79	3.90	25.67

with increasing overpotential. It follows that the rate of successful electron transfers does depend not only on the number of particles on the solution side of the metal-

solution interface which exist in appropriate quantum states but also on the height and width of the potential barrier.

Manuscript submitted Feb. 28, 1984; revised manuscript received Sept. 4, 1984.

Parametric Study of Zinc Deposition on Porous Carbon in a Flowing Electrolyte Cell

Charles D. Iacovangelo* and Fritz G. Will*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

X-ray radiography coupled with high resolution optical densitometry, as well as optical and scanning electron microscopy, was employed to study the effect of pivotal zinc deposition parameters on the zinc morphology within a porous C foam electrode. Deposition was carried out in zinc-bromine and zinc-zinc cells with circulating electrolyte. Results on the effects of flow rate, substrate thickness, current density, and electrolyte composition on zinc distribution in the substrate and on its surface are described. This study has shown that in the absence of organic inhibitors, very nonuniform zinc deposition occurs within the porous electrode. This zinc deposition corresponds to the nonuniform primary current distribution dominated by ohmic resistance. This study has led to the conclusions that high electrolyte flow rates, moderate current densities, and thick foams all aid in producing increasingly uniform zinc deposits. The most beneficial effects on the zinc morphology, however, were obtained by adding to the electrolyte a dendrite inhibitor-solubilizer combination consisting of certain fluorosurfactants and butyrolactone.

Commercialization of high power density secondary Zn batteries necessitates repeated uniform Zn plating at high current densities without dendrite formation or progressive Zn slumping. These problems have been addressed in state-of-the-art batteries by employing porous substrates and flowing electrolyte. Examples of such electrodes can be found in Zn-Cl₂ (1, 2), Zn-Br₂ (3-5), and Ni-Zn (6) batteries. Although the use of porous electrodes in Zn batteries has been widespread, little is known about the effects of pivotal deposition parameters on the Zn morphology within a porous substrate. Various mathematical models have been developed to explain the behavior of porous electrodes and aid the designer in development of battery systems. Newman and Tiedemann (7) recently summarized these models. Experimental verification of these models has been limited, and applied primarily to alkaline Zn cells (8). Experimental work on Zn morphology in acidic Zn cells (9, 10) has been limited to kinetic studies of nucleation on planar electrodes.

Three techniques have been reported for the experimental determination of current and reaction distribution within porous electrodes: direct measurement of potential distribution by use of multiple reference electrodes, direct measurement of current distribution among sectioned electrodes, and postmortem chemical analysis and sectioning of electrodes. Previously (11, 12), we described a novel technique of x-ray radiography coupled with high resolution optical densitometry to examine Zn morphology across and within porous C foams. This technique, along with optical and scanning electron microscopy, has now been used to optimize the effect of various electrode and process parameters on the Zn deposit morphology in terms of freedom of dendrites, small particle size, smoothness of the surface, and penetration into the substrate or utilization of the interstices of the porous substrate. The parameters examined included current density, flow

rate, electrolyte composition, substrate thickness, and substrate pore size.

Experimental

Zn was deposited in Zn-Br₂ and Zn-Zn cells on porous reticulated vitreous C (RVC) foams, cemented to graphite current-collector plates with a conductive adhesive. The dimensions of the foam and the graphite plate were $10 \times 10 \times 0.1-0.45$ cm and $13 \times 12 \times 0.64$ cm, respectively. In Zn-Br₂ cells, a Nafion 120 cation exchange membrane (E.I. du Pont de Nemours and Company) was spaced 0.2 ± 0.01 cm from the C foam, separating the Br₂ electrode from the foam. In Zn-Zn cells, the Br₂ electrode and Nafion membrane were replaced with a Zn plate to keep the concentration of Zn in the electrolyte invariant during plating. A schematic diagram of the "flow-by" cell and ancillary equipment is shown in Fig 1.

A Masterflex peristaltic pump was used to circulate the electrolyte at flow rates of 150, 395, and 730 cm³/min. Flow rates were controlled within ± 5 cm³/min. The equivalent Reynolds numbers were 100, 250, and 500, respectively,¹ defined as

$$N_{re} = \frac{2du}{\nu} \quad [1]$$

where d is the free electrolyte gap (cm), u the electrolyte velocity parallel to the face of the foam (cm/s), and ν the kinematic viscosity (cm²/s). Pressure drops due to the electrolyte flow resistance were monitored throughout plating to within 5 mm Hg. The electrolyte entered into a free electrolyte gap at the bottom of the cell, through a slotted distributor strip, flowed by the face of the porous substrate, and exited through another free electrolyte space at the top. This aided in attaining uniform electro-

¹In Ref. (12), N_{re} was defined as ul/ν , where l = length of the electrode.

*Electrochemical Society Active Member.

Fig. 1. Experimental cell schematic with ancillary equipment

lyte flow and Zn deposition across the electrode surface. A rubber gasket around the edges of the foam prevented the electrolyte from flowing directly through the foam. Flow of electrolyte past the foam face will cause some flow into the foam from momentum flux at the foam/electrolyte interface. As will be shown later, however, the dominant effect on zinc distribution in these platings was the ohmic resistance within the porous electrode. Substrates of two different pore sizes, namely, 0.25 and 0.55 mm (100 and 45 pores/in., respectively) were employed. The morphology of these foams has been described previously (11, 12). The void volume of each foam was about 97%. The values for surface area/volume ratio and resistivity are 26.2 cm²/cm³ and 0.5 Ω-cm for the 45 pore foam and 65.6 cm²/cm³ and 0.3 Ω-cm for the 100 pore foam, respectively. Zn deposition, corresponding to battery charging, was performed at room temperature at constant current densities from 25 to 100 mA/cm² for 1-8h. The electrolyte was an aqueous solution of 29% by weight ZnBr₂, 14% KBr, and 14% NaCl.

Reagent-grade chemicals and doubly distilled water were used in preparing the solution. Following plating, copious amounts of doubly distilled water were passed through the cell to wash the substrate free of electrolyte solution. Prior to analysis, electrodes were removed from the cell, dried, and cut into segments where applicable.

The effect of the various parameters on the Zn morphology was evaluated with optical microscopy, scanning electron microscopy, and x-ray radiography. X-ray radiographs were taken of the face and cross sections of the electrodes with a Hewlett-Packard, Faxitron series, x-ray system. Polaroid 55 positive/negative film was employed. A quantitative measure of the Zn density was obtained through densitometer measurements of the radiograph film negatives at a magnification of 20×. An automatic recording microdensitometer (Joyce-Loebel Model MKIIC) with slit dimensions 8 × 0.04 mm was employed for this purpose. The quantitative results, obtained with the densitometer, were compared with scanning electron micrographs of electrode surfaces and cross sections. The

morphology of the surface was examined over the entire 100 cm² area in one x-ray radiograph. In order to examine the Zn profile perpendicular to the foam, three 6 mm wide segments were cut from the top to the bottom of the electrode. These segments, taken from the center and each side of the electrode, were placed on edge during x-ray radiography. X-ray radiographs were taken of the bottom, middle, and top of each of the three segments, yielding nine traces for comparison of Zn distribution at different locations of the electrode. Unless otherwise stated, in comparing the effect of plating parameters, radiographs of the middle of the center segment were used. A detailed description of the x-ray radiography technique and its range of applicability has been described previously (12).

Results

Electrolyte flow rate.—The effect of electrolyte flow rate on Zn morphology and distribution within the porous substrate was examined for three flow rates of ~150, 395, and 730 cm³/min. These flow rates are equivalent to Reynolds numbers of 100, 250, and 500, and also equivalent to exchanging the electrolyte in the cell once every 15-30s. Plating was performed at 25 mA/cm² for 4h on 1.2 mm thick 100 pore foams. Scanning electron micrographs (SEM's) of the cross section of the 100 pore foam for $N_{Re} = 100$ and 500 are presented in Fig. 2. The SEM's relate to a slice taken from the center of the middle segment at a magnification of 14×. The major features of the Zn deposit evident from the SEM's are a nodular Zn growth at and near the surface of the foam with a tight Zn deposit on the internal strands of the foam. This nodular deposit is markedly different from the generally loose, mossy deposits obtained in stationary electrolyte under identical plating conditions (11). The effect of increasing flow rate is more evident in the x-ray radiographs shown in Fig. 3. Radiographs are of the entire length of the middle segment. The dark areas correspond to Zn and the light areas to voids or C foam. Plotted in Fig. 4 are densitometer traces taken from the center of the three segments shown

Fig. 2. SEM of 100 pore foam plated at 25 mA/cm² for 4h. Top: $N_{Re} = 100$. Bottom: $N_{Re} = 500$.

in Fig. 3. In this graph, $X = 0$ represents the foam/electrolyte interface and $X = 1.2$ mm the foam/backing plate interface. Negative values of " X " correspond to Zn extending from the foam into the free electrolyte gap. It can be seen from Fig. 3 and 4 that the pivotal effect of increasing flow rate is a decrease in Zn deposit thickness and an increase of Zn penetration into the foam. Although increasing the Reynolds number produces thinner, more compact, and smoother Zn deposits, it is obvious that Zn deposition has overwhelmingly occurred on and near the foam surface and decreased steeply within the first 0.2 mm into the foam. Listed in Table I are the amounts of Zn deposited in three relative areas of the substrate; on the surface extending into the free electrolyte gap $X/L < 0$, within the interior of the foam $0 \leq X/L \leq Y$, and near the graphite plate $Y \leq X/L \leq 1$. The dimensionless distance Y was chosen as the position at which the Zn density increased near the backing plate. As can be seen from Table I, the amount of Zn extending from the surface into the electrolyte decreased from 66% to 35% when increasing the Reynolds number, with a corresponding increase in Zn within the foam from 14% to 28%.

Substrate morphology.—The pore size of the substrate affects the specific interfacial area and the specific conductance of the electrode. The effect of two different pore sizes for constant electrode thickness (2 mm) was de-

Fig. 4. Densitometer traces of 100 pore foam shown in Fig. 2 and 3. Traces taken from the center of each segment.

scribed previously (12). In Fig. 5-7, the effect of varying the electrode thickness, L , for constant pore size is shown. The electrode thicknesses were chosen to facilitate the comparison of constant pore length to pore diameter (L/D) ratios. Figure 5 shows x-ray radiographs of the cross sections for two 45 pore foams plated at 25 mA/cm² for 4h with $N_{Re} = 100$. The top radiograph represents a 2 mm thick foam; $L/D = 3.5$. The bottom three radiographs are for a 4.5 mm thick foam ($L/D = 8$), taken of the left, middle, and right segments of the electrode. Comparison of the bottom three radiographs demonstrates the uniformity of the Zn deposit across the face of the electrode. The cross-sectional radiographs of Fig. 5 were evaluated

Fig. 3. Effect of flow rate with 100 pore foam. X-ray radiography of cross sections of 100 pore foam plated at 25 mA/cm² for 4h. Top: $N_{Re} = 100$. Middle: $N_{Re} = 250$. Bottom: $N_{Re} = 500$.

Table I. Fraction of zinc deposited on and in carbon foam

Foam	Thickness (mm)	L/D	N_{Re}	On surface $X/L < 0$	In interior $0 < X/L < Y$	Near plate $Y < X/L < 1$	Y
45 pore	2	3.5	100	0.52	0.12	0.36	0.6
45 pore	4.5	8	100	0.41	0.32	0.27	0.8
100 pore	2	8	100	0.37	0.38	0.30	0.63
100 pore	1.2	4.7	100	0.66	0.14	0.20	0.66
100 pore	1.2	4.7	250	0.49	0.18	0.34	0.6
100 pore	1.2	4.7	500	0.35	0.28	0.37	0.6

with the densitometer and the results are shown in Fig. 6. In this graph, $X = 0$ corresponds to the foam/electrolyte interface for each electrode, $X = 2$ mm to the foam/graphite plate interface for the 2 mm thick foam, and $X = 4.5$ mm to the foam/graphite plate interface for the 4.5 mm foam. The corresponding densitometer traces of 1.2 and 2 mm thick 100 pore foams, $L/D = 4.7$ and $L/D = 8$, are presented in Fig. 7. All four electrodes exhibited the same extremely nonuniform deposition of Zn. A predominant portion of Zn was present on the foam surface, dropping off sharply into the interior of the foam and rising sharply near the graphite backing plate. Changing the foam thickness had little effect on how far the Zn extended into the free electrolyte gap. In all four cases, Zn extended ~1 mm beyond the foam face. The extension of the Zn beyond the foam face, or dendritic nature of Zn morphology, was primarily a function of the electrolyte flow rate, as shown in Fig. 4. Increasing the substrate thickness did, however, increase the amount of Zn present within the porous substrate. This effect is clearly obvious in Fig. 7 for the 100 pore foam. Although not quite as obvious in Fig. 6 for the 45 pore foam, Table I shows a marked increase of Zn within the foam's interior from 12% to 32% of the total Zn. The corresponding increases for the 100 pore foam were from 14% to 38% of the total Zn. It is of interest to note that independent of pore size, the same L/D ratio of 8 resulted in essentially the same distribution of Zn. The 45 pore foam $L/D = 8$ resulted in a Zn distribution shown in Table I of 41%, 32%, and 27%, while the 100 pore foam $L/D = 8$ was correspondingly 37%, 33%, and 30%.

Electrolyte composition and current density.—The composition of the electrolyte, that is, the $ZnBr_2$ concentration, supporting electrolyte (inorganic salts), and organic dendrite inhibitors, plays a significant role in determining the morphology of the Zn plate in stationary electrolyte (11). The use of certain inhibitors with solubilizers produced Zn deposits which were smoother and more

uniform and reached farther into the interior of the foams than in electrolytes without inhibitor (13, 14).

Figures 3 and 4 above show that increasing electrolyte circulation, even without the use of inhibitors, produces increasingly less dendritic/nodular deposits. However, a significant fraction of the Zn is deposited on the surface of the foam. In the following experiments, the combined effects of electrolyte flow, $N_{Re} = 250$, and the use of inhibitors was examined. In these experiments, 1% by weight of FC170:L4048² (0.333 FC170 + 0.667 L4048) and 10% by weight of butyrolactone were added to the electrolyte. Platings were carried out at 25 mA/cm² for 4 and 8h, and at 100 mA/cm² for 1 and 2h, thus resulting in charge densities of 100 and 200 mAh/cm², respectively. Photomicrographs of the face and cross sections after plating at 25 mA/cm² for 4 and 8h are presented in Fig. 8 and 9. The intimate coating of the C strands with a Zn film and the lack of large nodular protrusions are clearly evident in the center micrograph of Fig. 9, referring to 4h plating and the use of 1% inhibitor. For comparison, the upper micrograph shows the pronounced nodular Zn growth and the lack of Zn penetration into the foam if no inhibitor is added to the electrolyte. Continued plating for 8h resulted in continued filling of the voids with little protrusion beyond the face of the electrode. The most salient feature in the photomicrographs for 8h plating is the greatly enhanced throwing power into the foam. The Zn extended on the average 1-1.5 mm into the 2 mm foam. The average density of this Zn layer was 1.63-2.44 g/cm³, as compared to ~0.6 g/cm³ in the absence of the inhibitor (see Fig. 3 and 4). Compared to a theoretical density of Zn equivalent to 7.14 g/cm³, the density of these Zn layers is 23%-34% of the theoretical density.

The effectiveness of the inhibitor at 25 mA/cm² shown in Fig. 8 and 9 is dramatic. For the battery designer, however, larger current densities are desirable since this results in higher power density and, hence, lower cost per unit of power and energy stored. Shown in Fig. 10 and 11 are results for identical test conditions as for Fig. 8 and 9, but at 100 mA/cm² for 1 and 2h, which corresponds to identical amounts of charge passed and Zn plated. The salient feature shown in these figures, like that of Fig. 8 and 9, is the excellent penetration of the Zn into the porous substrate. At a charge density of 100 mAh/cm², there was no discernible difference in the smoothness of the surface for plating of 100 mA/cm² compared to 25 mA/cm². However, at a charge density of 200 mAh/cm², the surface of the electrode plated at 100 mA/cm² gave evidence of increased roughness over the plating at 25 mA/cm². In addition, enhanced plating at the edges became evident when plating at 100 mA/cm² for 2h. This is shown in the three radiographs of Fig. 11, representing cross sections of the left edge, center segment, and right edge of the foam electrode. Such edge effects were absent at 25 mA/cm². The Zn penetration into the porous substrate at 100 mA/cm² was excellent. As can be seen from Fig. 11, the Zn was deposited completely into the foam with remarkably uniform density.

Discussion

It is obvious from these results that the effects and interactions of the various plating parameters are complex. For example, changing the pore size of the substrate

²These fluorinated surfactants are products of the 3M Corporation.

changes the specific conductance of the substrate, which affects the relationship between the conductance of the matrix and the conductance of the electrolyte; this, in turn, alters the active region of the porous substrate and, hence, the true current density of plating. Additional complications arise with time during plating since Zn deposition increases the conductance of the solid matrix and decreases the conductance of the electrolyte due to increased tortuosity. Furthermore, particularly in the case of dendritic growth from the face of the substrate, the electrode thickness increased with time. Qualitative comparisons to available models on the performance of porous electrodes can, however, be made.

Newman *et al.* (7) in their review of porous electrode theory, present four dimensionless ratios which govern the current distribution within the porous substrate. The first parameter is a dimensionless current

$$\delta = \frac{\alpha_c F I L}{RT} \left[\frac{1}{\kappa} + \frac{1}{\sigma} \right] \quad [2]$$

where α_c is the charge transfer coefficient in the cathodic direction, F the Faraday constant, I the superficial current density, L the electrode thickness, R the universal gas constant, T the absolute temperature, κ the effective conductivity of the solution, and σ the effective conductivity of the substrate. For a system such as ours, with matrix conductivity much larger than the solution conductivity, the matrix potential is uniform. Under these conditions, the reaction distribution within the substrate depends on δ when Tafel kinetics predominate. For the case of linear reaction kinetics, the current distribution depends on the dimensionless exchange current

$$v = [\alpha_a + \alpha_c] \frac{F a i_0 L^2}{RT} \left[\frac{1}{\kappa} + \frac{1}{\sigma} \right] \quad [3]$$

where α_a is the transfer coefficient in the anodic direction, a the specific interfacial area, and i_0 the exchange current density. For large values of either δ or v , the current is not evenly divided between the solution and the

matrix and the reaction distribution is highly nonuniform, being much larger near the foam/electrolyte and foam/backing plate interfaces than in the center of the substrate. The remaining two dimensionless parameters are the ratio of transfer coefficients, α_a/α_c , and the ratio of the effective conductivities of the solution and matrix phases, κ/σ . For small values of κ/σ , the reaction occurs preferentially near the foam/electrolyte interface. The value of these four dimensionless ratios for each of the plating conditions presented earlier are listed in Table II. The numerical values for the parameters of Eq. [1] and [2] are given in the list of symbols.

Several conclusions can be drawn from the data of Table II. First, all our experimental conditions result in large values of δ and ν , i.e., > 1 . For the first four experiments, conducted at 25 mA/cm², the electrode overpotential was very small, so that linear kinetics prevailed. We would, therefore, expect the reaction distribution to depend on ν , which was very large, ranging from 6.8 to 15.9. The overpotential for the last experiment, carried out at 100 mA/cm², was considerably higher, so that Tafel kinetics were likely to dominate. The reaction distribution for this experiment would, therefore, depend on the parameter δ which was also very large: 8.31. For all plating experiments, therefore, a highly nonuniform plating distribution within the foam is expected, decreasing sharply from either foam interface into the center of the foam. Also, the ratio of κ/σ is very small due to an order of magnitude larger conductivity in the matrix compared to the electrolyte. This should result in preferential Zn deposition on

Fig. 11. SEM and x-ray radiographs of the cross section of 100 pore foam shown on the right of Fig. 10. SEM corresponds to center segment of electrode. Top radiograph taken of left edge; middle radiograph taken of center segment; bottom radiograph taken of right segment of the foam.

the foam/electrolyte interface at the expense of the foam/backing plate interface. Each of these theoretical predictions were verified experimentally, i.e., Zn deposition occurred preferentially near the foam/electrolyte interface decreasing sharply into the center of the foam. The large amount of zinc found on the backing plate is not adequately explained by the model of Newman *et al.* (7). It should be noted, however, that the zinc deposit on the solid backing plate should be denser than on the porous strand at equivalent current densities. The penetration of the Zn into the foam from the foam/electrolyte interface can be related to the ratio L/ν defined as

$$L/\nu = \frac{RT\kappa\sigma}{[\alpha_a + \alpha_c] a i_0 F [\kappa + \sigma]} \quad (\text{cm}) \quad [4]$$

Predicted values for the Zn penetration, L/ν , for the experimental conditions examined here, as listed in Table II, are very small, i.e., 0.018-0.028 cm. With the exception of 100 pore foam 0.2 cm thick, these values correlate well with penetration depths observed, namely, 0.01-0.05 cm. It is clear from these analyses that ohmic effects are dominating the utilization of porous C foams. It should be noted that, with time, the values of Table II change. As Zn is deposited on the face of the foam, σ , a , and L increase, while κ decreases due to increased tortuosity. The combined effect is to produce sharper deposits located closer to the electrolyte/foam interface. This effect is enhanced at low flow rates where a more dendritic deposit predominates the Zn morphology.

Existing theoretical models do not address the effect of dendrite inhibitors on Zn deposit morphology. We will discuss these effects qualitatively. The two major effects of the organic inhibitors are the virtual elimination of dendrite growth and greatly increased throwing power. The latter means excellent plating into the porous substrate and significantly increased Zn deposit density. Separate studies of the reductive stability of the organic inhibitor had shown unmitigated inhibitor effectiveness

Table II. Summary experimental test conditions

Substrate	L (cm)	I (A)	κ/σ	δ	ν	L/ν (cm)
45 pore	0.2	0.025	0.1	2.0	7.1	0.028
45 pore	0.45	0.025	0.1	4.5	15.9	0.028

100 pore	0.20	0.025	0.06	2.08	11.4	0.018
100 pore	0.20	0.100	0.06	8.31	11.4	0.018

over more than 750 cyclic platings (11). These studies also demonstrated excellent stability to bromine after exposure to 1% by weight Br₂ for 6 months at 55°C. Therefore, we believe the inhibitor to be active by nondestructive adsorption on the most active growth sites during plating followed by desorption during anodic dissolution (discharge). The adsorption of the inhibitor is likely to decrease the rate of the charge-transfer reaction such that diffusion is no longer rate limiting. Under these conditions, it is generally known that dendritic growth no longer occurs and that the throwing power is increased owing to the better penetration of the electric field into the pores.

Conclusions

The application of x-ray absorption coupled with densitometry and microscopy allows quantitative analysis of Zn deposition within a porous C foam. Using these techniques, it is demonstrated that high electrolyte flow rates, high L/D ratio, and thicker foams all aid in producing more uniform Zn deposits. Overall, within the range of parameters studied, optimal results were obtained with 2 mm thick 100 pore RVC foams with electrolyte flow rates corresponding to Reynolds numbers close to 500. The Zn distributions obtained correspond to the primary current distribution modeled by Newman *et al.*, *i.e.*, highly nonuniform deposits decreasing sharply from either foam interface into the center of the foam with predominate deposition near the foam/electrolyte interface. The most striking effect on Zn morphology was obtained by adding to the electrolyte an organic dendrite inhibitor-solubilizer combination, consisting of certain fluorosurfactants and butyrolactone. The use of these inhibitors yielded dendrite-free Zn deposits well into the porous foam substrate when plating at current densities as high as 100 mA/cm² for 2h, equivalent to charge densities up to 200 mAh/cm².

Electrical Conductivity and Specific Mass of the Molten LiOH-LiNO₃, NaOH-NaNO₃, and KOH-KNO₃ Mixtures

P. Claes and J. Glibert

Department of Inorganic, Analytical and Nuclear Chemistry, Catholic University of Louvain, B-1348 Louvain-la-Neuve, Belgium

ABSTRACT

The specific mass, the conductivity, and the equivalent conductance of the mixed systems LiOH-LiNO₃, NaOH-NaNO₃, and KOH-KNO₃ were determined in the whole concentration range. The specific mass isotherms present unexplained irregularities and the conductances exhibit large departures from the additivity law of the transport properties of the pure components of the mixtures. The activation energies for the equivalent conductance show, for the three investigated systems, a maximum in the vicinity of the 50 mole percent composition. These departures from additivity are explained by invoking a change of transport mechanism when the composition of the mixtures shifts from one pure component to the other.

Results reported in the literature suggest that charge transport in hydroxide melts could proceed by a mechanism other than that operating in most salts (1, 2). Shvedov and Yvanov (3) measured transference numbers

near unity for hydroxide ions in molten alkali hydroxides. Hydroxide ions take thus the largest part of charge transport in the case of molten hydroxides contrary to what happens in fused lithium, sodium, or potassium salts

where the transference numbers of the cations are larger than those of the anions (4, 5).

Furthermore, the activation energies of transport properties of molten hydroxides are significantly lower than those of fused salts (1, 6, 7).

It seemed as if it would be interesting to investigate the concentration dependence of the conductivity of molten mixtures of alkali hydroxides and alkali salts. Mixtures of alkali salts generally exhibit negative departures from an additivity law of the conductivities. It seems reasonable to expect particularly large departures when the transport mechanism in the pure components of the mixture are different.

The melting points of molten hydroxides and of molten nitrates are quite comparable; mixtures of these compounds could thus be investigated in the whole concentration range and seem to be very suitable systems for such studies.

Experimental

Materials and device.—Chemicals were analytical-grade Merck reagents. Water elimination occurred by maintaining the melt at temperatures above 673 K under a stream of dry nitrogen during at least 12h. The stream of nitrogen was maintained during the experiments.

The container was a silver crucible placed in a Pyrex cell fitted with ground glass joints. Compact alumina (Degussa Al 23), which is specially stable in neutral or slightly acidic conditions, was selected as material for the bubbling tube and for the sheath of iron-constantan thermocouple.

Conductivity measurements.—The same conductivity cell was used as in previous work (1, 2). It was composed of two compact alumina "pseudo-capillary" electrodes of 4 mm id containing platinum conductors ended by coils located at about 2 cm above the lower end of the alumina tubings. The cell factor measured by standardization in pure molten potassium nitrate was ca. 25 cm⁻¹. This value is low as far as determinations in ionic liquids are planned and requires thus the use of a multifrequency LCR meter (Hewlett-Packard 4274 A) allowing measurements up to high frequencies in order to eliminate polarization effects.

The measurements were carried out after selection of a series equivalent circuit mode. The bridge enables to use a four terminal pair wiring giving the best accuracy by minimizing any stray capacitance and residual inductance in the test leads or test fixture. The tension applied between the electrodes was of the order of 250 mV.

The measured impedance decreased when the frequency was increased, a minimum value was reached from about 20 kHz. The LCR bridge allows the determination of the resistance, of the impedance, and of the angle θ between the impedance vector and the real axes. When the minimum value is measured for the impedance, (i) the impedance equals the resistance, meaning that the capacitive factor is negligible, and (ii) θ takes a minimum value.

Specific mass measurements.—Specific mass measurements were carried out by weighing a calibrated silver

bob dipped into the melt and hung on the pan of an analytical balance (Mettler) by means of a thin platinum wire. As for conductivity, the reproducibility of the measurements was quite good.

Results

The conductivity (κ) and the specific mass (ρ) of the three binary mixtures LiOH-LiNO₃, NaOH-NaNO₃, and KOH-KNO₃ were measured as a function of temperature at compositions ranging from pure nitrate to pure hydroxide. The equivalent conductances (Λ) were calculated according to the following equation where M^{eq} is the average weight of the electrochemical equivalent

$$\Lambda = \frac{\kappa M^{eq}}{\rho}$$

taking into account the molar fractions (X) of the components

$$M^{eq} = X_{MeOH}M_{MeOH} + X_{MeNO_3}M_{MeNO_3}$$

The temperature ranges extend from a few degrees above the melting point of the investigated pure compound or mixture up to 805, 723, and 761 K, respectively, for the lithium, sodium, and potassium systems. In the case of mixtures with high nitrate contents, the higher temperature was always significantly lower in order to avoid any decomposition.

The temperature dependences of the three investigated properties (P) are correctly described by a linear relationship where b and m are constants for a given system

$$P = b + mT \text{ (K)}$$

Tables I, II, and III give the values of these coefficients as well as the corresponding correlation factors for the conductivity, the specific mass, and the equivalent conductance of the lithium, sodium, and potassium containing mixtures.

In some cases, at the highest investigated temperatures, deviations of the temperature dependence from linearity were recorded. Therefore, temperature ranges were also included in Tables I-III. The upper limit is either the temperature above which departures from linearity are observed or the last investigated temperature.

The composition dependence of the specific mass, of the conductivity, and of the equivalent conductance are shown for the three mixtures in Fig. 1-6. Because of the lack of overlapping of the temperature ranges available for the sodium containing mixtures and for the lithium containing mixtures, isotherms at 723 K are compared for the lithium and potassium systems, while experimental results recorded at 673 K are shown for the sodium and potassium systems.

Discussion

Specific mass.—The specific mass of mixtures of molten salts generally changes with the composition in a regular way; the breaks observed in the specific mass isotherms of the mixtures of alkali hydroxides and alkali nitrates are rather uncommon (Fig. 1 and 4). These irregu-

larities, which become less apparent when the temperature is raised, suggest the occurrence of some structural event between the components of the mixture at the corresponding composition.

Distectic or transition points are observed at a mole fraction 0.5 in the phase diagrams of the three investigated systems (8-10).

The breaks occurring in the specific mass isotherms could thus be the indication of the formation of a definite compound between the components of the mixture. However, two irregularities are observed for the composition dependence of the specific mass of the potassium system when only one distectic point is found in the phase diagram (9). Furthermore, only one break appears in the

specific mass isotherm of the NaOH-NaNO₃ system, whose phase diagram exhibits two distectic points (8). These discrepancies rule out any relationship between the shape of the density isotherms and the phase diagrams of the corresponding systems.

However, the conductivity isotherms of molten salt mixtures are quite continuous, whereas anomalies in such curves are often related to the phase diagram of the investigated systems (11, 12).

Finally, it must be pointed out that the scale used for the specific mass in these graphs is largely expanded; the features of the corresponding isotherms are thus of little absolute importance.

Fig. 3. Composition dependence of the equivalent conductance of the NaOH-NaNO₃ and KOH-KNO₃ systems. Dotted line: additivity law. Dotted curve: Markov law.

Nevertheless, we believe that the peculiarities of the experimental curves are significant. This opinion is supported by the following arguments.

1. As shown in Tables I, II, and III, the fits to the linear dependence of the temperature are quite good for all the

Fig. 4. Composition dependence of the specific mass of LiOH-LiNO₃ and KOH-KNO₃ systems.

Fig. 5. Composition dependence of the conductivity of the LiOH-LiNO₃ and KOH-KNO₃ systems. Dotted line: additivity law.

investigated mixtures. A lack of accuracy of the compositions could eventually be at the origin of the discontinuities in the isotherms. However, errors as high as 10% must be invoked in order to explain the shapes of the experimental curves. Controls of the accuracy of the melt compositions have been carried out by analyzing melts prepared in the same way as those used in the reported experiments. The results of these tests are given in Table IV, which shows that the discordance between the compositions calculated from the weights of the components (A) and those determined from the titrations of the melts dissolved after cooling (B) never exceed 2%. Such departures could never explain the breaks observed in the experimental curves.

2. Errors in the composition of the melts would have the same consequences on the conductivity isotherms where such discontinuities are never observed.

3. The silver bob used for the specific mass measurements was regularly recalibrated.

4. The numerous experimental points reported on the diagrams were determined in a random sequence of compositions so that systematic errors could not be invoked in order to explain the break in the isotherms.

In the absence of any structural information about these mixtures, no grounded explanation could be provided at this time for the discontinuities in the specific mass isotherms.

Equivalent conductance of pure hydroxides in the molten state.—As shown in Fig. 3 and 6, the sequence of the equivalent conductances of the pure molten hydroxides is the following one

$$\Lambda_{\text{KOH}} > \Lambda_{\text{NaOH}} > \Lambda_{\text{LiOH}}$$

In the case of fused salts, the opposite sequence is always observed: the largest equivalent conductance is systematically measured for the lithium salt and the lowest one for the potassium salt (6). This observation strongly suggests that charge transport occurs in molten hydroxides by another mechanism than in fused salts.

In the case of molten alkali salts, the transference number of the cation is larger than that of the anion and the equivalent conductance is dictated mostly by the nature of the cation.

According to Shvedov and Yvanov, the transference numbers of the alkali cations are very low in pure fused hydroxides; they report, indeed, values of 0.1 ± 0.03 and 0.03 ± 0.03 , respectively, for sodium hydroxide and potassium hydroxide at temperatures ranging from 653 to 773 K (3). The fact that the equivalent conductances of these ionic liquids are quite different shows that the

Fig. 6. Composition dependence of the equivalent conductance of the LiOH-LiNO_3 and KOH-KNO_3 systems. Dotted line: additivity law. Dashed curve: Markov law.

values of the equivalent conductances are still dictated by the nature of the cation but in an indirect way. Because of its strong polarizing electric field, the lithium cation interacts more strongly with hydroxide ions than do the other alkali ions and so hinders more effectively the reorientation and/or translation motions of hydroxide ions. Such an effect was evidenced by Duke and Owens on the mobilities of nitrate anions in alkali nitrate melts (5).

Transport properties of mixtures of nitrates and hydroxides.—As shown in Fig. 2, 3, 5, and 6, the concen-

tration dependence of the isotherms of conductivity and of equivalent conductance show large deviations from a linear relationship characteristic of the additivity of the properties of the pure compounds. Taking into account the fact that the conductance is a kinetic property, the Markov (13) equation is often invoked to describe the ideal behavior of mixtures of molten salts; the Markov law applied to the equivalent conductance of the investigated systems yields the dotted curves presented on the graphs of Fig. 3 and 6.

Deviations from additivity are characteristic of the mixed alkali effect; Moynihan (14) suggests using the ratios r_k and r_A in order to quantify this effect. These parameters are respectively defined as the ratios of the conductivity and of the equivalent conductance, predicted on the basis of an additivity law, to the experimental values for the mole fraction where the maximum deviation occurs. Such parameters could also be defined with respect to the Markov behavior in place of additivity; the corresponding r_A^M values would, of course, be somewhat lower since Markov law yields small negative departures from additivity.

Table V gives the values of r_k , r_A , and r_A^M for the three investigated systems. These ratios are compared with r_A values calculated from the results of Spedding (15) for the conductances of mixtures of molten alkali carbonates. Relatively strong negative deviations from additivity were indeed evidenced in this case (15-17).

The departures from a linear relationship are of the same order of magnitude for both types of mixtures and seem even to be slightly more important in the case of mixtures of nitrates and hydroxides. Furthermore, these deviations become less important when the temperature is increased.

As shown in Fig. 7, the concentration dependence of the activation energy for the equivalent conductance exhibits a well-defined maximum in the vicinity of the equimolar composition for the three investigated systems. Such a maximum is another criterion of the occurrence of a mixed alkali effect pointed out by Moynihan (14). A maximum of the activation energy is indeed found for mixtures of molten alkali carbonates (15). This effect is the largest in the case of the $\text{Li}_2\text{CO}_3\text{-K}_2\text{CO}_3$ mixture, where a positive departure 0.42 kcal/mol is found for a 50 mole percent composition.

This deviation yields, when it is compared with the value of the activation energy deduced from an additive behavior, a relative value of 9.29%.

Relative deviations of the activation energies for equivalent conductance of 24.06%, 34.15%, and 38.18% are calculated, respectively, for $\text{KNO}_3\text{-KOH}$, $\text{LiNO}_3\text{-LiOH}$, and $\text{NaNO}_3\text{-NaOH}$ equimolar mixtures. These deviations are significantly larger than those observed for molten alkali carbonate mixtures.

Despite the similarity of these results with the behavior of systems exhibiting a mixed alkali effect, the same explanation could not be invoked in this case. Indeed, in order to explain the mixed alkali effect, the polarization of the common anion by cations of different sizes or charges (18, 19) is put forward. The same transport mechanism is working in the whole concentration range, but it becomes more difficult when polarization effects become important. Such an explanation, which is satisfactory in the

Table V. Departures from additivity and from Markov behavior of transfer properties of mixtures of alkali nitrates and hydroxides and of mixtures of alkali carbonates

System	r_k	r_A	r_A^M
LiOH-LiNO_3 (723 K)	1.59	1.49	1.26

Fig. 7. Composition dependence of the activation energy for equivalent conductance of molten mixtures of alkali nitrates and alkali hydroxides.

case of mixed cation systems, could not be extended to a mixed anion effect because of the low polarizability of the cation.

It seems reasonable to refer to a real change in the transport mechanism: the charge conduction by molten nitrates and by molten hydroxides would occur by two incompatible processes. The occurrence of a proton-transfer mechanism has been suggested in order to explain the water and oxide ion dependence of the conductivity of the molten NaOH-KOH eutectic mixture (1, 2). This kind of charge transfer would be enhanced by hydrogen bridging between hydroxide ions. Greenberg and Hallgren (20) invoke indeed such interactions to explain some features of the infrared spectra of molten hydroxides. On the contrary, hydrogen bonding between hydroxide and nitrate ions would hinder the proton-transfer mechanism by reducing the interactions between hydroxide ions. However, the same interactions could provide an explanation for the hindrance of ionic rearrangements in molten alkali nitrates in the presence of hydroxide ions.

This type of explanation, which invokes a transition of transport mechanisms, even if it is not actually supported by experimental evidence, goes in the same sense as other experimental data, such as (i) the values of the transference numbers of hydroxide ions reported by

Shvedov and Yvanov, (ii) the sequence of the equivalent conductances of molten alkali hydroxides which is opposite to that found for the fused alkali salts, and (iii) the high positive departures from additivity of the activation energies for equivalent conductance.

Acidity and Thermochemical Stability of Molten Sodium Nitrate and Nitrite Mixtures

G. S. Picard, T. A. Flament, and B. L. Trémillon*

Laboratoire d'Electrochimie Analytique et Appliquée, associé au CNRS (LA 216), Ecole Nationale Supérieure de Chimie de Paris, F-75231 Paris Cedex 05, France

ABSTRACT

The influence of acidity on the thermochemical stability of molten sodium nitrate-nitrite mixtures used as heat-transfer fluids (as in the case of the French electrosolar power system called Thémis) has been demonstrated by considering the potential- pO^{2-} diagram relative to redox systems corresponding to these mixtures and been established from thermochemical data. The importance of fixing the pO^{2-} value with a buffer has been clarified. The couple $H_2O(g)/OH^-$, whose acid-base constant was previously determined, appears as the most efficient for this purpose. The potential- pO^{2-} diagram could be set up experimentally by studying the disproportionation of nitrite ion into nitrate and nitrogen monoxide and by determining the standard potential of the electrochemical system NO_3^-/NO_2^- by means of potentiometric measurements with a platinum electrode and with an yttria-stabilized zirconia membrane electrode indicator of pO^{2-} . This diagram has allowed us to specify, as a function of temperature, the boundary values of pO^{2-} which should not be gone beyond in order to avoid the decomposition of the mixtures as a result of the nitrite disproportionation.

Molten alkali nitrate-nitrite mixtures are known for their high heat capacities and their low melting points, which have led to their use as heat-transfer fluids at temperatures not greater than 723 K. The use of the mixture called HITEC [KNO_3 , 53- $NaNO_2$, 40- $NaNO_3$, 7 weight percent (w/o)] in the French electrosolar power system Themis, built by Electricité de France, makes necessary that this liquid can circulate in a thermal loop where the extreme working temperatures are 523 and 773 K. In view of this use, we have decided to study the chemical factors influencing the thermal stability of molten $NaNO_3$ - $NaNO_2$ mixtures.

The thermochemical decomposition of nitrates (1, 2) and nitrites (3-5) has been the subject of many studies, but the authors do not agree about the reactions which take place. It seems, nevertheless, well established that decomposition is accompanied by the release of nitrogen, nitrogen oxides, and oxygen, with the production of alkali oxide. Because of the complexity of these reactions, we have undertaken a preliminary study based on the existing thermochemical data (6). Reactions in these media put into play the redox systems of nitrogen which depend on the oxide anion activity. So, the results have been expressed in the form of a potential-(oxo)acidity diagram. This sort of presentation has already been used for alkali nitrates and for alkali nitrites by Conte and Casiadao (7), Marchiadi and Arvia (8), and by Haan and Van Der Porten (9), but not for their mixtures.

The calculated diagram has subsequently been specified by experimental determinations, and the results obtained have finally permitted the definition of the conditions which would be favorable to the thermochemical stability of the heat-transfer fluid.

We present here a part of our investigation concerning the effect of acidity, in studying especially the sodium nitrate-sodium nitrite-nitrogen monoxide systems.

Concentration units used for mixtures.—The alkali nitrate-nitrite mixtures have been shown to behave ideally (10). So, the activities of their components can be expressed by their mole fractions $N(NO_3^-)$ and $N(NO_2^-)$. The concentrations m of the dissolved (and consequently solvated) species, other than the "solvent" ones, are given in the molality scale. In particular, the acidity of the medium is defined by $pO^{2-} = -\log m(O^{2-})$ (11). The partial pressures of gases are in atmospheres.

Experimental Section

Technical

Products preparation of melts and apparatus.—After drying at 423 K, sodium nitrate and nitrite (Merck) were

mixed in the desired proportions. Dehydration of the mixtures was carried out by a progressive raising of the temperature and by maintaining for 4h at work temperature while bubbling dry nitrogen. The other products used were sodium carbonate dried at 1273 K, sodium hydroxide without any previous treatment (pure products for analysis PROLABO), and nitrogen monoxide (99% pure) supplied by COOP-LABO.

For each experiment, 100g of the nitrate-nitrite mixture thus prepared were introduced into a cylindrical platinum crucible. Platinum was chosen in order to avoid the effect of silica as an acid (12-14). The platinum crucible was itself contained in a Pyrex glass cell. The temperature was maintained at the desired value 693, 743, or 793 K at ± 1 by means of an oven thermoregulated by a Digitop (Chauvin-Arnoux) coupled to a Teledyne (Tekelec-Airtronic) relay.

Alumina tubes (reference number: Al 23) from Desmarquest were used for the different fluids and for the thermocouples. Partial pressures of water vapor were imposed above the melt by saturators at fixed temperature. The EMF's were recorded with the help of a voltmeter Tacussel Aries 20000 and a Sefram recorder (Servo-gram type).

Reference electrode.—The reference electrode used was made up of a silver wire (C.M.P.) dipped into a 0.057 mol kg^{-1} $AgNO_3$ solution in $(Na-K)NO_3$ eutectic contained in a Pyrex glass tube. All potentials are given in volts *vs.* this reference electrode (whatever the $NaNO_3$ - $NaNO_2$ mixture used).

Platinum working electrode.—The indicator electrode used was made from 1 mm diam platinum rod supplied by Johnson-Matthey.

Acidity buffer.—Previous works (15, 16) have shown that acidity can be adjusted by using the buffer effect of $H_2O(g)/OH^-$ mixtures. As a matter of fact, if we add to the melt a quantity m_0 of sodium hydroxide (per kilogram of molten mixture), the respective molalities of free O^{2-} and remaining OH^- are linked by the equilibrium

the constant K_1 of which is given as a function of temperature (and whatever the compositions of $NaNO_3$ - $NaNO_2$ mixtures may be) in Table I. The acidity level (pO^{2-}) fixed by a given $H_2O(g)/OH^-$ mixture is so deduced from the expression

$$pO^{2-}_{(at\ T)} = -\log K_{1(at\ T)} + \log \frac{P(H_2O)}{m(OH^-)^2} \quad [1b]$$

pO^{2-} measurements (description of the indicator electrode used).—In order to measure pO^{2-} in alkali nitrates,

*Electrochemical Society Active Member.

Table I. Constants K_1 of chemical equilibria

Equilibrium	Mass action law expressions	$pK_1 = A + B/1000/T$	
		A	B
(1) $2\text{OH}^- = \text{H}_2\text{O}(\text{g}) + \text{O}^{2-}$	$K_1 = P(\text{H}_2\text{O})m(\text{O}^{2-})m(\text{OH}^-)^{-2}$	-4.80	5.48
(2) $3\text{NO}_2^- = \text{NO}_3^- + 2\text{NO}(\text{g}) + \text{O}^{2-}$	$K_2 = P(\text{NO})^2 m(\text{O}^{2-})N(\text{NO}_3^-)N(\text{NO}_2^-)^{-3}$	-15.8	15.75

it has been shown (17) that an electrode with an oxide ion selective membrane is preferable to an oxygen electrode. A calcia-stabilized zirconia membrane electrode with a solid inner filling used for the first time by Eichler *et al.* (18) and by Trémillon *et al.* (19) in molten alkali chlorides, works quite well at temperatures above 873 K, but its potentiometric response becomes slow (equilibrium potential reached with difficulty) at lower temperatures. Flinn and Stern (17) for molten alkali nitrates, and Picard *et al.* (20-22) for molten alkali chlorides, have, therefore, preferred to employ a membrane of yttria-stabilized zirconia, which is twice more conductive, and a liquid inner filling. Such a device does not present the same problems as mentioned above. The galvanic chain set up to measure $p\text{O}^{2-}$ is described below

(The yttria-stabilized zirconia is supplied by Desmarquest: ZFYE tube.)

The EMF of this cell has the theoretical expression

$$E = E^\circ + \frac{2.3RT}{2F} p\text{O}^{2-}$$

Calibration.—In order to verify the potentiometric response of the yttria-stabilized zirconia membrane electrode (YSZME) and to make its calibration, we have used sodium hydroxide. When the partial pressure of water is made sufficiently low, the dissociation of OH^- according to equilibrium [1a] can be considered as practically total, and the concentration of O^{2-} ions is given by

$$m(\text{O}^{2-}) = 0.5 m_0(\text{OH}^-)$$

We have shown that a partial pressure of H_2O less than 10^{-3} atm is convenient for this (15).

The introduction of oxide ions by dissociation of OH^- was preferred to the direct addition of sodium oxide because this product is generally impure (presence of peroxide and superoxide).

Acidity function.—Because of the dependence of K_1 with temperature, we preferred, in order to analyze the effect of acidity on the thermochemical stability of molten nitrate-nitrite mixtures, to use the acidity function $\log [P(\text{H}_2\text{O})/m(\text{OH}^-)^2]$, the value of which, for a given temperature, is related to the $p\text{O}^{2-}$ (at T) by the above relation, Eq. [1b], and may be obtained, whatever the temperature may be, directly from the temperature-independent factors water pressure and sodium hydroxide concentration, which are experimentally set. This procedure is analogous to that employed in molten chlorides (23).

Thanks to the values of constant K_1 of equilibrium [1a] which have been determined (Table I) and which do not vary practically with the composition of the mixtures at a given temperature (15, 16), it is possible to obtain the correspondence between this acidity function and $p\text{O}^{2-}$.

Disproportionation of nitrite ions.—It has been observed that increasing acidity produces the disproportionation of NO_2^- into NO_3^- and nitrogen monoxide, according to the equilibrium

characterized by the constant K_2 , defined by

$$K_2 = N(\text{NO}_3^-) P(\text{NO})^2 m(\text{O}^{2-}) N(\text{NO}_2^-)^{-3} \quad [2b]$$

This constant has been determined by simply measuring with the YSZME the $p\text{O}^{2-}$ imposed by bubbling nitrogen monoxide (1 atm) into $\text{NaNO}_3\text{-NaNO}_2$ mixtures of given compositions. The results obtained at three different temperatures verify a straight line variation of $p\text{O}^{2-}$ with the ratio $N(\text{NO}_3^-)/N(\text{NO}_2^-)^3$ as predicted by Eq. [2b] (see Fig. 1a). The variation of $-\log K_2$ with the temperature (Fig. 1b) has been determined by regression analysis.

$\text{NO}_3^-/\text{NO}_2^-$ electrochemical system.—The melts studied contained the two components of the redox couple

So, the redox potential E of a given melt (*i.e.*, at fixed

NO_3^- and NO_2^- mole fractions) has to follow the Nernst relations

$$E = E_3^\circ + (\lambda/2) \log [N(\text{NO}_3^-)/N(\text{NO}_2^-)] + (\lambda/2) p\text{O}^{2-} \quad [3]$$

$$\left(\lambda = \frac{2.3RT}{F} \right)$$

and, consequently, only varies with the activity of oxide ion. Then, measurements of the potential of a platinum electrode immersed in molten $\text{NaNO}_3\text{-NaNO}_2$ mixtures must allow us to determine the standard potential value of the $\text{NO}_3^-/\text{NO}_2^-$ redox couple.

But, while making these determinations, we have to take care not to let $p\text{O}^{2-}$ increase beyond the value corresponding to the disproportionation of nitrite ion according to equilibrium [2a]. This limiting value of $p\text{O}^{2-}$ depends on the nitrogen monoxide partial pressure, the maximum value of $p\text{O}^{2-}$ being reached for $P(\text{NO}) = 1$ atm. This limit is represented in Fig. 2 for the three temperatures considered. We have also plotted on this figure the variations of potential *vs.* $p\text{O}^{2-}$ observed with five mixtures of sodium nitrate and sodium nitrite.

We observe in all cases that the variations of potential check very well the Nernst relation [3]. It is thus justified to determine the potential of the $\text{NO}_3^-/\text{NO}_2^-$ system at $p\text{O}^{2-} = 0$ by extrapolation. Then by plotting as a function of the ratio $N(\text{NO}_3^-)/N(\text{NO}_2^-)$, this potential at $p\text{O}^{2-} = 0$, a

Fig. 1. Disproportionation of NO_2^- into NO_3^- and $\text{NO}(\text{g})$. a: Variation of $p\text{O}^{2-}$ (at T) for various $\text{NaNO}_3\text{-NaNO}_2$ mixtures (\blacktriangle : $T = 793$ K; \times : $T = 743$ K; \circ : $T = 693$ K). b: Variation of the logarithm of the constant K_2 corresponding to the disproportionation of NO_2^- (see text) as a function of temperature.

Fig. 2. Equilibrium potentials of the $\text{NO}_3^-/\text{NO}_2^-$ electrochemical system in various sodium nitrate-sodium nitrite mixtures for (a) $T = 693$ K, (b) $T = 743$ K, and (c) $T = 793$ K.

Symbol	■	□	●	○	◆
$N(\text{NO}_3^-)$	0.99	0.85	0.50	0.15	0.01
$N(\text{NO}_2^-)$	0.01	0.15	0.50	0.85	0.99

straight line agreeing with relation [3] is obtained and permits us to determine the standard potential of the $\text{NO}_3^-/\text{NO}_2^-$ electrochemical system. The results obtained according to this procedure at the three temperatures have led to the expression of the variation of the $\text{NO}_3^-/\text{NO}_2^-$ standard potential as a function of temperature given in Table II.

$\text{NO}_2^-/\text{NO}(\text{g})$ and $\text{NO}_3^-/\text{NO}(\text{g})$ electrochemical systems.—The standard potentials E_4° and E_5° of the $\text{NO}_2^-/\text{NO}(\text{g})$ and $\text{NO}_3^-/\text{NO}(\text{g})$ electrochemical systems

defined by the respective Nernst relations

$$E = E_4^\circ + \lambda \log [N(\text{NO}_2^-)/P(\text{NO})] + \lambda p\text{O}^{2-}$$

$$E = E_5^\circ + (\lambda/3) \log [N(\text{NO}_3^-)/P(\text{NO})] + (2\lambda/3)p\text{O}^{2-}$$

can be determined by combining the value of K_2 (constant of the NO_2^- disproportionation equilibrium) with the value of E_3° (standard potential of the $\text{NO}_3^-/\text{NO}_2^-$ system). We have in fact

$$E_4^\circ = E_3^\circ - (\lambda/2) pK_2$$

$$E_5^\circ = (2E_3^\circ + E_4^\circ)/3$$

The values of E_4° and E_5° are also given in Table II.

Discussion

Chemical and electrochemical properties of NaNO_3 - NaNO_2 mixtures at a given temperature.—It is possible to

Fig. 3. Potential-acidity diagram at 743 K

summarize our experimental results in the form of potential- $p\text{O}^{2-}$ diagrams. For example, we give in Fig. 3 the diagram relative to the equimolar sodium nitrate-sodium nitrite mixture at 743 K and in the cases where the nitrogen monoxide pressure is equal to 0.1 and 1 atm. In this diagram, the value of $p\text{O}^{2-}$ corresponding to the disproportionation of nitrite is given by the abscissa of the intersection of the straight lines connected with the systems $\text{NO}_3^-/\text{NO}_2^-$, $\text{NO}_3^-/\text{NO}(\text{g})$, and $\text{NO}_2^-/\text{NO}(\text{g})$. This intersection is designated, in the following, as the "nitrite disproportionation characteristic point." For example, in the case of the equimolar mixture, this characteristic point is represented by the letter A for $P(\text{NO}) = 0.1$ atm, and by B for $P(\text{NO}) = 1$ atm.

So, we can assert that a molten NaNO_3 - NaNO_2 mixture keeps its composition only if the $p\text{O}^{2-}$ value remains less than the value of the nitrite disproportionation characteristic point.

Besides the disproportionation of nitrite, which is largely responsible for the thermal instability of NaNO_3 - NaNO_2 mixtures, another equilibrium plays an important role: the decomposition of nitrate into nitrite and oxygen according to the equilibrium

So, if we wish to explain in a complete manner the stability of NaNO_3 - NaNO_2 mixtures, we have to take into account this equilibrium, the constant of which is defined by

$$K_6 = P(\text{O}_2)^{0.5} N(\text{NO}_2^-) N(\text{NO}_3^-)^{-1}$$

Several values of K_6 are found in the literature (24-26). We have considered the value given by Sirotkin (24) which is relative to the decomposition of NaNO_3 , a value which is very close to that given by Paniccia and Zambonin for $(\text{Na}, \text{K})\text{NO}_3$ (26). The variation of the cologarithm of K_6 as a function of temperature is given in Table III.

Figure 4 represents a composition-acidity diagram which gives the variation of composition of the NaNO_3 -

NaNO_2 mixtures [by the logarithm of $N(\text{NO}_2^-)$ vs. $p\text{O}^{2-}$ at $T = 743$ K. It was established from the constant K_2 of the disproportionation of nitrite ion (Eq. [2b]).

Partial pressures of oxygen were deduced from the constant K_6 of equilibrium [6]. From this diagram, it is possible to obtain the conditions for which a given mixture is stable under a total pressure of 1 atm. Toward the low values of $N(\text{NO}_2^-)$ (nitrate-rich mixtures), the limiting composition, due to the decomposition of nitrate ion, is given by Eq. [6] where $P(\text{O}_2)$ is equal to 1 atm. For high values of $N(\text{NO}_2^-)$, the limitation occurs from the disproportionation of nitrite ion into nitrate and nitrogen monoxide which takes place in acidic media. The limiting values (as a function of $p\text{O}^{2-}$) are given by $P(\text{NO}) = 1$ atm.

We can notice that the acidity range depends on the composition of the mixture considered. For example, the nitrate richer mixtures allow one to obtain the more acidic (and oxidant) media; on the contrary, the nitrite richer mixtures have weak acidity ranges.

We can also observe in Fig. 4 that $\text{NO}(\text{g})$ acts as an acid in a given molten NaNO_3 - NaNO_2 mixture, because when the partial pressure of $\text{NO}(\text{g})$ increases, the $p\text{O}^{2-}$ value increases. For example, in the case of the equimolar mixture, it is possible to win two units of $p\text{O}^{2-}$ by increasing $P(\text{NO})$ from 0.1 to 1 atm (points A and B).

The acidic properties of $\text{NO}(\text{g})$ correspond to the following equilibria

because in nitrate-nitrite mixtures, $P(\text{O}_2)$ is fixed by the equilibrium [6] of the decomposition of nitrate ion. For pure NaNO_2 (Eq. [7]) or pure NaNO_3 (Eq. [8]), the acidity is fixed by a $\text{NO}(\text{g}) + \text{O}_2(\text{g})$ gaseous mixture of given composition.

If partial pressures of $\text{NO}(\text{g})$ and $\text{O}_2(\text{g})$ are fixed, the partial pressure of $\text{NO}_2(\text{g})$ is also fixed through the equilibrium

and the preceding equilibria [7] and [8] can be, respectively, rewritten

Fig. 4. Composition-acidity diagram at 743 K

This last equilibrium, well known in molten alkali nitrate, shows that acidity can be adjusted by using $\text{NO}_2(\text{g}) + \text{O}_2(\text{g})$ gaseous mixtures. In particular, this fact was used recently by Drátovský and Havlíček for obtaining a qualitative acidity scale in molten $(\text{Na}, \text{K})\text{NO}_3$ at 533 K (27), and by Plumet *et al.* for establishing a potential-acidity diagram in molten $(\text{Na}, \text{K})\text{NO}_3$ at 748 K (28). As a consequence, if we maintain at a weak value (10^{-3} or 10^{-2} atm, for example) the partial pressure of $\text{NO}(\text{g})$ by means of bubbling argon, we see that it was not possible to modify acidity without modifying the composition of the mixture. We can also remark that it is impossible to reach media more acidic than $p\text{O}^{2-} = 6$ (point B) for the equimolar mixture and $P(\text{NO}) = 1$ atm without an increase of the nitrate ratio by disproportionation of nitrite. (The constants of the equilibria [7]-[11] were calculated from the constants K_2 and K_6 and from the literature thermodynamic data (6); they are given in Table III.)

Influence of temperature (and acidity) on the stability of NaNO_3 - NaNO_2 mixtures.—The influence of temperature on the stability of sodium nitrate-nitrite mixtures of various $p\text{O}^{2-}$ may be specified by establishing the potential-acidity diagrams of these mixtures as a function of temperature.

To obtain the stability domains of various molten sodium nitrate-nitrite mixtures, we shall conventionally consider in the following that nitrate or nitrite are "quasi-pure" if, respectively, they do not contain a proportion higher than 1 mole percent (m/o) of nitrite or nitrate. Then, we can distinguish at a given temperature (see, for example, Fig. 5, $T = 580$ K) three composition zones: those of quasi-pure nitrate and quasi-pure nitrite, and that of the NaNO_3 - NaNO_2 mixtures. The potential-acidity zone which is accessible in quasi-pure NaNO_3 is limited for high potential values by the oxidation of O^{2-} into oxygen (see Table IV) at a pressure of 1 atm (line a), and for low potential values, either by the reduction of NO_3^- ions into NO_2^- ions (line f) in the weak acidities range or by the reduction of NO_3^- into nitrogen monoxide in the high acidities range (line c), or even by the reduction of NO_3^- ions into $\text{NO}_2(\text{g})$ for very high acidity media. The characteristic points of this zone are thus, on the one hand, the reduction of NO_3^- by $\text{NO}(\text{g})$ for very high acidities (intersection of lines b and c) according to the reaction

and, on the other hand, the decomposition of nitrate into nitrogen dioxide and oxygen (intersection of lines a and b) according to

The potential-acidity zone which is accessible with the NaNO_3 - NaNO_2 mixtures whose compositions are comprised between 0.99-0.01 and 0.01-0.99 m/o is limited for high potential values by the line corresponding to the 0.99-0.01 mixture (line f), and for low potential values by the line relative to the 0.01-0.99 mixture (line h). For high acidity values, this area is limited by the disproportiona-

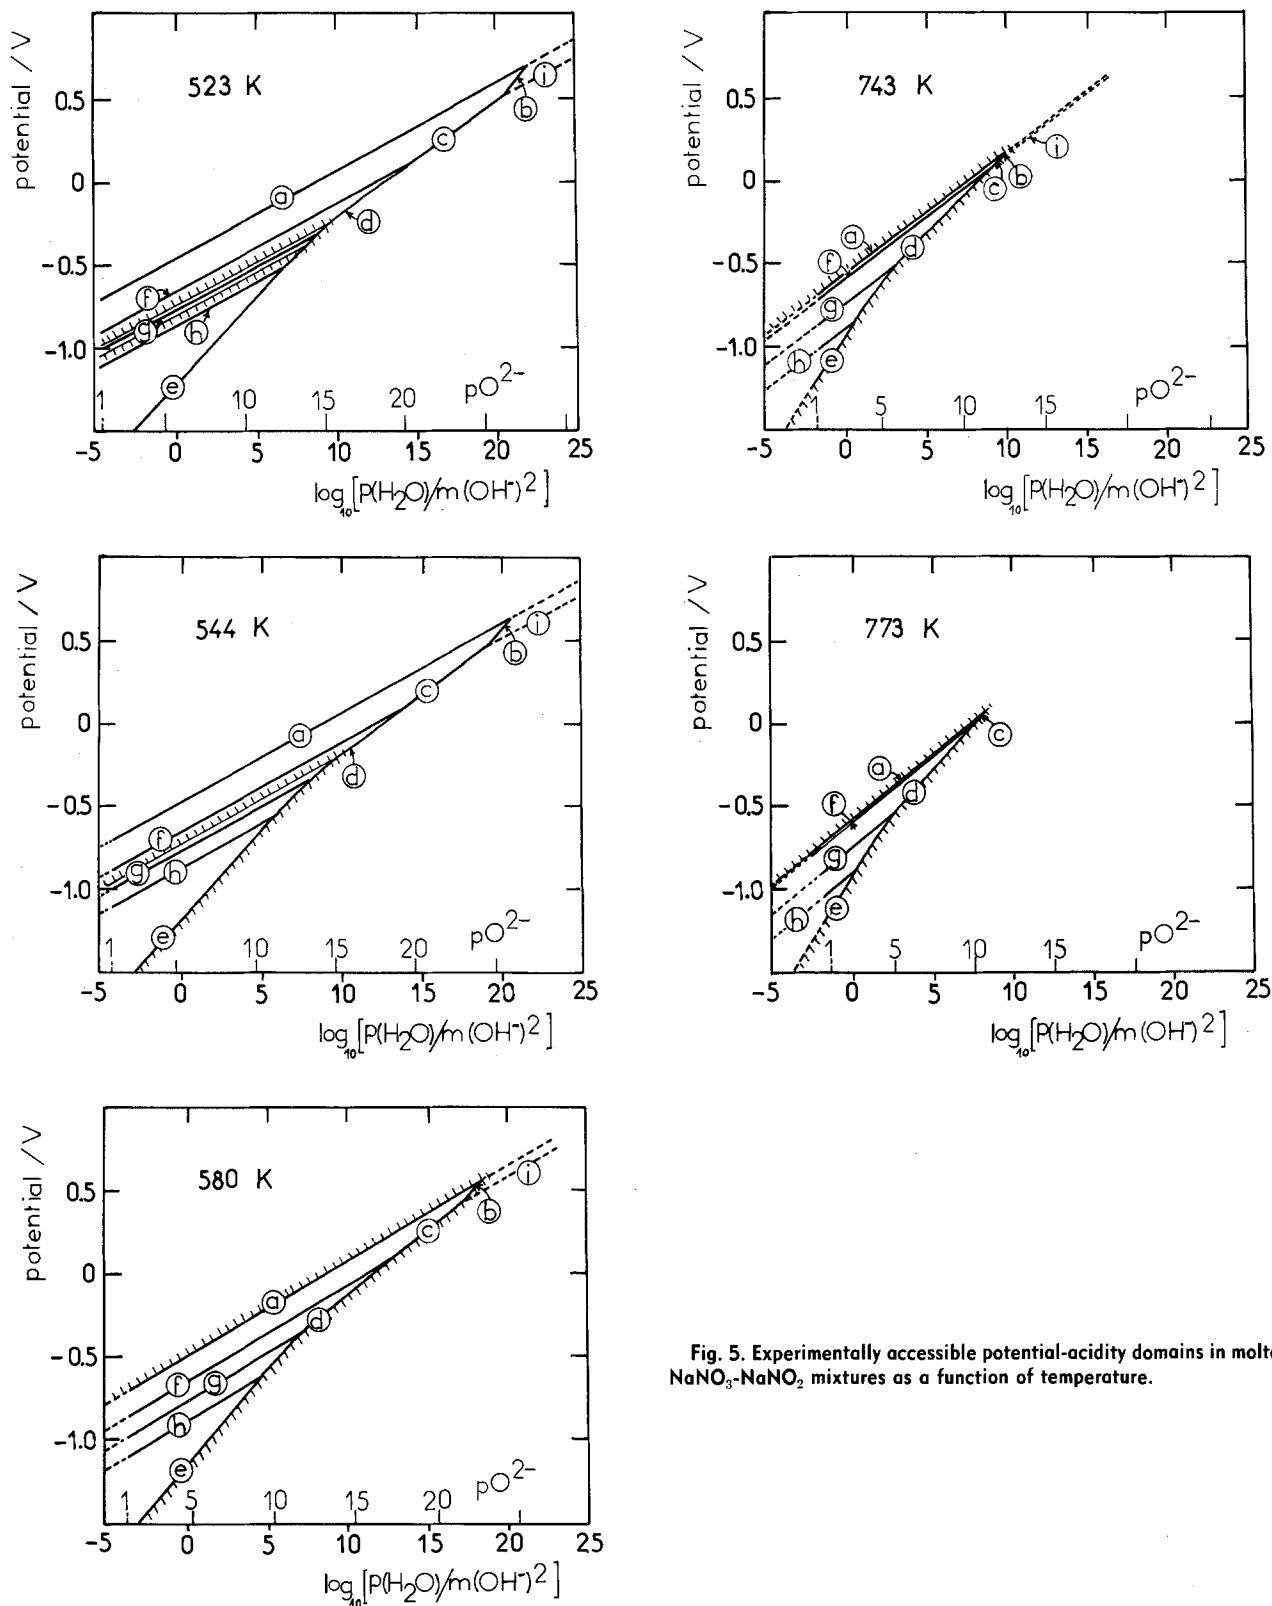

Fig. 5. Experimentally accessible potential-acidity domains in molten NaNO_3 - NaNO_2 mixtures as a function of temperature.

tion of NO_2^- into NO_3^- and $\text{NO}(\text{g})$ according to the equilibrium [2a] (line d).

At last, the potential-acidity area accessible in quasi-pure NaNO_2 is limited for high potential values by the oxidation of NO_2^- into NO_3^- (line h), and for low potential values, by the reduction of NO_2^- into nitrogen monoxide (line e). A characteristic point of this area is the intersection of lines e and h, which correspond to the beginning of the disproportionation of NO_2^- ions into NO_3^- and $\text{NO}(\text{g})$.

The whole of these three areas constitutes the accessible thermodynamical stability (potential-acidity) domain of all the NaNO_3 - NaNO_2 mixtures of every composition.

Yet at low temperatures, this domain may be limited by the melting points of pure salts or of their mixtures. Therefore, at 523 K (for which NaNO_3 and NaNO_2 are in the solid state), only the mixtures of average compositions included in the range 20 and 65 m/o NaNO_3 are melted and so can be used. At 544 K [melting point of pure NaNO_2 (29)], NaNO_2 and its mixtures with NaNO_3 till a composition of 78 w/o NaNO_3 can be used. At last, at $T > 580$ K [melting point of pure NaNO_3 (29)], the two pure salts and all their mixtures can be used.

When temperature increases, we can notice in Fig. 5 (i) an important decrease of the potential-acidity area accessible in molten NaNO_3 , which corresponds to a more im-

		A	B
(13) $O_2(g) + 4e^- = 2 O^{2-}$	$E = E^\circ_{13} + \frac{\lambda}{4} \log P(O_2) + \frac{\lambda}{2} pO^{2-}$	-0.731	-0.045
(14) $NO_3^- + e^- = NO_2(g) + O^{2-}$	$E = E^\circ_{14} + \lambda \log \frac{N(NO_3^-)}{P(NO_2)} + \lambda pO^{2-}$	-3.453	2.38
(15) $NO_2(g) + 2e^- = NO(g) + O^{2-}$	$E = E^\circ_{15} + \frac{\lambda}{2} \log \frac{P(NO_2)}{P(NO)} + \frac{\lambda}{2} pO^{2-}$	-1.036	0.353

portant decomposition of NO_3^- ions into NO_2^- ions and oxygen (line a draws nearer to line f), a disappearance of the decomposition, for high acidity media, of NO_3^- into $NO_2(g)$ and $O_2(g)$ (reactions which do not take place at $T > 766$ K) and also a progressive decrease of the acidity range in which NO_3^- ions can be reduced into $NO(g)$. Contrary to the preceding area, we observe (ii) that those corresponding to the quasi-pure nitrite and to the $NaNO_3 + NaNO_2$ mixtures stay noticeable whatever the temperature may be. At last, (iii) the acidity global area which may be accessible highly decreases with the temperature: the value of the acidity function relative to the more acidic media which can be reached goes from 18.1 (which corresponds to $pO^{2-} = 22.8$ at 580 K) to 8.6 ($pO^{2-} = 10.9$ at 773 K).

These types of diagrams are important in determining the experimental conditions necessary for obtaining a maximum stability of a $NaNO_3$ - $NaNO_2$ mixture of given composition. See, for example, the equimolar mixture which is always molten in the temperature range of 523-773 K. The higher acidity value which can be reached (intersection of lines g and d) under a nitrogen monoxide pressure equal to 1 atm varies from 9.2 ($pO^{2-} = 14.9$) at 523 K to 2.9 ($pO^{2-} = 5.2$) at 773 K. From this observation, we can easily deduce that the equimolar mixture is stable between 523 and 773 K if we maintain the cologarithm of $P(H_2O)/m(OH^-)^2$ at a value less than 2.9.

Conclusion

The influence of pO^{2-} and temperature on the decomposition of molten sodium nitrite-sodium nitrate mixtures has been studied. In particular, we have specified the influence and the part played by the mixture's composition, and the partial pressures of nitrogen monoxide and water.

At the present time, this research is being completed by studying the stability of the mixtures in basic media, in which peroxide and superoxide ions can appear as it has been shown in particular by Zambonin and Jordan for low temperature melts (30).

Passive Zinc Electrodes: Application of the Effective Medium Theory

B. Aurian-Blajeni* and Micha Tomkiewicz*

Department of Physics, Brooklyn College, Brooklyn, New York 11210

Zinc has found important applications as an electrode material in batteries. The properties of zinc are the subject of numerous studies. Comprehensive reviews have been published (1-3), and many useful references to recent literature may also be found in Ref. (4).

Under anodic bias, zinc electrodes passivate with formation of zinc oxide layers (4-6). The mechanism of formation of these layers in alkaline solutions is by a solution-precipitation path. This results in a wide morphological variety, depending on the growth environment. Basically, the passive layers were described in terms of a duplex structure with a thin compact component beneath a porous one. Our aim is to characterize the passive zinc electrode by impedance measurements. Although many studies using impedance techniques were carried out for zinc electrodes, most of them involved the active regime (7, 8).

During the growth of oxide layers at the surface of zinc electrodes, electrolyte solution is also imbedded. The dielectric properties of the resulting layer are not a linear combination of the dielectric characteristics of the components (i.e., oxide and solution), but cross-term effects appear as well (9). One of the ways of describing the dielectric behavior of composites is the effective medium approximation (10, 11). Among the most used forms of this approximation are: the Maxwell-Garnett, Bruggeman, and the self-similar or differential forms. The Maxwell-Garnett approximation for a two-component system is valid whenever a distinction may be made between a "host" and a "guest" component in the composite material. This limitation is not present in the Bruggeman version, which applies for spherical inclusions in a homogeneous medium consisting from the two components. The refinement of this latter approximation, the self-similar or differential effective medium theory, allows for any form of inclusions in media in which the conductive phase remains interconnected for any ratio of the components.

The present note illustrates the application of the effective medium approximation in its differential form to electrolytically grown zinc oxide layers.

Zinc oxide layers were grown on polished surfaces of vertical electrodes (area 0.08 cm²), under vigorous stirring, in 5M KOH solutions electrolytically saturated with zinc species. Impedance measurements were performed according to the method described in Ref. (12) in the same solution in which the oxide layers were grown. The changes in the film characteristics during the measurements were minimal from the point of view of the impedance, as attested by the fact that two successive measurements resulted in almost identical values.

The form of the effective medium approximation we used was developed for sedimentary rocks (9, 10, 13). In its closed form, for a composite consisting of a porous insulator saturated with electrolyte solution, it reads

$$P = \frac{\epsilon - \epsilon_d}{\epsilon_w - \epsilon_d} \left(\frac{\epsilon_w}{\epsilon} \right)^m \quad [1]$$

* Electrochemical Society Active Member.

where P is the porosity, ϵ , ϵ_w , ϵ_d are the complex dielectric constants of the composite, solution, and insulator, respectively, and $0 < m < 1$ is a screening factor (depolarization factor) dependent on the shape of the grains in the composite (10, 11).

The complex dielectric constant for the low frequency regime ($f < 10^7$ Hz) may be written as

$$\epsilon = k - i(4\pi\sigma/\omega) = |\epsilon| \exp i\theta \quad [2]$$

where k is the dielectric constant, i the square root of -1 , σ the conductivity, and ω the angular velocity. Introducing Eq. [2] in [1] for the insulator and solution results, after some manipulation, in the values of $|\epsilon|$ and θ of the composite, as a function of the dielectric characteristics of the components and two parameters, the depolarization factor, and the porosity.

On the other hand, the frequency-dependent impedance may be expressed as

$$Z = R + iX = i l(\delta A \omega \epsilon) \quad [3]$$

where l is the thickness, δ is the roughness factor, and A the area of the sample of material under consideration (l is parallel to the electric field).

Thus the imaginary and real parts of the impedance will have the form

$$X = -(1/\delta A \omega) \operatorname{Re}(1/\epsilon) = -(l/\delta A \omega) \cos \theta/|\epsilon| \quad [4]$$

and

$$R = -(1/\delta A \omega) \operatorname{Im}(1/\epsilon) = (l/\delta A \omega) \sin \theta/|\epsilon| \quad [4']$$

respectively.

The dissipation spectrum of the impedance will be dependent on the geometric factors of the sample, the dielectric characteristics of the components, their ratio, and the microstructure.

In Fig. 1, the experimental results obtained for the impedance of a zinc oxide layer anodically grown are compared with values predicted by the relations [4] and [4']. The measured values of the impedance suggest that they are characteristic for the thin, compact layer of the duplex. Some of the parameters used were taken from the literature as: $k_w = 70$ (10), $k_d = 8.5$ (14), $\sigma_w = 0.500$ ($\Omega \text{ cm}$)⁻¹ (1).¹ The adjustable parameters are: the thickness to roughness ratio l/δ (one parameter), the conductivity of zinc oxide σ_d (depending on the nonstoichiometry of the anodically formed zinc oxide), the porosity P , and the depolarization factor m . The adjustable parameters were fit by least mean squares fitting for nonlinear models. Fitting was performed only for the imaginary part of the impedance (Fig. 1a). As a check for the consistency of the model, the values obtained for the parameters were fed into the expression for the real part of the impedance (to which 60 Ω , representing the solution resistance, were

¹ It is true that hydrous oxides often act like ion-exchange materials, so there is every reason to expect that the conductivity of the solution in the film may be different than the conductivity in the bulk of the solution. Nevertheless, the exchange of one ion for another is not expected to alter the conductivity significantly enough to affect the results.

Fig. 1. Comparison between the experimental (\circ) and the predicted (\bullet) values of the impedance vs. frequency for a passive zinc electrode. a: Imaginary part. b: real part of the impedance.

added) and the results were compared with the experimental data (Fig. 1b).

The fit of the results in Fig. 1, resulted in the following set of parameters; porosity of 27.6%, depolarization factor of 0.44, conductivity of zinc oxide of $1.36 \times 10^{-11} (\Omega \text{ cm})^{-1}$, and thickness to roughness ratio of 0.8×10^{-8} cm. There is not much to say about the value obtained for the porosity, except that it is a credible figure. Work is under way focusing on its evolution as a function of the experimental conditions of growth of the oxide. The value obtained for the depolarization factor is indicative of particles shaped as prolate ellipsoids [$m = 0$ for needles, $1/3$ for spheres, $1/2$ for cylinders, and 1 for plates (10)]. Nevertheless, the value of m cannot be taken literally. Two hypotheses are involved: one is the isotropy of the dielectric constant, and the other is the parallelism of the axes of grains. In the case of electrolytic growth, the latter hypothesis is reasonable (6), while the first has to be considered with caution. From the value of σ_d an estimate of the free carrier concentration in zinc oxide of ca. 10^6 cm^{-3} is obtained, compared with ca. 10^{-11} cm^{-3} for pure zinc oxide (15) [data from Ref. (16) have been considered]. This is consistent with the coloration of the passivating layers, observed during our experiment and in the literature, which has been assigned to an excess of zinc atoms (5, 6). The apparently small value obtained for the thickness-to-

roughness ratio is deemed reasonable if the high roughness of a surface formed by a solution-precipitation mechanism and the fact that true passivation is due to a very thin layer are taken into account (4-6). Work for the elucidation of this point is currently in progress.

In conclusion, we found that the effective medium approximation is applicable to electrolytically grown zinc oxide layers. Since many of the electrolytically grown passivating layers include electrolyte, we believe that the effective medium approximation might be applied to other systems as well.

Acknowledgments

Helpful discussions with Mr. M. Kramer, from Brooklyn College, and Dr. P. Sheng, from Exxon, at various stages of this work are gratefully acknowledged. This work was supported by the Office of Naval Research.

Ellipsometric Study of Orientation-Dependent Etching of Silicon in Aqueous KOH

E. D. Palik, V. M. Bermudez, and O. J. Glembocki

Naval Research Laboratory, Washington, DC 20375

ABSTRACT

Ellipsometric measurements (in conjunction with observations of reflectance and cell current and voltage) have been performed in 2M aqueous KOH for Si wafers, of various crystallographic orientations and dopant types, during growth of surface films under anodic and cathodic bias and during open-circuit etch back. The optical effects have been modeled in terms of the formation and removal of thin SiO_x films ($0 \leq x \leq 2$) on the Si surface, with contributions, in some cases, from surface roughness. Changes in the thickness and stoichiometry of the surface SiO_x phase during various treatments provide a basis for a model of the Si etching chemistry and for the orientation dependence of the etch rate.

Orientation-dependent etching of Si is widely used to fabricate microstructures (1-3). Liquids such as aqueous KOH (4, 5), ethylenediamine (6), and hydrazine (7) are used. For these liquids, the etch rates follow the sequence $R\{100\} \approx R\{110\} \gg R\{111\}$, so that a variety of triangular and rectangular grooves and pyramids are made by proper masking with very slow etching SiO_2 (1, 3, 8). Etching is typically done at open-circuit potential (OCP).

In order to extend the versatility of orientation-dependent etching, we are studying the mechanisms for etching (9-12) and for control of the relative etch rates with externally applied bias (13, 14). It has proved useful to measure current and voltage and at the same time to monitor the Si/liquid interface with ellipsometry. For anodic potential, we see growth of a connective layer begin at the passivation potential (PP) and subsequent growth of SiO_2 on top of this connective layer. For cathodic potential, we see the appearance of a layer which grows for days after the potential is fixed. We have modeled these layers as forms of SiO_x in order to fit the experimental behavior of the ellipsometric parameters ψ and Δ . When the potential is released for either of these layers, they etch back slowly until the crystalline silicon interface is reached and fast etching begins. The slow etch back of the anodic-oxide layer is especially interesting, giving sharp dips in ψ and Δ when the connective layer is reached.

These experiments have been performed on n- and p-type Si of either $\{100\}$ or $\{111\}$ orientation over the doping range 10^{14} - 10^{20} cm^{-3} . The results for heavy doping ($> 10^{19}$ cm^{-3}), when all etching stops, have been discussed (15). Differences between the $\{111\}$ and $\{100\}$ surface are large in the case of etch back of anodic oxide and connective layer and small in the case of growth of connective layer and SiO_2 .

We have drawn some conclusions regarding the etching chemistry and suggest that attack of Si back bonds by H_2O and OH^- in sequence is the etching mechanism. This leads to the conclusion that the orientation dependence must depend on the shadowing of the back bonds and the ease or difficulty with which H_2O first, and OH^- second, can react with these shadowed Si-Si bonds.

Experimental Approach

We have used a spectroscopic, polarization-modulation ellipsometer (16) to study the Si/aqueous KOH interface.

A microcomputer read and printed ψ and Δ along with current (I) and potential (V) as controlled by a potentiostat. The ellipsometric parameters are defined by $\tan \psi \exp i\Delta = \tilde{r}_p/\tilde{r}_s$, where \tilde{r} is the complex amplitude reflection coefficient for polarization parallel (p) or perpendicular (s) to the plane of incidence. A standard calomel reference electrode (SCE) and platinum counterelectrode were used. Most experiments were performed at $\sim 22^\circ\text{C}$ in 2M KOH. Samples were Si wafers cleaved into $4 \times 1 \times 0.03$ cm^3 pieces with one side polished. Leads were made with InGa eutectic rubbed into the Si, followed by pressure contact with Cu wire. The liquid was contained in a BK-7 glass (angle of incidence $\theta = 60.2^\circ$) or fused quartz ($\theta = 54.6^\circ$) hollow prism. There were only small differences between data taken with the prism open to air (either with or without bubbling N_2) and the prism closed to air with bubbling N_2 to reduce CO_2 take-up. Therefore, most data were obtained in the presence of only a stream of N_2 bubbles to promote stirring. The I-V curves were obtained as the potential was slowly swept. Double peaks in I occurred in $\{111\}$ samples, the more cathodic one resulting from the $\{110\}$ and other fast etching edges. Coating the back and edges of the sample with glycol thiolate removed this "spurious" peak (15).

While a high level of accuracy is attainable in the ellipsometric measurements through application of various correction and averaging procedures (16), the present experiment requires only that changes in ψ and Δ be monitored in real-time with a high degree of precision. Therefore, we report ellipsometric parameters uncorrected (except where noted) for small systematic errors in the apparatus and stress the changes, $\delta\psi$ and $\delta\Delta$, rather than absolute magnitudes. The precision of the experiment is such that $\delta\psi$ and $\delta\Delta$ as small as 0.01° and 0.02° , respectively, are significant.

We monitored the high voltage bias on the photomultiplier which, as required for the ellipsometric measurements (16), was controlled by a programmable power supply in a feedback loop so as to maintain a constant dc anode current. The product of gain (G) and light intensity (I) impinging on the detector is a constant $GI = C$. Furthermore, G is related to bias voltage V by $\log G = \alpha + \beta V$, where α and β are constants (17). Combining these, we see that a change in unpolarized reflectance δR , leading to a change in intensity δI , corresponds to a δV given by $\log(1 + \delta R/R) = \log(1 + \delta I/I) = -\beta(\delta V)$. The calibration factor,

β , is determined using a neutral-density filter of known transmittance. The minimum detectable $\delta R/R$ was $\sim 5 \times 10^{-3}$, limited by low frequency noise and short-term drift in the light-source output.

Because light incident on the sample is focused (16) (and specularly reflected light is collected) at $\sim f/50$ to minimize the spread in the angle of incidence, the observed $\delta R/R$ is sensitive to intensity lost by scattering of light in nonspecular directions as well as to genuine changes in reflectance resulting from growth and removal of surface layers. A direct consequence of this fact is that we cannot reliably combine $\delta R/R$ with $\delta\psi$ and $\delta\Delta$ to obtain a "three-parameter" fit (n , k , and thickness) to data taken during film growth. However, useful information may be obtained from $\delta R/R$, even when surface texture is changing during film formation (16). In the present work, frequent use will be made of $\delta R/R$ as an indicator of surface roughness. The optical arrangement is such that the observed R is defined by $R = |\tilde{r}_p|^2 + |\tilde{r}_s|^2$ and, hence, represents the "unpolarized" reflectance. The calculated R at 435.8 nm for c-Si ($n = 4.88$, $k = 0.14$) in aqueous KOH at $\theta = 54.6^\circ$ is 0.322.

Model Calculations

The basis for data analysis is a model (12) consisting of a semi-infinite crystalline Si (c-Si) substrate, one or more layers of SiO_x ($0 \leq x \leq 2$), an amorphous SiO_2 (a- SiO_2) oxide film, and an aqueous KOH ambient. Different anodization and etching scenarios can be evaluated by variation of the parameters (complex indexes of refraction, $\tilde{n} = n - ik$, and/or layer thicknesses) and comparison of the observed and calculated $\delta\psi$ and $\delta\Delta$. For c-Si, a- SiO_2 , and 2M KOH, \tilde{n} was obtained from the literature, as described previously (12). For SiO_x , \tilde{n} vs. x was obtained for both the physical- and chemical-mixture models, with the results shown in Fig. 1. Here, the $x = 0$ limit corresponds to amorphous Si (a-Si) and $x = 2$ to a- SiO_2 . The physical model is based on an effective-medium microscopic mixture (18, 19) of a-Si and a- SiO_2 , while the chemical model (19) consists of a statistical distribution of $\text{Si}(\text{Si})_{4-y}(\text{O})_y$ ($0 \leq y \leq 4$) tetrahedra. Since the present experiments were carried out at only a small number of fixed wavelengths, we cannot determine which gives the better representation of the connective layer, and calculations based on either model can fit a given set of data equally well. Hence, most of the following discussion will invoke the computationally simpler (18) physical-mixture model. As noted previously (12), the connective layer is further modeled as an isotropic and homogeneous layer of composition SiO_x . Calculations (20) demonstrate that this is adequate for the present purposes. Our calculations are easily modified to include a large number of thin SiO_x

layers of varying x to represent a connective layer having a graded composition.

Figure 1 also shows \tilde{n} for c-Si at each wavelength (21) as solid circles and illustrates the reason for the high degree of sensitivity of these measurements to the thin SiO_x layer. At 435.8 nm and at 319 nm, \tilde{n} of SiO_x is very different from \tilde{n} of either c-Si or a- SiO_2 , sufficiently so that the effect of the layer on ψ and Δ is well above the precision limit of the experiment. The large variations in \tilde{n} with increasing x , in the $x = 0$ to $x \approx 1.2$ range, also account for the observed behavior of $\delta\psi$ and $\delta\Delta$ during the growth and removal of surface layers. While the experimental approach does not provide chemical information, it does afford a real-time, *in situ* probe of etching dynamics from which insight into the surface electrochemistry can be gained.

Growth of Anodic Oxide Layers

The etching of Si is drastically reduced when an anodic potential is applied. This arises from formation of a passive layer at the expense of the c-Si etching reaction. Ellipsometric results for the anodization process for p {111} Si are shown in Fig. 2 for $\lambda = 435.8$ nm. Here ψ , Δ , I , and V are plotted as functions of time. The features occurring during the first 1.5h result from etch back of the native oxide. Starting at OCP (-1.2V) at $T = 2\text{h}$ (between points d and A), there is virtually no change in ψ and Δ until about -0.7V when passivation begins. Small changes sometimes seen at OCP have been due to bubbles, roughening, or apparent growth of a "cathodic" layer at the effective OCP, which is established by the combined effects of the {111} surface, the {110} and {100} edges, and the rough back of the sample. There is a sudden decrease in Δ of $\sim 1^\circ$ from point A to B, followed by a slow change from B to C. A more rapid decrease in Δ and increase in ψ occurs from point C to D, indicating growth of SiO_2 . The p-type Si was in the dark except for the measurement light; n {111} Si behaves similarly, except that between points B and C, ψ and Δ stop changing. This confirms that holes are needed to grow oxide, but are not necessarily needed in the growth step A-B, which we term connective-layer formation. Illumination of n {111} Si with a 60W light bulb caused oxide to grow beyond B-C.

We have replotted the data in Fig. 2 as Δ vs. ψ in Fig. 3a. There are three distinct regions starting at point A, at which etching takes place and ψ and Δ change slowly as roughening gradually occurs (not shown). The regions A-B, B-C, and C-D follow. Small reverses in the direction of Δ near points B and C, clearer in Fig. 2, are lost in the linewidth of Fig. 3a. Layers grown at potentials up to $\sim 4\text{V}$ we term "soft" anodic oxides, while those formed above $\sim 6\text{V}$ are labeled "hard" anodic oxides. These two layers

Fig. 1. Optical constants n and k for SiO_x as a function of x at three wavelengths 319.0 (a), 435.8 (b), and 800.0 (c) nm for the physical-mixture model (solid curves) and the chemical-mixture model (dashed curves). The $x = 0$ limit corresponds to amorphous Si (a-Si) and $x = 2$ to amorphous SiO_2 (a- SiO_2). The circles along $x = 0$ ordinate are n and k for c-Si.

Fig. 2. The etch back and growth of anodic oxide on a p [111] Si sample with resistivity $\rho = 9 \Omega \text{ cm}$ ($1.8 \times 10^{15} \text{ cm}^{-3}$). The potential V (either open circuit or applied), current I , ψ , and Δ are displayed. $\theta = 60.2^\circ$ is the angle of incidence; $\lambda = 435.8 \text{ nm}$. Structure in ψ , Δ , and V during the initial 1.5h arises from etch back of the native oxide. Oxide grown to 1V begins to etch off at point a. Oxide begins to grow at point A.

have drastically different etch back properties when the connective layer is reached (the hard oxide resembling a thermal oxide) which will be discussed in the Etch Back of Anodic Oxides section. Oxide grown to 10V is about 200Å thick (11). Even the sweep speed in Fig. 2 (10 mV/min) is too fast for strict equilibrium, and when the sweep is stopped at 10V, the film continues to grow slowly to about 220Å before I saturates. To interpret the ψ , Δ plot, we first assume an equilibrium etching layer of 4Å of $\text{SiO}_{0.2}$ on top of c-Si at the starting point, A. We have found such a layer necessary for modeling the cathodic process, to be discussed in the Growth of Cathodic Layer section. This layer is also found to give a better fit when comparing ψ , Δ for an etching surface with ψ , Δ for a 10^{20} cm^{-3} p-Si etch-stopped surface (15). Furthermore, it is reasonable to assume that there is not a sharp $\text{H}_2\text{O}/\text{c-Si}$ interface, since the chemical reaction disrupts the crystal lattice near the surface. The exact values of x and thickness assumed for the SiO_x equilibrium etching layer are not critical.

The region A-B was modeled as shown in the inset of Fig. 3b. The $\text{SiO}_{0.2}$ layer is converted to $\text{SiO}_{0.4}$ and thickens suddenly. The region B-C is modeled as further gradation of the connective layer with some SiO_2 growing on top. Finally, at point C, the connective layer stabilizes and only further growth of SiO_2 occurs. Harvey and Kruger (22) have described the anodization process as a series of steps including slowing down of the etching process with accumulation of the soluble products, nucleation on the surface, deposition from a supersaturated solution, and stabilization of the film. Some of these steps are evident in the model in Fig. 3b. Our model also contains the salient features for a connective layer between a- SiO_2 and c-Si suggested by other experiments on thermal oxides (19, 23). The calculated results are shown in Fig. 3b with the SiO_2 thickness indicated by solid circles. The experimental ψ_e axis has been shifted by tenths of a degree with respect to the calculated ψ_c axis to emphasize the agree-

Fig. 3. a: The ψ_e , Δ_e data of Fig. 2 are replotted to show three distinct regions of growth of anodic oxide, A-B, B-C, C-D. Applied potentials are indicated by dashes along curve B-D. b: A model for growth shown in the inset gives results for Δ_c vs. ψ_c similar to the experimental Δ_e vs. ψ_e . The SiO_2 thickness is indicated by the solid circles.

ment between observed and calculated $\delta\psi$ and $\delta\Delta$. Obviously, the connective layer is changing in the region B-C, since the model does not fit the dip in Δ at B and the slight turnback of ψ after point C. On the whole, however, the observed ψ , Δ plot is well reproduced by the model calculation. This model is examined further in the Etch Back of Anodic Oxides section.

Interestingly, for B:Si with a doping density above 10^{19} cm^{-3} the anodization curve lacks with regions A-B and

B-C but shows C-D, indicating that at OCP $\approx -0.7V$ a connective layer has spontaneously formed to passivate the surface (9) and stop the etch (15).

Growth of Cathodic Layer

If at OCP (after etch back of any native oxide) we apply a cathodic bias, the changes in ψ and Δ are quite different from those in Fig. 2, as shown in Fig. 4a for n {111} Si and in Fig. 4b for p {111} Si. After about 0.3V cathodic, we stop the applied potential near $-1.5V$ which occurs within the first half-hour in Fig. 4. During this time, ψ and Δ decrease, indicating that a film is growing on the surface. Interestingly, the layer continues to grow for hours at this potential, slowing down gradually (22h in Fig. 4a and 64h in Fig. 4b). The layer begins to show a gray-tan color. The behavior of Δ vs. ψ is shown in Fig. 5 for n {111} Si and p {111} Si; the same qualitative behavior is observed. Growth of the n {111} layer is more rapid, as indicated by the initial slopes in Fig. 4a and 4b.

When the applied potential is released, the open-circuit potential is initially $-0.8V$ and then increases negatively to $-1.2V$ over 2-3h as the layer dissolves. Initially, Δ vs. ψ follows a path different from that during growth, as indicated by the dashed curves in Fig. 4a and Fig. 5. Only near $\Delta \approx 160^\circ$ does the curve begin to retrace the original path. Upon return to the equilibrium OCP, the final values of ψ and Δ differ only slightly from the initial values, and the gray-tan color has gone.

We have termed the cathodic layer, which has peculiar growth and etch-back characteristics, a "slush" layer. Since it is known (14) that n-Si stops etching for cathodic bias, we assume that the "slush" layer is composed of "incomplete" etch products (whence the term "slush") such as hydrogenated a-Si or incomplete silicates not in a soluble form of $Si(OH)_2(O^-)_2$. The "slush" layer disappears much more rapidly if slight anodic bias near PP is used. This behavior may be a consequence of an increase in OH^- concentration at the surface, which would accompany anodic potentials. The hydroxyl ions would then interact with the "slush" layer to produce "complete" silicates, thereby enhancing dissolution of the layer. It is interesting to note that an anodic current would require an interaction of $-OH$ with the surface (to provide an electron). We carried out a search for Si-H bonds in this

Fig. 4. a: Growth of cathodic slush layer for an n {111} Si sample with $\rho = 0.0045 \Omega \text{ cm}$ ($1.5 \times 10^{19} \text{ cm}^{-3}$) as indicated by the changes in ψ and Δ as a function of time. The cathodic potential was stopped at $-1.5V$ within the first hour, but ψ and Δ continued to change. The dashed curve represents etch back after the cathodic potential was released. Current (not shown) grew quickly as the potential was swept, but continued to grow slowly for hours finally saturating. $\theta = 54.6^\circ$; $\lambda = 435.8 \text{ nm}$. b: Growth of cathodic slush layer for a p {111} Si sample with $\rho = 0.010 \Omega \text{ cm}$ ($1.1 \times 10^{19} \text{ cm}^{-3}$) as indicated by changes in ψ and Δ as a function of time. Etch back is not shown.

Fig. 5. a: Plot of Δ vs. ψ for growth (solid curve A-C) and etch back (dashed curve C-E) of the slush layer as obtained from the data of Fig. 4a. At A, $T = 0$; at B, $T = 95 \text{ min}$; at C, $T = 1407 \text{ min}$; at D, $T = 1492 \text{ min}$; at E, $T = 1620 \text{ min}$. b: Plot of Δ vs. ψ obtained from the data of Fig. 4b. At A, $T = 0$; at B, $T = 787 \text{ min}$; at C, $T = 2882 \text{ min}$; at D, $T = 2932 \text{ min}$; at E, $T = 4140 \text{ min}$.

layer by Raman backscattering experiments. It was not successful, probably because of the small layer thickness. For the p-Si which maintains its etch rate under cathodic bias (14), the slush layer grows more slowly, suggesting formation of some incomplete silicates but mostly soluble $Si(OH)_2(O^-)_2$. It is not possible to follow growth of the slush layer on the n or p {100} surface for very long, since fast etching of the p surface and slow etching of the n surface produce roughness making interpretation of ψ and Δ difficult.

We have attempted to model the initial growth of the slush layer at small cathodic potential over the first hour. This layer is peculiar in that both ψ and Δ decrease as the layer grows, while for a classical dielectric layer of fixed $n > 1$ and $k \approx 0$, ψ increases and Δ decreases. The simplest model which fits the data is shown in the inset of Fig. 6c. It is vital to assume an equilibrium etching layer (4 \AA of $SiO_{0.2}$) to account for the results (net decrease of both ψ and Δ). In Fig. 6, we show how ψ and Δ would vary for 0.20 \AA of several different SiO_x from $x = 0$ to $x = 0.8$ for three wavelengths. Beyond $x = 0.8$, the curves tend to reverse with the slopes decreasing again. It is not possible to account for the data simply by varying the thickness of the $SiO_{0.2}$ layer. However, if we assume an equilibrium etching layer of 4 \AA of $SiO_{0.2}$ and then allow it to change toward $SiO_{0.8}$ and thicken, then ψ and Δ both decrease, as observed. We cannot specify the exact path from $SiO_{0.2}$ to $SiO_{0.8}$ but have calculated $\delta\psi$ and $\delta\Delta$ from the values of ψ and Δ for $SiO_{0.2}$ before slush-layer growth and for the $SiO_{0.8}$ layer after growth and list them in Table I for n {111} Si and p {111} Si. At each λ the same amount of time from OCP to $-1.5V$ was used; therefore, $\delta\psi$ and $\delta\Delta$ are smaller for the slower growing p {111} layer. For n {111} Si, reasonable agreement with experiment is obtained when a 10 \AA layer of $SiO_{0.8}$ develops. Similar agreement is obtained when an 8 \AA layer of $SiO_{0.8}$ forms on the p {111} Si. Note that $\delta\psi$ is very small at 800 nm compared to 435.8 and 319 nm ; $\delta\Delta$ is only slightly smaller at 800 nm compared to the other wavelengths. This is a direct result of the λ dependence of \tilde{n} vs. x (Fig. 1). Maintaining an $SiO_{0.2}$ equilibrium etching layer under a growing SiO_x layer did not fit the observed decreases in ψ and Δ nearly as well. This model could not account for thicker slush layers.

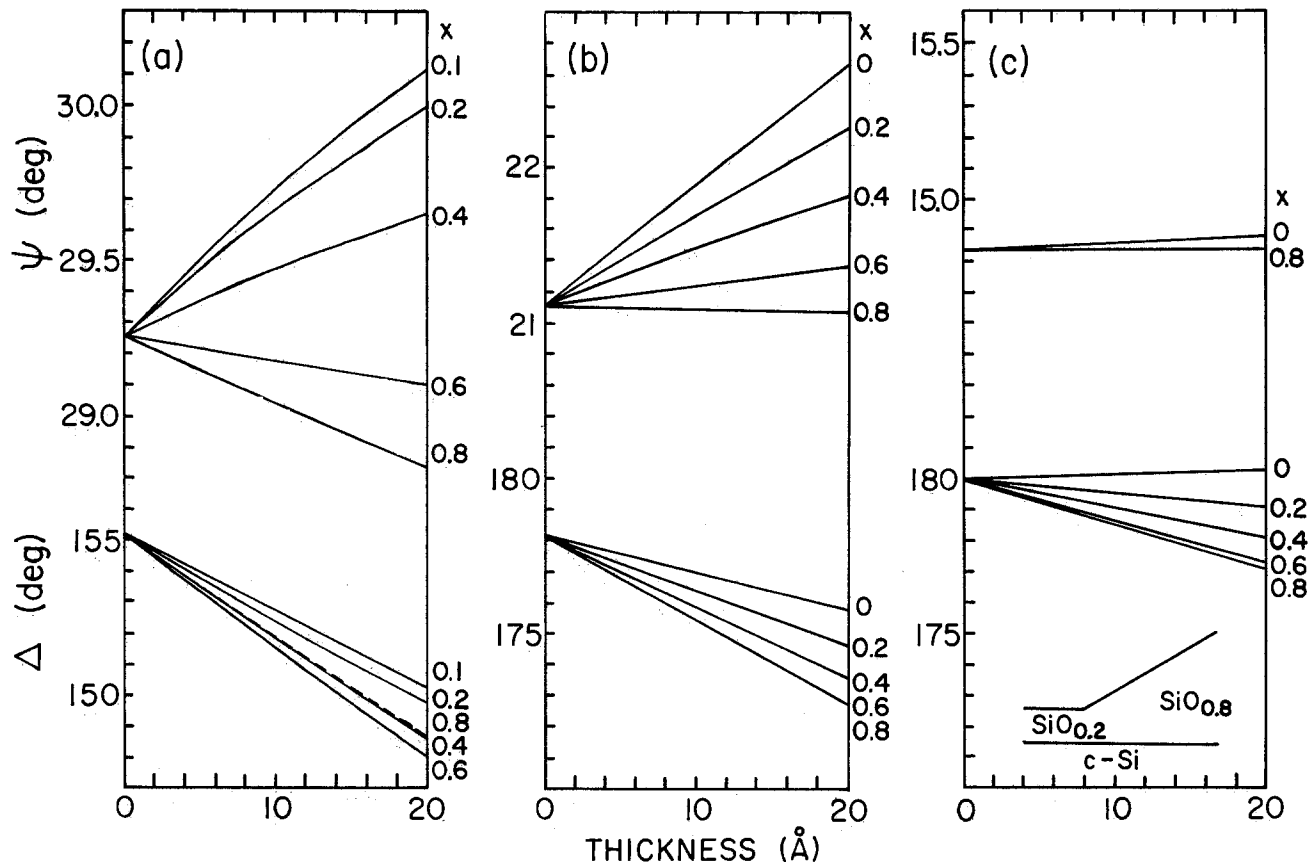

Fig. 6. Calculated changes in ψ and Δ at three wavelengths, 319.0 (a), 435.8 (b), and 800 nm (c), as function of thickness, for different SiO_x layers growing on a c-Si substrate. The curves are used to simulate the change of the 4Å $\text{SiO}_{0.2}$ equilibrium etching layer into a slush layer of $\text{SiO}_{0.8}$ as suggested by the inset in c. $\theta = 60.2^\circ$. In a, the Δ curve for $x = 0.8$ is dashed. In b, the Δ curves for $x = 0.6$ and 0.8 coincide.

Roughness

The etching of {111} and {100} surfaces at OCP produces roughness which is seen visually and in ψ , Δ , and $\delta R/R$. These effects are small on {111} wafers, since this is a slow etching surface, but are much larger on {100} and {110} surfaces. The usual effect is to decrease ψ , Δ , and R . The commercial {111} wafers are oriented to $\pm 1^\circ$. We have measured etch rates between 20 and 90 Å/min (9, 14) on various samples. As noted by Kendall (8), the {111} etch rates are pseudo-etch rates, since the ledges etch faster laterally than the {111} surface etches downward. In fact, for a $1/4^\circ$ -oriented n {111} wafer, we hardly notice H_2 bubbles and can recycle between open-circuit, anodic, and cathodic potentials for tens of hours before ψ and Δ degrade a few tenths of a degree. On the other hand, once the {100} surface is exposed to etchant after the first etch back of the oxide at OCP, roughness occurs in minutes with large changes in ψ , Δ , and $\delta R/R$, and the sample cannot be reused.

We have examined, with an optical microscope at 1000× magnification, {111}, {100}, and {110} surfaces after etching at OCP for a few minutes to hours. Some general features are noticed. After etching for ~2h, n and p {111} surfaces show triangular pits, mostly truncated as shown in

Table I. Experimental and calculated changes in ψ and Δ (in degrees) for a slush layer growing on an n {111} and a p {111} surface for the same amount of time at the same cathodic potential. The calculated values of $\delta\psi$ and $\delta\Delta$ were obtained from Fig. 6 for an initial layer of $\text{SiO}_{0.2}$ 4Å thick converting to a final layer of $\text{SiO}_{0.8}$ 10Å thick for n {111} and 8Å thick for p {111}. $\theta = 60.6^\circ$.

λ (nm)	n {111}				p {111}			
	$\delta\psi_e$	$\delta\psi_c$	$\delta\Delta_e$	$\delta\Delta_c$	$\delta\psi_e$	$\delta\psi_c$	$\delta\Delta_e$	$\delta\Delta_c$
319.0	-0.49	-0.39	-2.2	-2.2	-0.32	-0.34	-1.5	-1.4
435.8	-0.28	-0.27	-2.1	-2.0	-0.22	-0.27	-1.5	-1.5
800.0	-0.06	-0.0	-0.5	-1.3	-0.04	-0.0	-1.1	-1.0

Fig. 7a and 7c. Some samples show many pits, as indicated in Fig. 7a and 7c, while others show few; for the same time of etching, one wafer would show small triangles, and another would show large triangles. When {111} surfaces are etched for 24h or longer, the triangular pits tend to be less distinct with their corners rounded in some cases, so the surface texture appears grainy. These effects (a number of triangular pits and transition to grainy structure) are accelerated on the unpolished back side of the sample. After etching for 15 min, n and p {100} surfaces always show many dark, square pyramidal pits, some truncated, indicating very rough surfaces (Fig. 7e). An n {110} surface shows roughness in narrow bands (Fig. 7g).

When an n {111} surface is made cathodic for ~24h, producing a slush layer, and then returned to OCP until the slush layer dissolves, the surface has a cellular structure resembling triangles with their points rounded off (Fig. 7b). When a p {111} surface is made cathodic for ~24h, producing a slush layer, and returned to OCP until the slush layer dissolves, the surface has less distinct triangular pits (Fig. 7d) smaller than the triangles obtained at OCP (Fig. 7c). Remembering that the n surface stops etching while the p surface continues to etch, we might expect differences in surface textures. The results for n and p {100} surfaces both at OCP and cycled cathodically show similar roughened surfaces (Fig. 7e and 7f) with dark square pits.

The textures obtained at OCP are to be expected based on results in Ref. (24) and (25). The triangular pits for {111} wafers are either truncated or pointed with {111} planes. The {100} wafers show mostly square truncated pyramidal pits with some four-sided, pointed pyramidal pits also; the sides are various {111} planes. The {110} wafer shows boat-shaped pits with various {111} sides. Typical pits observed are drawn oversized next to the photographs for more clarity. Some planes are labeled to suggest ideal structures.

Visual observations of roughness have been augmented by measurements of ψ , Δ , and $\delta R/R$ with similar samples

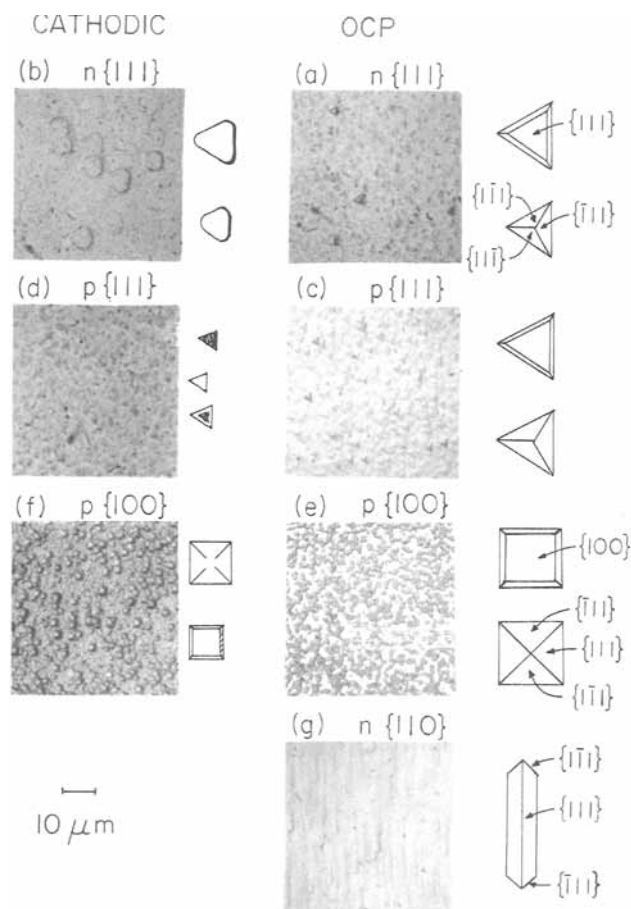

Fig. 7. Photographs of n, p {111}, {100}, {110} surfaces obtained at OCP and cathodic potential. Magnification 1000 \times . Total time of immersion; (a) 120 min, (b) 24h, (c) 120 min, (d) 36h, (e) 20 min, (f) 20h, and (g) 20 min. Typical pit shapes are drawn oversized next to each photograph with some indication of crystal planes.

and conditions. For example, for a {111} surface ψ and Δ are observed to decrease slowly ($\sim 0.1^\circ/\text{h}$) at OCP after an anodic oxide is etched back. A small portion of the decrease is due to bubbles on the surface. This effect varies from sample to sample because the pseudo-etch rate varies with the misorientation. R decreases gradually.

For a {100} surface after etch back of an anodic oxide, ψ and Δ decrease considerably, while R decreases toward zero. These results are in qualitative agreement with the results of Fig. 7a, 7c, 7e, and 7g, i.e., slight roughness for {111} surfaces and large roughness for {100} and {110} surfaces.

However, the triangular truncated pit structure on {111} surfaces suggests that considerable specular reflection still takes place. The results for ψ , Δ , and $\delta R/R$ for several {111} samples have been measured at OCP and suggest that, while ψ and Δ initially decrease by tenths of a degree, they do not decrease further, but R decreases more or less continually over hours. Then, when a connective layer is grown, eliminating bubbles, ψ and Δ tend to return toward their original values (if we take into account the changes in ψ and Δ due to the layer). R , however, does not return to anywhere near its original value. Such a phenomenon (large negative $\delta R/R$ with little effect on ψ and Δ) has been observed (26) for an n {111} Si surface treated with aqueous NaOH. The truncated triangular pits continue to give specular reflection with meaningful ψ , Δ values, while the sides scatter light out of the small collection solid angle of the ellipsometer.

Under cathodic bias the roughness appears somewhat different. The results of Fig. 5 were obtained before we began routinely to measure $\delta R/R$. Similar measurements on other samples were repeated; some are listed in Table II. From point A ($t = 0$) to point B (where the solid and dashed curves separate), there is a small negative change

Table II. Measurement of ψ , Δ , and $\delta R/R$ for slush-layer growth and etch back indicating how reflectance changed in going from point A to point E (in analogy to Fig. 5) for an n {111} sample with $\rho = 0.12 \Omega \text{ cm}$ ($n = 8 \times 10^{16} \text{ cm}^{-3}$) and a p {111} sample with $\rho = 1.4 \Omega \text{ cm}$ ($p = 9 \times 10^{15} \text{ cm}^{-3}$). $\theta = 54.2^\circ$; $\lambda = 435.8 \text{ nm}$.

	n {111}			p {111}		
	ψ	Δ	$\delta R/R$	ψ	Δ	$\delta R/R$
A	26.7	176.5	0	26.15	177.5	0
B			-0.033			0
C			-0.49			-0.19
D			-0.45			-0.087
E	26.85	176.0	-0.34	~ 26.0	~ 177.0	-0.072

in $\delta R/R$. From B to C, $\delta R/R$ increases significantly in the negative direction. This large change is probably partly absorption loss in the slush layer with some continued roughening. When the potential is released at point C, $\delta R/R$ decreases (becomes less negative) at point D, but never reaches its original value of zero. After total dissolution of the layer occurs, ψ and Δ have nearly reached their beginning values, but $\delta R/R$ is still significantly negative. We have listed values of ψ , Δ , and $\delta R/R$ at the points A-E for other samples in Table II mainly to indicate that while ψ and Δ return nearly to their original values, $\delta R/R$ is permanently different, indicating a larger decrease in R for the n {111} surface than for the p {111} surface. The slight differences in ψ and Δ from points A to E may be due to slight bubbling as well as roughness. Note that in each case, slush layer has continued to grow, faster on the n {111} surface than on the p {111} surface. While not obvious in Fig. 7b and 7d, the n {111} surface appears to have larger roughness features than the p {111} surface, in agreement with the results in Table II.

We believe that the slush layer is formed when complete etching, producing soluble $\text{Si}(\text{OH})_2(\text{O}^-)_2$, slows down. As will be discussed below, in the Etching Chemistry section, incomplete etching occurs when H_2O , but not OH^- , attacks Si-Si bonds. The incomplete silicates stick to the surface and accumulate. When complete etching is dominant, the slush layer can only grow slowly, as is observed on a p {111} surface. However, when complete etching is slowed down, the slush layer can grow more rapidly, as is observed on an n {111} surface. It is not obvious what to expect the roughness to do, although, at first glance, the p {111} surface after cathodic treatment might resemble the OCP surface since complete etching has continued. Since complete etching was reduced drastically on the n {111} surface, changes in surface texture might be expected because the etch-rate ratios of various surfaces can be altered with applied bias (14). The results of Fig. 7 and Table II indicate that $\delta R/R$ is greater for the n {111} surface than for the p {111} surface, but we have no model to account for the texture of the cathodic surfaces.

Etch Back of Anodic Oxides

Oxides easily grew on p-Si surfaces but required light to grow on n-Si surfaces. The final thickness was the same for the same potential above PP for both dopant types and both surface planes (11). The etch-back rate of these oxides was generally $\sim 0.3 \text{ \AA}/\text{min}$. However, just prior to the etching of c-Si (indicated by the appearance of H_2 bubbles), the behavior of ψ and Δ varied remarkably with {111} and {100} orientation and with the anodizing potential. Generally these etch-back effects were independent of whether the sample was n- and p-Si. Figure 8 summarizes typical etch-back results for {111} surfaces for both "soft" (Fig. 8a) and "hard" (Fig. 8b) anodic oxides. Also shown are the OCP (which generally increases negatively towards its equilibrium etching value as the anodic oxide layer etches back) and the reflectance change, $\delta R/R$.

For the {111} surface, as etch back of soft anodic oxide occurs (Fig. 8a), there is a sudden dip in ψ and Δ through points b-d, so that at point d, ψ "undershoots" (is less than) its b value and Δ "overshoots" (is greater than) its b

Fig. 8. a: Changes in ψ , Δ , V , and $\delta R/R$ during etch back of a soft anodic oxide on a p {111} Si sample with $\rho = 10.8 \Omega \text{ cm}$ ($1.6 \times 10^{15} \text{ cm}^{-3}$). $\theta = 54.6^\circ$; $\lambda = 435.8 \text{ nm}$. Anodizing potential was 0.3V. b: Changes in ψ , Δ , V , and $\delta R/R$ during etch back of a hard anodic oxide on the same sample. Anodizing potential was 6.5V.

value. The changes in ψ and Δ between b and c are typically $\delta\psi \approx -0.3^\circ$ and $\delta\Delta \approx -3^\circ$ with the dip feature having a full width at half maximum (FWHM) of 2-3 min. Also, point c' occurs after point c in time by a few seconds. At point d, etching of c-Si has commenced, as indicated by formation of H_2 bubbles. The reflectance R also starts to decrease slowly as roughening increases. For the hard anodic oxide in Fig. 8b, the dips in ψ and Δ are huge, with $\delta\psi \approx -6^\circ$ and $\delta\Delta \approx -17^\circ$ with a FWHM of ~ 15 min. In addition ψ and Δ usually both undershoot the respective starting values (point b), and point c' occurs before c in time by a minute or so. There is a large transient dip in R along with a slow overall decrease. Differences in the region b-c-d for the soft and hard oxides of Fig. 8 are dramatic and suggest either different connective layers or different structural effects during etching. It is evident from Fig. 3 that soft oxides are the formative stage of the connective layer, while for hard oxides, the connective layer is in its final form.

We have previously (12) modeled the observed changes in ψ and Δ for the soft oxide on a {111} surface. The model consisted of a c-Si/ $\text{SiO}_{0.4}$ /a- SiO_2 /2M KOH multilayer system. This model has been refined as shown in Fig. 9a, with the SiO_x connective layer modeled as in Fig. 3b. From point a to b, SiO_2 thins down until the graded connective layer is reached. Thereupon, the SiO_x is made more dielectric-like by increasing x to 2.0, followed by dissolution of the resulting SiO_2 and formation of the equilibrium etching layer (4Å of $\text{SiO}_{0.2}$). The horizontal axis is considered to be an arbitrary time scale which could be compressed or expanded to fit experimental results. To simulate linear time, x and d are varied linearly. The results in Fig. 9a for $\lambda = 435.8 \text{ nm}$ are in good qualitative agreement with the typical experimental results of Fig. 9b and 9c, especially as regards the overshoot of Δ

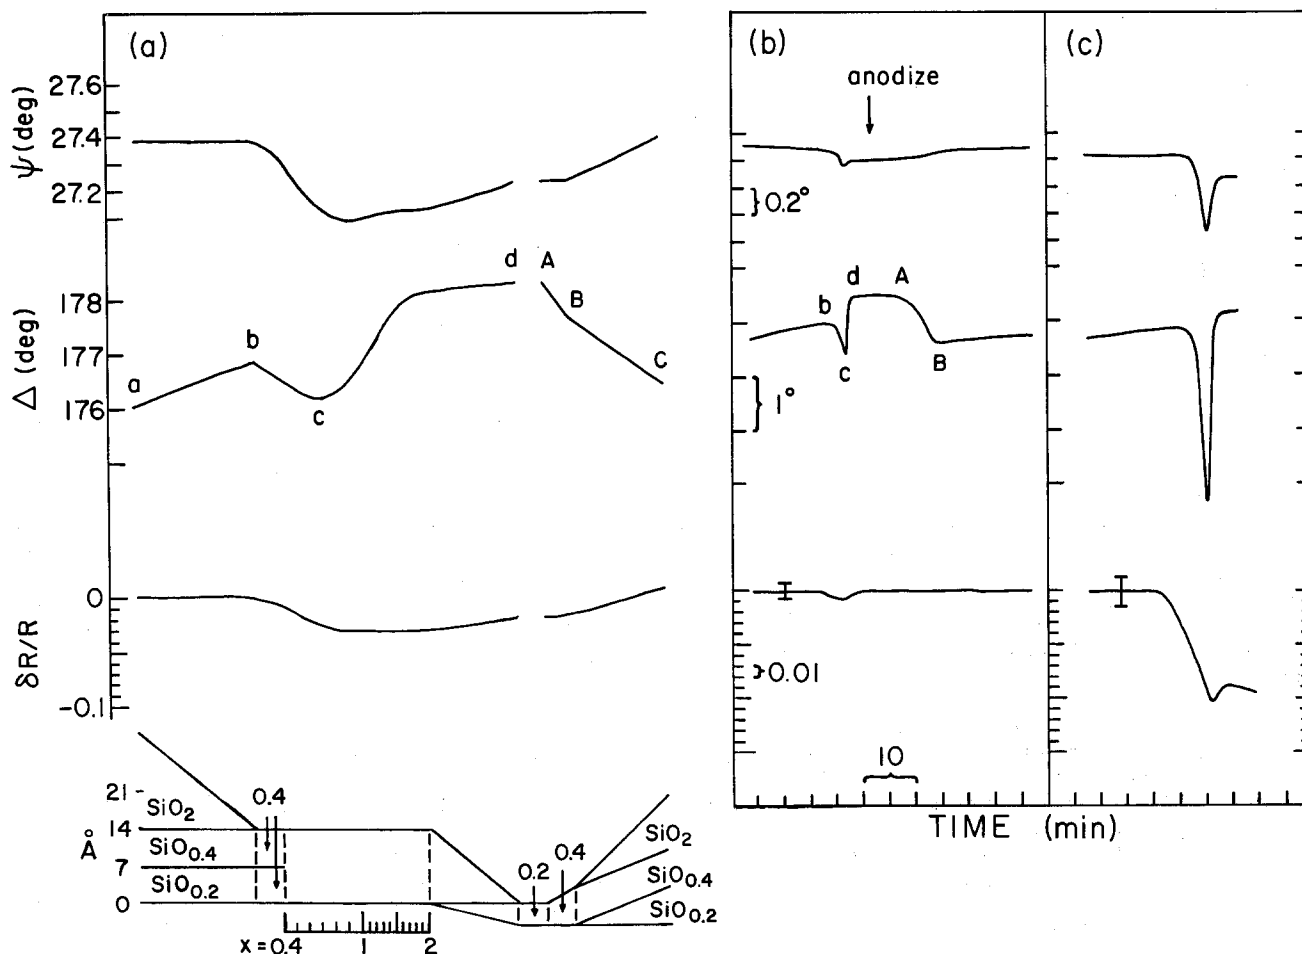

Fig. 9. a: Calculated changes in ψ , Δ , and $\delta R/R$ for the model shown in the inset, to account for the "soft" oxide etch-back results for a {111} Si sample and initial anodization. $\theta = 54.6^\circ$; $\lambda = 435.8 \text{ nm}$. b: Experimental changes in ψ , Δ , and $\delta R/R$ for an n {111} Si sample ($n \approx 1 \times 10^{15} \text{ cm}^{-3}$) with $1/4^\circ$ orientation. Anodizing potential was 0.3V. c: Experimental changes in ψ , Δ , and $\delta R/R$ for a p {111} Si sample ($p = 1.6 \times 10^{15} \text{ cm}^{-3}$). Anodizing potential was 0.3V.

and the undershoot in ψ from point b to d. Also, point c' occurs later in time than c. The reflectance change observed in going from a-b to d ($\delta R/R = -0.1$, Fig. 9c) is substantially larger than the value calculated ($\delta R/R = -0.002$) for simple removal of the SiO_x layer with no contribution from roughness-induced scattering. However, unlike the case for hard and thermal oxides (see below), the reflectance change is in the form of a step, with little or no additional time-dependent structure. The scatter in the high voltage signal before etch back has been converted into a scatter in $\delta R/R$, as indicated by the error bars. Within the scatter in $\delta R/R$ of ± 0.006 , there was hardly any change in reflection for the $\pm 1/4^\circ$ -oriented wafer (Fig. 9b).

The model described above for the removal of the exposed SiO_x connective layer is appropriate to an etching process in which voids filled with silicate material (with an index of refraction like that of SiO_2) are formed. Alternatively, the process could be described in terms of voids filled with the etching electrolyte (having an index like that of H_2O). In either case, the changing SiO_x layer is modeled within the context of an (microscopically rough) effective-medium mixture of a-Si and voids. Optically, the two models are virtually indistinguishable at the wavelengths used here, and, in reality, both probably contribute to making the exposed connective layer "dielectric-like".

The model in Fig. 9a has been extended to the anodization side to compare with the results of Fig. 9b, in analogy to Fig. 3b. While the observed magnitudes of the changes in Δ from B to C (Fig. 9b) are larger than those given by the calculation (Fig. 9a), we have not attempted detailed fits of anodization and etch back to obtain overall better fits. This might be done by using thinner connective layers and/or by changing the values of x slightly. We do not expect the connective layer at point a in Fig. 2 to be exactly the same as the connective layer at point C. These layers depend on the anodizing potential at points a and C.

Finally, we note that, in order to simplify the calculation, we have modeled the etch back as a series of discrete sequential steps; whereas one expects each new process to commence as the previous one is approaching completion. We altered this sequential approach only near point d in Fig. 9a allowing the equilibrium etching layer to develop as the " SiO_2 " layer etched back. The larger dips in ψ and Δ in Fig. 9c as compared to Fig. 9b suggest that here ψ and Δ are being affected by a slight transient roughness.

For the fast etching {100} surface, the soft anodic oxide is seen to etch back with large dips in ψ and Δ with a FWHM of 2-4 min, as Fig. 10a indicates. Then an immediate roughening of the surface occurs as ψ and Δ begin to decrease again with an accompanying large decrease in R . Some of the decrease in ψ and Δ after point d (usually less than half) is due to bubble formation. This is determined by growing the connective layer whereupon the bubbles disappear. Finally, for the hard anodic oxide on a {100} surface, we obtain a large dip in ψ and a decrease in Δ , with R decreasing towards zero within minutes. Part of the large changes in ψ and Δ results from bubble formation on the surface. Bubbles scatter light and tend to decrease ψ and Δ . For example, in Fig. 10b when the potential is changed anodic to produce the first vestige of connective layer (not shown), the dashed curves for ψ and Δ rise to $\sim 26^\circ$ and $\sim 168^\circ$, respectively, as bubbles disappear; $\delta R/R$ changes only slightly under these conditions.

An n {110} surface gave qualitatively similar results for the fast dips in ψ and Δ and decrease in $\delta R/R$ for a soft anodic oxide. A hard anodic oxide gave similar slow dips in ψ and Δ and large decrease in $\delta R/R$.

Roughening Model

The results of Fig. 8 and Fig. 10 indicated that roughening was a problem. The {111} surface can be recycled many times between anodization and etch back with little roughening. Even if left at OCP for hours, it roughens only slightly, ψ and Δ decreasing a few tenths of a degree.

Fig. 10. a: Changes in ψ , Δ , V , and $\delta R/R$ during etch back of a soft anodic oxide on a p {100} Si sample with $\rho = 4.1 \Omega \text{ cm}$ ($4 \times 10^{15} \text{ cm}^{-3}$). $\theta = 54.6^\circ$; $\lambda = 435.8 \text{ nm}$. Anodizing potential was 0 V. b: Changes in ψ , Δ , V , and $\delta R/R$ during etch back of a hard anodic oxide on another part of the same wafer. Anodizing potential was 7.3 V.

However, the {100} surface roughens immediately, so that ψ and Δ do not return to the values at point b but continue to decrease. This problem precludes more than one experiment per {100} sample, except in the case of the soft oxide, where it is possible to reanodize immediately at point d suffering only a few tenths of a degree drop in ψ and δ each cycle.

The $\delta R/R$ data in Fig. 8b indicate a transient roughness-induced light scattering as etching progresses through the n {111} hard oxide connective layer. The value of $\delta R/R = -0.23$ at the reflectance minimum strongly suggests gross macroscopic roughness, rather than a real change in specular reflectance caused by growth of a homogeneous film. Model calculations for a wide range of film \bar{n} and thickness, including those for which the film is taken to be a microscopically rough layer [modeled in the effective-medium approximation (27)], give $\delta R/R$ smaller by an order of magnitude. An estimate of the root mean square roughness σ at the $\delta R/R$ minimum is obtained (28) from $\delta R/R = \exp[-(4\pi n \sigma \cos \theta/\lambda)^2] - 1$, yielding $\sigma \approx 230 \text{ \AA}$. Here, n is the electrolyte refractive index. The fact that σ is at least an order of magnitude greater than the connective-layer thickness provides an important clue to the source of roughness.

We have considered whether it might be useful to model the effects of this transient macroscopic roughness on ψ , Δ , and $\delta R/R$. However, we are aware of no mathematical description of the consequences of roughness, of the type encountered here, for the polarization state of specularly reflected light. Presently available theories (29) treating scattering induced depolarization in ellipsometry are restricted to the small-roughness ($\sigma \ll \lambda/10$) limit and/or the small-slope regime ($\tan \beta \ll 1$, where β is the angle between the local surface tangent and the average surface plane). We note that several studies (30-33) of macroscopically roughened Si surfaces (by chemical or thermal treatment) reported ψ and Δ decreasing with increasing roughness.

Our qualitative model for the origin of transient roughness is based on the value of $\sigma \approx 230\text{\AA}$ [compared to a connective-layer thickness of $\sim 10\text{\AA}$, similar to that observed (19) for thermal oxides] and on the larger FWHM of the etch-back structure in ψ and Δ for hard (10-15 min) vs. soft (2-3 min) oxides.

In order to understand the transient roughness observed upon etch-back of a hard oxide (Fig. 8b), we note the following order for the etch rates for several crystal planes of Si: $R_{100} \approx R_{110} \gg R_{111} \gg R_{SiO_x} > R_{SiO_2}$. We also observe that the roughness for {111} planes is primarily transient, while for the {100} and {110} planes it is permanent. There appears to be a background roughness in Fig. 8b underneath the transient roughness which is comparable to the roughness in Fig. 8a. These facts suggest that the etching of the oxide is nonuniform. This might be due to nonuniformity of the oxide layer thickness or a lateral variation in the stoichiometry of the SiO_x connective layer.

We consider a {111} plane with simple aperiodic texture of oxide due to either of the above reasons as shown in Fig. 11a. We assume SiO_2 etches back at a rate of $\sim 0.3\text{\AA}/\text{min}$. Since the rudimentary connective layer grown at PP is modeled as 7\AA of $\text{SiO}_{0.4}$ and takes $\sim 2\text{ min}$ to etch off, we assume an average etch rate of $\sim 4\text{\AA}/\text{min}$ for the completed connective layer modeled as 14\AA of SiO_x (7\AA of $\text{Si}_{0.2}$ and 7\AA of $\text{SiO}_{0.4}$). For a laterally inhomogeneous connective layer, the area of smaller x will etch faster, presumably because it resembles Si. We assume $R_{111} \approx 25\text{\AA}/\text{min}$ and $R_{100} \approx R_{110} \approx 300\text{\AA}/\text{min}$ for c-Si (14).

Regardless of which $\text{SiO}_x/\text{SiO}_2$ layer is present, the net effect will be to open pinholes, exposing c-Si, as shown in Fig. 11b. At the moment the first c-Si is exposed, the c-Si surface is smooth with $\text{SiO}_x/\text{SiO}_2$ roughness patches. The depth of these patches is D and their width is L . We have now reached the point in Fig. 8b where $\delta R/R$ is about to drop steeply.

Fig. 11. a: Schematic diagram depicting two possible kinds of inhomogeneity in the $\text{SiO}_x/\text{SiO}_2$ oxide layers. b: Oxide caps remaining when etchant reaches c-Si. c: Etching of c-Si produces wells as last oxide layer etches away. d: Faster etching of c-Si walls in the lateral direction smooths out wells.

Experimentally, we observe that it requires $\sim 20\text{ min}$ to reach the minima in ψ and Δ (this time can be as short as 10 min). This number allows us to estimate the thickness D of the $\text{SiO}_x/\text{SiO}_2$ cap and the depth of the well D_R which is etched in c-Si as indicated in Fig. 11c. Using the values for R_{111} , R_{SiO_x} , and R_{SiO_2} given above, and assuming the SiO_x layer is 14\AA thick, we find that $D \approx 19\text{\AA}$, while $D_R \approx 500\text{\AA}$ in rough agreement with $\sigma \approx 230\text{\AA}$. We have now reached the extremum in $\delta R/R$ shown in Fig. 8b.

The transient effect can be accounted for by noting that the exposed walls of the wells are probably {110} and {100} planes (not necessarily vertical). Thus, the etch rate of the walls is substantially greater than that of the bottom {111} plane. This causes the walls of adjacent wells to approach each other at a rapid rate. Consequently, the thickness L is reduced toward zero. We have reached the plateau in $\delta R/R$ in Fig. 8b after the dips in ψ and Δ . Based on the observation that the dips in ψ and Δ are skewed, we assumed that 10 min (this time can be as short as 5 min) are required for this process. From $R_{100} \approx 300\text{\AA}/\text{min}$, we obtain a maximum value of $L \approx 6000\text{\AA}$ if the fast etching planes are vertical; otherwise, L will be somewhat less by a cosine factor. This characterizes the original aperiodicity in terms of average 19\AA thick $\text{SiO}_x/\text{SiO}_2$ patches which are $\sim 6000\text{\AA}$ across. Obviously, some roughness would persist, as suggested in Fig. 11d, probably as pyramidal pits, since the fast etching planes are not perpendicular to the {111} plane. This crude estimate of the roughness confirms that it is macroscopic in nature (deep, wide bumps). Independent evidence for the formation of pinholes comes from previously reported (34) ellipsometric electroreflectance (field-modulated ellipsometric) data showing that Fermi-level pinning begins just before significant penetration is made into the hard anodic-oxide connective layer.

The behavior of the {100} and {110} faces can be understood by observing that the walls of the exposed wells are probably slow etching {111} planes. Then in Fig. 11c, since $R_{100} \gg R_{111}$, D_R becomes deep and the roughness persists as Fig. 10 indicates, since the walls never etch away completely. It is most likely that random square pyramidal pits with {111} walls are formed after SiO_2 etch back on a {100} surface, as indicated in Fig. 7e.

For the fast etching {100} surface, $\delta R/R$ indicates that, even for the soft oxide, severe macroscopic roughening sets in even before the connective layer has been completely removed. Note in Fig. 7e that the lateral sizes of the pit structures are of the order of a micron.

At this point, we emphasize that the optical effects seen during etch back of the {111} soft-oxide connective layer are distinct from those for the other types of samples (Fig. 9b). First, this system exhibits little or no transient roughness effect above the $\delta R/R$ detection limit. Second, even the slightest degree of anodization (one need go no farther than point B in Fig. 2) gives the results shown in Fig. 8a and 9b during subsequent etch back at OCP. Finally, as discussed above, both the growth (Fig. 3) and etch back (Fig. 9) of the soft-oxide connective layer can be modeled successfully in terms of SiO_x .

As noted previously, based on the results in Fig. 3 and on the different etch-back characteristics of soft, hard, and thermal oxides, we identify the soft anodic oxide with a connective layer. The transition from soft to hard anodic oxide, as characterized by etch-back behavior, has been followed by monitoring the magnitude of $\delta\psi$ and $\delta\Delta$ from point b to c and the FWHM value of the dips (an indicator of the connective layer thickness-to-etch rate ratio) as shown in Fig. 12. The transition is rather abrupt around 5V. Interestingly, a plot of the maximum SiO_2 thickness vs. bias (11) shows a break at 5V, with a slope of $\sim 7\text{\AA}/\text{V}$ below and $\sim 42\text{\AA}/\text{V}$ above this critical bias. Presumably, the final stabilized connective layer is formed above 5V as the true SiO_2 oxide is growing. We have not attempted to fit the curve C-D in Fig. 3a by allowing further changes in connective layer beyond those shown in Fig. 3b.

Fig. 12. Changes $\delta\psi$ and $\delta\Delta$ (from point b to c in Fig. 8) and FWHM of the dips in ψ and Δ as functions of anodization potential for several p {111} Si samples with $\rho \approx 9 \Omega \text{ cm}$ ($\sim 1.8 \times 10^{13} \text{ cm}^{-3}$). A smooth curve has been drawn through the many data points (not shown) which scatter by as much as $\pm 50\%$. A transition occurs near 5V from soft to hard anodic oxide. The dashed portions indicate a leveling off as the potential nears 10V. $\theta = 54.6^\circ$; $\lambda = 435.8 \text{ nm}$.

Spectroscopic Experiments

Several attempts were made to obtain the optical spectrum ($800 > \lambda > 250 \text{ nm}$) of a thin layer of soft anodic ox-

ide for the purpose of comparison with calculated (18, 19) results for physical- and chemical-mixture models. Such data would, in the absence of vibrational spectra, provide some insight into the chemical composition of the connective layer in the early stage of formation.

The first step is an accurate measurement of the effective dielectric function, $\langle \epsilon \rangle$, of the clean substrate, in this case taken to be a {111} n-Si wafer etching at OCP in 2M KOH (before point A in Fig. 2). A sample oriented to $1/4^\circ$ was used to minimize roughness effects over the 2h run. $\langle \epsilon \rangle$ is obtained from ψ and Δ vs. λ for the etching substrate using expressions (16) appropriate to a film-free surface. Thus, $\langle \epsilon \rangle$ will differ from the "true" $\epsilon [= \epsilon_1 - i\epsilon_2 = (n^2 - k^2) - i(2nk)]$ if the supposed clean surface actually incorporates a film, such as a thin oxide, an equilibrium etching layer, or microscopic roughness layer. Aspnes and Studna (35) have shown that the presence of such a layer is most easily detected as a reduction of $\langle \epsilon_2 \rangle$, relative to ϵ_2 , at peaks in the optical joint density of states.

Figure 13 shows $\langle \epsilon_1 \rangle$ and $\langle \epsilon_2 \rangle$ for Si obtained during 2M KOH etching. To achieve accuracy, ψ and Δ were determined using two-zone averaging (16, 36) to reduce systematic errors, and the hollow fused-silica prism serving as the sample cell had been carefully annealed after fabrication to eliminate strain-induced birefringence. In obtaining $\langle \epsilon \rangle$ vs. λ from ψ and Δ , the index of refraction of the ambient was computed using a polynomial fit to n vs. λ for H_2O , corrected for the addition of the alkali (12).

The points in Fig. 13 show the results of Aspnes and Studna (35) for an optimally smooth and clean Si surface protected by flowing dry N_2 . The agreement is quite good throughout the whole spectrum, leading us to conclude that—at least for the amount of time required for a set of spectroscopic measurements ($\sim 1.5\text{h}$)—the etching surface remains relatively free of any film sufficiently thick to degrade $\langle \epsilon \rangle$ seriously. Such a film could be an adsorbed layer, an equilibrium etching layer, or a layer of microscopic roughness. Nevertheless, there are small systematic differences between $\langle \epsilon \rangle$ for Si in KOH and the "optimum" $\langle \epsilon \rangle$. The peak value of $\langle \epsilon_2 \rangle$ at the 4.25 eV (292 nm) E_2 critical point is 45.63 vs. 47.87 (35), and $\langle \epsilon_1 \rangle$ is seen to fall slightly below Aspnes-Studna results in the 300

Fig. 13. Real ($\langle \epsilon_1 \rangle$, solid) and imaginary ($\langle \epsilon_2 \rangle$, dashed) effective dielectric functions for Si (n {111} wafer) obtained while etching at OCP in 2M KOH. $\theta = 54.6^\circ$. The points are the data of Aspnes and Studna (35) for a clean, smooth surface protected by dry N_2 .

$< \lambda < 350$ nm range. These discrepancies are consistent with the presence of a very thin equilibrium etching layer (modeled above as 4Å of $\text{SiO}_{0.2}$) on the Si surface in KOH.

Having obtained ψ and Δ vs. λ at OCP, we biased the sample slightly anodically to form the beginning of a connective layer (point B, Fig. 2) and obtained a second set of ψ and Δ . If the A-B process is assumed to consist of the growth of a single isotropic homogeneous film, then $\langle \epsilon \rangle$ of the film can be obtained (16) from $\langle \epsilon \rangle$ of the substrate and the observed $\delta\psi$ and $\delta\Delta$. Unfortunately, ψ and Δ at OCP (and, to a lesser extent, at point B) "drift" with time, largely as a result of slowly increasing microscopic roughness as etching continues. During the measurement time for a set of ψ and Δ vs. λ , these small changes are a significant fraction of the true $\delta\psi$ and $\delta\Delta$ observed during the A-B process at fixed λ . Thus, when $\langle \epsilon \rangle$ of the film is obtained from these data, the result resembles a somewhat broadened and distorted version of the substrate $\langle \epsilon \rangle$ shown in Fig. 13. This result is consistent with formation of a thin microscopically rough surface layer [modeled as an effective-medium mixture (27) of electrolyte-filled voids in a c-Si host].

Etching Chemistry

Some possible etching reactions have been discussed previously (37, 38). We base our conclusions on several observations. After dissolution of Si in KOH, Palik *et al.* (10) observed the vibration modes of $\text{Si}(\text{OH})_2(\text{O}^-)_2$ by a Raman scattering experiment. Finne and Klein (39) have observed that 2H_2 are released for each Si dissolved by the ethylenediamine pyrocatechol etchant. We have collected the H_2 from a known amount of Si dissolved in $2M$ KOH and also find 2H_2 per Si.

We attempted to determine the OH^- consumed in the etching reaction by titration. Four beakers were prepared, each with an identical volume (50 ml) of the same KOH solution (nominally $2M$). To each of two beakers, a known weight ($\sim 0.5\text{g}$) of $\{100\}$ p-type Si wafer was added, while the other two were left "blank." After the wafers dissolved (several days), all four solutions were titrated to the phenolphthalein end point with $1M$ HCl. Near the end of each titration of the Si solution, the mixture turned viscous with agglomerated solid matter which prevented complete mixing. The volumes of HCl needed to neutralize the two reference solutions and the two etching Si solutions were the same to within 1 ml out of 131 ml. On the assumption that the HCl reacted with both OH^- in solution and OH on the silicate $\text{Si}(\text{OH})_2(\text{O}^-)_2$, the results indicate that the total OH is conserved in the etching process. If one OH^- had been consumed per Si removed, without being replaced by a silicate OH, the difference in titration volumes between sample and blank KOH solutions would have been 18 ml. Therefore, since 2H_2 are observed for each Si which dissolved, it follows that H_2O must be a reacting species. It cannot simply be a catalyst. While this result does not conclusively prove any one mechanism, it eliminates from further consideration any scheme in which OH^- is the only reacting species. Kolbanev and Butyagin (40) ground c-Si continuously in water exposing new surface area and observed conversion of the Si into silicates, with 2H_2 released per Si dissolved. Although it is not clear whether the process of breaking Si—Si back bonds is the mechanical grinding or actual chemical etching, the experiment suggests that Si will dissolve in water if a passivating SiO_2 layer does not grow first. Other experiments (4, 38) have shown that at large OH^- concentration ($>5M$) the etch rate decreases significantly. This could be an indication that H_2O is needed for etching (3). Block (41) reports that Si does not etch in water-free alcohol/KOH solutions. Study of the dissolution of SiO_2 in aqueous hydroxides and in water-free alcohols containing NaOH indicate that water is also necessary for etching silica (42).

From such observations, we conclude that the sequence in etching is hydration of the original surface with SiOH bonds, attack of the Si—Si back bonds by H_2O to form

Si—H and Si—OH, and then attack of the SiH bond by OH^- to form Si—O $^-$ and H_2 . Thus, the etch products are 2H_2 for each Si dissolved and $\text{Si}(\text{OH})_2(\text{O}^-)_2$ as the principal silicate with some $\text{Si}(\text{OH})_3(\text{O}^-)$ and $\text{Si}(\text{OH})(\text{O}^-)_3$ also formed. Also 2 OH^- should be consumed for each Si dissolved, reappearing in the form of $\text{Si}(\text{OH})_2(\text{O}^-)_2$. This may be expressed for one Si—Si bond by the reaction

For dissolution of one Si atom, the net reaction is

These reactions are shown schematically in Fig. 14 for a $\{100\}$ surface.

It is known (43) that the SiH bond is very reactive with OH^- but not with H_2O at pH 7. Thus, while the Si—Si bond can be attacked by H_2O , the second step of attack by OH^- would hardly be present in water. The presence of OH^- in aqueous KOH continues the attack producing a soluble silicate. Note that during the reactions of Eq. [1] no net charge flows across the interface. The electron charge on OH^- "enters" the Si as anodic current in the OH^- attack of the Si—H bond, but then "leaves" as cathodic current on the O $^-$ of the soluble silicate with H_2 evolution. We suggest that OCP etching is chemical rather than electrochemical (12, 14) because it is independent of doping type and density over four orders of magnitude (9).

This model suggests that the cathodic slush layer is formed when H_2O attacks Si back bonds but then OH^- attack is inhibited. An insoluble hydrogenated silicate forms which sticks to the surface. However, subsequent H_2O attack continues and the slush layer thickens. Note that no oxide can grow at cathodic potential to protect the c-Si from H_2O "etch." This layer would be rich in SiH bonds and might resemble hydrogenated Si in a vibrational-spectroscopy experiment. We have previously discussed the bias-dependent etch rates (14, 15) and noted that slush grows faster on n $\{111\}$ surfaces than p $\{111\}$ surfaces, while etching nearly stops on n $\{111\}$ surfaces and slows down slightly on p $\{111\}$ surfaces. Thus, there is a correlation between a drop in etch rate and the growth of slush.

Orientation Dependence

Making H_2O the primary etchant species suggests a reason for the orientation dependence. It has been demonstrated (44) that H_2O adsorbs dissociatively on clean $\{100\}$ and $\{111\}$ surfaces, forming Si—H and SiOH bonds by reaction with the dangling Si bonds. The dissociation of H_2O is found to be ~ 100 times faster on the $\{100\}$ surface compared to the $\{111\}$ surface. However, these experiments, which were carried out in ultrahigh vacuum using very small exposures to H_2O vapor, gave no indication of direct attack of Si—Si bonds by H_2O .

It is not easy to say just how this attack proceeds in the liquid environment. We have built scale models of the $\{100\}$ and $\{111\}$ surfaces shown schematically in Fig. 15 using the appropriate ionic radii for Si and for H_2O and OH. The chemisorbed OH contains an H atom (not shown) which can rotate about the Si—O bond direction. The shadowing of back bonds on the $\{100\}$ surface appears less than on the $\{111\}$ surface, making it harder for an isolated H_2O molecule to bridge two Si atoms on the $\{111\}$ plane to break the Si—Si bond. Moreover, in solution, water, and surely, OH^- are enclosed within hydration spheres so the geometric constraints may be even more severe. For the $\{110\}$ plane, each Si atom has two bonds in the plane, a third pointing up, and a fourth pointing down, also suggesting less shadowing.

The contrast between orientation-dependent etching and orientation-dependent oxidation (45, 46) is interesting. While the $\{100\}$ surface etches ~ 100 times faster than the $\{111\}$ surface, the $\{111\}$ surface oxidizes about 50% faster. In fact, Kendall (7) suggests that the $\{111\}$ surface is slow etching precisely because it is faster oxidizing.

Fig. 14. Schematic diagram of the etching of a {100} surface by H_2O and OH^- in sequence with 2H_2 produced and no net consumption of OH^- for each Si dissolved, since $\text{Si}(\text{OH})_2(\text{O}^-)_2$ is produced. The initial surface is covered by chemisorbed OH which has tied up the dangling bonds, or the OH is the result of etching of the previous Si layer.

Then, "spontaneously" grown oxide effectively stops {111} etching. Since etching in aqueous OH^- solutions is quite different from oxidation with gaseous O_2 or H_2O , we do not expect a direct correlation regarding shadowing arguments, which might suggest that {100} surfaces should oxidize faster than {111} surfaces. We have not measured the anodization rate of {111} and {100} surfaces in aqueous KOH .

It has been suggested (14) that a contributing factor to the orientation dependence was the weakening of back bonds by the surface OH group, which might withdraw charge from $\text{Si}-\text{Si}$ bonds. Therefore, water attack on back bonds would proceed more readily on {100} and {110} surfaces which have two OH groups per atom as compared to one on the {111} face. This effect would manifest itself in the activation energies for the various surfaces. While the activation energies of the {100} and {111} surfaces have been measured to be 16 kcal/mol from the temperature dependence of etch rates (4), it is not clear that the {111} wafers were not misoriented enough to make the pseudo-etch rate dominant. Consequently, the nature of the orientation dependence is still not clear.

Since both H_2O and OH^- are present in aqueous solutions of ethylenediamine (39), sodium hydroxide (37), and hydrazine (7), it is probable that the etching mechanism is the same in these etchants. The control of molarity and additives like alcohols simply varies the concentration of the etching species, blocks the surface, or expedites the removal of etch products.

Summary and Conclusion

The ellipsometric parameters ψ and Δ (together with $\delta R/R$ and I and V for the electrochemical cell) have been obtained under a variety of applied potentials. These data allow us to obtain information about the $\text{Si}/\text{SiO}_x/\text{SiO}_2/\text{aqueous KOH}$ interfaces.

Under cathodic potential, we observed formation of a slush layer, which is characterized as follows: (i) there is more rapid growth on the n-Si {111} surface (etch stopped) than on the p-Si {111} surface (still etching), (ii) ellipsometric results are accounted for by an equilibrium

etching layer of $\text{SiO}_{0.2}$ changing to $\text{SiO}_{0.8}$ and thickening, (iii) measurement of $\delta\psi$, $\delta\Delta$, and $\delta R/R$ indicates that a roughness dependent on carrier type develops as the slush layer grows, and (iv) the layer probably consists of insoluble silicates containing many SiH bonds resulting from incomplete etching by H_2O and/or electrolysis.

Under anodic potentials we have observed that oxide growth occurs in two stages. The soft oxide is characterized by: (i) Growth potentials between PP and 4V anodic of PP. (ii) Ellipsometric results for n- and p-Si {111} surfaces are accounted for by an equilibrium etching layer of $\text{SiO}_{0.2}$ converting to a graded SiO_x layer topped by a beginning SiO_2 layer. We term this SiO_x a connective layer. (iii) Etch back through SiO_x produces small dips in ψ and Δ (-0.3° and -3° , respectively) and a small negative increase in $\delta R/R$ over a time of 2-3 min prior to c-Si etching. (iv) Etch back through the connective layer is modeled as oxidation or hydration of SiO_x so as to reduce the value of \bar{n} .

The hard oxide, which resembles the thermal oxide, has the following properties: (i) growth potentials greater than 6V anodic of PP, (ii) a graded SiO_x connective layer which stabilizes while SiO_2 grows on top, developing out of the connective layer, (iii) etch back produces large dips in ψ and Δ (-6° and -17° , respectively) as well as a large negative increase in $\delta R/R$ over a time of 15-25 min, similar to thermal oxides, (iv) ellipsometric and $\delta R/R$ results of etch back are explained by a transient roughness due to spatial irregularities in oxide thickness or stoichiometry which produce pinholes where rapid Si etching occurs, and (v) results for the fast etching n- and p-Si {100} surfaces could not be modeled because of large roughening effects in general.

From our results we have inferred an etching mechanism which involves H_2O attack on $\text{Si}-\text{Si}$ back bonds followed rapidly for OH^- attack. This model is consistent with the following observations: (i) the soluble etch product is a silicate of the form $\text{Si}(\text{OH})_2(\text{O}^-)_2$, (ii) for each Si atom dissolved, 2H_2 are produced, (iii) the net hydroxyl concentration is constant in the form of hydroxyl ions in solution or hydroxyl groups on silicates, (iv) Si can be

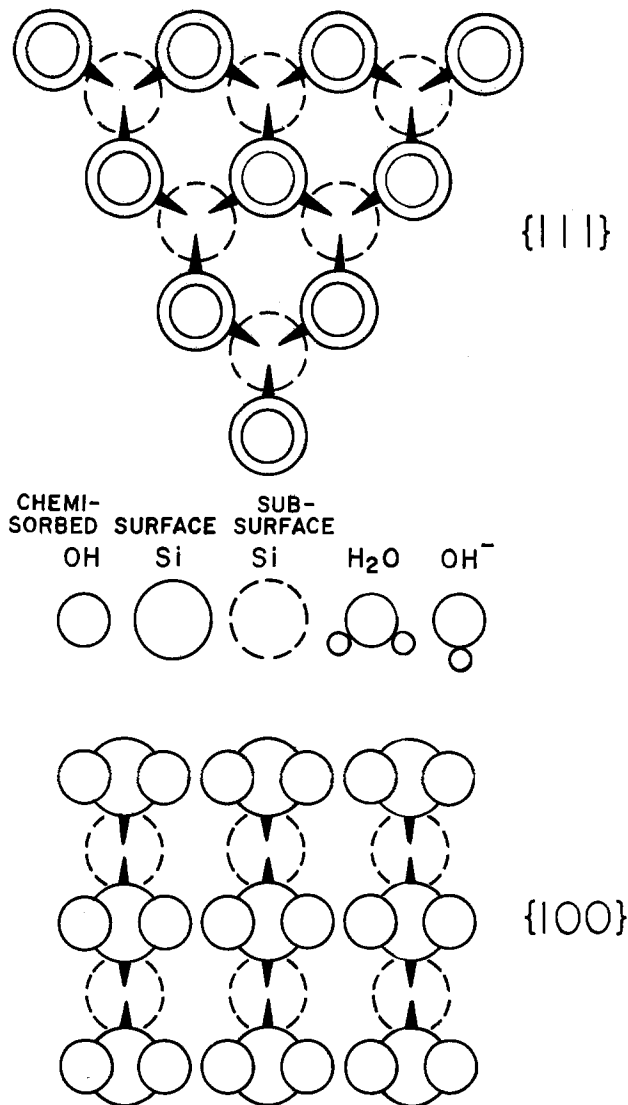

Fig. 15. Schematic diagram of the $\{111\}$ and $\{100\}$ surfaces with H_2O and OH^- molecules suggesting that more shadowing of the back bonds for the $\{111\}$ surface makes attack by H_2O and OH^- less likely with a resultant lower etch rate. Ionic radii were used in constructing the various atoms and molecules.

etched slowly by water (containing a small but finite amount of OH^-) through mechanical grinding, and (v) Si does not etch in water-free alcohol/KOH solutions.

Taking H_2O attack on Si—Si back bonds as the rate-limiting step provides an explanation for the orientation dependence. This strongly suggests that the orientation dependence is determined by a combination of different activation energies and stereoscopic effects having to do with the back-bond geometries on the different surfaces and on the relative ease of approach of the H_2O molecule in an orientation favorable for reaction.

We close by suggesting further experiments to explore some of the issues raised in the present work: (i) A vibrational-spectroscopy experiment using either Raman backscattering or infrared internal-reflection spectroscopy might identify Si—H bonds in the slush layer to help determine its chemical structure. (ii) As previously mentioned, the activation energy for etching of $\{111\}$ surfaces, as opposed to the $\{100\}$ and $\{110\}$ faces, is uncertain due to the fact that the experiments were probably done on misoriented $\{111\}$ samples. Therefore, it still remains to make this measurement on "perfect" $\{111\}$ surfaces to clarify the nature of the orientation-dependent effects. (iii) Our attempts to obtain the spectrum of the connective layer emphasize that a $\{111\}$ surface oriented to better than $1/4^\circ$ is needed. Then, there is a good chance of determining n and k and identifying the stoichiometry of this SiO_x layer and how it evolves into SiO_2 . (iv) Etching

surfaces tend to stay smoother at molarity near saturation, but the etch rate drops considerably. This suggests that repetition of some of the experiments described here would be useful to clarify roughness processes.

Acknowledgments

We thank D. E. Aspnes of Bell Communication Research for his calculated values of ϵ for the SiO_x chemical mixture. J. Freitas of NRL carried out a Raman scattering search for SiH bonds in the slush layer. G. Campisi, of NRL, and J. W. Faust, Jr., of the University of South Carolina, provided help in obtaining and interpreting the photographs of surface roughness. D. L. Kendall, of Instituto Nacional de Astrofisica, Optica y Electronica, Puebla, Mexico, participated in many discussions on etching mechanisms. One of the authors (O.J.G.) is an NRC-NRL Resident Research Associate.

n-Type Behavior of Chromium (III) Oxide

E. W. A. Young, P. C. M. Stiphout, and J. H. W. de Wit*

Department of Inorganic Chemistry, State University Utrecht, 3522 AD Utrecht, The Netherlands

ABSTRACT

The character of the electronic charge carriers under various conditions in chromium (III) oxide was investigated using Seebeck measurements on sintered compacts of Cr_2O_3 in the temperature range 800-1800 K. The compacts were prepared by various sintering procedures. Depending on the pretreatment of the compacts, n- or p-type materials were obtained. p-Type material resulted after sintering in an atmosphere with a high oxygen partial pressure. Sintering in an atmosphere with low oxygen partial pressure, however gave n-type material. This n-type behavior could be frozen in by cooling the compacts below 1100 K. These experimental results provide evidence for Cr interstitials being the predominating point defects in Cr_2O_3 at low oxygen partial pressure.

Chromium and many technologically important chromium containing alloys owe their high temperature oxidation resistance to the formation of protective Cr_2O_3 layers (1). The oxidation mechanism is determined by the transport properties of the formed Cr_2O_3 layer. Therefore, knowledge of the nature of the mobile species in the oxide forms the basis for the elucidation of the reaction mechanism (2, 3).

The oxidation kinetics of chromium and its alloys as well as the defect structure of bulk chromium (III) oxide have been subject to extensive studies. Considerable knowledge of the growth mechanism of Cr_2O_3 scales has accumulated. Measurements on bulk chromium (III) oxide indicated that the oxide had a metal-deficient defect structure (4). Therefore it was assumed until recently that during thermal oxidation the chromium (III) oxide layers grew by diffusion of chromium vacancies. Kofstad and Lillerud, however, concluded in a review paper on all the experimental data available that, at low oxygen partial pressures, chromium interstitials are the predominating point defects in Cr_2O_3 (3). This means that Cr_2O_3 should behave as an n-type material at low oxygen partial pressures. Kofstad and Lillerud suggest that only at relatively high oxygen partial pressures, including normal atmospheric pressure, should the material show p-type behavior. The p-type behavior of bulk Cr_2O_3 has been described in literature (5, 6). However, direct evidence for the n-type character at low oxygen partial pressures, in the form of Seebeck measurements, has not been published yet.

We have performed Seebeck coefficient measurements on sintered Cr_2O_3 compacts. Special attention was paid to the equilibration time of the samples at various temperatures and oxygen partial pressures.

Experimental

Chromium (III) oxide (Puratronic 99.999%) powder was pressed to tablets, uniaxially at a pressure of 4×10^8 Pa (0

= 8 mm, length = 15 mm). These tablets were sintered in an alumina tube furnace, in a chromium (III) oxide-coated alumina boat. Various sinter procedures were followed. A first series of samples was sintered in air at 1900 K for 3h. Only poorly sintered compacts were obtained this way (density 65%) (type A, Fig. 1A). A second series of samples was sintered at low oxygen partial pressure [after Ownby and Jungquist (7)] in a $\text{H}_2/\text{H}_2\text{O}$ (1% H_2O) mixture. Heating of the tablets up to 1770 K for 1h and cooling them in the same atmosphere resulted in moderately sintered compacts (density 85%) (type B, Fig. 1B). At 1770 K, the oxygen partial pressure of the gas mixture is 10^{-13} atm. After sintering at higher temperature, 1920 K, for 3h in $\text{H}_2/\text{H}_2\text{O}$ (1% H_2O), large grained high density samples were obtained (density 95%) (type C, Fig. 1C). At 1920 K, an oxygen partial pressure of 2×10^{-12} atm is obtained in the gas mixture.

Finally, samples sintered in CO/O_2 (0.2% oxygen) at 1770 K were prepared (p_{O_2} is 4×10^{-13} atm at 1770 K). These compacts, again, only show a moderate density (density 85%) (type D).

The sintered samples were mounted in an all-alumina Seebeck effect measuring system and pressed between two insulating alumina tablets. Only during the short period of time necessary to observe the Seebeck coefficient, Pt/Pt 10% Rh thermocouples were pressed onto the sample-ends, through a hole drilled through the two alumina tablets. The platinum leads of the thermocouples were also used for the measurement of the thermoelectric power. In this way a permanent heating of the thermocouples during equilibration of the samples could be avoided. Their lifetime was greatly enlarged, and the contamination of the samples with platinum could be kept to a minimum.

All Seebeck measurements were performed in air. Unless stated differently, the samples were given 24h equilibration time after each temperature change. The reported Seebeck coefficients are the average values from

measurements performed at three different temperature gradients at the same average temperature. Different temperature gradients were obtained by moving the samples in the hot zone of the furnace. The difference between the temperature at the hot and the cold end of the samples never exceeded 30° during measurements. The reproducibility of two parallel runs was within 5%.

Results

The sintering procedure turned out to have a major influence on the electronic properties of the samples.

All air-sintered samples show p-type behavior. The thermoelectric power of these air-sintered samples is independent of temperature up to 1300 K and decreases at higher temperatures from 750 to $300 \mu\text{V}/\text{K}$ at 1750 K (Fig. 2).

This is in accordance with Seebeck measurements reported by Hay *et al.* (5) and data of Fischer and Lorenz (6) for measurements at atmospheric oxygen pressures. Samples sintered in an atmosphere with a low oxygen partial pressure ($\text{H}_2/\text{H}_2\text{O}, \text{CO}/\text{O}_2$), however initially in air at temperatures below 1100 K show n-type behavior. A high temperature treatment in air alters the Seebeck coefficient of these samples.

The porous samples (Fig. 1B) rapidly shift from n- to p-type above 1300 K. Once shifted and equilibrated, the same variation of the thermoelectric power with temperature is measured for these samples as for the air-sintered samples. As can be expected, at lower temperatures more time is required for the n- to p-shift of the samples. A summary of the measured n- to p-shifts is given in Fig. 3. In Table I, a general survey of our results has been given.

Several samples already shifted from n- to p-type were given a new high temperature treatment at 1770 K in an atmosphere with a low oxygen partial pressure. These

samples, initially, at low temperatures show n-type behavior again. A new high temperature treatment in air shifts them back to p-type. These observations show that the n-to-p shift is a reversible process and that a possible contamination of the samples during the various heat-treatments cannot be the cause of the shift.

The large grained (n-type), high density samples (Fig. 1C) are not influenced by a heat-treatment in air below 1750 K. These samples simply remain n-type. However heating these compacts for several hours at 1870 K in air slightly reduces the thermoelectric power of these compacts.

Discussion

We interpret the n-type behavior as observed in air at low temperatures for the Cr_2O_3 compact (sintered in an at-

Fig. 2. Thermoelectric power of a Cr_2O_3 compact sintered in air (type A) as a function of temperature.

mosphere with a low oxygen partial pressure) as the result of a frozen in state.

At high temperatures, the compacts equilibrate with the surrounding atmosphere (air). Equilibration results in a shift from n- to p-type character of the samples.

The observed n-type behavior of chromia confirms the interstitial cation model of Kofstad and Lillerud (3). These authors based their interstitial model on an overall consideration of many defect depending properties, i.e., the sintering behavior of Cr_2O_3 while additional evidence was obtained from oxidation experiments (8, 9). Recently, high temperature oxidation experiments of Hindam and Whittle on chromium and chromium alloys provided evidence for the interstitial model (10). Various studies on the electrical behavior of Cr_2O_3 were performed, including the behavior at low oxygen partial pressures (5, 6, 11, 12). The conductivity measurements by Matsui and Naito suggest n-type behavior at low oxygen partial pressures (11). However, the n-type behavior of Cr_2O_3 at low oxygen partial pressures has never been measured directly from thermoelectric power observations. Hay *et al.* measured the thermoelectric power of Cr_2O_3 as a function of the oxygen partial pressure (5). There is a fair agreement between our experimental results and those reported by Hay *et al.* for measurements in near atmospheric oxygen partial pressures. A large discrepancy is found for the data measured at low oxygen partial pressure. Hay *et al.* observed a decreasing thermoelectric power with decreasing oxygen pressure, but they never obtained n-type material, not even in an atmosphere with a p_{O_2} of 10^{-20} atm at a temperature of 1850 K. Unfortunately, the authors do not give any experimental details concerning the density of their samples, the atmosphere nor the equilibration times that they used. Besides, the purity of the samples is not known.

Our equilibration measurements (Fig. 3) show that very long times are needed already for the equilibration of highly porous material. The large grained, high density samples we investigated (type C), in which gas-phase transport and grain boundary diffusion is reduced, even fail to equilibrate at 1870 K at all. New chromium tracer diffusion data (for single crystals), published by Hoshino and Peterson (13), show a very low self-diffusion coefficient of chromium ($10\text{--}13 \text{ cm}^2/\text{s}$ at 1770 K). Such low tracer diffusion data also predict a slow equilibration of Cr_2O_3 , as we observed ourselves. It can be assumed, therefore, that the Cr_2O_3 compacts studied by Hay *et al.* were not fully equilibrated with the low oxygen partial pressures of the atmosphere they used during measurements.

Fischer and Lorenz (6) as well as Hagel and Seybolt (9) did, in contrast with Matsui and Naito (11), not find a clear oxygen partial pressure dependence of the electrical conductivity. However, Fischer and Lorenz did not use very pure chromium oxide and nonpurified argon gas was used to control the atmosphere. This means that the atmosphere probably contained a fair amount of oxygen.

Table I. General survey of results

Sample type	Sinter conditions				Results	
	Gas	T (K)	t (h)	Density %	Sign thermoelectric power	
					After sintering	After heat-treatment in air
A	air	1920	3	65	p	p
B	$\text{H}_2/\text{H}_2\text{O}$	1770	1	85	n	p
C	$\text{H}_2/\text{H}_2\text{O}$	1920	3	95	n	n
D	CO/O_2	1770	1	85	n	p

Hagel and Seybolt used hot-pressed samples with a high density for their conductivity measurements, but short equilibration times (30 min). Thus it cannot be expected that n-type behavior would have been found by these authors.

Conclusions

From the above thermoelectric power measurements it was concluded that chromium (III) oxide equilibrated with a low oxygen partial pressure will behave as an n-type material.

Hoshino and Peterson (13), however, concluded from the increase of the chromium tracer diffusion coefficient with increasing oxygen partial pressure that Cr vacancies are the predominating defects in Cr_2O_3 even at low oxygen partial pressures. Thus the material would be p-type.

Our thermoelectric power measurements, the oxidation experiments by Hindam and Whittle (10), and the electrical conductivity data of Matsui and Naito (11) indicate that Cr interstitials are the predominating point defects at low oxygen partial pressures. Hoshino and Peterson themselves already call attention to the fact that both the temperature and the oxygen activity range for their measurements were severely limited, thus, possibly, giving misleading results. In all, one can conclude that, probably, in chromium (III) oxide, at low oxygen partial pressure, e.g., at the scale metal interface of thermally oxidized chromium and Cr alloys, Cr interstitials will be the predominating point defects.

In order to further solve the defect structure of chromium (III) oxide, additional measurements on the relation between the thermoelectric power and the oxygen partial pressure are being taken.

MOS Capacitors on Cadmium Telluride

R. T. Talasek and A. J. Syllaios*

Texas Instruments, Incorporated, Equipment Group, Dallas, Texas 75266

ABSTRACT

The behavior of MOS devices on cadmium telluride is reported. The oxides were grown by anodic oxidation in 1N KOH in methanol. These devices had normal C-V behavior with definite accumulation and depletion regions; however, constant capacitance was not observed in inversion. The effects of semiconductor surface damage and thermal stability of the oxide are also reported. The effects of series substrate resistance on capacitance-voltage and conductance-voltage have been discussed and an interface trap-level density estimated.

Cadmium telluride is extensively used both as a substrate for epitaxial growth of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ and as a material for solar cells and radiation detectors. CdTe is one of the constituents of the pseudobinary alloy $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (1), the device processing technology of which is based on oxide growth by anodization (2). Therefore, anodic oxide growth studies and studies of the electrical behavior of metal-insulator (oxide) semiconductor devices are appropriate both as a means of evaluating CdTe material properties and device performance and as an aid in developing a complete understanding of the oxide growth of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$.

To date, several reports of MIS behavior on wide bandgap semiconductors have been made. Good C-V behavior was reported on low resistivity p-type CdTe, using Langmuir-Blodgett films of cadmium stearate as an insulator, although results were not easily reproducible (3). MIS devices on CdTe were also reported using a native oxide grown in boiling H_2O_2 , but no C-V characteristics were reported (4). The C-V behavior of MIS devices on other wide bandgap semiconductors such as GaAs (5), $\text{GaAs}_{0.6}\text{P}_{0.4}$ (6, 7), and GaP (8) using anodically grown oxides as insulators have also been reported. Low thermal generation of minority carriers was observed in all of the last three cases.

Experimental

Anodic oxide films were grown on both n- and p-type CdTe. Material resistivities were typically 10^2 - 10^4 Ω cm. All samples were single crystals of random orientation, although some crystals were oxidized on the (111) "A" face. All of the results reported here were found for as-grown crystals that were not subjected to any annealing procedures.

Back-side ohmic contacts were produced by a process similar to one described elsewhere (9) for low resistivity p-type CdTe. This process involved etching in a solution containing a $\text{K}_2\text{Cr}_2\text{O}_7$ - H_2SO_4 mixture, followed by back-side Au evaporation. Contacts on p- and n-type samples were evaluated by measuring current as a function of applied voltage and were found to be ohmic with an RA product of about 25 Ω cm^2 .

Surface preparation prior to oxidation was found to be critical to device performance, as illustrated later. Surfaces were first mechanically polished to a 0.05 μm grit finish, followed by a noncontact polishing procedure in $\text{Br}_2/\text{CH}_3\text{OH}$ solutions similar to that described elsewhere (11). Following surface preparation, samples were anodically oxidized in a 1N solution of KOH in CH_3OH . Anodization was under constant current conditions. Current densities were typically 1 mA/cm^2 and were varied as necessary to compensate for variations in substrate resistance. These current densities were much larger than those typically used for anodization of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$, and were necessary to achieve reasonable anodization rates, since a large potential was being dropped from the back-side contact to the surface in contact with the solution. Samples were anodized under strong illumination to give uniform oxide films by minimizing the voltage drop across the sample. Following anodization, oxides were

typically subjected to a voltage annealing procedure similar to one outlined for $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (10), in which the sample was held at 80% of the final applied potential for an extended period to increase the oxide breakdown voltage. Nickel gates were deposited by vacuum evaporation. Gate area was 1×10^3 cm^2 .

Anodic passive film such as the oxide grown in this case usually follow one of two empirical rate laws

$$L = A + B \ln(t) \text{ (logarithmic law)}$$

$$1/L = C - D \ln(t) \text{ (inverse logarithmic law)}$$

to which a variety of mechanisms have been offered (12). In this case, the inverse logarithmic law was observed (Fig. 1). Oxide thicknesses were measured by ellipsom-

Fig. 1. Anodic oxide growth rate. Rate follows inverse logarithmic rate law.

Fig. 2. Dissolution of anodic oxide in water at 20°C.

* Electrochemical Society Active Member.

etry using a Gaertner 116A automated ellipsometer. Final oxide thicknesses were approximately 2000Å. The refractive index of the oxide was found to be 2.15 ± 0.10 by ellipsometry. The breakdown field of the oxide was found to be about 2×10^6 V/cm, which approaches values reported for SiO₂. Also, in order to qualitatively determine the extent of oxide hydration (as OH⁻ from basic solution), the dissolution rate in cold (20°C) water was followed by ellipsometry, as shown in Fig. 2. From this test it was concluded that approximately the last 100Å of oxide grown was hydrated to any extent.

Electrical evaluation of the MOS capacitors were made using a Hewlett-Packard automated test system, consisting of an HP4725A multifrequency LCR meter controlled by an HP9845B desktop computer equipped with a real-time clock. This configuration allowed extremely slow scan rates (10 V/h), which proved to be necessary to minimize injection-type hysteresis. This configuration also allowed simultaneous capacitance-voltage and conductance-voltage measurements to be made and provided real-time corrections for series substrate resistance. Corrections for series resistance were made as described elsewhere (13). Samples were tested at room temperature in ambient atmosphere. All measurements were made in the dark.

Fig. 4. Capacitance-voltage characteristic of a MOS capacitor on p-type CdTe.

Results and Discussion

Figure 3 illustrates a typical C-V plot achieved from an MOS capacitor fabricated on n-type CdTe. It shows definite accumulation and depletion regions. However, no inversion was observed due to the low thermal generation of minority carriers as is observed in other wide bandgap semiconductors. The C-V plot corrected for series resistance showed a significant capacitance correction in strong accumulation which steadily decreased in depletion until corrected and uncorrected capacitances were essentially equal. Injection-type hysteresis was typically observed and was minimized by slow voltage sweep rates. High frequency C-V's were observed down to frequencies as low as 100 Hz, also typical of low minority carrier generation. Capacitors subjected to test frequencies below 100 Hz were not well-behaved enough to observe any typical C-V behavior. Similar C-V behavior was also observed in MOS capacitors fabricated on p-type CdTe (Fig. 4). Essentially the same characteristics were observed on both n- and p-type material.

Noncontact polishing (11) was found to be an important procedure in the fabrication of MIS devices, since it removed mechanical damage better than normal chemical polishing techniques. The importance of

Fig. 5. Capacitance-voltage characteristic of a MOS capacitor on n-type CdTe with residual surface damage.

Fig. 6. Capacitance-time characteristic of a MOS capacitor on n-type CdTe. At time $T = 0$, the Ni gate is biased into depletion, and the capacitive delay is observed, as shown.

Fig. 7. (A): Measured conductance-voltage behavior. (B): Calculated parallel conductance-voltage curve corrected for series substrate resistance on n-type CdTe.

removing mechanical polishing damage is emphasized by the C-V curve shown in Fig. 5. Although chem-mechanical polishing in $\text{Br}_2\text{CH}_3\text{OH}$ followed mechanical polishing of this sample, damage removal by this method was incomplete. The effect of this damage was a drastic decrease in capacitance measured in accumulation. The samples in Fig. 3 and 4 show much better behavior than Fig. 5, due to less residual mechanical damage.

In order to determine the thermal stability of the oxide and the oxide-semiconductor interface, the C-V characteristics of a MOS capacitor were measured, then subjected to 24h at 90°C in ambient atmosphere. Subsequent retesting of the slice indicated no change in the C-V characteristics of the capacitor.

Dark storage times were also measured (Fig. 6). Average decay times of 200s were observed and were thought to be limited by leakage through the oxide.

Correction for series resistance proved to be even more important in G-V measurements than in C-V measurements. Figure 7 shows a typical example of the measured conductance and the parallel conductance corrected for series resistance. No peak was observed in the measured conductance, indicating that series resistance was the major loss. When the conductance was corrected for substrate resistance, a peak indicative of interface trap losses was observed. From such corrected conductance data, a plot of G_p/ω as a function of frequency was plotted (Fig. 8) and an interface trap density of $7 \times 10^{11} \text{ cm}^{-2} \text{ eV}^{-1}$ was estimated for a gate bias of 0.6V (approximate flatband voltage). Since no attempt was made to relate bias voltage to surface potential, the location of this trap level is not given.

Conclusion

Well-behaved MOS capacitors were fabricated on CdTe by anodic oxidation. C-V measurements yield high frequency curves with definite accumulation and depletion regions. Inversion was not observed due to low thermal generation of minority carriers. Corrections for series resistance had to be made in both C-V and G-V measurements, and corrected G-V curves were used to estimate interface trap densities.

Chemical Vapor Deposition of Al_2O_3 Thin Films under Reduced Pressures

Junji Saraie, Jongho Kwon, and Yutaka Yodogawa

College of Technology, Kyoto Institute of Technology, Matsugasaki, Kyoto 606, Japan

ABSTRACT

Al_2O_3 thin films were deposited by reduced-pressure CVD using aluminum tri-isopropoxide as a source. The dependence of the growth rate on the substrate temperature and the source gas supply was determined. The activation energy of the decomposition reactions was determined to be 18 kcal/mol. The electrical resistivity and the dielectric properties are characterized. The origin of the frequency dispersion in the sample prepared under the surface reaction limited conditions are discussed.

Chemical vapor deposition of amorphous thin films of Al_2O_3 for electron device applications has been reported by Aboaf (1). He obtained dense and etchable amorphous Al_2O_3 films using aluminum tri-isopropoxide [$\text{Al}(\text{OC}_3\text{H}_7)_3$, ATI in the following] as source material at the deposition temperature of 420°C . In his deposition system, the source gas with atmospheric pressure was heated in the quartz tube furnace, so that the deposition process included homogeneous reactions.

CVD- Al_2O_3 films were studied as insulator films for MIS structures of GaAs (2, 3) and InP (4, 5). In the case of Ref. (4), Al_2O_3 films are considered to be deposited through heterogeneous reactions on the substrates, although the authors did not refer to the situation explicitly. They did not report the systematic study of deposition conditions, however.

In this report, Al_2O_3 thin films were deposited through heterogeneous reactions on the substrate under reduced pressure at substrate temperatures below 420°C . The substrate temperature and the source gas supply were varied systematically as the deposition parameters. Their electric properties such as resistivity, dielectric constant, and dielectric loss factor are studied in relation to the deposition conditions.

Experimental

Figure 1 shows the deposition apparatus. The carrier gas is N_2 gas. The bubbler containing ATI is maintained at $120^\circ \pm 0.2^\circ\text{C}$, and the stainless steel pipes and the valves are heated to $130^\circ \pm 5^\circ\text{C}$ to avoid the condensation of ATI vapor. The total flow of gases was kept 1000 ml/min throughout the study and the gas flow through the ATI bubbler (referred to as an ATI flow rate in the following) was varied mainly from 50 to 200 ml/min. The ATI bypass line was used in order to settle the bubbling condition before starting the deposition. The reaction chamber was stainless steel and vertical type. The diameter of the substrate holder was 5 cm. The gases blow down onto the heated substrates through a stainless steel mesh diffuser to obtain films with a uniform thickness. The gases were not heated to the cracking temperature before reaching the substrate surface. The reaction chamber was evacu-

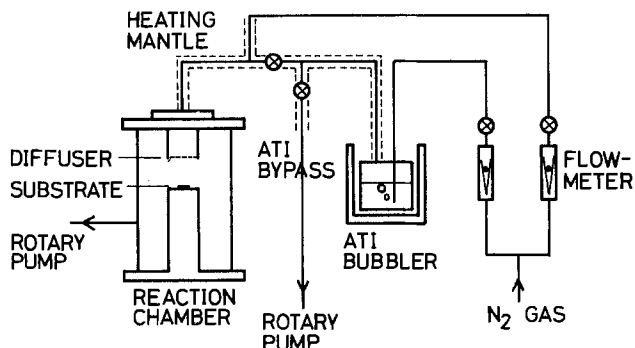

Fig. 1. Deposition apparatus

ated to a pressure of about 10 torr during deposition throughout the study. The homogeneous reactions can be minimized in the case of reduced-pressure CVD because of low concentration of gas molecules. Moreover, since the gas velocity is increased under the reduced pressure, the gas-phase heating by the substrate heater and gas convection can be largely avoided, which assures also the heterogeneous reactions and uniform gas flow as much as possible.

Silicon wafers and glass plates were used as substrates for the thickness measurement and the electrical properties measurement, respectively. Aluminum was evaporated as an electrode on the glass substrate prior to the Al_2O_3 deposition. The substrate temperature (T_{sub}) was controlled to an accuracy within 0.5°C .

ATI (Nakarai Chemicals Limited) is white, semitransparent, and brittle solid. But once melted, it does not solidify, even if the temperature is lowered to room temperature. The ATI melt is colorless and transparent. The liquid state is maintained for more than 10 days under N_2 atmosphere, but it begins to solidify in a few days if the melt is exposed to the air.

The film thickness was measured on the Si wafer sample by multi-interference microscopy. A part of Al_2O_3 films was etched off by HF, and Al was evaporated on it to obtain high reflectivity. The film thicknesses were usually 1000-2000Å.

Aluminum dots with the area of 0.025 cm^2 were evaporated on the $\text{Al}_2\text{O}_3/\text{Al}/\text{glass}$ structure. The current-voltage

Fig. 2. Dependence of the deposition rate on the substrate temperature and the ATI flow rate. The total gas flow rate is 1000 ml/min and the pressure during deposition is about 10 torr.

Fig. 3. ATI flow-rate dependence of the deposition rate in the mass-transfer limited region.

characteristics were measured step by step using picoammeter (Toa PM-18R), and the electrical resistivity was calculated from the slope between -0.5 and $+0.5$ V. The current was measured 1 min after applying a voltage. The dielectric properties were measured as a function of the frequency by a universal bridge (120 Hz-10 kHz, Delica 12K) and a capacitance meter (1 MHz, Boonton 72D).

Results and Discussion

Surfaces of the deposited films are mirror smooth on both thin (1000-2000Å) and thick ($\sim 1 \mu\text{m}$) films, and interference colors are observed clearly on the Si wafer substrates. Thickness was slightly larger at the periphery of the samples. The uniformity of the thickness was within 10% in the sample with dimensions of $20 \times 20 \text{ mm}^2$. X-ray diffraction experiments on the thick samples show that all the films deposited in this study are amorphous.

Figure 2 shows the dependence of the deposition rate on the substrate temperature and the ATI flow rate. The deposition rate increases and then saturates as T_{sub} increases at the same ATI flow rate. The saturation values increase with increasing the ATI flow rate. This tendency is similar to the case of usual chemical vapor deposition, that is, the deposition rate is limited by surface reaction at low T_{sub} and is limited by mass transfer (source gas supply) at high T_{sub} . The total gas flow rate and the ATI flow rate are about one order of magnitude smaller than

Fig. 4. Arrhenius plot of the deposition rate

those in the case of Aboaf (1). The lowest T_{sub} for Al₂O₃ deposition is found to be about 250°C. This critical temperature coincides with the results of Aboaf (1) and Tanaka *et al.* (3), but is higher than that after Kobayashi *et al.* (5).

Figure 3 shows the ATI flow rate dependence of the deposition rate in the mass-transfer limited region. The deposition rate increases linearly with the ATI flow rate, which is reasonable in the mass-transfer limited region.

Figure 4 shows the Arrhenius plot of the deposition rate in the surface-reaction limited region. The activation energy of the Al₂O₃ deposition was calculated from the slope to be 18.2 kcal/mol.

Figure 5 shows the dc electrical resistivity. The resistivity is in the range between 10^{13} and $10^{15} \Omega \text{ cm}$ and increases gradually with T_{sub} . The ATI flow-rate dependence was not so clear. These values are sufficiently high for electron device applications such as MIS structures. The time constant of the absorption current increases with decreasing T_{sub} . This fact shows that the samples prepared at low T_{sub} include slowly polarizing centers. The resistivity of these samples shown in Fig. 5 may be estimated slightly lower because the current was measured for all the samples 1 min after the application of voltages.

Figure 6 shows a typical example of the dielectric constant ϵ and the loss factor $\tan \delta$ as a function of the frequency for the samples prepared in the mass-transfer limited region. The dielectric constant is 8-9 and similar to the data of Aboaf (1). The value of $\tan \delta$ is 1-2% at low frequencies and increases to 10 kHz. These values are larger than that reported by Aboaf (1). The loss factor tends to decrease at higher T_{sub} and at a lower ATI flow rate, that is, at a slower deposition rate.

Figure 7 shows ϵ and $\tan \delta$ for the samples prepared at T_{sub} of 265°C and at the ATI flow rate of 100 ml/min, that is, prepared in the surface reaction limited region. Both ϵ

Fig. 5. DC electrical resistivity vs. the substrate temperature. The data include samples prepared at different ATI flow rates. The ATI flow rate does not affect the resistivity so much.

Fig. 6. Frequency dependence of the dielectric constant and the loss factor. The sample was prepared at T_{sub} of 420°C and at the ATI flow rate of 150 ml/min.

Fig. 7. Frequency dependence of the dielectric constant and the loss factor. The sample was prepared at T_{sub} of 265°C and at the ATI flow rate of 100 ml/min.

and $\tan \delta$ show a large dispersion at low frequencies, and the value of $\tan \delta$ is large. This fact shows that these samples include polarization centers whose response time is rather long, which coincides with the results in dc resistivity measurement. Such frequency dispersions have been reported also by Tanaka *et al.* (3). Similar but smaller dispersions were also found for the samples prepared at higher temperatures in the surface reaction limited region. The origin of the increase in $\tan \delta$ at 10 kHz observed in Fig. 6 and 7 is not clear at this stage.

Kobayashi *et al.* (5) have reported from Auger electron spectroscopic (AES) analysis that CVD- Al_2O_3 films prepared below T_{sub} of 300°C include carbon atoms, which were thought to form organic molecules. In our samples prepared at 265°-355°C, carbon signal was not detected by AES (signal ratio of O/Al was less than 0.015). But signal ratio differs by measuring conditions and is difficult to discuss without comparing the conditions in detail. Therefore, the possibility that such organic molecules contribute to the slow polarization cannot be excluded. And they may also be the origin of rather large values of $\tan \delta$. However, since from AES the content of carbon does not seem to increase with lowering the substrate temperature, large frequency dispersion in the samples prepared under the surface-reaction limited region should be attributed to an additional origin. In fact, these films were revealed to be weak under ion beam etching. Such

structural weakness, rather than the increase in numbers of molecular centers, seems to enhance polarization at low frequencies and contribute to the large frequency dispersions.

The low temperature deposition reported in this paper is important for III-V and II-VI compound semiconductors to avoid surface degradation at higher temperatures.

Summary

Smooth Al_2O_3 thin films were deposited reproducibly by reduced-pressure CVD through heterogeneous reactions of aluminum tri-isopropoxide. Substrate temperatures (250°-420°C) and source gas supply were systematically varied, and the dependence of the deposition rate on these parameters was determined. From the Arrhenius plot, the activation energy of the decomposition reaction was determined to be 18.2 kcal/mol. DC electrical resistivity is ranged from 10^{13} to 10^{15} Ω cm and increases gradually with the substrate temperature. The dielectric constant and the loss factor are 8-9 and 1-2%, respectively. The samples prepared under surface-reaction limited conditions show frequency dispersions at low frequency, that is, they include slowly polarizing centers. The structural weakness in these samples seems to enhance such polarizations. CVD- Al_2O_3 films reported will be useful for the combination with III-V and II-VI compound semiconductors, whose surfaces tend to degrade at higher temperatures.

Influence of Deposition Temperature, Gas Pressure, Gas Phase Composition, and RF Frequency on Composition and Mechanical Stress of Plasma Silicon Nitride Layers

W. A. P. Claassen,¹ W. G. J. N. Valkenburg, M. F. C. Willemsen, and W. M. v. d. Wijgert

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

We have studied the influence of different process parameters on the composition and mechanical properties of silicon-nitride layers deposited in a $\text{SiH}_4\text{-NH}_3\text{-N}_2$ plasma. The layers were deposited at temperatures between 300° and 600°C, at total pressures between 65 and 195 Pa and RF frequencies between 0.1 and 20 MHz. The Si/N ratio and the density of the as-deposited layers were determined by means of RBS. IR spectroscopy was used to measure the hydrogen content and Si-H/N-H ratio of the plasma nitride layers. It is shown that hydrogen content, density, and mechanical stress of plasma silicon-nitride layers strongly depend on deposition conditions. To explain the experimental data, a simplified reaction model is given. With this model, differences in densities, hydrogen content, and stress can be related to cross-linking reactions and to the extent of ion bombardment which takes place at different excitation frequencies.

Plasma silicon-nitride layers are widely used in the IC technology for passivation of devices. The layers act as barriers against the diffusion of impurity ions such as sodium, and they are also used for scratch protection during mounting operations. The electrical and mechanical properties of plasma silicon-nitride layers depend strongly on composition, density, and mechanical stress and, therefore, on the deposition conditions. Composition and stress measurements of plasma silicon-nitride layers have been reported (1-4), but attempts to make a more systematic study and quantitative evaluation of the results are relatively scarce. Therefore, a systematic experimental approach was applied to study composition, density, and stress of plasma silicon-nitride layers prepared under various deposition conditions.

In this paper, we report on the influence of deposition temperature, gas pressure, gas phase composition, and RF frequency on the composition, density, and stress of plasma silicon-nitride layers. The experimental data will be described by a simplified reaction model.

Experimental

The deposition experiments were performed in a home-built parallel-plate hot-wall plasma reactor, provided with two SiC coated carbon electrodes (dimensions $0.4 \times 9 \times 50$ cm). The equipment is shown schematically in Fig. 1. Silicon substrates ($\langle 100 \rangle$, 2-5 Ω cm, p-type) were placed on the grounded bottom electrode. The RF-excited electrode is the top electrode. The electrode distance is 1.8 cm. Prior to deposition, the reactor was pumped down to a pressure of about 0.1 Pa by a two-stage rotary pump (Edwards EH 500) followed by a nitrogen flux at working pressure for at least 10 min. The latter is necessary to stabilize the temperature of the substrate wafers. The temperature setting of the reactor was calibrated with an internal thermocouple, at the same pressure and gas flow used during the deposition experiments. Due to ion bombardment and a contact conductance between wafer and electrode, the temperature of the wafer could become somewhat higher than the electrode temperature. However, as mechanical stress, composition, and etch rate in buffered HF of the as-deposited plasma nitride layers does not depend on layer thickness (or deposition time), it can be assumed that the substrate temperature is close to the temperature of the electrode. During deposition, a mixture of the gases silane (SiH_4), ammonia (NH_3), and nitrogen (N_2) was passed over the slices. By varying the flow of the input gases, layers with different composition were deposited.

Most of the deposition experiments were performed at a deposition temperature of 300°C, a total pressure of 130

¹Present address: Nederlandse Philips Bedrijven Elcoma, Processes and Materials Development Group, 6543 AE Nijmegen, The Netherlands.

Pa, a total gas flow of 1500 sccm (giving a room temperature gas velocity of about 200 cm/s), an RF frequency of 310 kHz, and a deposition rate of about 25 nm/min, which was obtained by adjusting the RF power. In some experiments, we varied deposition temperature (300°-600°C), total pressure (65-195 Pa), and frequency (0.1-20 MHz). At a deposition temperature of 300°C, a fixed distance between the electrodes of 1.8 cm, an RF frequency of 300 kHz, and a total pressure of 130 Pa, the thickness spread over five 3 in. wafers is about $\pm 3\%$, while the variation in refractive index is less than 0.01. These low values can be realized when only a small fraction of the input gases is used in the process. For this reason, we worked at a relatively high gas velocity. At higher or lower pressures within the applied pressure regime, the wafer-to-wafer reproducibility becomes worse. However, the variation in deposition rate was always less than $\pm 10\%$. Variation of deposition temperature shifts the optimum deposition conditions. At 600°C, the best wafer-to-wafer uniformity was achieved at a total pressure of 160 Pa.

For characterization of the as-deposited layer, we used the central area (~ 4 cm²) of a wafer placed in the middle of the reactor. Under all deposition conditions, the variation in film thickness over the characterization area of 4 cm was less than 1%, while the refractive index was constant within 0.005. The Si/N ratio and the density of the plasma nitride layers was measured by Rutherford backscattering.

The RBS measurements were performed using 2 MeV He^+ ions generated by a Van de Graaff accelerator (5). The hydrogen content and the Si-H/N-H ratio in the nitride layers was obtained from IR spectra, by means of the method given by Lanford and Rand (6). Due to background pressures of O_2 and H_2O , small concentrations of oxygen are incorporated in the nitride layers. Using AES, it was estimated that under the applied deposition conditions the oxygen content was about 0.4 atom percent (a/o). The thickness of the deposited layers, which value is needed to calculate the density of the nitride, was measured with an ellipsometer and with a Talystep technique. For the latter measurement, an etched step was

Fig. 1. Schematic view of the hot wall parallel-plate plasma reactor

Fig. 2. Deposition rate, density, and atomic composition of layers deposited at a deposition temperature of 300°C, a RF frequency of 310 kHz, and total pressure of 65 Pa. $\phi_{\text{SiH}_4} = 100$ sccm; $\phi_{\text{N}_2+\text{NH}_3} = 1400$ sccm.

made in the middle of the wafer. Within the experimental error, the Talystep and the ellipsometrically measured thicknesses gave the same values.

The total stress in the layers was determined at room temperature by measuring the bending of nitride-coated Si <100> wafers with an x-ray diffraction topography goniometer (Lang Camera) (7). The curvature of the crystal planes (r) is directly related to the film stress

$$\sigma = \pm \frac{Ed^2}{b(1-\nu)tr} \quad [1]$$

where + and - denote tensile and compressive stresses, respectively. The stress is compressive if the wafer has a convex shape, as seen from the film side. Further, d is the substrate thickness, t the film thickness, E the Young modulus, and ν the Poisson ratio of the substrate. For Si <100>, $E/(1-\nu) = 1.8 \times 10^{11}$ Pa. Mostly layers with a thickness of 0.5 μm were used for the stress measurements. Variation of the thickness between 0.1 and 1 μm has, of course, influence on the bending of the substrates but not on the stress in the layer.

Results

The composition of plasma silicon nitride layers can be influenced by the deposition parameters: gas phase composition, deposition temperature, total gas pressure, and RF frequency. One set of experiments was performed at different values of one parameter while the other parameters were kept constant. In Fig. 2 are plotted the atomic composition (N_A), the density (ρ), and the deposition rate (G) vs. the relative ammonia pressure in the system. The deposition conditions are given in the figure caption. The ammonia concentration was changed by varying the ratio of the input gases N_2 and NH_3 while the SiH_4 flow was kept constant. The Si/N ratio of the deposited layers de-

creases with increasing ammonia partial pressure and varies between 1.08 and 0.68 for the data given in Fig. 2. At the same time, the hydrogen content varies from 14 to 26 at.%. These effects of the ammonia partial pressure are ascribed to its lower dissociation energy as compared to N_2 . A high concentration of N-H-like radicals leads to a high content of hydrogen in the plasma nitride layers. The density of the nitride layers shows a maximum which corresponds to a Si/N ratio of about 0.75. The deposition rate of silicon nitride layers depends slightly on the ammonia partial pressure. In Fig. 3 are plotted the atomic composition, the density, and the deposition rate of silicon nitride layers deposited at temperatures between 300° and 600°C. For comparison, data are also given for a layer deposited at 700°C without the presence of a glow discharge. With a glow discharge, the deposition rate increases slightly with increasing deposition temperature. With increasing deposition temperature, the hydrogen content of the layers decreases and the density increases.

Figure 4 shows the influence of total pressure on the deposition rate, density, and composition of plasma nitride layers. With increasing total pressure, the Si/N ratio and the hydrogen content increase slightly, while the density decreases. The deposition rate depends only slightly on the total pressure. In Fig. 5, the atomic composition and the density of nitride layers, deposited at different RF frequencies at 300°C, are plotted vs. the operating frequency. The deposition rates were about 25 nm/min, which was achieved by adjusting RF power. There is a large difference in the composition and the density between layers deposited below and above 4 MHz.

In Fig. 6 is given the mechanical stress for layers deposited at different temperatures, frequencies, and pressures (deposition conditions are given in the captions of Fig. 3-5). Layers deposited at low temperatures (< 550°C) and low frequencies (< 4 MHz) show a compressive stress,

Fig. 3. Deposition rate, density, and atomic composition of layers deposited at different temperatures between 300° and 600°C with a glow discharge (310 kHz) and at 700°C without a glow discharge. $P = 130$ Pa; $\phi_{\text{SiH}_4} = 100$ sccm; $\phi_{\text{N}_2} = 200$ sccm; $\phi_{\text{NH}_3} = 1200$ sccm.

Fig. 4. The influence of total pressure on deposition rate, density, and atomic composition. $T = 300^\circ\text{C}$, $f = 310\text{ kHz}$. $\phi_{\text{SiH}_4} = 100\text{ sccm}$; $\phi_{\text{N}_2} = 300\text{ sccm}$; $\phi_{\text{NH}_3} = 1100\text{ sccm}$.

while layers deposited at higher temperatures and high frequencies ($> 4\text{ MHz}$) show a tensile stress behavior. Furthermore, the stress in the layer decreases with increasing total pressure.

The number of Si-H and N-H bonds per cubic centimeter can be calculated from the IR spectra using a method

Fig. 5. Variation of composition and density of layers deposited at different RF frequencies at 300°C and a total pressure of 130 Pa. $\phi_{\text{SiH}_4} = 100\text{ sccm}$; $\phi_{\text{N}_2} = 700\text{ sccm}$; $\phi_{\text{NH}_3} = 700\text{ sccm}$.

given by Lanford and Rand (6). Figure 7 gives the fraction of Si-H bonds vs. the Si/N ratio of the layers deposited at temperatures between 300° and 600°C and an operating frequency of 300 kHz and for layers deposited at 3, 8, and 20 MHz at 300°C . At high Si/N ratios or Si-rich layers, almost all hydrogen is bonded to silicon, while at lower Si/N ratios the amount of N-H bonds increases. In a preceding paper, we reported observing the same trend for layers deposited in $\text{SiH}_4\text{-NH}_3\text{-H}_2$ or $\text{SiH}_4\text{-NH}_3\text{-Ar}$ atmospheres (1).

Discussion

Theory.—Before discussing the experimental data, we shall give some characteristics of a glow discharge which are typical for a plasma-deposition system (8). By electron impact of relatively stable molecules, active species such as ions, excited molecules, and radicals are formed. In a low pressure plasma (total pressure around 100 Pa), the mean electron energy is around 2 eV, while the electron concentration and also the positive ion concentration are about 10^{10} cm^{-3} . The electron density is determined by the mean electron energy, the electric field, the geometry of the system, the gas species, and the total pressure. Furthermore, the electron density is determined by the balance between the generation rate and the loss rate of electrons. Ionization is the most important process in sustaining the plasma, while electrons are lost by diffusion and recombination at surfaces. According to literature, at pressures around 100 Pa, the concentration of ions is two to three orders of magnitude smaller than the free radical concentration (9). The formed radicals may react via conventional pathways, but chemical reactions at the surface can also be enhanced by processes such as ion bombardment. The bombarding energy depends on the difference between the plasma potential and the substrate potential, the total pressure and the frequency of the applied field (10). At low frequencies, ions and electrons can follow the alternating RF field and, therefore, ion impingement can take place on the growing layer. Ions which leave the plasma are accelerated in the dark space

Fig. 7. Correlation between the amount of hydrogen bonded to silicon and the Si/N ratio for different deposition conditions.

and acquire a maximum energy of $V_p - V_s$, where V_p is the plasma potential and V_s the substrate potential, when they reach the substrate. In reality, collisions take place in the dark space and, therefore, the bombarding energy decreases with increasing total pressure. As the frequency of the applied field is increased, a point is reached at which the ions cannot follow the alternating field, leading to a strong reduction of the ion flux to the electrode. According to Bruce (10), who studied ion bombardment at different RF frequencies using an Ar-Kr plasma, the transition frequency at which ions cannot follow the RF field is at about 4 MHz.

Reaction scheme.—Several authors have studied the deposition of amorphous silicon from silane plasmas using mass spectrometric and optical analysis (11, 12). On the basis of these data, we propose a simplified reaction scheme for the deposition of plasma silicon-nitride from $\text{SiH}_4\text{-NH}_3\text{-N}_2$. The following reactions are taken into account: (i) gas phase ionization

(ii) gas phase dissociation

For simplicity and based on experimental data as can be found in literature (11, 13), we assume in the following that SiH_2 and NH are the most important intermediates in the gas phase.

(iii) Gas phase reactions, i.e.

and (iv) Insertion

Adsorption on free surface sites can be neglected due to the presence of the large amounts of N-H and Si-H bonds at the surface. Formation of N-N bonds is not likely.

(v) Hydrogen elimination by cross-linking

As will be discussed below, breaking of N-H or Si-H bonds depends on temperature and on the extent of ion bombardment. This simplified reaction scheme will be used to explain the experimental data. As for CVD systems operating at low temperatures and reduced pressures, the rate-limiting step for deposition had to be found in reactions which take place at the surface. Hydrogen elimination by cross-linking (Eq. [5]) cannot be rate-limiting because the hydrogen content of the nitride layers strongly depends on deposition temperature, while the deposition rate is hardly affected by the deposition temperature (Fig. 3). In conclusion, it can, therefore, be said that hydrogen desorption takes place after the rate-limiting step for deposition being the insertion of NH or SiH_2 radicals into Si-H and N-H bonds (Eq. [4]).

According to Fig. 2-4, the deposition rate of plasma silicon nitride depends only slightly on gas phase composition, deposition temperature, and total pressure. This can be explained as follows. In a glow discharge, the rate of dissociation processes can be described by (11)

$$R = k_d [e][X] \quad [6]$$

where $[e]$ and $[X]$ are the mean concentrations of electrons and monomers, respectively, and k_d is the rate constant for dissociation. This constant depends on the average electron energy, the shape of the electron distribution function, and the cross section of the different species. As the mean electron energy or electron temperature is much higher than the substrate temperature, it can be concluded that in the experimental regime under investigation the electron impact dissociation rate is nearly independent of the deposition temperature. The rate of ionization can also be described by the expression given by Eq. [6]. However, in the pressure regime under discussion, the rate coefficient for ionization is at least two orders of magnitude smaller than the rate coefficient for dissociation (9). The formed radicals may react in the gas phase or are removed by diffusion to the electrodes where they are incorporated into Si-H or N-H bonds (Eq. [4]). The temperature dependence of these insertion reactions is small as radical-radical reactions are often either unactivated or weakly activated processes (12). Based on the discussion given above, the experimental data concerning the deposition rate vs. the deposition temperature (Fig. 3) can be described by reactions which are only slightly dependent

on or independent of the substrate temperature. Without a glow discharge, radicals can only be formed via thermal dissociation of the parent molecules, which reaction is highly dependent on temperature, leading to a deposition rate which strongly depends on temperature (15).

The small variations in deposition rate measured for different gas phase compositions (Fig. 2) can be explained by small variations in the cross sections for ionization and dissociation for the different gases. Furthermore, the mean electron energy also slightly depends on the gas phase composition. According to Fig. 4, the deposition rate of plasma silicon nitride hardly depends on pressure. This can be explained by a combined effect, as at low pressures the mean electron energy tends to be higher, while the ionization and dissociation rate are proportional to both total pressure and mean electron energy (8).

Layer-related properties.—As discussed before, the insertion reaction given by Eq. [4] can be assumed to be the rate-limiting step for the deposition process. The rate of this reaction is denoted in the following by τ_1 . The hydrogen elimination reaction, with rate τ_2 (Eq. [5]) can be much faster or much slower than τ_1 . This, however, has no influence on the deposition rate but only on the structure of the deposited layer. If $\tau_2 \gg \tau_1$, the film will contain almost no hydrogen, whereas in the opposite case a polymer is formed with a large hydrogen content. According to this model, the ratio of the rates of the two steps τ_1/τ_2 depends only on the deposition temperature, provided the Si/N ratio is constant. This is approximately the case for the experimental data given in Fig. 3. As is shown in this figure, the hydrogen content of layers deposited at different temperatures using an RF frequency of 310 kHz varies from 25 a/o at 300°C to 6 a/o at 600°C. Layers deposited at 700°C, without the presence of a glow discharge, contain about 3 a/o hydrogen, while layers deposited at room temperature under almost the same conditions are those given in Fig. 3 contain about 40 a/o hydrogen. These data are plotted in Fig. 8 in a logarithmic form vs. the reciprocal temperature. If hydrogen desorption is thermally activated, a plot of $\log [H]$ vs. $1/T$ should give a straight line. According to Fig. 8, this is approximately true at temperatures between 400° and 700°C. As discussed before, under these circumstances the hydrogen content in the plasma nitride layer is only a function of τ_1/τ_2 . At lower temperatures, the hydrogen content is lower than expected from the model. This can be explained by an enhancement of the hydrogen elimination step by ion bombardment. As discussed before, at "high" operating frequencies the extent of ion bombardment decreases, which leads in the present model to a higher hydrogen content in the layer, as is indeed observed in Fig. 5. According to Fig. 6, layers deposited at a temperatures below 550°C have a compressive stress and layers deposited at higher temperatures exhibit a tensile stress. Layers deposited at room temperature also show a compressive

stress, indicating that the stress has an intrinsic character. According to Retajczyk and Sinha (4), stress values can be corrected for thermal stress by adding a value of approximately $+2 \times 10^7$ Pa for every 100° difference between the measuring temperature (room temperature) and the deposition temperature. This leads to the conclusion that under almost all conditions applied in this study stress has intrinsic characters. As discussed before, hydrogen desorption can be enhanced by increasing the deposition temperature or, at low RF frequencies, by ion bombardment. The influence of ion bombardment on the hydrogen desorption rate can be assumed to be independent of the deposition temperature. At low temperatures, ion bombardment determines the hydrogen content in the layer, while at high temperatures this is taken over by thermal desorption. At high temperatures, the stress has a tensile character which can be explained by a hydrogen desorption rate which is not fast compared to the rate at which gas phase formed radicals are inserted into Si-H or N-H bonds. This leads to a top layer with a relatively high hydrogen content. Due to the high temperatures, hydrogen desorption and cross-linking do not stop after the actual deposition step but continue for a while, which leads to a nitride layer which shrinks at the deposition temperature, giving the tensile stress behavior. Going to lower temperatures, the stress shifts from tensile to compressive. The compressive intrinsic stress behavior at low deposition temperature is somewhat difficult to explain. From literature, it is known that tensile silicon nitride layers become compressive when they are exposed to ion bombardment (16). This is explained by expansion of the layer due to implanted atoms and broken Si-N bonds, which leads to a disturbed short-range order of the Si-N structure. In plasma CVD at "low" operating frequencies, the growing layer is exposed to ion bombardment. As ion bombardment could take place after deposition of the silicon- or nitrogen-containing radicals, the layer expands at the deposition temperature, leading to a compressive stress. According to Fig. 6, the stress shifts from compressive to tensile with increasing RF frequencies. This shift coincides with a strong variation in density and hydrogen content. According to Bruce (10), at frequencies above roughly 4 MHz the ions become slow compared to the oscillating frequency, leading to a decrease in the ion bombarding energy and of the flux of ions to the electrodes: As discussed before, in absence of ion bombardment thermal processes determine the hydrogen content and the nitride layer shrinks at the deposition temperature. This leads to a tensile stress behavior at high frequencies. According to Fig. 4, the stress in plasma nitride layers decrease with total pressure. This can also be described by the presented model, as the extent of ion bombardment decreases with increasing total pressure, due to collisions in the dark space.

We will now comment briefly on the influence of the deposition parameters on the density, the Si/N ratio, and the Si-H/N-H ratio of the deposited layers. According to the figures, the density of the deposited layers decreases with increasing hydrogen content, provided the ammonia partial pressures are constant (Fig. 3-5). This can be explained by the effect of cross-linking and hydrogen desorption (Eq. [5]) on the structure of the deposited layer. The maximum density in Fig. 2 coincides with a Si/N ratio of 0.75. At high total pressures (or silane partial pressures) (Fig. 4), the density of the deposited layers decreases enormously, possibly due to gas phase reactions such as are given by Eq. [3]. Gas phase reactions generate particulates or haze.

According to Fig. 2, the Si/N ratio of the deposited plasma-nitride layer depends on the ammonia partial pressure. This can be ascribed to the higher dissociation energy of N_2 compared to that of NH_3 . At higher frequencies, the Si/N ratio is higher than at low RF frequencies (Fig. 5). This can be explained by differences in the nature of the chemical species arriving at the substrate, due to an influence of the RF frequency on the ionization and dissociation cross sections of the different gases (Eq. [6]),

Fig. 8. $\log [H]$ vs. $1/T$ using the experimental data given in Fig. 3 and the hydrogen content of a layer deposited at room temperature using almost the same conditions as those given in Fig. 3.

or it may be attributed to a contribution of dissociative adsorption of N_2^+ ions [$N_2^+ + e \rightarrow 2N(17)$] to the deposition of nitrogen atoms, notably at low frequencies. The influence of total pressure on the Si/N ratio (Fig. 4) can be explained by a reduction in ion energy with increasing total pressure (as discussed before). This leads to higher Si/N ratios at the lower ion energies (higher pressures).

According to Fig. 7, the Si/N ratio of the deposited layers determines, in a first approximation, the way in which hydrogen is bonded. At high Si/N ratios (Si-rich layers), almost all the hydrogen is bonded to silicon. At Si/N ratios below 0.75, most of the hydrogen is bonded to nitrogen.

Conclusions

The composition and density of plasma silicon-nitride layers can be adjusted within certain limits by variation of the deposition temperature, total pressure, gas phase composition, and RF frequency. A simplified model is proposed for the deposition kinetics of plasma silicon-nitride. It is concluded that the deposition rate is determined by the insertion of silicon and nitrogen containing compounds into Si-H and N-H bonds at the surface of the growing layer. The deposition rate is almost independent of total pressure and deposition temperature. After insertion of the formed radicals into Si-H or N-H bonds, hydrogen elimination takes place by cross-linking. It is concluded that the hydrogen-elimination step can be influenced by temperature and by ion bombardment.

Layers deposited at high temperatures ($>550^\circ\text{C}$) or at high frequencies (>4 MHz) show a tensile stress behavior. This is explained by a hydrogen desorption rate which is smaller than the rate-limiting step for deposition. After deposition of silicon and nitrogen containing radicals, hydrogen desorption continues for a while, leading to a layer which shrinks at the deposition temperature and consequently to a tensile stress behavior. Layers deposited at low temperatures ($<550^\circ\text{C}$) and at low frequencies (<4 MHz) show a compressive stress. Due to ion bombardment, atoms are implanted and bonds are broken, leading to a disturbed short-range order of the Si-N structure and to an expansion of the plasma nitride layer.

Electrical Properties, Structure, and Phase Morphology of Au-Ga Alloy Films Codeposited on GaAs Substrates

S. Leung, T. Yoshiie,¹ C. L. Bauer, and A. G. Milnes*

Center for the Joining of Materials, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

ABSTRACT

Electrical properties, structure, and phase morphology of gold-gallium alloy films codeposited on {100} substrates of gallium arsenide have been investigated by measurement of Schottky barrier height ϕ and breakdown voltage V_b as a function of film composition and annealing conditions and comparison with corresponding structure and phase morphology, as determined by x-ray diffraction and transmission electron microscopy. Both ϕ and V_b decrease with increasing composition of gallium in the codeposited films and with increasing severity of annealing conditions. These decreases are attributed to formation of gold-gallium phases, either directly through codeposition of alloy films or through annealing of pure gold films on substrates of gallium arsenide, and localized current or field concentrations due to nonplanar phase morphologies. General behavior of electrical properties is reported and interpreted in terms of the existing structure and phase morphology near the original alloy film/gallium arsenide interface.

Certain electrical properties of metal contacts to semiconductor devices, such as Schottky barrier height ϕ and reverse voltage breakdown V_b , are known to depend on composition, structure, and phase morphology near the original interface. This dependence can be demonstrated by subjecting the metal/semiconductor couple to mild thermal treatments. For example, heating a gold film de-

posited on {100} substrates of gallium arsenide to about 350°C results in release of arsenic and formation of certain new phases, including Au_3Ga_2 , Au_5Ga , and a hexagonal gold-gallium phase (1-6). Such change, in turn, reduces ϕ from approximately 0.85-0.50 eV (7) and V_b by as much as a factor of two depending on doping concentration, film thickness, annealing time and atmosphere, and details of specimen preparation (8).

In a recent investigation, Yoshiie *et al.* (9) have characterized evolution of structure and phase morphology of

* Electrochemical Society Active Member.

¹ Present address: Faculty of Engineering, Hokkaido University, Sapporo 060, Japan.

thin films of gold deposited on {100} and {111} substrates of gallium arsenide during annealing by transmission electron microscopy, incorporating a unique cross sectioning technique. The most evident structural changes are formation of elongated pyramidal pits, bounded by {111} planes of gallium arsenide and containing gold-gallium reaction products, and formation of a continuous layer of orthorhombic Au₂Ga near the original interface, accompanied by the release of arsenic. However, concomitant changes in electrical properties were not correlated with such evolution of structure and phase morphology. An earlier investigation, however, indicates that the Schottky barrier height (0.75 eV) remains constant for a eutectic gold-gallium alloy (85 weight percent [w/o] Au) up to an annealing temperature of 400°C (10). The purpose of this investigation is to modify the aforementioned system by codeposition of gold-gallium alloys on {100} substrates of gallium arsenide and to determine concomitant electrical properties, both in the as-deposited and annealed state. In this manner, a better appreciation of how various gold-gallium phases in contact with gallium arsenide affect electrical properties can be achieved.

The remainder of this article is divided into several sections: fabrication details are described in the next section, then experimental results are presented and analyzed in the "Microstructure and Phase Morphology" and "Discussion" sections, respectively, and, last, salient features of this investigation are summarized.

Experimental Procedures

Two types of {100} gallium arsenide substrates were used throughout the course of this investigation: (i) n-type wafers doped to about $5 \times 10^{16} \text{ cm}^{-3}$ and cut from the center of 10 cm diam boules grown in boron nitride crucibles under B₂O₃ (designated LEC), obtained from Westinghouse Electric Research and Development Center, and (ii) n-type wafers doped to about $5 \times 10^{17} \text{ cm}^{-3}$ cut from boules grown by the Bridgman technique (designated BM), obtained from Morgan Semiconductor. Pure (99.999 weight percent [w/o]) gold and gallium (99.999 w/o) were simultaneously coevaporated from separate sources in an ion-pump vacuum system at a pressure of about 100 μPa and deposited to a thickness of about 200 nm on three types of substrates: (i) either {100} LEC or BM substrates of gallium arsenide with a Au-Ge/Au ohmic contact already in place on the back side, (ii) a masked glass slide for eventual electrical resistivity measurements, and (iii) a glass slide coated with photoresist for eventual x-ray diffraction measurements. Prior to metal deposition, the polished wafers were cleaned with trichloroethylene, acetone, and ethyl alcohol, etched in H₂O₂-H₂SO₄-H₂O solution for 2 min, and then soaked in HCl-H₂O solution for 5 min. After rinsing in deionized water, the wafers were loaded into an ion pump vacuum system for film deposition. The deposition rates varied from 10 to about 50 nm/min and no significant effects were found that were attributed to changes within this range. The substrate temperatures were monitored during evaporation and did not exceed 320 K. Deposition was through a molybdenum mask in contact with the specimens that defined evaporated mesas of area 1.33 mm². Composition of the deposited films was determined by independent quartz crystal monitors, precalibrated by interference microscopy. For x-ray diffraction measurements, alloy films were first produced as described above, then removed as powder by scraping, and glued on an appropriate specimen holder. In this manner, sufficient intensity could be achieved to accurately index the resulting diffraction patterns. Certain other alloy thin films, deposited on {100} substrates of gallium arsenide, were subsequently annealed in a quartz tube furnace under flowing hydrogen at temperatures ranging from 150° to 350°C.

Forward current-voltage and current-temperature (Richardson) plots were determined with the aid of a Keithley 616 digital electrometer, and capacitance-voltage characteristics were determined with the aid of a 1 MHz

Boonton 72B digital capacitance bridge. X-ray diffraction data were obtained with a Rigaku D/MAX II powder x-ray diffraction system using a scintillation counter.

Specimens were prepared for examination by transmission electron microscopy, TEM, by bonding two gallium arsenide substrates with (preannealed) alloy films face to face with an epoxy resin, curing under moderate temperature and pressure, slicing perpendicular to the alloy films with a diamond saw, thinning by mechanical grinding to approximately 50 μm , and finally thinning further with a Gatan Model 600 ion miller, using a collimated beam of argon ions accelerated by a potential difference of 6 kV. The thinned region, perpendicular to the deposited alloy film, was then examined in a JEOL JEM 120CX electron microscope. Further details concerning specimen preparation for examination by TEM are presented elsewhere (5, 9).

Experimental Results

Details of various alloy thin films of gold and gallium, codeposited on {100} substrates of gallium arsenide, are presented in Table I, where compositions of the alloy films, film thickness, and phases identified by x-ray diffraction are presented for both (a) LEC and (b) BM gallium arsenide substrates. Typical results for phase identification by x-ray diffraction are presented in Fig. 1, wherein segments of x-ray diffractometer traces (intensity vs. twice the Bragg angle 2θ) are reproduced for alloy films containing (a) 0, (b) 42, and (c) 62 atom percent (a/o) gold. In Fig. 1a, only diffraction peaks corresponding to pure gold are present. As the composition of gallium is increased, however, small amounts of hexagonal β or Au₇Ga₂ are observed (≥ 4 a/o Ga), followed by Au₂Ga (cf. Fig. 1b) and AuGa₂ (cf. Fig. 1c). In general, these results demonstrate that, as the percent of gallium is increased, compounds containing higher percentages of gallium are formed during the codeposition process. Moreover, except for specimens containing 42 and 57 a/o Ga, the observed compounds agree with those expected from the equilibrium phase diagram (11).

Electrical properties and concomitant structure and phase morphology obtained from these alloy films are presented, sequentially, in the following sections.

Electrical properties.—Typical current density (J) vs. forward voltage bias (V) plots for selected specimens are presented in Fig. 2. These data can be compared with the expression

$$J = A^*T^2 \exp(-\phi/nkT) [\exp(qV/nkT) - 1]$$

where A^* is the effective Richardson constant, n is an ideality constant, and q , k , and T denote, respectively, the electron charge, Boltzmann's constant, and absolute temperature. In order to extract ϕ , however, A^* and n must be determined by varying J as a function of T at a sufficiently large (constant) value of V . These results are presented in Table II, along with values for the doping concentration N_d , obtained from capacitance-voltage measurements, for both as-deposited and annealed specimens.

Before annealing, values of n range between 1.01 and 1.10, reflecting acceptable cleanliness of the Au/GaAs interface (13). The values for N_d range between 3 and 8 \times

Table I. The gold-gallium films deposited, composition, thicknesses, and the phases identified by x-ray diffraction

Atomic percent of Ga in the film	Film thickness (nm)	Phases identified by x-ray diffraction

27	100	Au ₂ Ga ₂ , Au ₂ Ga
42	170	Au ₂ Ga
62	250	AuGa ₂
80	140	AuGa ₂ , Ga
90	270	AuGa ₂ , Ga

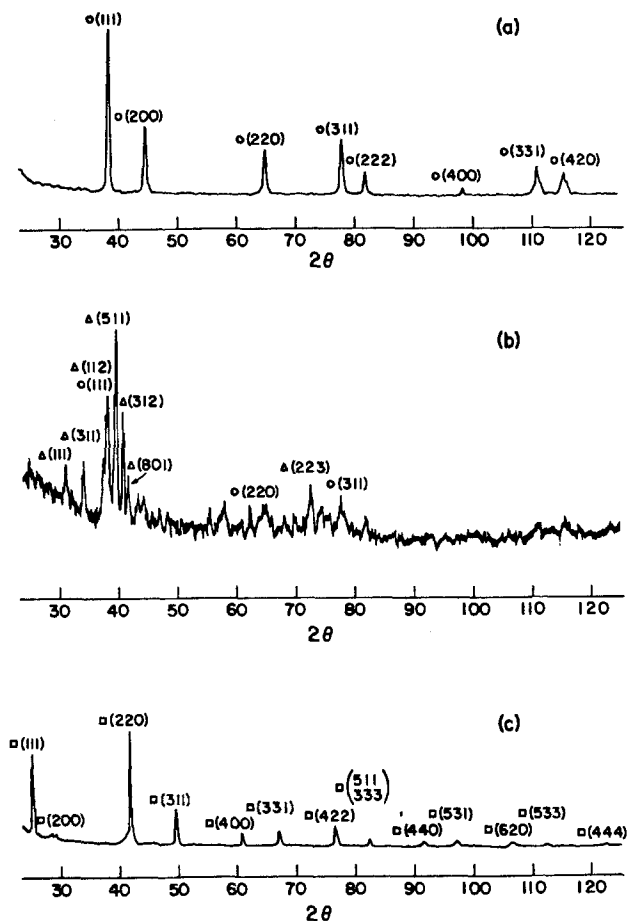

Fig. 1. X-ray powder diffraction patterns (intensity vs. $2 \times$ Bragg angle) for (a) Au, (b) Au-42 a/o Ga, and (c) Au-62 a/o Ga films (co)deposited on glass coated with photoresist. Major peaks due to diffraction from pure gold, (orthorhombic) Au_2Ga , and (Bravais lattice) AuGa_2 ore denoted by \circ , Δ , and \square , respectively.

10^{16} cm^{-3} for the LCE substrates and between 4 and $6 \times 10^{17} \text{ cm}^{-3}$ for the BM substrates used as determined by $1/C^2$ vs. V measurements. These values of N_d did not change significantly after annealing. This suggests that if doping changes were occurring in the first few micrometers of the wafer due to out-diffusion of gallium and arsenic or in-diffusion of gold, the effects were in the less than 10^{16} cm^{-3} range.

The effective Richardson constants A^* are considerably scattered in value, ranging from 2 to $100 \text{ A/cm}^2\text{K}^2$ without strong bias for either type of specimen. Such scatter is

^a Doping (average) of the LEC wafer was $0.47 \times 10^{17} \text{ cm}^{-3}$, and the A^* value measured (unheated) averaged $57 \text{ A cm}^{-2} \text{ K}^{-2}$.

^b For the BM wafer, the values were $4.7 \times 10^{17} \text{ cm}^{-3}$ and $47 \text{ A cm}^{-2} \text{ K}^{-2}$.

^c Indicates junction too conductive for measurements.

Fig. 2. Current density J vs. forward voltage bias V for various gold-gallium films deposited on {100} LEC ($0.47 \times 10^{17} \text{ cm}^{-3}$) substrates of gallium arsenide: (\circ) pure Au, (Δ) Au-13 a/o Ga, (\square) Au-47 a/o Ga, and on {100} BM substrates ($4.7 \times 10^{17} \text{ cm}^{-3}$) of gallium arsenide: (\bullet) Au-42 a/o Ga, and (\blacktriangle) Au-90 a/o Ga.

not uncommon in Schottky barrier studies (12) and reflects the limited accuracy of the measurement method and slight interface perfection problems. However, the A^* values fall within acceptable ranges, although the values tend to average somewhat larger than the theoretical value of $4.4 \text{ A/cm}^2\text{K}^2$ (12-14). After annealing, however, n increases and A^* decreases for alloy films containing less than 50 a/o Ga, whereas they remain approximately constant for alloy films containing more than 50 a/o Ga, even after annealing for 30 min at 350°C .

Schottky barrier heights obtained from forward current-voltage and current-temperature (Richardson) plots at constant forward voltage are reported in Table II, both before and after annealing for 30 min at 150° , 250° , and 350°C . These two methods of obtaining barrier heights gave very similar values (within 0.03 eV for most specimens) and the average of the two values is presented in Table II and termed ϕ_{bn} . As shown in Fig. 3, the values for the BM material are slightly smaller than for the LEC material and this is because the doping density of the Bridgman wafer is larger.

After annealing, the barrier height values ϕ_{bn} tend to decrease although this decrease is considerably more pronounced for films containing less than 50 a/o Ga and is particularly serious above 200°C for the Au films that were without Ga. The ideality factors, n , tend to remain at values of 1.03-1.08 until the barrier height has been seriously affected by the heat-treatment.

Values of Schottky barrier heights were also extracted from capacitance reverse voltage plots and termed ϕ_{bc} , and the voltage V_b was recorded at which the junction reverse current was 10^{-4} A (corresponding to a current density of 7.5 mA/cm^2). These values are presented in Table III. The barrier heights ϕ_{bc} from capacitance measurements tend to be lower by 0.06 - 0.09 eV than the ϕ_{bn} values determined by the other two methods. It is possible that the ϕ_{bc} values are being influenced by surface state (15) and/or deep level (16-18) impurity states. Some transient

Fig. 3. Schottky barrier height ϕ_{bn} for various gold-gallium films deposited on {100} gallium arsenide substrates as a function of gallium composition, where ϕ_{bn} is the average value from forward current-voltage plots and from activation energy plots for the LEC material ($0.47 \times 10^{17} \text{ cm}^{-3}$) and the BM material $4.7 \times 10^{17} \text{ cm}^{-3}$.

capacitance measurements DLTS, were made of metal-n-GaAs junctions that had been heated to temperatures of 150° and 250°C to see if the development of electron traps could be seen as a result of the gold interaction. In the upper half of the bandgap, we could see no significant change of point defect levels down to a concentration of mid 10^{14} cm^{-3} . More extensive studies of this kind, however, need to be made.

The most important variations to be observed from Table III are those for V_b . Before annealing, the values of V_b are in reasonable agreement with those that might be expected for the doping of $0.47 \times 10^{17} \text{ cm}^{-3}$ and $4.7 \times 10^{17} \text{ cm}^{-3}$. After heat-treatment at 250°C, the values of V_b exhibit dramatic decreases, and this is especially true for the specimens with film compositions that are low in Ga.

Microstructure and Phase Morphology

In order to compare electrical properties with microstructure and phase morphology near the alloy film/gallium arsenide interface, Au/GaAs specimens were prepared and subsequently annealed at various temperatures. Typical forward current-voltage characteristics are presented in Fig. 4 for (i) an unannealed Au/GaAs specimen, and similar specimens heated for 30 min at (ii) 200°, (iii) 275°, and (iv) 345°C. In general, ϕ_b decreases and n increases with increasing annealing temperature, suggesting a degradation of the Au/GaAs interface.

Similar specimens were annealed at various temperatures and subsequently prepared for examination by TEM. Typical results are presented in Fig. 5, wherein bright-field images of the Au/GaAs interface, perpendicular to the deposited gold film, following an anneal for 30 min at (a) ambient temperature, (b) 130°, (c) 200°, (d) 275°, (e) 345°, and (f) 400°C, are pictured. No discernible reaction is evident at ambient temperature (cf. Fig. 5a); however, after annealing for 30 min at 130°C, well defined (pyramidal) pits, bounded by {111} planes in gallium arsenide are clearly visible (5, 9). After annealing for 30 min at 200°C, a new continuous phase separating the gold film and gallium arsenide substrate, in addition to the aforementioned pyramidal pits, is visible. Upon annealing for 30 min at higher temperatures, the continuous phase first becomes more evident (cf. Fig. 5d and 5e) and then appears to become more uniform and to decrease in thickness (cf. Fig. 5f). For a specimen heated for 30 min at 275°C (cf. Fig. 5d), the phase positioned between the gold film (top dark layer) and the gallium arsenide substrate has been determined, from electron diffraction patterns and corresponding dark field images, to be the orthorhombic Au_3Ga intermetallic compound. Existing crystal structures were not determined at other temperatures; however, from previous investigations, it may be assumed that a hexagonal gold-gallium compound forms in the pyramidal pits on {111} faces of gallium arsenide and the orthorhombic gold-gallium phase exists at temperatures well below 275°C (5, 9).

Table III. Schottky barrier height ϕ_{bc} from capacitance measurements and breakdown voltage V_b (reverse voltage for 10^{-4} A) for Au-Ga films on {100} GaAs with annealing for 30 min at various temperatures

Atomic percent Ga	Unheated (eV)		Heated

Fig. 4. Variation of current density J with forward voltage bias V for gold films deposited on {100} LCE substrates of gallium arsenide and annealed for 30 min at (○) 20°, (Δ) 200°, (▽) 275°, and (□) 345°C. Corresponding values of ϕ_{bn} decrease from 0.95 (○) to 0.76 eV (▽) at 275°C; for higher annealing temperatures, the plots become too nonlinear to extract meaningful values of ϕ .

(e) 345°, and (f) 400°C, are pictured. No discernible reaction is evident at ambient temperature (cf. Fig. 5a); however, after annealing for 30 min at 130°C, well defined (pyramidal) pits, bounded by {111} planes in gallium arsenide are clearly visible (5, 9). After annealing for 30 min at 200°C, a new continuous phase separating the gold film and gallium arsenide substrate, in addition to the aforementioned pyramidal pits, is visible. Upon annealing for 30 min at higher temperatures, the continuous phase first becomes more evident (cf. Fig. 5d and 5e) and then appears to become more uniform and to decrease in thickness (cf. Fig. 5f). For a specimen heated for 30 min at 275°C (cf. Fig. 5d), the phase positioned between the gold film (top dark layer) and the gallium arsenide substrate has been determined, from electron diffraction patterns and corresponding dark field images, to be the orthorhombic Au_3Ga intermetallic compound. Existing crystal structures were not determined at other temperatures; however, from previous investigations, it may be assumed that a hexagonal gold-gallium compound forms in the pyramidal pits on {111} faces of gallium arsenide and the orthorhombic gold-gallium phase exists at temperatures well below 275°C (5, 9).

It must be emphasized that annealing and subsequent examination by TEM were performed immediately after deposition; when specimens are maintained at room temperature for approximately 6 months and then annealed, somewhat different results are obtained. Typical results are presented in Fig. 6, where bright-field images of specimens consisting of 300 nm of gold deposited on {100} substrates of gallium arsenide, that had been stored for 6 months at room temperature, and air ambient, and then annealed for 30 min at (a) 20, (b) 130, and (c) 300°C, are pictured. In addition to the fact that reaction products form at room temperatures, slight differences in the phase morphology may be noted after annealing at elevated temperatures, such as absence of well-defined pyramidal pits

Fig. 5. Bright-field image of the cross section of a gold film deposited on {100} LEC gallium arsenide substrates and subsequently annealed for 30 min at (a) room temperature, (b) 130°, (c) 200°, (d) 275°, (e) 345°, and (f) 400°C. The phase formed between gold and gallium arsenide at 275°C has been identified by a combination of electron-diffraction and dark-field images as orthorhombic Au_2Ga .

after annealing for 39 min at 300°C (cf. Fig. 6c). Possible relationships between electrical properties and such phase morphology are considered in the discussion that follows.

Discussion of Results

Values of various electrical parameters presented in Tables II and III seem to be relatively self-consistent. Slightly lower values of ϕ are obtained with LEC than with BM substrates. Such differences are almost certainly due to the factor of ten difference in doping. In general, values of ϕ decrease with increasing composition of gallium, although this decrease is more pronounced for low compositions (< 30 a/o Ga), which corresponds approximately to the phase Au_2Ga (33 w/o Ga). Since the value and decrease in value of ϕ_b corresponds closely to those obtained after annealing in both the present and previous investigations (7), it is likely that this decrease is due to formation of new phases, especially orthorhombic Au_2Ga , at the original alloy film/gallium arsenide interface.

Composition of alloy films produced by codeposition of gold and gallium on {100} substrates of gallium arsenide and measured by independent calibrated quartz crystal monitors is self-consistent with electrical resistivity measurements. Although the complete dependence of electrical resistivity ρ on composition is unknown, values range from $8 \mu\Omega \text{ cm}$ for pure gold to a maximum of $25 \mu\Omega \text{ cm}$ for an alloy film consisting of 50 a/o Ga, which is consistent with reported bulk values of 2.4 and $40 \mu\Omega \text{ cm}$ for gold and gallium, respectively (19), since additional electron scattering (resistance) is expected for their films. Likewise, compounds identified in unannealed alloy film by x-ray diffraction correspond well with the most recent gold-gallium phase diagram. Of course, generally, any alloy film is expected to consist of a mixture of two separate phases in equilibrium with one another. These results are also consistent with results of Simc and

Fig. 6. Bright-field images of the cross section of a gold film deposited on {100} LEC gallium arsenide substrates and subsequently (inadvertently) annealed for approximately 6 months at room temperature and then for 30 min at (a) room temperature, (b) 130°, and (c) 300°C. A ~ 100 nm layer of reaction product is clearly evident, even without annealing above room temperature.

Marinkovic, who investigated interdiffusion between films of gold and gallium deposited on glass (19).

Results presented in Fig. 1 and Table I demonstrate clearly that several gold-gallium compounds are formed when gold and gallium are codeposited on a glass substrate coated with photoresist. Assuming that the compounds formed on gallium arsenide are equivalent to those formed on photoresist, electrical properties of the probable phases formed during codeposition can be compared with those of the phases produced by annealing. In this manner, the decrease of ϕ_b in Fig. 3 may be attributed to the presence of certain gold-gallium compounds. Such decreases, however, cannot be attributed to the presence of a specific phase because (i) generally a phase mixture is present and (ii) the distribution of phases at the alloy film/gallium arsenide interface is not uniform (cf. Fig. 5 and 6). Therefore, a weight-average value of ϕ_b for several dissimilar contacts should be used. Tu *et al.* (20, 21) have shown that, under certain conditions, it is possible to determine respective values of ϕ_b and contact area for each species. In the present investigation, however, the structures are not clearly enough defined to apply this procedure, although it does appear that, in certain cases, a continuous layer of Au_2Ga separates the metallic contact and the gallium arsenide substrate. In any event, it may be surmised that ϕ_b is reduced when phases such as Au_2Ga , Au_2Ga , and AuGa_2 are in contact with gallium arsenide in-

stead of pure gold. Annealing a pure gold/gallium arsenide contact promotes formation of these same phases, and thus concomitant reductions in ϕ_b are comparable to those of as-deposited phases.

Over and above the intrinsic interest in relationships between structure and electrical properties, evolution of structure and phase morphology at the metal/gallium arsenide interface is related to a wealth of kinetic reactions. Of special interest is the formation of pyramidal pits bonded by {111} planes in gallium arsenide and corresponding orientation relationships, as reported by Yoshiie *et al.* (5, 9). Values of V_b are especially sensitive to formation and shape of these pits, because the electric field is concentrated by the curvature of the pit apex r . Assuming a value of about 20 nm for the radius, r , it can be shown that V_b is likely to be reduced to about 40% of its original value (22). Slight differences in reaction rate between previous results of Yoshiie *et al.* (5, 9) and the present investigation stem mainly from differences in film thickness, which controls the rate of release of arsenic and, therefore, the availability of gallium to react with gold.

Surprisingly, the reactions reported herein can easily be detected after (inadvertent) annealing for about 6 months at room temperature, as clearly illustrated in Fig. 6a. This result implies mean diffusion lengths of about 100 nm and a diffusion coefficient of about 10^{-17} cm² s⁻¹. If the Au diffusion line for the range 1200°-850°C given by Kendal (23) is extrapolated (unwisely) to room temperature, this order of magnitude of diffusion coefficients might be expected. However, other high temperature data (24, 25), when extrapolated, suggest much lower diffusion coefficients, and so detailed studies of diffusion of Au in the 600°-100°C range seem desirable.

Upon annealing the aged specimens for 30 min at 130°C, pyramidal pits are formed, whereas annealing for 30 min at 300°C produces only an increasingly thick layer of reaction product. Further investigations are in progress to determine the identity of these phases.

Summary

Electrical properties and phase morphology of gold-gallium films deposited on {100} substrates of gallium arsenide have been investigated by measurement of Schottky barrier height and reverse voltage rating as a function of film composition and annealing conditions and compared with corresponding phase morphology. Either codeposition of alloy films or annealing of pure gold on gallium arsenide promotes formation of various gold-gallium compounds, the most prominent being Au₂Ga, and pyramidal pits bounded by {111} planes of gallium arsenide. Values of ϕ and V_b are reduced by the presence of Au₂Ga and, especially, by the voltage concentration at the tip of the pyramidal pits. The rate of formation of such

microstructure and phase morphology depends on deposition and annealing conditions and, therefore, affects the degradation of electrical properties and concomitant reliability of actual devices.

A New Method to Supply Solute Elements into Growth Solutions

Demonstration by Liquid-Phase Epitaxial Growth of $\text{In}_{1-x}\text{Ga}_x\text{As}$

Kazuo Nakajima and Susumu Yamazaki

Fujitsu Laboratories Limited, Atsugi Laboratories, 1677 Ono, Atsugi, 243-01 Japan

ABSTRACT

A controllable method to supply solute elements into growth solutions was developed by using a source current-controlled (SCC) method. A dc electric current was passed through a binary semiconductor compound used as the source material for solute elements. It was found that the source compound could be dissolved into even a saturated solution due to Peltier heating and Joule heating at the interface between the source compound and the solution, and that the composition of growing crystals could be controlled by the electric current passed through the source compound. The SCC method was demonstrated by the liquid-phase epitaxial growth of $\text{In}_{1-x}\text{Ga}_x\text{As}$ on InP, GaAs and InAs were used as source compounds.

Good quality epitaxial layers such as $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ and $\text{In}_{1-x}\text{Ga}_x\text{As}_{1-y}\text{P}_y$ compounds must be lattice-matched to substrates. If bulk single crystals of the ternary or quaternary compounds were available, epitaxial layers with various lattice constants could be freely grown on bulk single crystals used as substrates, and available crystals for device fabrication would remarkably increase. $\text{In}_{1-x}\text{Ga}_x\text{As}$ (1, 2), $\text{InAs}_r\text{P}_{1-r}$ (3, 4), $\text{In}_{1-x}\text{Ga}_x\text{Sb}$ (5), $\text{GaAs}_r\text{P}_{1-r}$ (6), and $\text{In}_{1-x}\text{Ga}_x\text{As}_{1-y}\text{P}_y$ (7) bulk single crystals were prepared by liquid-encapsulated Czochralski and gradient freeze methods. However, the largest problem to prepare homogeneous bulk crystals is compositional variation during the growth due to depletion of solute elements. Similarly, it is difficult to grow thick epitaxial layers without compositional gradients by liquid-phase epitaxy (LPE) because solute elements in a finite solution are depleted during the growth.

The problem of depletion can be solved only by developing controllable methods to supply solute elements during growth. Recently, Nakajima *et al.* (8) demonstrated a controllable method to supply solute elements into a growth solution. In their work, a dc electric current was passed through a binary semiconductor compound used as the source material of the solute elements. The source compound was dissolved into the saturated growth solution because of Peltier heating and Joule heating at the interface between the source compound and the growth solution. Thus, the source compound played a dual role as the source material for solute elements and the self-heater in such a source current-controlled (SCC) method. However, their experiments were preliminary and fairly rough, and detailed experimental results on the SCC method have not been reported.

In this work, the SCC method was applied to the LPE growth of $\text{In}_{1-x}\text{Ga}_x\text{As}$ on InP substrates, and it was studied in detail to determine if the composition of LPE layers could be controlled by the SCC method. The lattice constant and wavelength of $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers grown from solutions in which solute elements were supplied by the electric current were measured to determine how much the composition of the LPE layers could be changed by the electric current passed through GaAs or InAs source compounds. In order to determine if enough solute elements to adjust the compositional variation in LPE layers could be supplied into growth solutions by the SCC method, the compositional variation in the thick LPE layers was studied.

Experimental Procedure and Results

Apparatus used in this work.—Figure 1 shows a schematic drawing of the parts of the boat used in this work. The boat consists of three parts, 1, 2, and 3. Part 1 is a carbon (C) boat slider with a boron nitride (BN) block as insulation. The source compound is covered by this BN block. A negative electrode (–) made of stainless steel is screwed into the carbon boat slider. Part 2 is a boron nitride (BN) slider with a cut in which a growth solution is

placed. Part 3 is a carbon (C) boat holder with a boron nitride (BN) plate and a positive electrode (+) made of stainless steel. The substrate is set in a depression in this boat holder, as shown in Fig. 1. These parts, 1, 2, and 3, were assembled into a boat, as shown in Fig. 2. Cross sections of this boat are shown in Fig. 3. When solute elements are supplied to the growth solution, the source compound and the growth solution are arranged as shown in Fig. 3-1. One side of the source compound is in contact with the growth solution, and the opposite side touches the carbon boat slider through the medium of In melt. The other four faces of the plate are covered with boron nitride (BN). The growth solution is surrounded by boron nitride. The bottom is in contact with the carbon boat holder. A dc electric current is passed through the carbon boat holder, the growth solution, the source compound, and the carbon boat slider in that order. The source compound is dissolved in the saturated growth solution because of Peltier heating and Joule heating at the interface between the source compound and the solution. When an epitaxial layer is grown, the substrate and the growth solution are arranged as shown in Fig. 3-2. The growth solution is removed from the source compound and brought over the substrate. The epitaxial layer is grown from the solution whose composition is changed by the supply of solute elements from the dissolved source compound.

LPE growth conditions for lattice matching.—The LPE growth conditions for obtaining lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ layers was determined prior to performing the SCC method. $\text{In}_{1-x}\text{Ga}_x\text{As}$ ternary layers were grown from solutions with compositions on the liquidus isotherms at 790°C (9, 10). (111)A-oriented InP single crystals were used as substrates. No supersaturated solutions were used in the growth. $\text{In}_{1-x}\text{Ga}_x\text{As}$ layers were grown at a constant cooling rate of 0.5°C/min by the ramp cooling technique. The lattice constants of $\text{In}_{1-x}\text{Ga}_x\text{As}$ were measured by the double-crystal x-ray diffraction technique. The precise diffraction angle of the ternary layers were determined from the (333) $\text{Cu-K}\alpha_1$ reflection by using the

Fig. 1. A schematic drawing of the parts of the boat used in this work

Fig. 2. A schematic drawing of the boat used in this work

Fig. 3. Cross sections of the boat when solute elements are supplied (1) and when an LPE layer is grown (2).

substrate reflection as an internal standard (11). The lattice constant is displayed as a function of X_{Ga}^1 in Fig. 4, where X_i^1 represents the atomic fraction of an element i in the solution. The dashed line represents the lattice constant of InP. They are lattice constants of the epitaxial lattice perpendicular to the wafer surface. The solution composition for growing lattice-matched layers on InP (111)A substrates can be determined from the results.

LPE growth of thin layers using the SCC method.—In order to determine how much the composition of $In_{1-x}Ga_xAs$ LPE layers can be changed by the electric current passed through GaAs or InAs source compounds, the lattice constant and wavelength of $In_{1-x}Ga_xAs$ LPE layers grown from solutions in which solute elements, Ga, In, and As, were supplied by the electric current were measured. The apparatus employed in this experiment is

shown in Fig. 1, 2, and 3. The size of the InP substrate was $10 \times 9 \text{ mm}^2$. The thickness and weight of the solution were about 3 mm and 2.7g, respectively. The thickness of GaAs or InAs source plate was 2 mm. The area of the source plate in contact with the solution was 0.2 cm^2 , and the depth of the plate was 8 mm. The initial composition of the In-Ga-As ternary solution was $X_{Ga}^1 = 0.040$, $X_{As}^1 = 0.170$, and $X_{In}^1 = 0.790$, which was derived from Fig. 4. Pd-purified H_2 flowed through the fused-silica tube set in which the boat with the InP (111)A substrate, the GaAs or InAs source plate, and the solution were set.

Prior to passing the electric current through the source plate, the solution without contact with the source plate was rapidly heated to 20°C above the saturated temperature of 790°C and held there for about 30 min. Then, the solution was cooled to 789°C at a constant cooling rate of $1^\circ\text{C}/\text{min}$, and the solution was brought in contact with the source plate at 789°C . The electric current was passed from the solution to the source plate of GaAs or InAs for 1 min. The temperature of the solution increased by $1^\circ\text{--}5^\circ\text{C}$ due to Peltier heating and Joule heating at the interface between the source plate and the solution. When the temperature was cooled to 789°C again, the solution was brought over the InP (111)A substrate and the epitaxial growth was performed for 10s. The thickness of the epitaxial layers grown by this process was $0.7\text{--}0.9 \mu\text{m}$.

The lattice constant and wavelength of the epitaxial layers were measured to determine how much the composition of the LPE layers could be changed by the electric current passed through GaAs or InAs source compounds. Figure 5 shows the lattice constant of the $In_{1-x}Ga_xAs$ epitaxial layers as a function of the density of the electric current passed through the source compound, i_s (A/cm^2). The lattice constant of the epitaxial layer grown only by the conventional ramp cooling method, that is to say, $i_s = 0 \text{ A}/\text{cm}^2$, is 5.882\AA . When GaAs is used as a source compound, the lattice constant of the LPE layers decreases as i_s increases due to the supply of solute Ga and As from GaAs dissolved into the solutions. When InAs is used as a source compound, the lattice constant of the layers increases as i_s increases due to the supply of solute In and As from InAs dissolved into the solutions. The wavelength of the epitaxial layers was determined by the photoluminescence (PL) measurements (12). Figure 6 shows the PL wavelength of the epitaxial layers as a function of i_s . The wavelength is $1.672 \mu\text{m}$ when $i_s = 0 \text{ A}/\text{cm}^2$. When GaAs is used as a source compound, the wavelength decreases as i_s increases. When InAs is used as a source compound, the wavelength increases as i_s increases. These results show that the composition of the LPE layers can be sufficiently changed by the electric current

Fig. 5. The lattice constant of (111)A $In_{1-x}Ga_xAs$ LPE layers as a function of the electric current passed through the source compound, i_s (A/cm^2).

Fig. 6. The PL wavelength of (111)A In_{1-x}Ga_xAs LPE layers as a function of the electric current passed through the source compound, *i_s* (A/cm²).

passed through GaAs or InAs source compounds because enough solute Ga, In, and As can be supplied from the dissolved source compounds into the growth solutions.

In order to determine how much the composition of Ga in the ternary solution, X_{Ga}^1 , could be changed by the electric current passed through GaAs source compounds, the amount of varied X_{Ga}^1 was estimated from the experimental results shown in Fig. 4 and 5. Figure 7 shows the estimated X_{Ga}^1 at 790°C as a function of i_s . X_{Ga}^1 varies from 0.0362 to 0.0465 as i_s increases from 0 to 176 A/cm². As shown in Fig. 7, the solution composition can be controlled by the electric current. The amount of GaAs dissolved into the growth solutions was estimated by using Fig. 7. Figure 8 shows the amount of GaAs (mg) required to make 1g of an In-Ga-As ternary solution with X_{Ga}^1 shown in Fig. 7, as a function of i_s . As shown in Fig. 8, an amount of GaAs (mg) required to make 1g of the ternary solution with $X_{Ga}^1 = 0.040$, $X_{As}^1 = 0.170$, and $X_{In}^1 = 0.790$ is 24.3 mg when $i_s = 0$ A/cm². Therefore, the amount of GaAs dissolved into 1g weight of the solution by the electric current can be determined by subtracting 24.3 mg from the amount shown in Fig. 8, and it increases from 0 to 7.2 mg as i_s increases from 0 to 176 A/cm².

It was studied how the solution composition depended on the time while the electric current was being passed

Fig. 7. Estimated amount of varied X_{Ga}^1 at 790°C as a function of the electric current passed through the source compounds, i_s (A/cm²).

Fig. 8. Amount of GaAs (mg) required to make 1g weight of an In-Ga-As ternary solution with X_{Ga}^1 shown in Fig. 7, as a function of the electric current passed through the source compound, i_s (A/cm²).

through GaAs sources. The electric current of 88 A/cm² was passed through GaAs sources at 789°C. The epitaxial growth was performed by using the same procedure mentioned above. The epitaxial layers were grown for 10s at 789°C from the solutions in which solute Ga and As had been supplied. Figure 9 shows the lattice constant of the epitaxial layers as a function of the time (min) passing the electric current through GaAs sources. The thickness of the layers was 0.5-0.9 μm. The lattice constant varies greatly for the initial 2 min, and it varies gradually after that. The results mean that GaAs sources dissolve largely into the growth solutions for the initial 2 min because the temperature of the solution near the interface between the sources and the solutions becomes rapidly high. The results also imply that, after 2 min, GaAs sources dissolve gradually because the temperature of the solution increases slightly due to scattering of heat. Figure 10 shows the PL wavelength of the epitaxial layers as a function of the time (min) passing the electric current through GaAs sources. The wavelength varies greatly for the initial 2 min, and it varies gradually after that. As shown in Fig. 9 and 10, the solution composition varies most largely for the initial 1 min after passing the electric current.

LPE growth of thick layers using the SCC method.—In order to determine if enough solute elements to adjust the compositional variation in the LPE layers could be supplied into growth solutions by the SCC method, the compositional variation in the thick LPE layers was studied. The same apparatus as shown in Fig. 1, 2, and 3 was used. Prior to the growth, the In-Ga-As solution without contact with the source plate was rapidly heated to 20°C above the saturated temperature of 790°C and held there for about 30 min. Then, the solution was cooled to 789°C at a constant cooling rate of 1°C/min, and the solution was brought over the InP (111)A substrate. The ramp cooling method was used to grow $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers from 789° to 760°C. The electric current was passed through the GaAs source plate after interrupting the LPE growth by removing the solution from the InP substrate and bringing the solution in contact with the source plate. The epitaxial growth was allowed again by removing the solution from the source plate and bringing it over the substrate.

Electron probe microanalysis (EPMA), employing energy dispersive x-ray detection, was used to determine the intensities of the Ga-K $_{\alpha}$ line from the sample and from the GaP standard. An electron beam energy of 25 keV

Fig. 11. Composition variation of Ga, x , in (111)A $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers as a function of the distance, d (μm), from the interface between the layers and the InP substrates. Open circles show the composition of the LPE layer grown only by the ramp cooling. Closed circles show the composition of the LPE layer grown from the solution in which solute Ga and As were supplied by the electric current of 88 A/cm 2 for 2 min.

was used. The measured intensities were converted to concentrations by performing the atomic number, absorption, and fluorescence corrections.

Figure 11 shows how the composition of Ga, x , in $\text{In}_{1-x}\text{Ga}_x\text{As}$ epitaxial layers varies with the distance, d (μm), from the interface between the layers and the InP substrates. The open circles show the composition of the epitaxial layer grown by only the ramp cooling. The composition varies from $x = 0.45$ at the interface to $x = 0.35$ at the surface due to the depletion of Ga in the solution. The solid dots show the composition of the epitaxial layer grown from the solution in which solute Ga and As were supplied by the electric current passed through the GaAs source plate. This epitaxial layer was grown by the ramp cooling method from 789° to 760°C at a constant cooling rate of 1°C/min. At 785°C, the epitaxial growth was interrupted by removing the solution from the substrate and bringing it in contact with the GaAs source plate. The electric current of 88 A/cm 2 was passed through the source plate for 2 min in order to dissolve the GaAs source. Then, the epitaxial growth was allowed again by bringing the solution over the substrate. As shown in Fig. 11, enough solute Ga and As to adjust the compositional gradient can be supplied into the solution by the SCC method. Figure 12 shows the composition of Ga, x , in $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers as a function of the distance, d (μm), from the interface between the layers and the InP substrates. The epitaxial layer was grown by the ramp cooling method from 789° to 760°C at a constant cooling rate of 1°C/min. The epitaxial growth was interrupted twice at 780° and 770°C. The electric current of 134 A/cm 2 was passed through the GaAs source plate for 2 min at 780°C and for 3 min at 770°C to supply solute Ga and As into the solution. Therefore, two humps appear on the curve of the composition variation, as shown in Fig. 12. The solid line shows the composition variation of the LPE layer grown only by the ramp cooling, and the broken line shows that of the LPE layer grown by using the SCC method, which were derived from Fig. 11.

Figures 13 and 14 show the composition of Ga, x , in $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers as a function of the distance, d (μm). These LPE layers were grown by the ramp cooling at 1°C/min from 789° to 730°C. The open circles show the compositions of the LPE layer grown by only the ramp cooling. The composition varies from $x = 0.45$ at the interface to $x = 0.29$ at the surface. The solid dots show the composition of LPE layers grown from the solutions in

Fig. 12. Composition variation of Ga, x , in (111)A $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers as a function of the distance, d (μm), from the interface between the layers and the InP substrates. Closed circles show the composition of the LPE layer grown from the solution in which solute Ga and As were supplied by the electric current of 134 A/cm 2 for 2 min at 780°C and for 3 min at 770°C. The solid line shows the composition variation only by the ramp cooling. The broken line represents the composition variation shown in Fig. 11.

Fig. 13. Composition variation of Ga, x , in (111)A $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers as a function of the distance, d (μm), from the interface between the layers and the substrates. Open circles show the composition of the LPE layer grown only by the ramp cooling. Closed circles show the composition of the LPE layer grown from the solution in which solute Ga and As were supplied by the electric current of 134 A/cm^2 for 3 min at 760°C .

which solute Ga and As were supplied by the electric current passed through the GaAs source plate. For the LPE layer shown in Fig. 13, the LPE growth was interrupted at 760°C and the electric current of 134 A/cm^2 was passed through the GaAs source plate for 3 min. For the LPE layer shown in Fig. 14, the LPE growth was interrupted at 740°C and the electric current of 134 A/cm^2 was passed for 3 min. As shown in Fig. 13 and 14, enough solute Ga and As to adjust the compositional gradient can be supplied into the solution by the SCC method. The peak value of the curve shown in Fig. 13 is $x = 0.48$, and the value is larger than the value at $d = 0 \mu\text{m}$, $x = 0.45$. That is to say, the amount of supplied solute Ga into the solution by passing the electric current of 134 A/cm^2 for 3 min is larger than the amount of depleted solute Ga in the solution during the growth from 789° to 760°C . The curve shown in Fig. 14 is flatter than that in Fig. 13. This means that the amount of supplied solute Ga is almost equal to that of depleted Ga during the growth from 789° to 740°C . Although thick epitaxial layers without compositional gradients were not obtained in this work, these results

Fig. 14. Composition variation of Ga, x , in (111)A $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers as a function of the distance, d (μm), from the interface between the layers and the InP substrates. Open circles show the composition of the LPE layer grown only by the ramp cooling. Closed circles show the composition of the LPE layer grown from the solution in which solute Ga and As were supplied by the electric current of 134 A/cm^2 for 3 min at 740°C .

imply that thick LPE layers without compositional gradients can be obtained by controlling the electric current in proportion to the depletion of solute Ga in the solution during the growth.

Figures 15 and 16 show the cross section and surface of the $\text{In}_{1-x}\text{Ga}_x\text{As}$ epitaxial layer grown by the SCC method. The thickness of the layer is $79 \mu\text{m}$. As shown in Fig. 16, this epitaxial layer did not have a mirror-like surface and had hillocks, but cracks were not observed.

Discussion

These are preliminary results of the SCC method. Nevertheless, they show that enough solute elements to vary the composition of LPE layers can be supplied into the solutions by passing the electric current through the source compounds. Therefore, there is a possibility of the preparation of homogeneous multicomponent thick LPE layers by applying computer control of electric current during the growth to this method. There is also a possibility of the preparation of homogeneous multicomponent bulk crystals by applying the computer-controlled SCC method to the crystal pulling system.

The magnitude of Peltier heating and Joule heating in these experiments was estimated. The magnitude of the heat generated by Peltier heating, P (W/cm^2), is given (13) by

$$P = \pi_p J \quad [1]$$

where π_p (V) is the Peltier coefficient, and J (A/cm^2) is the density of the electric current. π_p of n-type GaAs is about 0.2V (14) near 800°C . The magnitude of the heat generated by Joule heating, Q (W/cm^2), is given by

$$Q = \rho J^2 l \quad [2]$$

where ρ ($\Omega\text{-cm}$) is the resistivity of the source plate and l (cm) is the depth of the source plate. ρ of Si-doped GaAs used in this work is $0.002 \Omega\text{-cm}$. l of the GaAs source plate is 0.8 cm . The area of the GaAs source plate in contact

Fig. 15. The cross section of the $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layer grown by the SCC method.

Fig. 17. Estimated Peltier heating value, P , and Joule heating value, Q , generated in the GaAs source plate as a function of the density of the electric current, J (A/cm^2).

with the solution is 0.2 cm^2 . The Peltier heating value, P , and the Joule heating value, Q , were estimated by using Eq. [1] and [2]. The estimated result is shown in Fig. 17. Figure 17 shows the total heating value per 1s as a function of J (A/cm^2). When J is smaller than 126 A/cm^2 , the Peltier heating value, P , is larger than the Joule heating value, Q . When J is larger than 126 A/cm^2 , Q is larger than P . The total heating value of P and Q at $J = 100 \text{ A/cm}^2$ is about 1.7 cal/s . In order to make P larger than Q , it is necessary to use a source plate with small ρ ($\Omega\text{-cm}$) and l (cm). In either case, enough amount of heat to dissolve a source plate into a solution can be generated by enlarging the density of the electric current, J (A/cm^2), and solute elements can be supplied into the solution in proportion to J .

Conclusions

The principle of the SCC method has been confirmed by the LPE growth of $\text{In}_{1-x}\text{Ga}_x\text{As}$ on InP . The electric current passed through the source compound (GaAs or InAs) can heat the compound due to Peltier heating and Joule heating at the interface between the compound and the solution. The composition of the solution can be changed by the electric current passed through the source compound because solute elements are supplied

from the source compound into the solution due to Peltier heating and Joule heating. The lattice constant and wavelength of $\text{In}_{1-x}\text{Ga}_x\text{As}$ LPE layers grown from solutions in which solute elements are supplied can be changed by the electric current. It was confirmed by studying the compositional variation of the thick LPE layers that enough solute elements to adjust the compositional variation in the LPE layers could be supplied into growth solutions by the SCC method.

A Silicon Containing Positive Photoresist (SIPR) for a Bilayer Resist System

Y. Saotome, H. Gokan, K. Saigo, M. Suzuki, and Y. Ohnishi

NEC Corporation, Fundamental Research Laboratories and Microelectronics Research Laboratories, Miyazaki 4-chome, Miyamae-ku, Kawasaki 213, Japan

ABSTRACT

A new silicon containing positive photoresist (SIPR), which has excellent durability against oxygen dry etching, was prepared and evaluated as the thin top, or resolution layer, in a bilayer resist system. SIPR, a partly trimethylsilylmethylated resorcinol-formaldehyde resin mixed with a naphthoquinonediazide, was thinly coated onto a thick layer of polyimide resin on a silicon wafer. After exposure and development, positive patterns, including $0.7 \mu\text{m}$ lines, were obtained in this thin top layer. Those patterns were transferred into the bottom layer of polyimide either by reactive oxygen ion etching ($\text{O}_2\text{-RIE}$) or oxygen ion beam etching ($\text{O}_2\text{-IBE}$) with good accuracy. No residues were observed on wafers after the transfer.

The movement of semiconductor industry toward greater integration has imposed severe requirements on photoresists. These materials have to possess not only many indispensable properties, such as film formability, adhesion without striations, and masking functions for a

wide variety of processing conditions, but also the ability to produce submicron relief images over topography.

The use of trilayer resist techniques for the production of submicron patterns was suggested by Moran and Maydan (1) to meet the above requirements, but the fabrica-

tion process is much more complex than that of the usual single-layer resist system. In order to simplify the trilayer system, a bilayer process using E-beam exposure and oxygen plasma etching was proposed by Hatzakis *et al.* (2). They indicated that the imaging (top) layer and the etch mask (middle) layer in the trilayer system can be combined into a single layer by using E-beam-sensitive poly(vinylmethylsiloxane).

We have also developed an E-beam and deep UV resist, which is a copolymer of trimethylsilylstyrene and chloromethylstyrene (3). A related copolymer of trimethylsilylstyrene and chlorostyrene (4) was reported by MacDonald *et al.* These materials showed that silicon containing polymers without siloxane linkages are also resistant to oxygen plasmas, and can be used as a top imaging layer in a bilayer resist system.

Several kinds of silicon containing resists have been reported (5-8), but there appeared only two candidates which are suitable for use in near UV region: our negative resist, TAS (7), and the positive resist containing m-trimethylsilylphenol reported by Wilkins *et al.* (8).

In this paper, a newly developed silicon containing positive photoresist (SIPR) and its application as a bilayer system is described.

Experimental

Base resin preparation.—3-Trimethylsilylmethoxyphenol (1) was prepared by the following procedure. To an ethanol (40 ml) solution of sodium ethoxide (0.1 mol) was added resorcinol (11.0g, 0.1 mol). Then, trimethylsilylchloromethane (12.3g, 0.1 mol) was added dropwise at reflux with stirring. After continuous refluxing for 48h, the solution was acidified with concentrated hydrochloric acid, filtered, evaporated, extracted with chloroform, and washed several times with water. Subsequent vacuum distillation affords pure 1 (12.0g, 61%), bp 86°C at 26 Pa, ¹H NMR (CDCl₃); δ 0.2 (s, 9H, SiCH₃), 3.5 (s, 2H, CH₂), 5.5 (br, 1H, OH), 6.2-7.3 (m, 4H, C₆H₄).

2-Methyl-3-trimethylsilylmethoxyphenol (2) and 3-(3-trimethylsilylpropoxy) phenol (3) were prepared similarly. 2: yield 65%, bp 102°-104°C at 93 Pa, ¹H NMR (CDCl₃); δ 0.1 (s, 9H, SiCH₃), 2.1 (s, 3H, CH₃), 3.5 (s, 2H, CH₂), 4.9 (s, 1H, OH), 6.2-7.1 (m, 3H, C₆H₃). 3: yield 49%, bp 115°-117°C at 13 Pa, ¹H NMR (CDCl₃); δ 0.1 (s, 9H, SiCH₃), 0.4-0.8 (m, 2H, SiCH₂), 1.5-2.1 (m, 2H, CH₂), 3.9 (t, 2H, OCH₂), 5.2 (s, 1H, OH), 6.3-7.1 (m, 4H, C₆H₄).

Subsequent addition condensation of the prepared phenols 2-methylresorcinol and formaldehyde was performed in ethanol. A typical procedure is as follows: to an ethanol (20 ml) solution of 1 (5.0g, 26 mmol), 2-methylresorcinol (2.1g, 17 mmol) and 35% formalin (3.7g, 43 mmol) was added ten drops of concentrated hydrochloric acid. The mixture was refluxed with stirring for 6h. The resin was obtained quantitatively after reprecipitation with 500 ml of water, followed by vacuum drying at 80°C for 10h.

Wafer processing.—The bottom organic layer used in this study was polyimide (PI-2555, du Pont). PI-2555 was spun on silicon wafers and cured at 350°C for 1h, to yield 1.3 μm thick films. The top layer, SIPR, consisting of 10 weight percent (w/o) of the prepared base resin, 3 (w/o) of p-tolyl 1,2-naphthoquinone-2-diazide-5-sulfonate, and 87 w/o of 2-ethoxyethyl acetate, was spin-coated onto the polyimide layer, to produce 0.29 μm thick films after baking at 80°C for 30 min. Imaging was conducted with a Kasper 2001 contact printer, and development was carried out with aqueous sodium hydroxide solutions. For the image transfer into the bottom layer of polyimide, a parallel-plate reactor with a quartz etch table (DEM-451, Anelva) operating at 13.56 MHz at 1.6 Pa oxygen pressure, or an oxygen ion beam etching system with a Kaufman ion source was used. When O₂-RIE transfer was used, silicon wafers were immersed in buffered hydrofluoric acid after the transfer to remove redeposited materials from the quartz table.

Measurement technique.—¹H NMR spectra were obtained with a JEOL JNM-PMX60SI nuclear magnetic spectrometer. Gel permeation chromatograms of the res-

ins were recorded on LC-1 equipped with a polystyrene gel (Shimadzu) column. Initial resist thicknesses after baking, and residual thicknesses after development or etching, were measured by Talystep (Rank Taylor Hobson). The resist profiles were examined with a scanning electron microscope JSM-T200 (JEOL).

Results and Discussion

A system comprised of a combination of a novolak-type resin and naphthoquinonediazide, which works by a solution inhibition mechanism, was chosen as the positive working top layer resist. In order to introduce silicon atoms into the above combination, the preparation of a silicon containing novolak was undertaken. The acid-catalyzed condensation of p-trimethylsilylphenol with formaldehyde was unsuccessful, since p-trimethylsilylphenol is readily decomposed to phenol itself under acidic conditions, as mentioned in the literature (9). Since the silicon-aromatic carbon bond is much more easily cleaved by acid than the silicon-aliphatic carbon bond, attempts were made to prepare the novel silicon containing phenol without the former bond. In order to obtain such a phenol, silyl groups have to be connected to the phenol ring through an alkyl or alkoxy linkage. Following these considerations, three kinds of silylalkoxyphenols were synthesized by a phenoxide alkylation method. The reaction scheme is shown below

The stability of these phenols to acid was examined by ¹H NMR in a sample tube with DCl/D₂O-CD₃OD at 110°C. These results revealed the three silicon containing phenols are completely stable and, accordingly, should survive the addition condensation conditions. Furthermore, treatment with NaOD instead of DCl confirmed they are not decomposed by alkali. This suggests that the trimethylsilyloxyalkylphenolic structure is sufficiently stable to the development in an alkaline solution. Moreover, the above-mentioned stability to both acid and alkali indicates that novolak resins produced from these phenols will be stable and can be stored as ordinary novolak resins.

The addition condensation of the prepared phenols (1-3) with formaldehyde was carried out in ethanol, since the phenols are immiscible with water even at elevated temperatures

The above resins were obtained in quantitative yield. The polymer structures were confirmed by ¹H NMR. Although these polymers are soluble in most organic solvents, they are not soluble in dilute sodium hydroxide solution. This insolubility is apparently caused by the hydrophobic silylalkyl groups, and necessitated the incorporation of a hydrophilic co-monomer, 2-methylresorcinol (4)

Table I. Base resins preparation

R11	3	0.30	0.70	101	+	5.07

^a Calculated value.

As shown in Table I, the incorporation of a certain amount of 4 solubilized the resin in a sodium hydroxide solution, at the slight expense of the silicon concentration in the resin.

R4 and R8 were selected for the reasons of solubility and silicon content, and a photosensitive inhibitor, p-tolyl 1,2-naphthoquinone-2-diazide-5-sulfonate, was added. Two resist solutions, SIPR-1 containing R4 and SIPR-2 containing R8, were prepared by dissolving the above mixtures in 2-ethoxyethyl acetate. Composition of the resist solutions was described in the Experimental section.

The sensitivity characteristics of SIPR-1 and 2 were examined on silicon wafers with a Kasper 2001 contact printer. The required developer concentration for SIPR-2, defined as the minimum concentration of aqueous sodium hydroxide solution for dissolving the base resin without residue, was lower than that of SIPR-1, even though number of hydroxyl groups (phenolic OH's) in the base resin is the same in both resists. As shown in Fig. 1, the γ value for SIPR-2 was higher than that for SIPR-1.

In order to trace the difference between SIPR-1 and 2 with regard to both solubility and the γ value, the molecular weight distributions of the resins were examined. The gel permeation chromatogram for R4 (the resin used in SIPR-1) shows a discernible shoulder at the higher molecular weight side of the main distribution peak, while that for R8 (used in SIPR-2) shows a single distribution peak, as shown in Fig. 2. This difference in the molecular weight distribution might be caused by the difference in the monomer structure

Fig. 1. Sensitivity characteristics for SIPR. The coated initial film thickness was 0.29 μm for both materials.

The arrows show the reactive positions in the addition condensation reaction with formaldehyde, 1, which has three "arrows," may cause a branched structure when polymerized to R4. Accordingly, R4 seems to have more widespread molecular weight distribution than R8 having a more linear structure. This may be responsible for the difference in the solubility and γ values.

The resistance of SIPR-2 to O_2 -RIE and O_2 -IBE was investigated in comparison with the polyimide, PI-2555. The remaining film thickness *vs.* etching time under O_2 -RIE conditions is shown in Fig. 3. Lower RF power was found to give a higher etch-rate ratio of PI-2555 to SIPR-2, although it takes longer time to etch PI-2555

Fig. 2. Gel permeation chromatograms for R4 (SIPR-1) and R8 (SIPR-2).

Fig. 3. O_2 -RIE characteristics for PI-2555 and SIPR-2

Fig. 4. Etch-rate ratio of PI-2555 to SIPR-2 vs. acceleration energy under O_2 -IBE.

away. Similarly, in ion beam etching, lower acceleration energy gave a higher etch-rate ratio, as shown in Fig. 4. The remaining film thickness vs. etching time, with 50 or 100 eV acceleration energy, is shown in Fig. 5. The etching of SIPR-2 practically stopped at 50 eV, whereas the etching of a considerable amount of PI-2555 was still observed. This is because the rate-limiting process for the

Fig. 5. O_2 -IBE characteristics for PI-2555 and SIPR-2

Fig. 6. SEM photograph of fabricated patterns in SIPR-2 on PI-2555. Markers $\approx 1 \mu m$.

etching of SIPR-2 is the sputtering of silicon atoms, whereas that for PI-2555 is the sputtering of carbon atoms. Generally, the sputtering yield of metals decreases significantly with decreasing acceleration energy. The threshold is observed at around 20-40 eV (10). On the contrary, the sputtering yield of carbon atoms under oxygen bombardment does not show such a strong energy dependence (11).

Typical etch-rate ratios of PI-2555 to SIPR-2 are summarized in Table II. Although the etch-rate ratio depends not only on the etching system, but also on the etching condition, it is concluded that the lower bias gives a higher etch-rate ratio.

For the bilayer resist processing, SIPR-2 was coated onto the layer of polyimide resin PI-2555, exposed for 20s ($\sim 68 \text{ mJ/cm}^2$) with Kasper 2001 and developed with 0.25N NaOH for 60s. Patterns including submicron features, 0.7 μm lines, and 0.9 μm spaces, were obtained without variance from mask patterns, as shown in Fig. 6. No adhesion promoters were necessary, and neither were intermixing inhibition techniques for coating SIPR-2 on PI-2555. Then the top layer patterns were transferred into the polyimide layer. O_2 -RIE transfer with 50 (0.08 W/cm^2) and 100W (0.16 W/cm^2) RF power gave the patterns shown in Fig. 7a and 7b, respectively. No residues were observed. A slight rounding off of the top layer patterns, observed after the etching, may be due to the temperature rise during etching. Linewidth was reduced more with 100W RF power than with 50W, as is presumed by the etch-rate ratios in Table II. In the case of the O_2 -IBE transfer, acute profiles were obtained without the top layer deformation, although longer etching time than that in O_2 -RIE is necessary. Patterns are shown in Fig. 8a and 8b, transferred with 50 and 100 eV accelerating energy, respectively. No change in linewidth was observed in the 50 eV transfer.

Judging from the transferred pattern profiles by O_2 -RIE and by O_2 -IBE, change in linewidth is mainly caused by the shrinkage in the top layer, not by the un-

Fig. 8. SEM photographs of patterns transferred under O_2 -IBE (O_2 pressure of 2.7×10^{-2} Pa. (a, left): 50 eV acceleration energy. (b, right): 100 eV acceleration energy. Markers $\equiv 1 \mu\text{m}$.

dercut due to radical species. Since the radical contribution is not significant, the degree of ion bombardment may be estimated from the etch-rate ratio data. The etching condition for 100W in O_2 -RIE is roughly equal to that for 100 eV in O_2 -IBE. Since the self-bias voltage V_{dc} under 100W condition in O_2 -RIE was 550V, as shown in Table II, effective self-bias is estimated to be one-fifth of the V_{dc} . Similarly, effective self-bias for 50W in O_2 -RIE is also estimated to be 70V. This self-bias reduction may be caused by the cascade collisions in the plasma reactor acceleration region.

Conclusion

A new silicon containing positive photoresist (SIPR) was prepared. The etch-rate ratio of SIPR to polyimide (PI-2555) under oxygen dry etching (RIE and IBE) was less than one-tenth when a properly lower bias was employed. SIPR resolved submicron features on a layer of PI-2555 without variance from mask patterns with a near-UV exposure system. Those patterns were transferred into the layer of PI-2555 under such etching conditions and steep profiles were obtained accurately without any residues remaining on the wafers.

Application of Rapid Isothermal Annealing to Shallow p-n Junctions via BF₂ Implants

N. Chan Tung

Centre National d'Études des Télécommunications, Chemin du Vieux Chêne, 38243 Meylan Cedex, France

ABSTRACT

Results of rapid isothermal annealing (RIA) experiments are reported. Wafer warpage, temperature homogeneity, slip lines, and reproducibility of temperature cycles have been investigated. Sheet resistance measurements were carried out for RIA (1000°C, 10s) and for conventional furnace annealing for 30 and 50 keV BF₂ implants, the ion dose varying between 5×10^{13} and 7×10^{15} cm⁻². Spreading resistance measurements revealed that, in the case of RIA, junctions as shallow as 0.17, 0.19, and 0.21 μm have been obtained, respectively, for ion doses of 1×10^{13} , 3×10^{15} , and 5×10^{15} cm⁻² at a BF₂ energy of 50 keV. Junction depths obtained through RIA are a factor of 3-4 lower than those obtained by conventional annealing; dopant redistribution is negligible. Boron and fluorine atom concentration profiles have been equally investigated by secondary ion mass spectrometry (SIMS).

Recently, considerable research has been conducted to anneal damage and activate implanted dopants with minimal redistribution. Lasers and electron beams have been used to anneal implanted silicon samples in the milli-second time regime (1-3). Although complete dopant activation has been achieved, defects near the junctions have degraded their electrical characteristics (4). Furthermore, the implanted damaged layers are annealed by raising only the surface region of the sample to the desired temperature. The drawbacks of using these techniques are beam overlapping, low throughput, and interface problems for devices composed of thin film layers. These disadvantages can be overcome through the use of rapid isothermal techniques. In this category are included large area scanned electron beams (5), high intensity arc lamps (6), resistively heated graphite sources (7), and tungsten halogen lamps (8-9). One attractive application of rapid isothermal annealing (RIA) is the production of shallow p-n junctions required for future complementary metal-oxide-silicon (CMOS) technologies.

In this paper, we present the characteristics of the machine¹ with particular attention to wafer warpage, temperature homogeneity along an axis, slip lines, and reproducibility of the temperature cycle. Sheet resistance measurements were performed for rapid and conventional furnace anneals for BF₂ implants in the energy range of 30-50 keV and ion doses ranging from 5×10^{13} to 7×10^{15} cm⁻². Radial family sheet resistivity measurements of rapid anneals were also performed on 4 in. wafers. Profiles of the activated dopants were obtained by spreading resistance and p-n junction depths were measured for 30 and 50 keV BF₂ implants. Boron and fluorine atom concentration profiles of 50 keV implants were measured by SIMS for ion doses of 1×10^{15} and 3×10^{15} cm⁻². The redistribution of the boron atoms is negligible.

Description of the Apparatus

The RIA apparatus used for the annealing of the implants is shown schematically in Fig. 1. It consists of two banks of six tungsten infrared quartz lamps separated by a distance of ~15 cm. To avoid overheating and early failure, electrical connections of the lamps are air-cooled. Three phase-angle fired power supplies provide 30 kW to the lamps, which is sufficient to raise wafers to a temperature in excess of 1200°C.

A quartz chamber is inserted between the lamps, and annealing can be carried out in an inert atmosphere. A movable quartz plate is placed inside the chamber and supports a 4 in. wafer as well as a fixed temperature sensor. The fixed temperature sensor consists of a Chromel-Alumel thermocouple embedded inside a 2 × 2 cm² silicon piece and supported by a quartz rod. During annealing, the temperature recorded by the fixed sensor allow us to deduce the temperature of the annealed 4 in.

¹Atelier Electro Thermic, Chemin des Malacher, 38243 Meylan, France.

sample since a correlation has been previously established between the temperature of the radiation sensor and that of a 4 in. wafer inside which a thermocouple has been similarly embedded.

Temperature profiles were monitored by a movable 1 × 1 cm² sensor along the longer axis of the quartz chamber (i.e., perpendicular to the lamps). The measurements were carried out at every centimeter over a distance of 9 cm. The maximum temperature difference as measured at these different locations is ~16°C ($\sim 1.6 \times 10^{-2}$) for a 1000°C run. This good temperature uniformity allows the measurements of the wafer flatness, since it is a prerequisite for bow-free processing.

A series of measurements was conducted to determine any change in flatness on standard <100> 4 in. wafers 0.5 mm thick. The measurements were performed along two perpendicular axes before and after annealing. For a 10s anneal at a temperature of 1000°C, only negligible changes in wafer flatness were detected, namely, of ~0.5 μm. This result falls within the experimental resolution of the apparatus. Before annealing, parallel and perpendicular wafer bowings were 4.5 and 1.5 μm, respectively; after annealing, they were 5 and 2 μm, respectively. No slip lines were observed after the annealing experiments.

The reproducibility of our 1000° and 1100°C temperature heat pulse curves for 4 in. wafers is very good; only 4°-5°C separate the various 1000° or 1100°C runs. However, it must be noted that the machine does not contain any closed loop temperature monitoring. The cycle of the injected power (power value vs. time) is adjusted to obtain the desired temperature profile. For the temperature profiles of 1000° and 1100°C, the rates of temperature rise are, respectively, 150°C/s (350°-950°C in 4s) and 180°C/s (400°-1000°C in 3.3s). Such a rate of change in temperature is typical of commercially available machines that use tungsten lamps.

Sheet Resistance Measurements

In all our experiments, the wafers used were n-type and of resistivity 5-8 Ω cm. The wafers contained no oxide cap, and annealing of the implants was carried out in a nitrogen atmosphere for both the rapid and furnace an-

Fig. 1. Schematic cross section of the RIA apparatus

$R_{\square} (\Omega/\square)$ 

Fig. 2. Sheet resistance measurements for RIA and furnace anneals

neals. The BF_2 implants were carried out in a High Voltage Engineering (H.V.E. 500) implantation machine whose main feature is that it contains two mass separating magnets. The first magnet allows the separation of the particles extracted from the ion source, while the second one, located at the opposite end of the acceleration column, filters out the undesired products of dissociation of the molecular implants, here BF_2 , in the acceleration region.

Radial family sheet resistivity measurements were carried out with a four-point probe on 4 in. wafers for 50 keV BF_2 implants and a dose of $3 \times 10^{15} \text{ cm}^{-2}$, the annealing temperature and time being 1000°C for 10s. These sheet resistance measurements were performed along eight radial axes corresponding to an angular variation of 45° . Along each axis, measurements were carried out every centimeter. The load applied to the probe was 50g. The mean value of the sheet resistivity measurements for a 4 in. wafer is $83.6 \Omega/\square$, and $\sigma = 1.3 \times 10^{-2}$.

Sheet resistivity measurements for rapid and conventional furnace anneals (1000°C , 30 min) are shown in Fig. 2 for 30 and 50 keV implants. For both rapid and furnace anneals, R_{\square} decreases when the ion energy is increased. For the 30 keV implants, R_{\square} decreases with increasing ion dose in both cases. This should be the case since an increase in the ion dose leads to an enhancement of the solid-phase epitaxy. For 50 keV molecular ions, R_{\square} measurements reached a minimum at an ion dose of $3 \times 10^{15} \text{ cm}^{-2}$ both for the rapid and furnace anneals. In the case of RIA, $R_{\square} \sim 80 \Omega/\square$. Our sheet resistivity measurements are in agreement with those published by Kato *et al.* (10), who obtained an R_{\square} value of $85 \Omega/\square$ for 60 keV BF_2 implants; the ion dose and annealing time being, respectively, $4 \times 10^{15} \text{ cm}^{-2}$ and 3s.

Spreading Resistance and SIMS Measurements

RIA activated (1000°C , 10s) dopant concentration profiles measured by spreading resistance are shown in Fig. 3 for 50 keV BF_2 implants. The measured junction depths vary from 0.16 (dose = $1 \times 10^{14} \text{ cm}^{-2}$) to $0.21 \mu\text{m}$ (dose = $5 \times 10^{15} \text{ cm}^{-2}$).

Fig. 3. Dopant concentration profiles for 50 keV BF_2^+ RIA(1000°C , 10s).

$\times 10^{15} \text{ cm}^{-2}$). These junction depths increase with the dose except for a fluence of $1 \times 10^{15} \text{ cm}^{-2}$. It must, however, be noted that, for each increase in dose, the corresponding increase in junction depth is very slight ($\sim 0.01\text{-}0.02 \mu\text{m}$) and is within the estimated accuracy of our measurements ($\sim 200\text{\AA}$). The activated dopant concentration profiles have a quasi-gaussian shape, and the maximum peak concentration increases with the ion dose. This is a natural occurrence of ion implantation process. It must, however, be noted that the concentration profile broadens slightly near its base ($\sim 0.03 \mu\text{m}$ for an ion dose of $3 \times 10^{15} \text{ cm}^{-2}$). In that region, the concentration is about five orders of magnitude lower than the peak value. This profile broadening near the base may be due to the following reasons: (i) the second magnet located at the end of the acceleration column may not have completely eliminated the dissociated BF_2 products formed in the acceleration region, (ii) slight diffusion of the dopants during the rapid anneals, or (iii) a channeling process which is not negligible for these low energy equivalent B ions. This point will be developed later on.

Our junction depth measurements [$0.19 \mu\text{m}$ for a dose of $3 \times 10^{15} \text{ cm}^{-2}$; $0.21 \mu\text{m}$ for a dose of $5 \times 10^{15} \text{ cm}^{-2}$ (50 keV implants, 1000°C , 10s anneals)] are compatible with the results of Kato *et al.* (10), who obtained a junction depth of $0.16 \mu\text{m}$ for 60 keV implants. Their ion dose and annealing conditions were $4 \times 10^{15} \text{ cm}^{-2}$ and 1000°C , 3s. It must, however, be noted that Kato's implants were performed through 400\AA SiO_2 . This may explain the slight difference between their results and ours.

Carrier concentration profiles for 50 keV ions implanted with an ion dose of $1 \times 10^{15} \text{ cm}^{-2}$ are presented in Fig. 4. For a 1000°C , 10s rapid anneal, the junction depth is $0.17 \mu\text{m}$ as compared to $0.40 \mu\text{m}$ junction depth obtained by furnace annealing (1000°C , 30 min); the increase is due to dopant diffusion. Also shown in the same figure for comparison purposes are SIMS profiles of boron

Fig. 4. Carrier profiles of electrically active dopants (BF_2^+ implants) obtained by RIA and furnace anneals, SIMS profiles of B atoms for as-implanted and annealed samples.

atoms and calculations obtained from LSS theory. These curves give rise to the following remarks.

1. The LSS theory is in good agreement with the RIA activated dopant profile.

2. The LSS theory differs from the SIMS as-implanted atomic profile. This is due to the fact that calculations from the LSS model refer to an amorphous solid (dense gas) and channeling is responsible for the broadening of the as-implanted profile. In fact, the calculated acceptance angle for channeling of 11 keV B ions in $\langle 100 \rangle$ Si, corresponding to 50 keV BF_2 , is about 10° . This angle is larger than the 7° tilt used in our experiments. Channeling processes have equally been observed by Wilson (11) for those low energy equivalent B ions (energy of $\text{BF}_2 = 45 \text{ keV}$).

3. The redistribution of the boron atomic profiles, before and after rapid annealing, is very slight ($\sim 0.025 \mu\text{m}$).

4. After rapid annealing, a second peak of same height as the first one is located at a depth of $\sim 0.055 \mu\text{m}$. The location of that peak is consistent with the region of residual damage. Such a double peak for boron atomic profiles has also been observed by Wilson (11) and Fuse *et al.* (12) for furnace annealing of 36 and 111 keV BF_2 , respectively.

The degree of activation of the 50 keV BF_2 implants with an ion dose of $1 \times 10^{15} \text{ cm}^{-2}$ is $\sim 85\%$. Fluorine atom concentration profiles are presented in Fig. 5 for 50 keV implants; the rapid annealing conditions are 1000°C , 10s. The calculated profile is in good agreement with the fluorine as-implanted atomic profile. The rapid annealed fluorine profile behaves differently. In fact, the fluorine atoms pile up in the region of damage, the transition between the amorphous and the crystalline regions. The fluorine peak is situated at $\sim 0.060 \mu\text{m}$, not far from the second boron peak ($\sim 0.055 \mu\text{m}$). The same considerations developed previously can be applied to the RIA boron and fluorine atomic profiles (Fig. 6), the ion dose being $3 \times 10^{15} \text{ cm}^{-2}$.

Spreading resistance measurements showed that for 30 keV BF_2 , junction depths are 0.10 and $0.15 \mu\text{m}$ for ion

Fig. 5. Fluorine atom concentration profiles measured by SIMS before and after RIA.

Fig. 6. Profiles of boron and fluorine atoms measured by SIMS before and after RIA.

doses of 3×10^{15} and 5×10^{15} cm^{-2} , respectively. The rapid annealed conditions are 1000°C , 10s. In the case of furnace annealing (1000°C , 30 min), the junction depth is increased to $0.30 \mu\text{m}$ for an ion dose of 3×10^{15} cm^{-2} , the ionic energy being the same (30 keV).

Conclusion

The rapid isothermal annealing experiments presented exhibit good temperature homogeneity along the axis of the chamber. Wafer warpage is $0.5 \mu\text{m}$ for a 4 in. wafer. The reproducibility of the temperature cycles is excel-

lent; only $4^\circ\text{--}5^\circ\text{C}$ separates the various runs either for the 1000° or the 1100°C annealing.

For 50 keV BF_2 RIA, junction depths exhibit ion dose dependence. Junction depths as shallow as 0.17, 0.19, and $0.21 \mu\text{m}$ have been obtained, respectively, for ion doses of 1×10^{15} , 3×10^{15} , and 5×10^{15} cm^{-2} . Junction depths obtained through rapid annealing (1000°C , 10s) are a factor of three to four lower than those obtained by conventional furnace annealing. In the case of RIA, negligible dopant redistribution has been noted.

The Effects of Ion Beam Etching on Si, Ge, GaAs, and InP Schottky Barrier Diodes

C. S. Wu, D. M. Scott, Wei-Xi Chen, and S. S. Lau

Department of Electrical Engineering and Computer Sciences, University of California at San Diego, La Jolla, California 92093

ABSTRACT

The effects of ion beam etching (IBE) on the electrical properties of Schottky barriers on four kinds of semiconductors (Si, Ge, InP, and GaAs) were investigated. For diodes processed with IBE after metal deposition where the active device region is protected by the metal layer and only the surrounding substrate area is exposed to the beam, our results showed that the diode breakdown voltages increased 2-15 times for p-type substrates, but decreased 2-4 times for n-type substrates. The barrier heights, ϕ_B^p , on p substrates were observed to remain unchanged, while the barrier heights, ϕ_B^n , were found to decrease on n substrates. For diodes processed with IBE before metal deposition, the diode characteristics are similar to those processed with IBE after metal deposition; the only notable exception is that the barrier heights on p substrates increased for this case, while ϕ_B^p remained unchanged for diodes processed with IBE after metal deposition. The effects of IBE are observed to disappear and the diodes recover to their original characteristics upon annealing at temperatures between 300° and 375°C. These effects are consistent with the concept that ion beam processing induces donor-like defects near the surface region of the semiconductor exposed to the ions.

Ion beam etching (IBE) is becoming a commonly used processing technique in microelectronics. The properties of substrate surfaces after IBE, therefore, are of scientific and technological interests.

Fonash *et al.* (1) have found that argon ion beam etching followed by thermal deposition or ion-beam deposition alone can drastically affect the characteristics of Schottky barrier diodes made on Si, thus pointing out the importance of ion-beam-induced damage in barrier formation. They observed that ion-beam damage can lead to ohmic contacts on n-Si but does not affect Schottky barriers on p-Si for Au and Mo contacts. Chow *et al.* (2) have also observed that Schottky barrier height was increased for p-Si and decreased for n-Si when gold films were thermally deposited on reactive-ion-etched Si substrates.

Numerous other studies have found that sputter depositions of metals can also cause abnormal I-V characteristics for Schottky barrier diodes on Si (3, 4) as well as on GaAs (5-7). Electrical behavior of heterojunctions formed by RF sputtering of materials such as indium-tin-oxide (ITO) on several compound semiconductors (InP, CdTe) has been reported to change due to sputtering damage (8).

In each of these studies, either the substrate was etched prior to the metal deposition or the substrate was etched during metal deposition. The influence of ion etching on diodes after metal deposition has rarely been reported. Since ion etching to fabricate device structures after metallization is a common practice, we report here the effects of IBE on diode characteristics after the deposition of metal layers on semiconductor substrates. For comparison, diodes processed with IBE before metal deposition were also investigated for certain cases. For the case of IBE after metallization, the ion etching time was short such that the substrate area under the metallized region (circular dots) was protected from the ion beam with the remaining substrate area exposed to the beam. In this study, the I-V and breakdown characteristics of Schottky diodes on Si, Ge, InP, and GaAs were examined.

Experimental

Sample preparations.—Four different substrate materials were used in this study: Si, Ge, GaAs, and InP. For x-ray and MeV He⁺ backscattering measurements, the samples were ~ 0.5 cm in size. For electrical evaluations, diodes of 1 and 3 mm diam were formed on the wafers using mechanical masks for Si, Ge, and GaAs samples and diodes of 152 and 229 μm diam were formed using photolithography for InP samples.

Si.—Silicon substrates (n- and p-type, 1-10 $\Omega\text{-cm}$, <100> in orientation) were first cleaned ultrasonically with acetone and isopropyl alcohol, followed by the RCA cleaning process (9) and a final rinse in 10% HF:H₂O immediately

before loading into an oil-free evaporation system. On p-type Si substrates, about 500Å of Er was first deposited followed by the deposition of a Si layer (~ 750Å) from a n⁺ Si charge. The deposition rate was ~ 10 Å/s for Er and 20-30 Å/s for Si. The pressure during evaporation was ~ 10⁻⁷ torr in all cases. The samples were then annealed at 380°C for 30 min in flowing forming gas or in vacuum (~ 3 × 10⁻⁷ torr) to form the ErSi₂ contact. The deposited Si (~ 750Å) is sufficient to consume entirely the Er layer (~ 500Å) to form ErSi₂ with the excess Si removed by chemical etching after reaction. It has been shown that uniform layers of ErSi₂ can be formed on samples with this configuration with a barrier height of 0.78 eV on p-Si (10, 11). On n-type Si substrates, ~ 1000Å of Pd was thermally deposited. The deposition rate of Pd was 10Å/s at a pressure of ~ 1 × 10⁻⁷ torr. No annealing was performed on these Pd/n-Si samples. The barrier height, ϕ_B^n , is ~ 0.75 eV for as-deposited samples.

Ge.—For the Ge case, n-type, <100>-oriented Ge wafers with a resistivity of 0.8-1.5 $\Omega\text{-cm}$ were used. The wafers were first cleaned with acetone and isopropyl alcohol, followed by a rinse in a solution of H₂O:HNO₃:HF 28:3:1 at room temperature with a final rinse in 10% HF:H₂O. A layer of Er (~500Å) followed by a layer of Ge (~ 850Å of Ge at ~ 20-30 Å/s) were deposited onto the substrate. Thermal annealing at this structure at ~ 330°C has been shown to form a planar ErGe₂ layer (12).

InP.—For the InP case, the InP substrate material (10¹⁵/cm³, 0.3-0.4 $\Omega\text{-cm}$ for <n,100> and 5 × 10¹⁵/cm³, 7-8 $\Omega\text{-cm}$ for <p,100>) were cleaned with trichloroethylene, acetone, and methanol, etched in dilute HF, then etched further in a solution of H₂O:HF:HCl 4:1:1 plus one drop of H₂O₂/10ml.

Ta-Si films 1300-1500Å thick were deposited by RF sputtering (200W in Ar) from a hot-pressed Ta-Si target with a Ta to Si atomic ratio of 1:2. A pattern of Ta-Si dots was then formed from the sputtered film using a photoresist (AZ 1350) mask and dry plasma etching in a parallel plate system (CF₄ with 4% Oz, 0.4 torr, 15W, ~ 500 Å/min). The diameters of the contact dots used were 229 μm for p-InP and 152 μm for n-InP. The p-InP samples were then annealed at 350°C for 30 min in forming gas to give a ϕ_B^p of 0.97 eV and the n-InP samples were annealed at 400°C for 5 min to give a ϕ_B^n of 0.4 eV (13).

GaAs.—For the GaAs case, n-type GaAs (<100>, Si doped, 2 × 10¹⁷/cm³) wafers were used. The wafers were first cleaned with acetone and isopropyl alcohol, followed by a rinse in the diluted solution of 1:1 HCl:H₂O and a final rinse in DI water. 500Å of Er and 750Å of Si were then sequentially deposited under the same conditions as described in the p-Si case. The barrier height, ϕ_B^n ,

is ~ 0.68 eV for as-deposited samples and ~ 0.8 eV for samples annealed at 380°C for 30 min in forming gas.

Ion beam etching (IBE).—Following sample preparation, ion beam etching was carried out using a Millatron IV system.¹ This system has been described by Heath (14, 15) in detail. The system consists of a Kaufman-type (16) ion source, sample chamber, and cryogenic pump system. The ions are extracted from a gaseous plasma and accelerated to the substrate. The beam current density and ion energy can be independently controlled. In our experiment, either Ar or Freon-116 (C_2F_6) was used. The ion beam was incident normal to the substrate which was located 20 cm from the ion source and rotating during IBE. The ion energy was set at 500 eV, and the pressure of the chamber was kept at $\sim 2.3 \times 10^{-4}$ torr. The ion beam current density was set at 0.5 mA/cm^2 for this experiment.

Postannealing after IBE.—To investigate the stability of the electrical properties, certain samples were annealed between 300° and 375°C in forming gas (10% H_2 , 90% N_2) for times ranging up to 25 min after IBE.

Metal layers deposited on ion-etched substrates.—In order to compare the effects of IBE before and after metal deposition, p-Si, n-Ge, and n-GaAs substrates were first ion beam etched for 30s under the same condition as described previously and then cleaned with acetone, isopropyl alcohol and a final rinse in DI water before loading into our evaporation system. About 500\AA of Er was then deposited on each substrate to form three types of samples: Er (500\AA)/Si<p,100>, Er(500\AA)/Ge<n,100>, and Er(500\AA)/GaAs<n,100>.

Electrical measurements. The breakdown voltage (V_B) and barrier heights (ϕ_B) were determined by current-voltage measurements before and after IBE process. The samples were measured within 24h after IBE except as noted.

Experimental Results

Si.—Figure 1 shows a plot of $\log I_f$ vs. V_f for diodes of ErSi_2 on p-type Si before and after IBE for 20s. The diodes exhibit almost identical forward characteristics before and after IBE. The barrier height, ϕ_B^p , for the diodes is ~ 0.78 eV, with an n factor of 1.05. The reverse breakdown voltages, however, are quite different before and after IBE, although both types of diodes exhibit a sharp breakdown, as shown in Fig. 2. Before IBE, breakdown (V_B) takes place at $\sim 80\text{V}$ (curve A), after IBE, breakdown does not occur until about 300V (curve B). The variation in V_B vs. IBE time is shown in Fig. 3 for diodes formed either by annealing in forming gas or in vacuum. Diodes formed in vacuum initially have a much lower V_B ($\sim 22\text{V}$) values compared to those for diodes prepared in forming gas (\sim

¹ Made by Commonwealth Scientific Corporation.

Fig. 2. I-V curves for a $\text{ErSi}_2/\text{p-Si}$ diode (1 mm diam) before (A) and after (B) IBE, indicating the effect of IBE on breakdown voltages.

Fig. 3. Breakdown voltage as a function of ion etching time for $\text{ErSi}_2/\text{p-Si}$ diodes (1 mm diam).

80V). However, in both cases V_B rises with IBE and saturates at nearly identical breakdown voltages of $\sim 325\text{V}$.

The increase in breakdown voltage after IBE is not permanent. Annealing these p-type samples at 300°C in forming gas for only 5 min caused V_B to decrease from over 300V to $\sim 70\text{V}$, nearly equal to the initial value for the samples annealed in forming gas without IBE.

The behavior of diodes formed on n-type Si substrates is very different from those obtained with diodes on p-type Si. Figure 4 shows a plot of $\log I_f$ vs. V_f for Pd on

Fig. 4. $\log I_f$ vs. V_f for a Pd/n-Si diode (3 mm diam) before and after IBE.

n-type Si diodes before and after IBE for 10s. Before IBE, the diodes are nearly ideal ($n = 1.05$). ϕ_B^n is 0.75 eV, which agrees with published values (17). After IBE, the diodes no longer show ideal behavior. The $\log I$ vs. V curve is nonlinear throughout the entire range of investigation. It is not possible to deduce a unique value of ϕ_B^n from this curve. However, at forward voltage of $\sim 0.1V$, ϕ_B^n can be assigned to be ≈ 0.64 eV with $n \approx 1.4$; we can take these values to represent the change in the electrical properties after IBE. The crossover of these two curves is due to a difference between these devices in the resistance of the back contact.

Figure 5 shows the linear I-V characteristics of Pd/n-Si diodes before and after IBE for 10s. Both diodes show soft breakdowns. The reverse bias voltages measured at 1 mA decreased significantly from an initial value of 50V to about 15V after IBE for 10s. This voltage remained unchanged after further IBE up to 40s, as shown in Fig. 6. Similar breakdown voltages were observed irrespective of the gas used for IBE.

Ge.—Diodes on n-type Ge exhibited soft breakdowns similar to those on n-type Si. For the as-deposited samples with 1 mm diam dots, V_B decreased from ~ 55 to $\sim 18V$ at $I_r = 1$ mA and ϕ_B^n decreased from 0.54 to 0.51 eV after IBE for 10s. For diodes annealed at $330^\circ C$ for 1h to form a Er germanide contact, the breakdown voltage decreased from ~ 40 to $\sim 13V$ and ϕ_B^n decreased from 0.51 to 0.49 eV after 10s of IBE. Postannealing of these samples for only 5 min at $300^\circ C$ is sufficient to restore the breakdown voltage and ϕ_B^n to those initial values prior to IBE. Diodes on p-type Ge were not investigated.

Fig. 6. Breakdown voltages of Pd/n-Si diodes (3 mm diam) as a function of ion etching time.

Fig. 7. I-V curves of Ta-Si/p-InP diodes ($229 \mu m$ diam) before (A) and after (B) IBE.

InP.—Figure 7 shows the reverse I-V characteristics of the diodes with Ta-Si on p-type InP. The breakdown was relatively abrupt. Initially, the breakdown voltage, V_B , was about 45V (curve A). After 10s of IBE, the V_B increased to $\sim 70V$ (curve B). After an additional 10s of IBE, V_B increased further to $\sim 90V$ (not shown in Fig. 7). The barrier height ϕ_B^n did not change significantly after IBE, although the forward currents increased slightly in the low bias region ($V_f < 0.3V$) after IBE. It is interesting to note that V_B was not altered by postannealing at $300^\circ C$ for 25 min but recovered to the original values at $375^\circ C$ for 25 min in forming gas.

The diodes ($152 \mu m$ diam) formed on n-type InP showed relatively soft breakdowns. For a reverse current of 5 mA, the corresponding reversed-biased voltage decreased from 13 to 7V after a 10s of IBE (not shown). The barrier height also decreased from 0.4 to 0.35 eV. Postannealing at $375^\circ C$ for 25 min led to the recovery of both V_B and ϕ_B^n to their original values.

GaAs.—For the ErSi₂ diodes formed on n-type GaAs, the breakdown was relatively soft, and at a reverse current of 1 mA the corresponding reverse-biased voltage decreased from 12 to $\sim 7V$ after a 10s of IBE (Fig. 8). The barrier height also decreased from 0.8 to 0.64 eV after IBE. These diodes recovered to their initial V_B of 12V and ϕ_B^n of 0.80 eV after annealing at $300^\circ C$ for 25 min.

Comparison with IBE before metal deposition—To verify some of the results reported in the literature, we checked the diode characteristics of three systems processed with IBE before metal deposition. The substrates

Fig. 8. I-V curves of ErSi₂/n-GaAs diodes (1 m diam) before (A) and after (B) IBE.

(p-Si, n-Ge, and n-GaAs) were IBE for 30s before a layer of Er was deposited on them. For the case of Er/p-Si, the barrier height ϕ_B^p increased from ~ 0.68 eV (as-deposited without IBE) to ~ 0.80 eV and the breakdown voltage increased from 60 to 300V. For Er on n-Ge substrates, the diodes exhibited ohmic behavior at room temperature. For the Er/n-GaAs case, ϕ_B^n was found to be ~ 0.41 eV as reduced from 0.68 eV for as-deposited samples. The breakdown voltage decreased from ~ 12 to 3V after IBE. These results are consistent with those reported in the literature and are similar to those obtained on diodes processed with IBE after metal deposition. The notable difference is that the barrier height on p-type substrates, ϕ_B^p , increases for samples processed with IBE before metal deposition, whereas ϕ_B^p remains unchanged for samples processed with IBE after metal deposition.

Discussion

It has been reported in the literature that RF (3), dc (4), and ion-beam (1) sputter deposition of metals on Si can cause anomalies in the I-V characteristics of Schottky barrier contacts, *i.e.*, a decrease in barrier heights on n-type Si and increase in barrier heights on p-type Si. To rationalize these results, Mullins *et al.* (4) have proposed a model suggesting that sputtering may induce donor-like defects at the metal-Si interface with a defect density distribution decreasing exponentially into the substrate. Assuming that the donor-like defects are ionized, this can lead to a narrowing of the depletion region on n-type substrates and an increase in apparent barrier height on p-type substrates. Ion-induced damage such as dislocation loops, small defect clusters, cavities, and embedded sputter gas as a result of sputtering of Si surfaces have been reported by Bean and his co-workers (18).

Sputter damage has also been found to cause the formation of an n-type layer on p-type InP (8). Bayliss *et al.* (19) have reported that P is preferentially depleted from the surface of InP under Ar bombardment. Temkin *et al.* (20) have reported that a P vacancy in InP behaves as a donor-like level.

For GaAs, Chiang *et al.* (21) and Jaros *et al.* (22) have reported that an As vacancy in GaAs behaves as a single donor. Yamaski *et al.* (6) and Wang *et al.* (7) have suggested the formation of donor-like defects by ion sputtering due to the depletion of As near the surface region. We believe that our experimental results can be rationalized in terms of the concept mentioned above.

Our results in this investigation show primarily two effects of ion-beam etching after metal deposition on Schottky barrier contacts.

First, on n-type semiconductors, the breakdown voltages (V_B) are lowered 2-4 times by IBE. In addition, the forward I-V characteristics (linearity, ϕ_B^n , and n) degrade as a result of IBE.

Second, on p-type semiconductors, the forward I-V characteristics remain unchanged while the breakdown voltages increase 2-15 times as a result of IBE.

These results appear to be consistent with the notion that ion beam processing induces donor-like defects near the surface region in semiconductors. In our experiments where metal dots were deposited onto the substrates before IBE, donor-like defects are expected to be present only in areas of the substrate exposed to the ion beam and not in regions of the substrates covered by metal dots. The observed IBE effects are most likely to be edge effects around the active regions of the Schottky barriers where the electric field is increased. Figure 9 shows the schematics that depict the situations before and after IBE under reverse bias. For p-type substrates, the substrate surface region around the diode is converted to n-type, thus forming a guard-ring structure around the diode, resulting in much higher breakdown voltages without changing ϕ_B^p . For n-type substrates, the substrate surface region around the diode becomes n^+ , the edge effect is intensified which leads to the tunneling of carriers resulting in lower barriers and lower breakdown voltages.

Upon annealing the samples (300°C for Si, Ge, and GaAs and 375°C for InP), the diodes recover to their original characteristics. This suggests the IBE induced defects are reduced or removed. The temperature at which recovery occurs for InP (375°C) agrees with results reported by Tsai *et al.* where n-type layer is reconverted to p-type after ion bombardment (8).

For cases where metal dots are deposited after IBE, barrier heights and breakdown voltages are raised on p-type substrates and are lowered on n-type substrates. These observations are consistent with results reported in the literature and the ion-induced donor-like defect model.

Summary

1. For the case of IBE after metal deposition, the breakdown voltages increase and the barrier heights of Schottky diodes remain unchanged on p-type substrates; on n-type substrates, both breakdown voltages and barrier heights decrease.

2. On annealing the samples at temperatures of 300°-375°C, the diode characteristics recover to their original values.

3. For the case of IBE before metal deposition, the effects of IBE are similar to those for IBE after deposition, except the barrier heights on p-type substrates are observed to increase.

4. These results are consistent with the concept of ion-beam induced donor-like defects near the surface region of the semiconductor substrates.

ABSTRACT

Polycrystalline silicon films have been deposited on thermally oxidized wafers. The films have been implanted with As, B, or BF₂ and annealed with a Varian IA-200 rapid thermal annealer. The system uses infrared radiation from a resistively heated sheet of graphite to heat the entire wafer to temperatures in excess of 1000°C for times on the order of a few seconds. The effects on sheet resistance, sheet carrier concentration, and mobility due to exposure time, heater temperature, dopant species, and resultant grain size are discussed. Higher temperatures and longer exposure times produce the lowest sheet resistances. These results are compared to CW laser and conventional furnace-annealed films. A substantial loss of As occurs during the anneal unless the films are capped with SiO₂. Results on B and BF₂ implanted films indicate no boron loss has occurred during the anneal. The As and B uniformly distribute throughout the film when exposed to anneal conditions that produce very little diffusion in single-crystal Si. This implies that As and B diffusion is much faster in polycrystalline Si than in single crystal under these anneal conditions. The anneal causes both components of a bimodal grain size distribution to grow significantly until grain growth is slowed by geometrical constraints. Increased grain size results in a substantial increase in mobility. The grain growth has been modeled by an interfacial energy-driven mechanism.

Removing implantation damage and activating implanted dopants in Si with some form of transient annealing technique is becoming a very important research topic as device dimensions shrink (1-16). Transient annealing allows better control of impurity diffusion than conventional furnace annealing because of the shorter time the wafer is at an elevated temperature. This tight control of diffusion will provide for precise control in the formation of shallow junctions, narrow base width, and fine geometry devices.

Although lasers and electron beams have been successfully used to anneal implanted Si (1-5), incoherent light sources appear more applicable to device processing. Thin film interference effects are eliminated and wafer throughput is greater for the incoherent light sources. Since the entire wafer is heated and cooled uniformly, nonuniformities due to thermal gradients are reduced.

Several papers have reported using incoherent sources to anneal ion-implanted, single-crystal silicon (6-16). How-

ever, very few results have been reported for annealing polycrystalline silicon with an incoherent light source (17-20). Polycrystalline Si is used as a gate material for most metal/oxide/semiconductor (MOS) devices. Polycrystalline Si is also used as an interconnect material and as load resistors in many integrated circuits. In self-aligned implant process technology, the source, gate, and drain are all implanted in the same step and annealed in a subsequent step. Therefore, if transient annealing of source and drain implants is to be successful in MOS technology, the technique must also be useful in annealing the implanted polycrystalline Si gate material.

We report results obtained on As-, B-, and BF₂-implanted polycrystalline Si films that were deposited on 0.1 μm of SiO₂ and annealed with a Varian IA-200 rapid thermal annealer. This system uses infrared radiation from a resistively heated sheet of graphite to uniformly heat the wafers. Changes in sheet resistance (R_s), sheet carrier concentration (N_s), and mobility (μ) as a function of exposure time, heater temperature, and dopant species are presented. These effects are correlated with grain

growth and dopant diffusion as measured by transmission electron microscopy (TEM), Rutherford backscattering (RBS), and neutron depth profiling (NDP). The surface morphology has been examined with a scanning electron microscope (SEM) and measured with a surface profilometer. The effect of different dopants and oxide caps is discussed.

Sample Preparation and Analysis

The substrates used in these experiments were 3 in. (100) Si wafers. Silicon dioxide, 0.1 μm thick, was grown on the substrates. Undoped polycrystalline Si, 0.3 μm thick, was deposited at 630°C on the SiO_2 by low pressure chemical vapor deposition (LPCVD). The polycrystalline Si films were implanted with either As (60 keV, $5.0 \times 10^{15}/\text{cm}^2$), B (50 keV, $3.0 \times 10^{15}/\text{cm}^2$), or BF_2 (223 keV, $3.0 \times 10^{15}/\text{cm}^2$). ^{11}B was used in all cases except on samples where NDP was performed. ^{10}B was implanted into the samples where NDP was performed. A cap of sputtered SiO_2 was deposited on some of the wafers. The remaining wafers were left uncapped. Wafers from each group were subjected to rapid thermal annealing using the Varian IA-200. This system has been described previously (11-14, 16). The exposure times ranged from 10 to 30s. The nominal heater set point temperatures used were 1150° and 1200°C as measured by a thermocouple, which was located ~2 mm from the heater. This temperature is measured on the thermocouple and is estimated to be 35°-50°C lower than the actual graphite temperature based on the temperature a silicon wafer achieves for long exposure times.

Figure 1 shows a typical plot of wafer temperature *vs.* exposure time for an 1150°C heater set point. The wafer temperature is measured by an optical pyrometer located directly behind the wafer. The polycrystalline Si was implanted with ^{75}As (60 keV, $5.0 \times 10^{15}/\text{cm}^2$). The temperature measured at 0 s is indicative of the heater and not the wafer since Si is essentially transparent to infrared radiation at room temperature. As the wafer heats up the transmission decreases until only the wafer is being monitored. After 10s the wafer temperature reaches 875°C (the lowest reading on the meter) and rises to 1185°C after 20s. The wafer temperature remains nearly constant after 20s. The final wafer temperature is greater than the heater set point temperature because the heater thermocouple is located 2 mm from the heater rather than in direct contact with the heater. Therefore, the heater is actually hotter than the set point reading. The time required to reach the annealing temperature depends on the doping concentration, wafer thickness, etc. (16).

The electrical properties of the polycrystalline Si films were measured using a four-point probe and Hall effect measurements. The Hall measurements were made using van der Pauw patterns which had been etched into the films. The measurements yielded sheet resistance (R_s), sheet carrier concentrations (N_s), and mobilities (μ_n , μ_p).

The grain size in the polycrystalline film was determined by TEM. These samples were prepared by first

Fig. 1. Temperature *vs.* time for As-implanted Si. The anneal conditions were a heater set point of 1150°C and exposure time of 25s.

lightly ion thinning the polysilicon, floating the film off the substrate in dilute hydrofluoric acid, and finally picking the film up on a holey carbon film on a copper grid. The films were bright and dark field imaged at 200 kV in a JEOL 200CX by standard techniques. Through section images of the films were viewed in the electron microscope with no tilt of the sample holder. Cross-sectional images of many samples were viewed by tilting the sample holder to a high angle (about 60°), and examining thin edges of film fragments resting on the holey carbon film. Grain sizes were determined by counting at least 100 grains from through section views, plotting the distribution, and then choosing the peak (or peaks) in the distribution as the average grain size(s).

The As dopant profiles and the net loss of As during annealing were determined by RBS. A 2.0 MeV He beam was used with the particle detector located at a scattering angle of 154°. The samples were tilted such that the surface normal was 45° relative to the incident beam. The depth resolution for the RBS measurement was 22 nm.

The boron profiles were determined by implanting ^{10}B and performing neutron depth profiling (NDP) before and after annealing. The technique (21) and the facility used for this study (22) have been described elsewhere. The samples and standards were mounted to a mask constructed with an aperture of 7 mm diam being smaller than the neutron beam diameter in order to analyze equal and known volumes. The detector face was placed parallel to that of the surface of the sample with center points aligned and separated by a distance of 50 mm.

Results

^{75}As -implanted films.—We reported previously (18) that, unless As-implanted films were capped with SiO_2 , a substantial loss of As to the vacuum can occur during the anneal. This loss of dopant resulted in an increase in R_s with increasing exposure time. As expected, the As loss was greater for the higher heater temperature compared to the lower temperature anneal (1200° *vs.* 1150°C) (18). The loss of As from polycrystalline Si films was much greater than the loss from single-crystal silicon (12) due to the faster diffusion of As in polycrystalline Si relative to single-crystal silicon. These results are confirmed by the work of Powell and Chow (20).

Electrical results of As-doped polycrystalline Si.—To prevent As loss during annealing, an SiO_2 cap (0.05 μm) was sputter deposited on the other As-implanted films. The R_s , μ_n , and N_s *vs.* exposure time are presented in Fig. 2 for wafers annealed with a heater set point of 1150° and 1200°C. The R_s decreases and N_s and μ_n increase with increasing exposure time for both temperatures. The R_s for the 1150°C set point is always higher than the 1200°C set point. The minimum R_s of 98 Ω/\square in the 1150°C case (25s exposure) is approximately a factor of five lower than the minimum achieved on the uncapped samples where As was lost to the vacuum (18) and a factor of two lower than the R_s on a film which was furnace annealed at 950°C for 30 min (199 Ω/\square). The N_s increases rapidly for the two shortest exposure times (10-15s) regardless of set point temperatures. The N_s increases very little between 20 and 25s. The value for N_s for the 1200°C data is slightly higher than the 1150°C data. The mobility follows a similar trend of rising at the shorter times and changing very little for the two longest times. The higher μ_n and slightly higher N_s for the higher temperature anneals explains the differences in R_s as a function of temperature. The initial increase in N_s with time implies that the film must be above 1000°C (see Fig. 1) for a short time (a few seconds) in order for nearly complete activation of the dopant to occur. The increase in μ_n with exposure time implies that the average grain size in these films is increasing with exposure time. However, the R_s was a factor of about four higher and μ_n a factor of about two-and-one-half lower than films implanted with As to the same dose and CW laser annealed (23). The CW laser annealed films were thicker, but this would not account for all the differences we observed. However, the CW laser annealing caused

Fig. 2. Sheet resistance, carrier concentration, and mobility vs. exposure time for anneals with 1150° and 1200°C heater set point temperatures. The As implant dose was $5.0 \times 10^{15}/\text{cm}^2$.

complete melting and subsequent freezing of the polycrystalline Si film. The rapid thermal anneal is strictly a solid-phase annealing process. Differences are discussed below.

Profiles.—The As profiles for the as-implanted and 1150°C, 10 and 12.5s exposure samples are shown in Fig. 3. No loss of As was measured for the annealed samples confirming that the SiO₂ cap prevents the loss of As. The As has just begun to diffuse after 10s. There is evidence for a faster diffusion coefficient in the deep tail region ($> 0.12 \mu\text{m}$) of the wafer. In this case, the wafer reached a peak temperature of 1050°C. This faster diffusion in the tail is due to grain boundary diffusion, which is much faster than the diffusion which occurs in single-crystal silicon. Diffusion inside the grain would be similar to diffusion in single-crystal silicon and therefore much slower than grain boundary diffusion. After a 12.5s exposure, the As has uniformly distributed throughout the entire film at a concentration of $\sim 1.6 \times 10^{20}/\text{cm}^3$. The wafer reached a peak temperature of 1120°C in this case. In this case, we assume that the spreading of the dopant is dominated by grain boundary diffusion. Since these profiles were measured on films which were annealed with an oxide cap, the surfaces were smooth and the hillocks (which are discussed in the Surface morphology section) were not a problem in these profile measurements. Using an activation energy of 2.3 eV obtained by Baumgart *et al.* (24), we have calculated an effective diffusion time at the peak temperature (25). We then solved the diffusion equation numerically on a computer. To fit the 12.5s anneal profile required a diffusion coefficient for As in polycrystalline Si of $\sim 8 \times 10^{-11} \text{ cm}^2/\text{s}$ (18), which is nearly an order of magnitude greater than the diffusion coefficient reported by Baumgart *et al.* (26). Swaminathan *et al.* (26) reported an activation energy of 3.9 eV for grain boundary diffusion in polycrystalline Si. Using the same approach

Fig. 3. As dopant profiles before annealing and after an 1150°C anneal for 10 and 12.5s.

to fit the profiles as we discussed in Ref. (18) and an activation energy of 3.9 eV requires a minimum diffusion coefficient of $\sim 2.0 \times 10^{-10} \text{ cm}^2/\text{s}$. This is a somewhat lower diffusion coefficient than the $6.7 \times 10^{-10} \text{ cm}^2/\text{s}$ that would be predicted by extrapolating the results of Swaminathan *et al.* (26) to this temperature (1120°C). The faster diffusion coefficient of Swaminathan *et al.* (26) would be consistent with the data presented here since it would produce a flat profile also. Therefore, the present results indicate a somewhat faster diffusion coefficient for As in polycrystalline silicon during rapid thermal annealing than was predicted by Baumgart *et al.* (24), but the diffusion coefficient of Swaminathan *et al.* (26) would agree with the present data.

The distribution of As throughout the film is similar to the results on CW laser annealing (23). However, there is no As spike at the surface on the graphite heater-annealed film. This spike occurs because of As segregation which occurs in the liquid-solid freezing process. The rapid thermal annealing process is a solid-phase process. The uniformly distributed As can precipitate throughout the film, especially at grain boundaries or interfaces. The furnace-annealed sample shows that As has diffused throughout the polycrystalline film. There was no loss of As detected. There was some pile-up of As at the polycrystalline Si-SiO₂ interface. This is probably due either to As segregation at the grain boundaries, as reported previously (27, 28), or to segregation at an Si-SiO₂ interface.

Although RBS indicates As is uniformly distributed throughout the film after 12.5s, the maximum in sheet carrier concentration is not obtained until after a 20s exposure (see Fig. 2). This indicates that a large amount of the As is still in the grain boundaries and inactive after the 12.5 and 15s exposure. This is due to the fact that grain boundary diffusion is much greater than diffusion inside the grains. Therefore, for the shorter exposures most of the dopant is moving in the boundaries. After longer exposure times ($\geq 20\text{s}$), the As has uniformly spread throughout the grain boundaries and there is no longer a concentration gradient to move the As through the boundaries. However, the concentration in the interior of the grains is low and now there is a gradient causing some of the dopant to move from the grain boundaries to the interior of the grains, where it can become electrically active. These data are in agreement with the work of Powell and Chow (20).

Grain size of As-doped polycrystalline Si.—The as-deposited films, prior to annealing, displayed a bimodal distribution of grain sizes. The first population is composed of elongated grains of a columnar morphology with an average diameter of 39 nm. These evidently arise from preferential growth of some grains during deposition. The second population is composed of small equiaxed grains of about 5 nm diam. The bimodal distribution is shown in Fig. 4 and 5 in cross-sectional and through section views of an as-deposited film. In the through section view, two different sets of diameters can be seen. Duffy *et al.* (29) have also reported observing a bimodal distribution of grains for polysilicon films deposited at 622°C.

In this study, the bimodal distribution of crystallite sizes was preserved in the grain-growth process during transient annealing. However, as determined from cross-sectional TEM views, both populations assumed equiaxed morphologies as grain growth progressed. Figure 6 shows a through section view of an arsenic-implanted film after 12.5s of annealing at a heater set point temperature of 1150°C. Two different sets of grain sizes with averages of about 23 and 90 nm are clearly evident in this view. At the longest times at the highest annealing temperature, the two grain size populations have grown to maximum diameters of about 160 and 330 nm. The progression of grain growth during transient annealing is shown in Fig. 7, where grain size is plotted as a function of annealing time for films subjected to treatment with an 1150°C set point heater temperature. These results are detailed in Table I, which shows annealing time, actual peak wafer temperature, and the associated grain sizes. Significant grain growth does not begin until annealing time has reached 10s. Grain growth occurs rapidly between 10 and 20s, but then slows down due to geometrical constraints to be discussed later. This is consistent with electrical measurements which show significant mobility

increases from 10 to 20s, but little increase after 20s (see Fig. 2). The difference in grain size between these films and films which were CW laser annealed (23, 24) explains the difference in mobility between these films and polycrystalline Si films which were CW laser annealed.

In transient annealing, significant diffusion and grain growth occur during the temperature rise and fall and must be taken into consideration. In order to account for this, we have developed a modified model for interfacial energy driven grain growth. This model successfully describes grain growth for both populations in this study and helps explain the appearance of the S-shaped curves in Fig. 7. By measuring the mean grain size (\bar{r}) and effective time (t^*) at temperature the grain boundary migration rate can be determined. In a pure material, the migration rate is equal to the grain boundary mobility times the driving force

$$G = M\bar{r} \quad [1]$$

Wada and Nishimatsu (30) have shown that the grain boundary mobility (M) is proportional to the grain bound-

Table I. Grain size and effective times for polycrystalline films annealed with a variety of heater temperatures and exposure times

Set point temperature (°C)	Peak wafer temperature (°C)	Exposure time (s)	Effective time (s)	$\sqrt{Dt^*/T}$ (cm/K ^{1/2} × 10 ⁻⁶)	Grain size (nm)

ary silicon diffusion coefficient divided by kT . If the temperature is accurately varied during grain growth, then the average grain boundary migration rate $G(T)$ can be determined from $d\bar{r}/dt(T)$. It is frequently found that the average grain size follows a time law of the form

$$r = (at)^n$$

and by determining n the recrystallization mechanism is determined. Wada and Nishimatsu (30) have shown that grain growth in doped polycrystalline Si is driven by interfacial energy, and grain size (r) is, therefore, proportional to the square root of time at constant temperature. However, we have modified the interfacial energy model in two ways to compensate for time required for heating and cooling during transient annealing. First, the effect of changing temperature has been compensated for by calculating the diffusion coefficient (D) of Si in polycrystalline Si based on the peak temperature of the wafer. Second, an effective time (t^*), as described by Shewmon (25), is calculated based on the time-temperature profile, the peak temperature (T), and the appropriate activation energy. In this study, we have used a value of 2.4 eV for activation energy of diffusion of Si in polycrystalline Si as specified by Wada and Nishimatsu (30) in their study of grain growth of doped polysilicon. Based upon a classical model for grain growth, as discussed by Wada and Nishimatsu (30), by McLean (31), and by others, a new modified model for interfacially driven grain growth can be given by the relationship: $\bar{r} \propto \sqrt{Dt^*/T}$. D may be calculated from $D = D_0 \exp(E_a/kT)$, where D_0 is the proportionality constant (and is assumed here to be 1 cm²/s for simplicity), E_a is the activation energy, and k is Boltzmann's constant.

In Fig. 8, grain size is plotted as a function of $\sqrt{Dt^*/T}$ for samples annealed at various time-temperature conditions. Both populations of grain sizes from the bimodal distributions have been plotted. The solid circles represent sizes of grains of the first population which have grown from the larger as-deposited grains with the columnar morphology. The open circles represent sizes of grains which have grown from the second population of smaller as-deposited grains with an equiaxed morphology.

A linear least squares fit was applied to the data for each population up to a value of $\sqrt{Dt^*/T}$ less than 4×10^{-6} cm/K^{1/2}, as shown by the solid line. This results in a correlation coefficient of approximately 0.98 for both grain size populations. At values of $\sqrt{Dt^*/T}$ higher than 4×10^{-6} cm/K^{1/2}, there is a break in the least squares fits due to geometrical constraints affecting grain growth. For the first population, the one with larger grains, the growth rate is lowered when the grain size reaches the thickness of the film. A similar effect has been observed for growth of polycrystalline Si films by Jain and Overstraeten (32). For the second population, the one with the smaller grains, the growth rate is reduced when the grains impinge upon one another. Similar effects for metals have been documented by McLean (31). The regions for the reduced growth rates are represented by dashed lines on the plot because the scatter of the data is high.

The reduced growth rates also explain the flattening of the S-shaped curves at longer annealing times as shown in Fig. 7. Thus, we find that, prior to geometrical interference, grain growth processes during transient annealing of doped polysilicon can be described by a modified model for interfacially driven grain growth.

B-implanted films.—Electrical results.—The R_s , N_s , and μ_p as a function of exposure time for films implanted with B (50 keV, 3.0×10^{15} /cm²) are shown in Fig. 9. The films were capped with SiO₂. However, no differences were observed between capped and uncapped films. This implies boron is not being lost during the anneal which is similar to results we obtained previously on single-crystal Si (15, 18). The N_c is essentially constant at 3.5×10^{15} /cm² for the 1150°C heater anneal. The fact that N_c is greater than the dose is not understood completely. The μ_p increases with increasing anneal time. Note that μ_p is actually higher than the μ_n obtained on the As-implanted films (Fig. 2). In single-crystal silicon with a dopant concentration of 2.0×10^{20} /cm³, μ_n would be a factor of two greater than μ_p . The reason for the higher μ_p than μ_n may be that some of the As (~30%) has segregated into the grain boundaries and acts as a barrier to electron flow, thus lowering mobility. In the case of B-implanted polycrystalline Si, no segregation to the grain boundaries occurs (33).

Profiles.—Figure 10 shows the boron profile before and after annealing as measured by neutron depth profiling. The results are analogous to those obtained from As implants (see Fig. 3) in that boron has diffused uniformly throughout the film after 12.5s anneal. The 10s anneal shows a spreading of the dopant throughout the film, but

Fig. 8. Grain size as a function of $\sqrt{Dt^*/T}$ for As-implanted polycrystalline Si films annealed at 1150° and 1200°C set point heater temperatures.

Fig. 9. Sheet resistance, carrier concentration, and mobility vs. exposure time for an anneal with an 1150°C heater set point temperature. The B implant dose was $3.0 \times 10^{15}/\text{cm}^2$.

the concentration is not yet uniform through the film. Within the repeatability of the implant doses between samples (<5%), there was no loss of boron even though the film was not capped during the anneal. This is in agreement with the previously published results on single-crystal Si (15, 18). The average thickness of the boron containing layer is $0.31 \mu\text{m}$, compared to the original deposited polysilicon thickness of $0.3 \mu\text{m}$. The apparent thickness of the film lacks sharp definition in the NDP profile as a result of averaging the various thicknesses due to hillocks in the region of the sample illuminated by the beam. In addition, the system resolution, which is not deconvolved from the data shown, adds a full width at half maximum broadening of $0.02 \mu\text{m}$. Nonetheless, there is no evidence for diffusion of boron into the underlying SiO_2 layer.

Grain size.—Results of grain growth for boron-implanted polycrystalline Si films display trends similar to those of arsenic-implanted films, but there are some differences. Similar to the As-doped films, we find significant grain growth initiates at an annealing time of about 10s. Throughout the grain growth process, the bimodal distribution continues to exist, as was observed with the arsenic-implanted films. Grain growth continues up to 20s, but does not slow down. This is because impingement of the growing grains with the film surface or with other grains does not occur because grains are not as large as in As-doped films. This is consistent with electrical measurements, which show significant mobility increases beginning at 10s of annealing and continuing through 20s of annealing. When the grain size of the population of large grains of arsenic vs. boron is compared for a 20s, 1150°C anneal, that of the arsenic is 300 nm vs. 220 nm for the boron. The larger grain size of the arsenic film is due to the well-known phenomenon of dopant-enhanced diffusion where arsenic increases the diffusivity of Si in polycrystalline Si (30). The increase is dependent on the concentration of arsenic in the Si. The dopant level in the films studied here is about $1.5 \times 10^{20} \text{ cm}^{-3}$. For this level of arsenic doping, the diffusivity of Si should be about two times that of undoped Si (30). Boron, however,

Fig. 10. B dopant profiles before annealing and after an 1150°C anneal for 10 and 12.5s.

does not significantly affect the diffusivity of Si, which would mean that the grain size would then be roughly the same grain size as for undoped silicon. Since the average grain size \bar{r} is proportional to the square root of the diffusivity (\sqrt{D}), the ratio of the grain size of the population of larger grains in the arsenic-doped polysilicon to that of the boron-doped silicon should be about $\sqrt{2}$ or about 1.41. The experimental result of $\sqrt{300/200}$ or 1.35 is in reasonable agreement with the predicted result. The ratio of the grain sizes of arsenic- and boron-doped polysilicon for the second population of smaller grains is $168/90 \text{ nm}$, and the square root of the ratio is $\sqrt{168/90}$ or 1.37. This ratio is in reasonable agreement with the ratio of 1.41 predicted by diffusivity.

Surface morphology.—Although no differences in the electrical properties or grain size were observed on the boron-implanted, capped and uncapped films, the surface was much rougher on the uncapped films. Figures 11a and 11b show SEM micrographs of capped and uncapped films. The films were annealed for a 20s exposure time with a 1200°C heater setting. Figure 11c is a surface profilometer measurement indicating the surface roughness on the uncapped film is $\sim 50 \text{ nm}$. This surface roughening on uncapped films was also observed on undoped films, but was not seen on the As-implanted films. We have not seen any relation between surface roughness and grain size or electrical properties. We believe the surface roughness is due to rapid diffusion of Si along the grain boundaries to form hillocks on the surface. We believe this rapid diffusion of Si up the boundaries is due to stress in the film. Hillock growth in metal films has been modeled by Chaudhari (34) and depends upon stresses in the film as well as mass transport along interfaces and grain boundaries. The kinetics of hillock growth for metals are inhibited by precipitation in the grain boundaries and dielectric overlayers (35). Similar characteristics were observed for transient annealing of polycrystalline Si films. The use of a SiO_2 cap layer mini-

Fig. 11. B-implanted polycrystalline Si annealed at 1150°C for 25s. The figures show (a) SEM view of 50 nm SiO₂ capped film, (b) SEM view of uncapped film, and (c) surface profilometer measurement of uncapped film.

mizes hillock growth. For As-implanted films, hillocks are not observed. We believe this is due to the partial segregation of As into the grain boundaries. As segregation to the grain boundaries has been reported by Swaminathan *et al.* (27) and Batson *et al.* (28). The fact that we do not obtain 100% electrical activation for As in polysilicon (see the Electrical results of As-doped polycrystalline Si section) further supports this assumption. We believe the As in the boundaries is preventing the rapid diffusion of Si up the boundaries to the surface and thus preventing the formation of hillocks.

BF₂-implanted films.—Films were also implanted with BF₂ and annealed to determine any differences between B- and BF₂-implanted polycrystalline Si. The implant conditions for the BF₂ were adjusted to give the same range as the regular boron implant. Figure 12 presents the BF₂ sheet resistance results as a function of exposure time. The R_s is slightly higher for the 1150°C anneals as compared to the 1200°C heater set point anneals. The R_s for the B-implanted samples (see Fig. 9) are consistently lower than the BF₂ results. The TEM results indicate that the crystals in the BF₂-implanted films are not quite as large as the crystals in the boron-implanted films. The uncapped, BF₂-implanted films showed less surface roughness than the uncapped B-implanted films. However, these films were not as smooth as the uncapped As-implanted films. This suggests that some of the fluorine is moving to the grain boundaries and preventing some of the migration of Si to the surface.

Summary

We have shown that B and As ion implanted into polycrystalline Si films can be activated with a Varian IA-200 Rapid Thermal Annealer. The R_s on the As-implanted films increased with exposure time on uncapped wafers due to a loss of dopant from the film. The loss of As from the polycrystalline Si films is much greater than the loss from single-crystal Si which we reported earlier (12, 16). This greater loss is due to the faster diffusion of As in polycrystalline Si relative to single-crystal silicon. The As-implanted films which were annealed with a SiO₂ cap showed a rapid decrease in R_s and increase in N_s and

μ_n for exposure times up to 20s. Longer exposure times produced little change in these parameters.

The R_s of the B-implanted films decreased with exposure time out to 20s and then changed very slowly. The mobility of these films increased with increasing exposure time. Although B was not lost during annealing, a surface roughness due to the formation of hillocks was observed on the B- and BF₂-implanted films unless the wafers were capped. The surface roughness is due to mi-

Fig. 12. Sheet resistance vs. exposure time for anneals with 1150° and 1200°C heater set point temperatures. The BF₂ implant dose was 3.0 × 10¹⁵/cm².

gration of Si up grain boundaries to the surface to form hillocks. However, in the case of As some of the dopant segregates to the grain boundaries and prevents this Si migration. This explains why we see more hillocks on B-implanted films, fewer with BF_2 implants, and no hillocks with As-implanted film.

For polycrystalline Si films in this study, a bimodal distribution of grains is present which is composed of large columnar grains and smaller equiaxed grains. The bimodal distribution of grain sizes is generally preserved in grain growth during transient annealing in both boron- and arsenic-doped polycrystalline Si films. A modified model for interfacial energy driven grain growth has been developed which describes grain growth during transient annealing of As- or B-doped polycrystalline Si. In transient annealing of arsenic doped films, dopant-enhanced diffusion increases the diffusivity and the grain growth rate for silicon in polycrystalline Si when compared to undoped or boron-doped polysilicon. Grain size increases during rapid thermal annealing for either As- or B-doped films. This grain growth increases the mobility. However, the grain size and mobility for rapid thermal annealing are less than for CW laser-annealed films.

The R_s on the rapid thermal-annealed films was lower than on the conventional furnace-annealed films. The R_s on the transient annealed films was higher than on CW laser-annealed films (23). The lower R_s on the CW laser-annealed films is due to a larger grain size and increased mobility. However, this rapid thermal anneal is a solid-phase process rather than a liquid-phase process like CW laser annealing of polycrystalline Si. Also, the present technique does not result in the large thermal gradients across a wafer that laser annealing causes. Therefore, this process will not encounter the same problems in annealing polycrystalline Si over various dielectrics that the CW laser annealing does (36). Concurrent rapid annealing of ion-implanted single-crystal silicon and polycrystalline silicon can be achieved. Anneal conditions similar to those reported here have been used to fabricate low reverse leakage diodes and functioning bipolar transistors as well as CMOS ring oscillator (37). Thin film interferences have made concurrent annealing very difficult with CW lasers.

GaAs Growth Using TMG and AsCl₃

M. Yoshida, H. Terao, and H. Watanabe

NEC Corporation, Fundamental Research Laboratories, Miyazaki 4-chome, Miyamae, Kawasaki, Kanagawa 213, Japan

ABSTRACT

A new GaAs vapor-phase epitaxial (VPE) technique using trimethylgallium (TMG) and arsenic trichloride (AsCl₃) has been developed. This VPE is free from the source instability in chloride VPE and fatally toxic arsine (AsH₃) in hydride and metalorganic VPE. The growth reaction is based on the gallium chloride transport method. Growth rates of 300-4000 Å/min were obtained at growth temperatures between 650° and 780°C. At III/V ratios below 2.3, the growth rate increased as the TMG flow rate increased and the AsCl₃ flow rate decreased. The growth rate was independent of the temperature in the gas mixing region of the reactor. High purity n-GaAs with a 77 K mobility of 36,000 cm²/Vs was obtained.

Because of its superior high frequency performance, GaAs has been used for microwave devices. As the demand for faster electronic devices increases, mass production of GaAs epitaxial layers becomes required (1). However, VPE techniques developed to date have problems in productivity. The chloride VPE has a problem of source instability (2) and, thus, the potential for scaling up of this system is limited. Both hydride VPE and metalorganic VPE have the problem of using fatally toxic arsine (AsH₃), which has hindered them from operating as a mass production system.

In this paper, a new metalorganic-chloride (MOC) VPE technique using trimethylgallium (TMG) and arsenic trichloride (AsCl₃) for GaAs growth is described. The electrical properties of GaAs layers grown in the system using triethylgallium (TEG) instead of TMG are also shown. The MOC-VPE is free of the source instability and the fatally toxic AsH₃. Since TMG and TEG decompose perfectly in a hot region (3), they act as sources for gallium which is dispersed in the vapor phase. Therefore, the MOC-VPE is also free from incomplete liquid-vapor reaction (4).

Experimental

Figure 1 shows a schematic illustration of the MOC-VPE system for GaAs growth. The TMG and the AsCl₃ were introduced separately into a hot-wall reactor together with H₂ carrier gas. An additional dilution flow of H₂ was kept at 500 standard cubic centimeter per minute (sccm) throughout the experiment. In order to prevent early decomposition of TMG, it was passed through a 30°C water-cooled quartz tube. A widely used hot-wall reactor system for chloride VPE can be used for MOC-VPE with this slight modification of the reactor inlet. It is important to complete the reaction between TMG and AsCl₃ to form gallium chloride and arsenic vapor; otherwise, epitaxy is not achieved (5). The temperature in the gas mixing region was kept high enough to eliminate wall deposition. Downstream from the mixing region, epitaxial growth proceeded on a substrate.

The temperatures of TMG, TEG, and AsCl₃ containers were 2°C (vapor pressure of 0.1 atm), 18°C (vapor pressure of 0.005 atm), and 18°C (vapor pressure of 0.01 atm), respectively. Triethylarsine (TEAs) vapor was used to pre-

vent thermal dissociation of the substrate during the heat-up. The metalorganic sources were supplied by Sumitomo Chemical Company. The substrates were 3 × 1 cm² Cr-doped 2° off (100) towards <110>. Thicknesses of the grown layers were measured in an optical microscope after 5° bevel lapping and staining with 1:1:10 HF:H₂O₂:H₂O etchant. The growth rate was related to the layer thickness at 1 cm from the front edge of the substrate. Carrier concentrations and mobilities at temperatures of 77 and 300 K were measured by the van der Pauw method with a magnetic field of 0.6T.

Results and Discussions

The dependence of the growth rate on various growth parameters was investigated. Figure 2 shows the dependence of the growth rate on the flow rate of H₂ passing through the TMG container (TMG flow rate), where that of H₂ passing through the AsCl₃ container (AsCl₃ flow rate) was 200 sccm. The mixing temperature was 850°C, and the growth temperature was 740°C. The growth rate increased linearly as the TMG flow rate increased. It reached the maximum at a TMG flow rate of 42 sccm (a III/V ratio of 2.3). At higher TMG flow rates, the growth rate decreased as the TMG flow rate increased because high supersaturation in the mixing region resulted in GaAs deposition there and caused arsenic vapor depletion in the growth region. At TMG flow rates below 25 sccm (III/V ratios below 1.4), the substrate is etched.

As shown in Fig. 3, the dependence of the growth rate on the AsCl₃ flow rate forms a contrast to Fig. 2. The TMG flow rate was 42 sccm there. At AsCl₃ flow rates below 100 sccm, no deposition occurs on the substrate.

Fig. 1. Schematic illustration of growth apparatus

Fig. 2. Dependence of growth rate on flow rate of H₂ passing through TMG container.

Fig. 3. Dependence of growth rate on flow rate of H₂ passing through AsCl₃ container.

The growth region is fully arsenic depleted because of unwelcome deposition in the mixing region. As the AsCl₃ flow rate increased up to 200 sccm, the growth rate abruptly increased but the surface of the grown layer was still rough due to the arsenic depletion. At higher AsCl₃ flow rates (III/V ratios below 2.3), the growth rate decreased as the AsCl₃ flow rate increased. At these AsCl₃ flow rates, the wall deposition in the mixing region disappeared. The substrate is etched at AsCl₃ flow rates above 330 sccm. The surface etched at 400 sccm was smooth. The *in situ* gas etching for making a well-controlled interface between the substrate and the epitaxial layer (6) can be carried out in the MOC-VPE system by reducing the III/V ratio.

It should be mentioned that the growth rate is independent of the mixing temperature, as shown in Fig. 4. This is a feature of MOC-VPE. Therefore, it can be said that the MOC is single-temperature VPE method like MOVPE. Figure 5 shows the variation of the growth rate with the growth temperature. The typical dependence observed in chloride VPE (7) can be seen. The growth is kinetically limited at growth temperatures below 760°C and thermodynamically limited at higher growth temperatures.

Fig. 4. Dependence of growth rate on mixing temperature

Fig. 5. Dependence of growth rate on growth temperature

Figure 6 shows the relation between the Hall mobilities and the Hall electron concentrations for nondoped GaAs layers. The electrical properties of layers grown in the TEG/AsCl₃/H₂ system are also shown. The grown layers exhibited n-type characteristics, except for some highly resistive samples grown at high III/V ratios, larger than 2.3. The epitaxial layers were grown at temperatures between 700° and 780°C in the TMG/AsCl₃/H₂ system and at temperatures between 650° and 750°C in the TEG/AsCl₃/H₂ system. The typical input concentration of TMG was 6.3×10^{-3} with an AsCl₃ input concentration of 2.7×10^{-3} in mole fraction. That of TEG was 1.4×10^{-3} with an AsCl₃ concentration 5.9×10^{-4} . The thickness varied between 0.9 and 18 μm, corresponding to growth rates of 300-4000 Å/min. The GaAs layers with lower electron concentrations were grown in the TMG/AsCl₃/H₂ system. The difference between using TMG and TEG seems to be due to the difference in the input AsCl₃ concentrations, since high purity GaAs layers with low electron concentrations are obtained at high input AsCl₃ concentrations (8).

A GaAs epitaxial layer with a thickness of 11 μm grown at a TMG flow rate of 42 sccm, and AsCl₃ flow rate of 200 sccm, a mixing temperature of 800°C, and a growth temperature of 740°C showed a mobility of 36,000 cm²/Vs with an electron concentration of 1.4×10^{14} cm⁻³ at 77 K. That compensation ratio, N_A/N_D , is 0.88 using an interpolation of the data of Walukiewicz *et al.* (9). The net impurity concentration is thus 2.2×10^{15} cm⁻³. At higher TMG and AsCl₃ concentrations, the purity of the GaAs epitaxial lay-

Fig. 6. Relation between electron mobility (μ) and electron concentration (n).

ers may be improved further. Since the growth reaction in MOC-VPE is similar to that in chloride and hydride VPE, it should be possible to use conventional VPE doping techniques.

To determine residual acceptors present in the layers, 11 K photoluminescence (PL) measurements with 5145Å excitation radiation from an Ar laser were performed (10). The PL spectrum of a GaAs layer grown in the TEG/AsCl₃/H₂ system with an electron concentration of $8.2 \times 10^{16} \text{ cm}^{-3}$ and a thickness of 4.62 μm showed a peak at 8300Å with a full width at half maximum (FWHM) of 66Å and a weak broad peak around 8500Å besides a main peak at 8198Å with a FWHM of 60Å. Therefore, carbon seems to be the main acceptor in this layer, since 8300Å luminescence is attributed to carbon acceptor (11).

Summary

MOC-VPE using TMG and AsCl₃ for the GaAs₃ growth shows promising features. It excludes the liquid source instability and fatally toxic AsH₃. At III/V ratios less than 2.3, the wall deposition in the mixing region was suppressed and GaAs layers with smooth surface were grown. In this III/V ratio range the growth rate increased as the TMG flow rate increased and the AsCl₃ flow rate decreased. The growth rate could be controlled over a wide range between 300 and 4000 Å/min. The growth rate is independent of the mixing temperature, which means that MOC-VPE is a single-temperature method like MOVPE. The substrate was gas etched with a smooth surface at low III/V ratios. Though carbon may have been introduced into the epitaxial layer, a high purity GaAs epitaxial layer with a 77 K mobility of 36,000 cm²/V and a 77 K electron concentration of $1.4 \times 10^{14} \text{ cm}^{-3}$ was obtained.

It should be noticed that a widely used chloride VPE system can be used for MOC-VPE with only a slight

modification of the reactor inlet. Furthermore, the *in situ* gas etching necessary for a well-controlled interface between the substrate and the epitaxial layer can be easily carried out in the MOC-VPE system by reducing the III/V ratio.

Effect of Annealing on Chemical State of Phosphorus in SiO₂ Films

Owen K. T. Wu*

A. N. Saxena

Gould AMI Semiconductors, Santa Clara, California 95051

ABSTRACT

The chemical state and concentration of phosphorus in SiO₂ influence its thermal flow and etch rate. These properties of phosphorus-doped SiO₂ are quite important in both bipolar and MOS VLSI, and they influence the final yield of these circuits. In this paper, ESCA and Auger measurements were made to determine the chemical state of phosphorus in SiO₂ and its distribution through the film. Samples studied were CVD SiO₂ containing 8% phosphorus by weight, and ion-implanted phosphorus in thermal SiO₂, both annealed and unannealed. ESCA data confirmed the existence of two types of states corresponding to P-O bonds and P-Si bonds. The change in these states due to annealing is discussed.

It is well known that thermally grown SiO₂ films are absolutely essential for planar technology, and its many variations are used in the fabrication of bipolar and metal oxide semiconductor integrated circuits (MOS IC's). Almost equally important are the deposited SiO₂ films, in particular those doped with phosphorus. Today's very large scale integrated circuits (VLSIC's) cannot be fabricated without phosphorus-doped SiO₂ [such as phosphorus-doped vapox (PVX)] films, and they are expected to remain indispensable even for future VLSIC's.

PVX films are most commonly deposited by chemical vapor deposition techniques, with the weight percent (w/o) of phosphorus ranging between 4 and 8. A majority of the MOS processes use PVX as the first-layer-deposited dielectric, through which contact holes to Si

are etched and which isolates first-layer metal from the poly-Si or polycide interconnect underneath. In both MOS and bipolar processes, PVX is also used as the interlayer dielectric in the multilevel metallization schemes. Even though a few of the properties of PVX, e.g., reflow, etch rate, passivation, and their dependence on phosphorus concentration in SiO₂, are understood qualitatively, little is known about some of the basic properties like the chemical state of phosphorus and its change due to annealing (1, 2). The chemical state and concentration of phosphorus in SiO₂ influences the charge trapping centers (3), reflow, etch rate, stress, and the passivation properties. For a review of dielectric films as needed in multilevel metallizations, see Ref (4).

In this paper, ESCA and Auger measurements were made to determine the chemical state of phosphorus in SiO₂ and its distribution through the films.

*Electrochemical Society Active Member.

Experimental

Samples studied were CVD SiO₂ (PVX) containing 8% phosphorus by weight. Also, samples having ion-implanted phosphorus in thermal SiO₂, both annealed and unannealed, were used to generate P-O and P-Si states in SiO₂ and to study the effects of annealing on them. Phosphorus ions were implanted into SiO₂ with the energy of 50 keV and the dose of 1×10^{17} ion/cm². After the implantation, samples were annealed in either dry N₂ or dry O₂ at 700°-1100°C for 10-100 min. In addition, P₂O₅ powder and a phosphorus ion-implanted Si wafer were used to generate ESCA reference spectra to characterize the P-O and P-Si states.

All ESCA and Auger data were obtained using a PHI Model 548 ESCA/Auger system with computerized (PDP-11) automated data collection system. Mg K α x-rays (1253.6 eV) were used in this study, and Au foil was employed to calibrate the spectra energy. ESCA data were collected using a 25 eV pass energy and were signal averaged using 100 sweeps. Most Auger data were collected using a 5 keV electron gun and 3×10^{-6} A of electron beam current. For thick samples ($\sim 1 \mu\text{m}$), the electron gun energy was reduced to 2 keV to avoid any charging problems. The Auger phosphorus peak at 120 eV (LMM) and silicon peaks at 76 eV (LMM) and 1606 eV (KLL) were monitored for depth profiles. The ion beam used for sputter etching was Xe⁺ at 5 keV to avoid sputter artifacts (5). The total ion current for this study was 4.3×10^{-6} A. The sputter crater was 3×3 mm for Auger and 9×9 mm for ESCA studies. The sputtering rate was calibrated by Dektak IIA, which is a microprocessor-based instrument used for making measurements on the depth of a sputter crater.

Results and Discussion

Reference ESCA spectra of P-O and P-Si states.—P₂O₅ powder and a phosphorus ion-implanted Si wafer were investigated to confirm the identification of the P-O and P-Si states, respectively. Figure 1 shows the ESCA spectrum of the P₂O₅ powder which has the reference state corresponding to the P-O bond. The peak in the spectrum is phosphorus 2P characterizing the P-O bond at 134 eV. Figures 2 and 3 show the ESCA spectra of the phosphorus ion-implanted Si wafer on the surface, unannealed and annealed, respectively. Even though the P-Si state undoubtedly exists in the annealed (1100°C, 30 min, N₂) sample, the ESCA data show that the phosphorus 2P peaks are at the same energy, *viz.*, 130 eV, for both unannealed and annealed samples. The peak in the annealed sample (Fig. 3) is slightly sharper than that for the unannealed sample (Fig. 2). The difference in full width at half maximum is about 0.3 eV. This is probably due to phosphorus occupying substitutional sites in Si in the annealed sample and having a well-defined P-Si bond. In the unannealed sample (Fig. 2), phosphorus is in the interstitial as well as substitutional sites, and host Si atoms are displaced from their substitutional sites. These give rise

Fig. 1. The ESCA spectrum of the P₂O₅ powder which shows the reference state corresponding to the P-O bond at 134 eV.

Fig. 2. The ESCA spectrum of the phosphorus ion-implanted Si wafer on the surface (unannealed) which shows the reference state corresponding to the P-Si bond at 130 eV.

Fig. 3. The ESCA spectrum of the phosphorus ion-implanted Si wafer on the surface (annealed). Please note that the peak is slightly sharper than that for the unannealed sample in Fig. 2.

to defect states which, while still representing P-Si bonds, have a broader energy distribution. Both the unannealed and annealed samples were sputter etched to reach the peak concentration of implanted phosphorus in bulk Si. The ESCA data on these samples were identical to those in Fig. 2 and 3.

CVD SiO₂ (PVX) films.—ESCA data were taken on CVD SiO₂ (PVX) films containing 8 w/o phosphorus. The results show that there is only one phosphorus 2P peak at 134 eV on the surface (see Fig. 4). The samples were sputter etched to remove thicknesses ranging from 400 to 1000Å, and ESCA data were taken on each sample. ESCA spectra on all these samples were the same. A representative spectrum for a sputter-etched sample is shown in Fig. 5. It shows two peaks corresponding to the energies 130 and 134 eV, respectively. These two peaks are due to two different chemical states of phosphorus in the film. The high energy state at 134 eV occupied about 70% and is

Fig. 4. The ESCA spectrum of the surface of CVD, SiO₂ (PVX) film containing 8% phosphorus which shows that there is only one phosphorus 2P peak corresponding to the P-O bond at 134 eV.

Fig. 5. A representative ESCA spectrum for a sputter-etched CVD SiO_2 (PVX) film containing 8% phosphorus which shows two peaks corresponding to the P-Si bond at 130 eV and P-O bond at 134 eV.

identified as the P-O state, and the low energy state at 130 eV occupied about 30% and is identified as the P-Si state.

The population of the P-O and P-Si states, *viz.*, 70% and 30%, respectively, in the above sputter-etched samples remained unchanged irrespective of the sputter etching condition (such as sputtering rate and time) needed to etch various thicknesses of the PVX. This suggests that the two states, P-O and P-Si, observed within the film as opposed to only one state, P-O, observed on the surface are not artifacts of the sputtering. To confirm further that sputter etching was not responsible for the creation of the P-Si state within the PVX film, chemical etching with buffered HF was used to remove 400 Å of PVX. ESCA measurements made on such a chemically etched film gave data similar to those shown in Fig. 5.

It should be noted that the peak widths of the P-O and P-Si states observed in the PVX film are slightly larger than those observed in the reference spectra shown in Fig. 1 (P-O state) and 3 (P-Si state). It is clear that a well-defined P-O state exists in the standard sample of P_2O_5 , and the P-Si state exists in the phosphorus-implanted Si sample. However, these two states are not so sharply defined in the PVX as in each of the standard samples. Instead, both the P-O and P-Si states exist simultaneously in the PVX film. It is expected that the energy distributions of the P-O and P-Si states in the PVX film are broader than those in each of the standard samples having only one state. This leads us to believe that the P-O and P-Si bonds in the PVX films are somewhat distorted and nonideal as compared to those in the reference samples.

As discussed earlier (1), the P-O state is defined to be "substitutional" corresponding to the phosphorus atom substituting for Si in the SiO_4 tetrahedron, and the formation of P_2O_5 -like agglomerates (6). The P-Si state is

Fig. 6. The Auger depth profile of a CVD SiO_2 (PVX) film containing 8% phosphorus by weight (or 5.3% by atomic percentage) which shows that the phosphorus concentration is uniform throughout the film except at the SiO_2 -Si interface.

Fig. 7. The Auger depth profile of a phosphorus ion-implanted thermal SiO_2 film which shows that phosphorus has a peak concentration at about 600 Å depth.

defined to be "interstitial" corresponding to the phosphorus atom replacing oxygen atom in and interposed between the SiO_4 tetrahedra.

Auger electron spectroscopy was used along with *in situ* sputter etching to study the distribution of phosphorus in the CVD SiO_2 (PVX) films. The data are shown in Fig. 6. It can be observed that the phosphorus concentration is uniform throughout the film except at the SiO_2 -Si interface. It is approximately 30% higher at the interface as compared to the bulk of the film. Similar observations have been reported earlier (7-9). The phosphorus pile-up at the interface depends on the Si surface and deposition conditions.

Ion-implanted thermal SiO_2 films.—Unannealed.—Figure 7 shows the Auger depth profile of an unannealed phosphorus ion-implanted thermal SiO_2 film. The result indicates that phosphorus has a peak concentration at about 600 Å depth. ESCA data taken on the surface of this unannealed sample show only one state of phosphorus corresponding to P-O bond similar to that in Fig. 4. Figure 8 shows the ESCA phosphorus 2P peaks for the same unannealed phosphorus ion-implanted thermal SiO_2 film after sputter etching 600 Å. The data again show that there are two chemical states of phosphorus present in the film as in the CVD SiO_2 films. However, the P-O state occupies only 15%, and the P-Si state occupies 85%. This kind of population inversion in the unannealed sample suggests that the Si-O bonds are broken by the phosphorus implantation in thermal SiO_2 ; however, P-Si bonds are more predominant than the P-O bonds. To ensure that the Xe^+ ion beam sputter etching has no perturbation on the population of the chemical states, samples were etched by a wet chemical method such as HF etching. The data show similar results for both sputter- and chemically etched samples (see Fig. 9).

Fig. 8. The ESCA phosphorus 2P peaks for a phosphorus ion-implanted thermal SiO_2 film after sputter etching 600 Å, which shows that there are two chemical states of phosphorus present in the film.

Fig. 9. The ESCA phosphorus 2P peaks for a phosphorus ion-implanted thermal SiO₂ film after 400Å of HF etch, which shows that there are two chemical states of phosphorus present in the film.

Annealing effects.—Figure 10 shows the Auger depth profile of a similar phosphorus ion-implanted thermal SiO₂ film as that used in the previous section, after annealing at 1100°C for 30 min in N₂. A comparison of Fig. 7 and 10 indicates that significant amounts (approximately 50%) of phosphorus are lost after annealing. It has been suggested by the previous study that phosphorus (probably pentoxide) is lost to the gas phase from the porous glass structure due to evaporation (10). Phosphorus leaching combined with moisture exposure is a main contributor to aluminum line corrosion (11, 12). The amount of phosphorus loss depends on annealing conditions such as annealing temperature, time, and environment. The blister formation of isolated P₂O₅ region observed under certain annealing conditions and phosphorus concentrations is important for multilevel metallizations (4). Such regions are apt to contribute to loss of yield in VLSIC's if precautions are not taken to avoid such formations. A more detailed study on the effect of annealing on the blister formation of P₂O₅ in SiO₂ will be published later (6).

Figures 11a and 11b show SEM micrographs of the ion-implanted SiO₂ film before and after annealing at 1100°C for 30 min in N₂. The results clearly show that blisters have been formed on the surface after annealing. We believe that this is due to phosphorus aggregates near the surface. The phosphorus in these aggregates exists as phosphorus oxides (probably P₂O₅) as confirmed by the ESCA studies shown later.

Figures 12 and 13 show the phosphorus 2P peak of the annealed (at 1100°C in N₂ for 30 min) ion-implanted SiO₂ film before and after sputtering. The results indicate that there is only one P-O state on the surface similar to that for unannealed implanted and CVD PVX samples. However, after 600Å of sputter etching, the P-O state occupied 68% and the P-Si state occupied 32%. The population of

Fig. 10. The Auger depth profile of a phosphorus ion-implanted thermal SiO₂ film after annealing at 1100°C in N₂ for 30 min, which shows that about 50% of phosphorus is lost after annealing.

the P-O state and P-Si state for samples annealed under different conditions was determined by ESCA measurements and summarized in Tables I and II.

Table I shows the population of the P-O and P-Si state of the ion-implanted samples annealed under dry N₂ for

Fig. 12. The ESCA phosphorus 2P peak of the annealed (at 1100°C in N₂ for 30 min) ion-implanted SiO₂ film before sputtering, which shows that there is only one P-O state on the surface.

Fig. 13. The ESCA phosphorus 2P peak of the annealed (at 1100°C in N₂ for 30 min) ion-implanted SiO₂ film after sputter etching 600Å, which shows that there are two chemical states of phosphorus present in the film.

Table I. The population of the P-O and P-Si states of the phosphorus ion-implanted samples annealed under dry N₂ for 30 min at different temperatures

	P-Si state (%)	P-O state (%)
(1) As implanted	85	15
(2) 700°C	80	20
(3) 900°C	75	25
(4) 1000°C	69	31
(5) 1100°C	32	68

Table II. The population of the P-O and P-Si states of the phosphorus ion-implanted samples annealed under O₂ at 950°C for different lengths of time

	P-Si state (%)	P-O state (%)
(1) As implanted	85	15
(2) 10 min	27	73
(3) 30 min	21	79
(4) 100 min	20	80

30 min at different temperatures. The results clearly show that the sample annealed at higher temperature has more population of P-O state as compared to that annealed at lower temperature. It is interesting to note that a drastic change occurred between 1000° and 1100°C, *i.e.*, P-O state became more dominant than P-Si state, which corresponds to the reflow temperature for phosphosilicate glass (about 1050°C). It is the authors' opinion that the reflow of the phosphosilicate glass depends more on P-O state than P-Si state. Further work is underway to correlate the reflow temperatures and chemical states (5).

Table II shows the population of the P-O and P-Si state of the ion-implanted samples annealed at 950°C under O₂ for different lengths of time. The results indicate that most of the changes occurred in the first 10 min. A comparison between Tables I and II suggest that one can obtain more P-O state at lower temperature and shorter annealing time in O₂ environment. This is probably the reason why the phosphosilicate glass can be reflowed at lower temperature in oxygen or steam ambients as compared to the inert gas ambient reported previously (12, 13).

Summary

In summary, we have observed P-O and P-Si states in phosphosilicate glasses. The populations of these two

states depend upon the deposition and annealing conditions. The P-O state is observed on the surfaces of both CVD and ion-implanted SiO₂ films having phosphorus. As these films are sputter or chemically etched, both P-O and P-Si states are observed. In the CVD SiO₂ (P) film, the P-O state dominates over the P-Si state. In the P ion-implanted SiO₂ samples, the P-Si state dominates over P-O state in the unannealed samples. However, depending on the annealing conditions, the P ion-implanted samples show the conversion of the P-Si state to P-O state. It is anticipated that the reflow, stress, and etch properties of SiO₂(P) film depend on the relative population of the P-O and P-Si states. Further work to establish such a correlation is in progress.

Submicron Silicon Epitaxial Films Deposited at Low Temperatures

C. J. Atkinson,* G. L. Wright, S. J. White, and J. D. Greenwood

GEC Research Laboratories, Hirst Research Centre, Wembley, England HA9 7PP

ABSTRACT

Submicron silicon epitaxial films have been deposited at low temperatures using only wet chemical cleans for the substrate surface preparation. The layers have been assessed by crystallographic (RHEED) techniques coupled with the electrical measurement of Schottky barrier diodes and transistors fabricated in the layers. In addition, XPS studies of the substrate surface prior to the deposition are also reported. Good quality epitaxial films have been produced at deposition temperatures of 900°C and below.

Low temperature growth of epitaxial films is of great interest to the development of many silicon technologies. Low temperature processing minimizes the diffusion of dopant atoms, whilst low temperature epitaxial growth also reduces gas phase autodoping effects. Researchers

*Electrochemical Society Active Member.

reporting direct low temperature epitaxial growth have all used an *in situ* clean prior to epitaxial growth. Typical *in situ* cleaning techniques used include heating (1), etching at high temperatures in hydrogen chloride (2), or sputter cleaning (3). The pre-epitaxial cleaning process removes native oxide which would prevent epitaxial

growth and removes some defects and surface contamination which would impair device performance. High temperature cleaning treatments reduce the advantages of lower temperature processing by increasing both the dopant diffusion and autodoping effects. *In situ* sputter cleaning requires additional expensive equipment. In this paper, a technique is described which enables device quality epitaxial films to be grown at temperatures of 900°C or lower using only wet chemical cleaning prior to loading the wafers into the reactor.

Experimental

All growth experiments were carried out in a vertically configured, RF-heated, atmospheric pressure reactor using silane in hydrogen as the deposition source. All temperature readings are derived from the in-built optical pyrometer on the reactor. Attempts to calibrate that instrument have indicated that the true substrate temperature within the reactor is somewhat lower than those readings would indicate. Substrates used were p- or n-type 100 silicon. Both float zone and Czochralski substrates were used. X-ray photoelectron spectroscopy was used to evaluate the efficiency of predeposition cleaning schedules. This method measured the thickness of native oxide present on the surface of the wafers by relating the area of the silicon peak to that of the silicon dioxide peak using the formula of Seah and Dench (4). The thickness of the deposited films was determined by including sapphire or oxidized test wafers with each growth run. Optical interferometry (or in some cases surface profilometry) was used to measure the thickness of silicon on the test wafers. Resistivity was monitored using silicon test wafers and spreading resistance measurements.

Crystal quality was largely evaluated using reflection high energy electron diffraction (RHEED). RHEED allows the observation of the top surface of the film (~50-100Å) and so gives information about crystal orientation and quality at the surface. Electrical characteristics of the films were investigated by fabricating Schottky barrier diodes (with titanium metallization) and simple structure bipolar transistors.

Results and Discussion

The effects of predeposition cleaning schedules on the thickness of native oxide grown is summarized in Table I. Immediately after a dilute hydrofluoric acid clean and brief rinse, no oxide could be detected on the surface of the wafers using XPS. Accordingly, a dilute hydrofluoric acid clean followed by a brief rinse in deionized water was used immediately prior to each epitaxial growth ex-

Fig. 1. RHEED photographs of epitaxial silicon grown in the epitaxy reactor.

periment. Following the cleaning procedure, the wafers were loaded quickly into the reactor and the system purged with dry nitrogen. (The actual cleaning schedule used is summarized in the Appendix). RHEED photographs of samples grown at temperatures between 770° and 950°C indicate that it is possible to grow high quality epitaxial films directly (*i.e.*, without the use of the high temperature hydrogen chloride etch) at temperatures as low as 830°C. The RHEED results are summarized in Table II, whilst Fig. 1 shows typical RHEED photographs for epitaxial films grown without an *in situ* clean at temperatures of 910°, 930°, and 950°C. A RHEED photograph of a film grown at 1015°C with an *in situ* hydrogen chloride etch at 1150°C prior to epitaxial growth is also shown for comparison. If the hydrofluoric acid clean was omitted, only polycrystalline growth was obtained, as the native oxide was sufficiently thick to mask the crystal structure of the underlying substrate. If a high temperature etch at 1150°C in hydrogen chloride was incorporated, some evidence of epitaxial growth was obtained at growth temperatures as low as 650°C, although some polycrystalline silicon was also noticeable. It is postulated that for epitaxial growth to occur, not only must the interface be largely free of contamination, but the temperature must be sufficiently high to allow some migration of the deposited atoms to lattice sites.

Schottky barrier diodes were fabricated on the epitaxial layers to obtain information about electric and crystal quality of the material. To a good approximation, the forward characteristics of Schottky barrier diodes are given by

$$I = I_0 \exp(qV/nkT)$$

where I is the forward current, V is the forward bias voltage, I_0 is the saturation current obtained by extrapolating the I vs. V plot to $V = 0$, T is the temperature, q is the charge on the electron, and n is the diode ideality factor. When $n \approx 1$, crystal quality is good and recombination in the space charge layer is small. When n approaches 2, space charge recombination is occurring, which implies

Table III. Ideality factors for diodes fabricated at various growth temperatures

Growth temperature (°C)	Ideality factor
950	1.04
930	1.05
910	1.05
890	1.1
870	1.09
850	1.11
830	1.2

Fig. 2. Typical V_{cc} vs. I_c curves for the 0.3 and 0.6 μm films.

that crystal quality is poor. The results for test diodes fabricated in epitaxy grown directly at temperatures ranging between 830° and 950°C are summarized in Table III. The diode ideality factors tend to increase as the deposition temperature is lowered, confirming that crystal quality deteriorates as the growth temperature is decreased.

Simple bipolar transistors were fabricated in epitaxial films of thickness 0.3 and 0.6 μm grown at 900°C. For the device structure used, the collector-base junction is 0.3 μm deep, so the transistor gain is highly dependent on interfacial crystal quality. For both thicknesses of film, the transistor gain was in excess of 200, implying good elec-

trical quality. Figure 2 shows typical V_{cc} vs. I_c curves for the 0.3 and 0.6 μm films.

Conclusions

It has been shown that device quality epitaxial growth can be brought about without using *in situ* predeposition cleaning schedules. The simple cleaning technique described could produce a considerable improvement in device fabrication technologies, for example, for bipolar transistors, IMPATT diodes, and Schottky barrier diodes.

Reduction of Radiation Damage on Silicon Substrates in Magnetron Reactive Ion Etching

Kado Hirobe and Hideaki Azuma

Hitachi Limited, Musashi Works, 1450, Josuihon-cho, Kodaira-shi, Tokyo 187, Japan

ABSTRACT

Radiation damage on silicon substrates has been reduced by decreasing the cathode dc bias in reactive ion etching (RIE). A magnetic field has been applied in the direction perpendicular to RF electric field between the parallel-plate electrodes to decrease the dc bias across the cathode dark space. Silicon substrates treated under RIE in CHF_3 and SF_6 mixed gas have been investigated by reflection high energy electron diffraction observation and lifetime measurement of the minority carrier. Low dc bias less than about 150V was found to be necessary for obtaining low damaged silicon surface.

Reactive ion etching (RIE) has been widely used to delineate fine patterns in silicon oxide films in fabrication of VLSI circuits. It is known, however, that bombardment of ions which are accelerated by the dc bias across the plasma sheath region degrades the crystal structure of the silicon substrate (1-4). Decrease in lifetime of the minority carrier (5), increase in the contact resistance between silicon substrate and metal film (6), low breakdown voltage of the oxide grown on RIE-treated silicon surface (7) are considered to be partly due to defects in the silicon crystal induced by bombardment of energetic ions. An effective method to reduce this kind of radiation damage induced by RIE is to decrease the energy of ions impinging on the silicon surface. In a conventional parallel-plate type of RIE apparatus, the decrease of RF power density, and/or the increase of operating pressure

of etch gas must be accomplished in order to reduce the cathode dc bias. Under these conditions, however, undesirable phenomena such as decrease in etch rate of silicon oxide and deposition of organic polymer films often arise. Furthermore, as the etch rate is decreased, and, consequently, as the throughput of etching apparatus is also decreased, the RIE cannot be economically operated at a low RF power density and at a high pressure.

Recently, RIE with magnetron discharge has been investigated for etching silicon oxide films at a low dc bias (8-10). Magnets are set behind the cathode to form a magnetic field perpendicular to the dc electric field over the cathode surface. These systems are called Band Magnetron (9) and planar Magnetron-HIRRIE (8). The magnetron discharge can generate highly dense radicals and ions. In the magnetron discharge system, the SiO_2 etch

rate of 500-1000 nm/min can be obtained, even if the dc bias is fairly low around 50-300V.

In the present paper, a relation between the silicon surface damage induced by RIE and the dc bias voltage across the plasma sheath is reported. Variation in dc bias voltage has been carried out using a discharge system in which a static magnetic field is applied perpendicular to the RF electric field to generate highly dense chemical species in the plasma. Radiation-induced defects on RIE-treated silicon surface have been investigated with reflection high energy electron diffraction (RHEED) and lifetime measurement of the minority carrier.

Experimental

The RIE apparatus used in this work is shown schematically in Fig. 1. Two parallel-plate electrodes of 130 mm diam are set in a cylindrical reactor made of aluminum. A sample was put on a silicon plate 1 mm thick placed on the cathode. An RF power supply at a frequency of 13.56 MHz was capacitively coupled to the cathode through a matching network. A permanent magnet system was placed in the reactor to apply a static magnetic field perpendicular to the RF electric field between the electrodes. Two magnet systems of the same external shape were used in this work. Their external shape was cylindrical, as shown in Fig. 2. The inside and outside diameters of the magnet system were about 180 and 240 mm, respectively. The height of the magnet system was 50 mm. A magnet system consists of two half-cylindrical magnets and two pole pieces made of soft steel. Their magnetic field strengths in the direction parallel to the magnetic field B were 200 ± 15 and 400 ± 50 G, over the range of 76 mm diam.

An optical emission spectrometer was attached to the reactor. The spectrometer was able to measure the light intensities of spectra emitted from any 4 mm thick layer in the discharge between the electrodes. Applying the optical system to SiO_2 RIE, light intensities of 321 nm emitted from CF_2 radical (11, 12) and of 520 nm from CO radical (13) were measured. A distribution of light intensity between the two electrodes can give a spatial distribution of relative concentration of these radicals.

A mixed gas of 99% CHF_3 and 1% SF_6 was used as an etch gas (14). The etch gas was introduced into the reactor through a hole in the top plate of the reactor and exhausted from a hole in the bottom reactor plate. No polymer deposition on silicon oxide films was detected under the conditions investigated in the work.

The silicon substrates used in this study were (100)-oriented, boron-doped single crystals of about $10 \Omega \cdot \text{cm}$ resistivity. Silicon oxide films were prepared by oxidizing the substrates at 1000°C , in dry O_2 ambient.

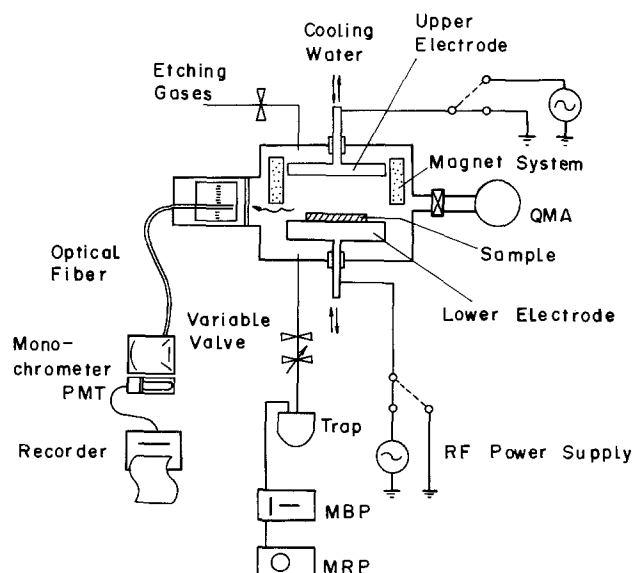

Fig. 1. Schematic drawing of experimental RIE apparatus

Fig. 2. Schematic drawing of permanent magnet configuration

An experimental procedure for investigating RIE-induced defects on a silicon surface was as follows: first, silicon wafers were treated under different RIE conditions, as summarized in Table I, then the silicon wafers were exposed to O_2 plasma (at 100W and 1 torr, for 10 min) to remove a trace of carbon compounds. After that, the samples were immersed into an aqueous HF solution to remove a thin silicon oxide film on the silicon surface. To investigate crystalline properties of the RIE exposed silicon surface, images of RHEED were taken. In addition, these silicon wafers were oxidized at 1000°C , in dry O_2 ambient, for 10 min to stabilize the silicon surface. After oxidation, the samples were submitted for lifetime measurement of minority carrier. An optical lifetime measurement technique was used. The measurement technique itself is published elsewhere (15). In the measurement system equipped in this study, a laser light of 904 nm wavelength used to generate hole-electron pairs in the silicon substrate can penetrate 20-30 μm deep into the silicon crystal (16). A frequency of microwave for measuring conductivity of electrons was 9.6 GHz, at which the microwave can be assumed to penetrate the silicon substrate about 500 μm deep, and so we could measure the lifetime of electrons in the region where RIE-induced defects locate.

Experimental Results and Discussion

Realization of low dc bias in magnetron RIE.—Figure 3 shows relationship between dc bias voltage across the cathode dark space and RF power density as a function of the magnetic field strength applied to the discharge. The dc bias voltage $|V_{dc}|$ was found to increase with increasing RF power density. When the magnetic field was applied perpendicular to the electric field, $|V_{dc}|$ decreased with increasing the strength of magnetic field. For example, $|V_{dc}|$ was 860V at 13 Pa (0.1 torr) and 1.5 W/cm^2 without a magnetic field. However, when the magnetic field strengths were 200 and 400G, $|V_{dc}|$ values were 340 and 120V, respectively.

Enhanced plasma discharge in the electromagnetic field, for example, in SiO_2 RIE, was indicated by in-

Fig. 3. Cathode dc bias $|V_{dc}|$ as a function of power density, for different pressures and magnetic field strengths.

creased emission intensities and increased SiO_2 etch rate. Figure 4 shows distributions of the emission intensity emitted from plasma discharge between two electrodes. A wavelength 321 nm is from an etchant CF_2 (Fig. 4a) and

520 nm from an etch product CO radical (Fig. 4b). In the figure, the intensity of light from CF_2 was found to be about two times stronger with a magnetic field of 400G than that without a magnetic field. In the observation of 520 nm light from CO, the light intensity was also found to be stronger with a magnetic field than that without a magnetic field. These results indicate that the application of magnetic field to the RF electric field enhances an efficiency of discharge and consequently increases a concentration of etchant radicals such as CF_2 .

In addition, the stronger light intensity of a reaction product CO suggests increased etch rate of SiO_2 in the magnetron RIE. In fact, unlike conventional RIE, high etch rates have been obtained in low $|V_{dc}|$ values by applying the magnetic field of 200 and 400G. Figure 5 shows SiO_2 etch rate as a function of $|V_{dc}|$ value and applied magnetic field strength. As shown in the figure, higher etch rates were obtained at lower $|V_{dc}|$ values by increasing the magnetic field. For example, the etch rate of SiO_2 was improved from 40 nm/min without a magnetic field to 600 nm/min with the magnetic field of 400G at 3 W/cm^2 of power density. From these results, the magnetron RIE was found to etch SiO_2 at high etch rates even with a low $|V_{dc}|$ value.

Observation of damaged silicon surface by RHEED.—Figure 6 shows RHEED patterns of the silicon surface treated under the RIE conditions summarized in Table I. In the RHEED experiment, the electron acceleration voltage was 75 kV and the incident angle of electron onto the silicon surface was about 4° . As shown in Fig. 6a, when $|V_{dc}|$ was very high such as 1170V, RHEED pattern was halo, indicating that the silicon surface is amorphous. As $|V_{dc}|$ became lower, Bragg spot patterns became stronger (Fig. 6b and 6c), and single crystalline Kikuchi line patterns were observed. At $|V_{dc}|$ of 150V, almost the same pattern as that of a control sample was observed. Polycrystalline silicon ring pattern was not observed in this study.

Deterioration in the crystal structure of the silicon surface treated under high $|V_{dc}|$ RIE is due to bombardment

Fig. 4. Distribution of emission intensity between two parallel-plate electrodes. (a): For 321 nm from CF_2 radical; and (b) for 520 nm from CO radical.

Fig. 5. Etch rate as a function of cathode dc bias $|V_{dc}|$, for different magnetic field strengths and power densities.

of energetic ions. It is considered that the kinetic energy of ions impinging onto a silicon surface is at maxima about a bias voltage $|V_{dc}|$ (17). Consequently, ions with a high kinetic energy such as 1170V disorder the crystalline structure of the surface, while ions with low energy such as 150V do not seriously deteriorate the crystal structure.

To investigate the depth of damaged surface layer at a typical $|V_{dc}|$ value of 340V in SiO₂ RIE, silicon samples were etched by 40, 80, and 120 nm with a HNO₃ and HF mixed etchant. RHEED patterns of the 40 nm deep etched sample were weak spot patterns, while single-crystalline silicon spot pattern was observed for the 80 nm deep etched sample. This result showed that the region of damaged layer was as deep as about 40 nm under the RIE condition of 340V of $|V_{dc}|$. In addition, it was

Fig. 6. RHEED patterns of silicon surface treated under RIE, for different cathode dc bias $|V_{dc}|$.

Fig. 7. Lifetime of minority carrier as a function of cathode dc bias $|V_{dc}|$.

found from RHEED patterns that the damaged layer at $|V_{dc}|$ of 340V was annealed out in dry O₂ oxidation ambient, at 1000°C, for 10 min.

From these results, the magnetron RIE which is able to obtain a low $|V_{dc}|$ such as 150V has no serious damage on the silicon surface. This is one of the advantages of the magnetron RIE over the conventional one.

Evaluation of damaged layer by lifetime measurement.—The lifetime of a minority carrier is decreased with increasing defect density in a silicon substrate. Using the phenomenon, crystalline properties of RIE-treated silicon surface were evaluated. Figure 7 shows relationship between lifetime and $|V_{dc}|$ for samples treated under the RIE conditions mentioned in Table I. The value of lifetime on the ordinate was normalized by that of a control sample. It was found that the lifetime of minority carrier (in our case, an electron) was changed from 100% to 70% of the lifetime of the control sample in the range of $|V_{dc}|$ from 0 to 150V. The lifetime was decreased sharply between 150 and 800V and leveled off at higher $|V_{dc}|$ values. In the range of $|V_{dc}|$ below 150V, plasma-exposed silicon surfaces were thought to be almost perfectly crystalline from the low decrease in the lifetime of minority carrier. However, it became clear that in the higher $|V_{dc}|$ values over 800V, RIE-treated silicon surface was not perfectly crystalline, from the low lifetime values. The results of lifetime measurement were in good agreement with RHEED observations.

Conclusions

Radiation damage on silicon substrates induced by RIE has been investigated using RHEED observation and lifetime measurement of minority carrier. RIE-induced defects could be reduced by decreasing the cathode dc bias during RIE. To decrease the dc bias across the cathode dark space, a magnetic field has been applied perpendicular to RF electric field between the parallel plate electrodes. Low dc bias less than 150V was found to be necessary for obtaining low damaged silicon surface. It was found that an advantage of the magnetron RIE over the conventional RIE is to be able to obtain high etch rates at low dc bias voltages.

Acknowledgments

The authors would like to thank Mr. Yoshifumi Kawamoto for his helpful discussion and Mr. Yoshimasa Shimizu for his RHEED observation.

Partial Pressures over the Pseudobinary Solid Solution $\text{Hg}_{1-x}\text{Cd}_x\text{Te(s)}$ for $x = 0.70$ and 0.95 and over Four Te-rich Ternary Melts

Ching-Hua Su, Pok-Kai Liao, and R. F. Brebrick*

Materials Science and Metallurgy Program, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The partial pressures of Hg, Cd, and Te_2 have been determined between 420° and 840°C from optical absorption measurements for four Te-rich compositions and for the Te-saturated solid solution ($\text{Hg}_{1-x}\text{Cd}_x\text{Te(s)}$) with $x = 0.70$ and 0.95 . In addition to further thermodynamically characterizing the melt, the former measurements yield ternary liquidus points. They also yield tie lines when combined with the present and previous measurements on Te-saturated solid solutions. These results, from an essentially steady-state technique, agree well with those of Harman. The measurements on the solid solutions yield values for the mixing quantities which are more accurate than our previous values. These are described well in terms of a quasi-regular solution of HgTe and CdTe components with an enthalpy of mixing of 1074 cal/g-atom and an excess entropy of mixing of 0.893 cal/K-g-atom at 50 mole percent CdTe.

The partial pressures of Hg, Cd, and Te_2 have already been reported (1, 2) for a number of compositions in the Hg-Cd-Te system. Here we report measurements for additional compositions. These include four Te-rich ternary melts. The liquidus points obtained from the measurements have already been given in a thermodynamic analysis of the phase diagram and thermochemical data (3, 4), and the partial pressures fit satisfactorily with an associated solution model for the liquid phase. However, the partial pressures themselves and the tie-line data obtainable from them have not been reported. In addition, we have determined the partial pressures for Te-saturated solid solutions, $\text{Hg}_{1-x}\text{Cd}_x\text{Te(s)}$, with x values of 0.70 and 0.95, so that the partial pressures are now known over the entire composition range for Te saturation. These measurements allow another, and, we believe, more reliable, determination of the enthalpy and entropy of mixing of the solid solution from its binary compounds, HgTe(s) and CdTe(s).

Experimental

Partial pressures were determined from measurements of the optical absorbance between 200 and 800 nm of the vapor in a sealed, initially evacuated, T-shaped silica optical cell. The upper leg of the T was the optical cell proper through which the light beam passed, while the lower leg contained the solid or liquid sample. During measurements, the cell proper was held at some fixed high temperature and the sample temperature at a num-

ber of lower temperatures. Care was taken to insure the sample temperature was always the lowest in the cell. Full details of the experimental arrangement and measurement technique and accuracy have been given in Ref. (1). As described in Ref. (2), the sample portion of the sidearm was enlarged to 2.0 cm od and a heat pipe placed around the sample to reduce the temperature variation to a few tenths of a degree centigrade or less. Temperatures are conservatively estimated as accurate to within $\pm 1.5^\circ\text{C}$. The volume of each optical cell was measured as a function of distance along the sidearm by adding water from a burette with 0.05 cm³ divisions before outgassing the cell.

The starting materials were six-nine spectroscopically pure, chunk Cd and Te and High Purity Grade Hg from Cominco American, Spokane, Washington. For the solid solution samples, the elements were weighed to the nearest 0.1 mg and in stoichiometric proportions for a total of about 15g. The elements were loaded into a carbon-coated silica tube, 12 cm long and 1.6 cm od that had been previously outgassed for 16h at 1000°C and $3(10^{-7})$ torr. The loaded tube was connected to a vacuum system and sealed off after 5-10 min at about 10^{-5} torr. The loaded tube was then placed in the center of a 20 cm long, 2.2 cm id heat pipe and put into a box furnace. The temperature was raised in steps to 690°C for the 70 mole percent (m/o) CdTe sample and 680°C for the 95 m/o CdTe sample and held for 72h. The furnace was then cooled to room temperature over a period of about 50h. Each tube was opened, and all of the black, porous material collected and ground in an agate mortar to pass a 63 μm stainless

*Electrochemical Society Active Member.

steel sieve. There was no sign of elemental Hg, which would have been detectable as a smear on the agate mortar. All of the material was then loaded with a funnel into an optical cell and sealed off at about $3(10^{-7})$ torr.

The four Te-rich ternary samples were made by loading the weighed elements directly into a previously outgassed optical cell, sealing off under $3(10^{-7})$ torr, placing the cell in a T-shaped furnace centered on the sample light beam, and heating the sample for 72h at a temperature just above the estimated liquidus temperature while the optical cell proper was hotter. Table I lists the optical path length, the free volume, the total sample mass, and the starting composition x and y in the formula $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}$ for each sample cell. In Table I, the uncertainty in the free volume is ± 0.1 ml. The other numerical quantities are accurate to the number of significant figures shown.

Calibration Measurements

The quantitative relations between the characteristic absorption of the predominant vapor species in this system, Hg, Cd, and Te₂, and the respective vapor partial pressures have been determined previously by Schwartz *et al.* (1) for one optical cell temperature, 755°C. In this investigation, we repeated and extended the calibration for higher optical cell temperatures to make possible partial pressure measurements at higher sample temperatures than before. The foreign gas broadening of the Cd lines by Hg(g) was also studied more closely and the broadening parameters redetermined. A detailed description of the calibration has been given (5). Here we confine ourselves to a brief summary and give some new results of the calibration.

Mercury.—Recently, Su *et al.* (6) have measured the absorption of the red wing of the 253.7 nm Hg line between 255.4 and 330.4 nm at five optical cell temperatures between 460° and 860°C. For each optical cell temperature, the values of the optical absorbance, D_λ , for each wavelength, λ , and temperature of the liquid Hg sample, $T_s(\text{K})$, fell on a straight line on a plot of $\log D_\lambda$ vs. $1/T_s$ with a slope twice that of the vapor pressure in a similar plot. The vapor pressure is given to within 1% by (1)

$$\log_{10} P_{\text{Hg}}^\circ (\text{atm}) = -3157/T_s + 5.028; 10^{-3} < P_{\text{Hg}}^\circ < 0.1 \text{ atm} \quad [1]$$

$$\log_{10} P_{\text{Hg}}^\circ (\text{atm}) = -3099/T_s + 4.920; 0.1 < P_{\text{Hg}}^\circ < 38 \text{ atm} \quad [2]$$

Therefore, the absorption coefficient varies as the square of the concentration of Hg atoms in the vapor phase, and, from the statistical theory of broadening

$$D_\lambda \equiv \log_{10} (I_0/I_\lambda) = LA_\lambda (P_{\text{Hg}}/T)^2 \exp(-V_\lambda/kT) \quad [3]$$

where I_0 and I_λ are intensities at a given wavelength, λ , of the incident and transmitted beams, respectively, L is the optical path length, and T is the optical cell temperature, *i.e.*, the temperature of the vapor through which the light passes as opposed to the temperature, T_s , of the liquid Hg sample generating the vapor. The parameters A_λ and V_λ have been tabulated (6) for 24 wavelengths between 254.4 and 330.4 nm so that P_{Hg} can be obtained from a measurement of D_λ at any temperature of the optical cell proper between 460° and 860°C. When one uses the tabulated

values for A_λ and V_λ in Eq. [3], the standard deviation in $(D_\lambda T^2/LP_{\text{Hg}}^2)$ is less than 2% for wavelengths between 257.4 and 310.4 nm (2.8% at 300.4 nm). Thus, when Eq. [3] is inverted to solve for P_{Hg} , the standard deviation in P_{Hg} is less than 1%, assuming no error in the measured values of D_λ , T , and L .

For P_{Hg} lower than about 0.5 atm, D_λ for $\lambda \geq 254.4$ nm is about 0.01 and comparable to the ± 0.02 noise in our measurement of D_λ . In these cases, the optical absorbance was integrated over the entire 253.7 nm Hg peak. For a 755°C optical cell and a 9.83 cm optical path, a pure Hg sample gave an integrated area, A , in units of optical absorbance (\AA), that depended upon the slit width used and the pressure range. If Eq. [1] is used to eliminate the sample temperature, then the results for P_{Hg} between 10^{-2} and 10^{-1} atm are

$$\log_{10} P_{\text{Hg}}(\text{atm}) = 0.7877 \log_{10} (9.83A/L) - 1.6054; \\ 0.042 \text{ nm bandpass, } \sigma_A = 0.028$$

$$\log_{10} P_{\text{Hg}}(\text{atm}) = 0.7276 \log_{10} (9.83A/L) - 1.5689; \\ 0.083 \text{ nm, } \sigma_A = 0.018$$

$$\log_{10} P_{\text{Hg}}(\text{atm}) = 0.6975 \log_{10} (9.83A/L) - 1.5366; \\ 0.125 \text{ nm, } \sigma_A = 0.016 \quad [4]$$

If Eq. [2] is used to eliminate the sample temperature, then for P_{Hg} between 0.1 and 0.5 atm the results are

$$\log_{10} P_{\text{Hg}}(\text{atm}) = 0.8773 \log_{10} (9.83A/L) - 1.6761; \\ 0.083 \text{ nm, } \sigma_A = 0.061$$

$$\log_{10} P_{\text{Hg}}(\text{atm}) = 0.8617 \log_{10} (9.83A/L) - 1.6606; \\ 0.125 \text{ nm, } \sigma_A = 0.056 \quad [5]$$

We have assumed Lambert's law in inserting the optical path, L (cm), into these equations, which should be approximately valid for path lengths near 9.83 cm. As can be seen, the integrated optical absorbance area, A , is almost proportional to P_{Hg} . In the low pressure range, this is more nearly so the smaller the slit width and the spectral bandpass of the spectrophotometer. For the absorption lines of monatomic vapor species at low pressure, the true optical absorbance area is proportional to the concentration of absorbers in the light path and hence to the partial pressure of absorbers (7). However, these lines are extremely sharp near the line center and can attain optical absorbance values in the thousands even at low pressures. Thus the areas measured here and characterized by Eq. [4] and [5] are not the true areas as evidenced, for instance, by the fact that the observed line half-widths equal the spectrophotometer spectral bandpass used. Use of a bandpass comparable to, or greater than, the true half-width of the line reduces the observed value of the optical absorbance. The observed value is also reduced at high values, in the range 2 to 3 here, when the transmitted light intensity is so small as to produce an increase in the photomultiplier current that is smaller or comparable to that observed in the dark. Therefore, in order to establish Eq. [4] and [5] it was necessary not only to set the slit widths but to also maintain the same intensity of the incident light beam. Thus, these equations are not necessarily transferable to other experimental setups in contrast to those embodied in Eq. [3]. However, they can be used with our arrangement and serve as an empirical calibration that is valid as long as all other partial pressures are negligible compared to that of Hg.

The standard deviations σ_A , shown after Eq. [4] and [5], are those in $\log A$ as a function of $\log P_{\text{Hg}}$, if one assumes Eq. [1] and [2] for the vapor pressure of Hg are correct. When Eq. [4] and [5] are used to calculate P_{Hg} from a measured value of A , the standard deviation is that in the measured value of A plus a contribution from the uncertainty in the calibration measurements. Expressed as a

Table I. Optical path length (cm), free volume (cm³), total mass (g), and starting composition x and y in the formula $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}$

Cell	Optical path length	Free volume	Total weight	x	y
HCT-70	5.00	20.5	14.8964	0.7000	0.4966

TER-2	9.78	25.0	12.2645	0.0605	0.2002
TER-3	9.79	24.8	10.9815	0.2110	0.0786
TER-4	9.79	25.8	14.1803	0.1280	0.2580

percentage, the latter is $c(e^{\sigma_A} - 1)$, where c is the numerical coefficient of $\log_{10}(9.83 A/L)$ in Eq. [4] and [5]. This amounts to less than 2.3% for Eq. [4] and less than 5.5% for Eq. [5].

Tellurium.—The diatomic molecule, Te_2 , exhibits a broad vibronic absorption band between 380 and 550 nm. It is observed that Beer's law holds for many of these peaks for a pure Te sample and the optical absorbance is proportional to the vapor pressure of $\text{Te}_2(\text{g})$, P_2° . The latter is given to within 2% by (1)

$$\log_{10} P_2^\circ (\text{atm}) = -5960.2/T + 4.7191; T > 450^\circ\text{C} \quad [6]$$

Thus, one can write

$$P_2 = \alpha_\lambda(D_\lambda/L) \quad [7]$$

The values of α_λ for a 755°C optical cell temperature have been given (1). Here we made measurements with optical cell temperatures of 800° and 860°C and the values of α_λ are listed in Table II. The standard deviation in α_λ given at the bottom of Table II, of course, contributes to that in P_2 when Eq. [7] is used to calculate P_2 . This contribution is generally less than 4% of the value of P_2 and always less than 6.5%.

Cadmium.—In the experiments of this investigation, the partial pressure of Cd, P_{Cd} , varied over a range of low values from 10^{-7} to 10^{-4} atm while P_{Hg} was in the 10^{-1} to 15 atm range. One expects that the optical absorbance or the area under the absorbance curve observed for the Cd lines is, therefore, broadened by $\text{Hg}(\text{g})$ and depends upon P_{Hg} as well as P_{Cd} . The calibration methods described in the Mercury section are, therefore, not applicable for Cd. Therefore, we measured the transmission as a function of wavelength and obtained the area in the transmission minimum of the Cd absorption line. Even though the transmission curve is distorted when the spectral band-pass is larger than the true line half-width, the area in the transmission minimum is approximately correct (7). If the transmission values are converted to optical absorbance, then neither the observed line shape nor its integrated area is correct. The disadvantage of transmission area measurements lies in the fact that they yield the partial pressure of the absorber only upon the assumption of a specific line shape and generally require extensive measurements in order to establish the broadening parameters. The general theory is developed in Mitchell and Zemansky (7) and has been outlined in Ref. (1) for absorption by Cd. Therefore, we summarize the minimum theoretical results required to describe our experimental measurements. A variable y' is defined as

$$y' = [(\ln 2)^{1/2}/\Delta\nu_D] \int_0^\infty (1 - I_\nu/I_0) d\nu \quad [8]$$

where I_ν/I_0 is the transmission at a given frequency, and $\Delta\nu_D$ is the Doppler half-width of the line. The integral, of course, is the area between the line for transmission equal to unity and the curve for the observed values of the transmission as a function of frequency. This integral is simply related to the experimental quantity in which the transmission is taken as a function of wavelength. If one

expresses transmission in terms of the absorption coefficient, k_ν , where

$$k_\nu = 2.303D_\lambda/L \quad [9]$$

then Eq. [8] becomes

$$y' = [(\ln 2)^{1/2}/\Delta\nu_D] \int_0^\infty (1 - \exp(-k_\nu L)) d\nu \quad [10]$$

The common assumption for low absorber partial pressures is that k_ν is given by the Voigt line shape, which is symmetrical about the line center, and that k_ν is proportional to the product of the absorber concentration, N , and the oscillator strength of the line, f . The Voigt line shape also depends upon a broadening parameter, a' . If a variable, x' , is defined as

$$x' = NfL(\ln 2)^{1/2}/\pi\Delta\nu_D \quad [11]$$

then y' depends upon x' and a' . Curves of y' vs. x' for a few fixed values of a' have been calculated and are given by Mitchell and Zemansky (7) and by Penner (8). The broadening parameter is given in terms of a natural half-width, $\Delta\nu_N$, a self-broadening half-width, $\Delta\nu_S$, and a foreign gas broadening half-width, $\Delta\nu_F$, as

$$a' = (\Delta\nu_N + \Delta\nu_S + \Delta\nu_F)(\ln 2)^{1/2}/\Delta\nu_D = a_N + a_S + a_F \quad [12]$$

The values of a_S and a_F have been determined experimentally (1) for the 228.7 and 325.7 nm Cd lines, and the values of a_N calculated from the known oscillator strengths of the lines. The results were

$$325.7 \text{ nm}; a_N = 2.69(10^{-5}), a_S = 1.50P_{\text{Cd}}(\text{atm}),$$

$$a_F = 1.18P_{\text{Hg}}(\text{atm}) \quad [13]$$

$$228.7 \text{ nm}; a_N = 0.0236, a_S = 108P_{\text{Cd}}(\text{atm}),$$

$$a_F = 4.60P_{\text{Hg}}(\text{atm}) \quad [14]$$

The foreign gas broadening coefficients were redetermined here using Hg-Cd amalgams as samples in a manner similar to that used previously (1) and described in detail elsewhere (5). The results are

$$325.7 \text{ nm}; a_F = (1.40 \pm 0.26)P_{\text{Hg}}(\text{atm}) \quad [15]$$

where 0.26 is one standard deviation and

$$228.7 \text{ nm}; a_F = 8.89P_{\text{Hg}}^{1.29} - 2.59P_{\text{Hg}}^{1.46}/P_{\text{Cd}}^{0.068} \quad [16]$$

With Eq. [16] for a_F , the standard deviation in the calculated and observed values of y' in the calibration runs is 4.6%. The new and old results are in fair agreement for the 325.7 nm line. The new result for the 228.7 nm line is not obviously interpretable from a theoretical point of view. Its form is determined largely by the results for a dilute amalgam for which the ratio of $P_{\text{Hg}}/P_{\text{Cd}}$ was about 10^7 . For the range of P_{Cd} and P_{Hg} obtained for the Hg-Cd-Te samples studied here and previously (1-3), Eq. [16] gives values for a_F that are within a factor of about two of the values calculated with Eq. [14] for a_F . However, as discussed in the next section, the new results for a_F are superior.

Table II. Values of α_λ in the equation, $P_2(\text{atm}) = \alpha_\lambda(D_\lambda/L)$ for $\text{Te}_2(\text{g})$ at 800° and 860°C optical cell temperatures. α_λ in atm-cm.

^a Not a vibronic maximum.

^b The standard deviation in α_λ is less than 4% except for those values distinguished by a superscript "b." For the latter, the standard deviation in α_λ is between 4% and 5.5% for $\alpha_\lambda(800^\circ\text{C})$ and 4% and 6.5% for $\alpha_\lambda(860^\circ\text{C})$.

Results

General.—For mercury pressures higher than 0.30 atm, a contribution due to $\text{Te}_2(\text{g})$ to the absorbance in the 255-340 nm region was first subtracted from the net optical absorbance. This contribution was determined from the observed $\text{Te}_2(\text{g})$ absorbance in the 363-550 nm region and the assumption that the values of the $\text{Te}_2(\text{g})$ absorbance in the 255-340 nm region and the values in 363-550 nm region are in the same ratio as observed in pure $\text{Te}_2(\text{g})$ vapor. The $\text{Te}_2(\text{g})$ contribution so determined was never greater than 20% of the net optical absorbance. The value of P_{Hg} was then obtained as the average of values calculated with Eq. [3] and the corrected net optical absorbance at two to five wavelengths in the 255-340 nm region. The standard deviation of P_{Hg} was generally less than $\pm 4\%$. We estimate an uncertainty of about $\pm 5\%$ in the value of P_{Hg} .

When P_{Hg} was below about 0.5 atm, the partial pressures of Te_2 and Cd were also considerably smaller and the contribution of foreign gas broadening to the 253.7 nm Hg line was assumed to be negligible. The area obtained from a trace of optical absorbance vs. λ was used to calculate P_{Hg} with Eq. [4] and [5]. The values of P_{Hg} obtained from two methods generally agreed within the experimental error of 5% in the range between 0.3 and 0.5 atm where both could be used.

The partial pressure of $\text{Te}_2(\text{g})$ was calculated from the measured optical absorbance between 363.4 and 550.4 nm where $\text{Hg}(\text{g})$ and $\text{Cd}(\text{g})$ absorption is negligible. The values of P_2 calculated for the various wavelengths with Eq. [7], Table II and Table II of Ref. (1) generally agreed to within $\pm 2\%$. The average value was taken. Taking account of the uncertainty in the Beer law parameters we estimate an uncertainty of about $\pm 5\%$ in the value of P_2 .

The area of the transmission minima for Cd lines was measured and the quantity y' obtained for each run. The

foreign gas broadening contribution, a_f , was calculated with Eq. [15] and [16]. The self-broadening coefficient was calculated with Eq. [13] and [14] and the measured value of P_{Hg} and an initial estimate for P_{Cd} . The quantity x' (or P_{Cd}) was solved numerically for the given y' and a' . A trial and error routine (9) was used to vary P_{Cd} until the initial and final values for P_{Cd} agreed to within 1%. The 228.7 nm Cd line is stronger than the 325.7 nm line and was used to obtain P_{Cd} from its lowest values to an upper limit where the line became asymmetric. The 325.7 nm line was used to obtain P_{Cd} in its upper range. In the range where reliable measurements could be obtained for both lines, the values of P_{Cd} from each one generally agreed to within 15%. With the old values of a_f given by Eq. [13] and [14] the analogous comparison gave agreement only to within about a factor of two. Over the whole range observed, we estimate an uncertainty of about $\pm 40\%$ for P_{Cd} .

Pseudobinary.—The partial pressures along the Te-saturated three-phase curves for 70 and 95 m/o CdTe, HgTe-CdTe solid solutions are listed for representative runs and in the order of increasing sample temperature in Tables III and IV, respectively. Complete tables are given elsewhere (5). In the first column of the tables, each run is represented by a four-digit number with the first two digits indicating the date and the last two digits the sequential number of the run. It can be seen that although the sample temperature was raised and lowered several times during the run, the measured partial pressures are reproducible. The second column gives the number of hours the sample was at the temperature before measurement. The third column is the sample temperature in $10^3/T$, where T is in Kelvin. The last two columns are the calculated values for the gross composition, x and y , of the condensed phase or phases expressed by the formula $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}$. These values were obtained from the

Table III. Partial pressures (atm) over Te-saturated 70 m/o CdTe, HgTe-CdTe solid solution and composition x and y in the formula $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}$. The contribution to the uncertainty in x and y due to that in the amount of each element in the gas phase is approximately proportional to P_{Hg} . For run 2529, this contribution is $\pm 2(10^{-3})$ for x and $\pm 7(10^{-4})$ for y .

known weight of the starting materials, the volume profile and the corresponding temperature profile along the cell, and the assumption that Cd(g) and Te₂(g) are ideal gases while Hg(g) is a slightly imperfect gas with an equation of state given by Sugawara and Sato (10). The partial pressure of Hg was greater than that of either Te₂ or Cd in all of the measurements. Consequently the condensed phase or phases became progressively poorer in Hg with increasing reservoir temperature.

The uncertainty in the value of x or y arises from two causes. One is due to the ± 0.2 mg accuracy in the original weighing of each element. This contributes $\pm 2(10^{-5})$ or less to the uncertainty in x and y for the samples studied in this work. The other is due to the uncertainties in the number of moles of each element in the gas phase. These were taken as $\pm 10\%$ for Hg and Te and $\pm 40\%$ for Cd, allowing not only for an uncertainty in each partial pressure, but also in the sum of the volume-to-temperature ratio for the various segments of the optical cell. The resulting contribution to uncertainty in x and y from this second cause is approximately proportional to P_{Hg} and is indicated in Tables III and IV, as well as in Tables V-VIII, which are discussed later. Thus the total uncertainty in x (or y) is $[4(10^{-10}) + \delta^2]^{1/2}$, where δ is the contribution from the second cause and can be obtained by interpolation from the information in each table.

The partial pressures along the Te-saturated three phase curves are shown in Fig. 1, 2, and 3 for, respectively, P_{Hg} , P_{Te} , and P_{Cd} . Those data determined previously (1, 2, 5, 11) for CdTe of 0, 10, 20, 40, and 60 m/o are also shown for comparison. Near the 10^{-2} atm lower limit of measurement in Fig. 1, the data for 95 and 70 m/o CdTe show curvature and P_{Hg} for 60 m/o is lower than that for 70 m/o. The latter effect is probably due to experimental error. The solid curves in Fig. 1 and 2 are calculated (4) with an associated solution model for the liquid with species Hg, Cd, Te, HgTe, and CdTe. The closeness of P_{Cd} for various x values seen experimentally in Fig. 3 is also given theoretically (4).

Ternary runs.—Tables V-VIII give the partial pressures for representative runs with four Te-rich samples. Complete tables are given elsewhere (5). Figures 4 and 5 show the plot of $\log(P_{\text{Hg}})$ vs. $10^3/T$ for each sample. The liquidus temperature for each ternary composition was determined by the change of the slope on the plot (denoted by symbol X). By comparing P_{Hg} at the liquidus temperature with those for the various Te-saturated solid solutions shown in Fig. 1, the composition of the solid solution in equilibrium with that liquid was determined by interpolation. Table IX summarizes the liquidus temperature, the partial pressures of Hg, Cd, and Te₂ at that temperature, and the composition of the coexisting solid solution, for each ternary run. The least precise quantities are the liquidus temperature and the x value of the coexisting solid solution, the estimated uncertainties for these are given in Table IX.

Table V. Partial pressures (atm) over Te-rich ternary sample TER-1 and composition x and y in the formula $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}$. The contribution to the uncertainties in x and y due to those in the amounts vaporized are, respectively, $\pm 4(10^{-5})$ and $\pm 6(10^{-5})$ for run 0420 and $\pm 5(10^{-4})$ and $\pm 7(10^{-4})$ for run 0730.

Fig. 1. Partial pressures of Hg along the Te-saturated three-phase curves for various values of x in $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ solid solutions as a function of $10^3/T$. Open triangles: $x = 0.0$ [Ref. (11)]. Circles: 0.094 [Ref. (2)]. Solid triangles: 0.196 [Ref. (5)]. Crosses: 0.197 [Ref. (2)]. Squares: 0.39 [Ref. (5)]. X's: 0.416 [Ref. (1)]. Diamonds: 0.581 [Ref. (2)]. Inverted triangles: 0.70. X's with superimposed squares: 0.95. Solid lines are the calculated results from Ref. (4) for x -values labeled adjacent to the lines.

Analysis

For a solid solution, $(\text{A}_{1-x}\text{B}_x)_y\text{C}_{1-y}(\text{s})$, with A and B atoms occupying the sites of one sublattice and C atoms occupying the sites of the other sublattice of the structure, it can be shown theoretically (12) that the sum of the chemical potentials of A and C and that of B and C in the solid are each independent of the composition y , if y is confined to values near $1/2$, *i.e.*

$$\mu_{\text{A}}^{\text{s}} + \mu_{\text{C}}^{\text{s}} = \mu_{\text{AC}}^{\text{s}}(T, x) \quad [17]$$

$$\mu_{\text{B}}^{\text{s}} + \mu_{\text{C}}^{\text{s}} = \mu_{\text{BC}}^{\text{s}}(T, x) \quad [18]$$

Thus AC and BC can be chosen as thermodynamic components of the solid solution whose chemical potentials are independent of the C to A + B atom ratio. Equations [17] and [18] hold within experimental error (1, 2) for $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}(\text{s})$. From the quantitative analysis of Tung *et al.* (2), the solid solution of HgTe and CdTe is almost ideal. We will therefore characterize this solid solution by assuming that its components mix like a quasi-regular solution, *i.e.*

$$\mu_{\text{HgTe}}^{\text{s}} = (W - VT)x^2 + RT \ln(1 - x) + \mu_{\text{HgTe}}^{\text{s}0} \quad [19]$$

$$\mu_{\text{CdTe}}^{\text{s}} = (W - VT)(1 - x)^2 + RT \ln x + \mu_{\text{CdTe}}^{\text{s}0} \quad [20]$$

where W and V are the interaction constants to be determined.

Table VI. Partial pressures (atm) over Te-rich ternary sample TER-2 and composition x and y in the formula $(\text{Hg}_{1-x}\text{Cd}_x)_y\text{Te}_{1-y}$. The uncertainties in the amount of each element vaporized contributes $\pm 4(10^{-5})$ to the uncertainty in x and $\pm (10^{-4})$ to that in y for run 2818. For run 0955, the corresponding uncertainties are $\pm 5(10^{-4})$ and $\pm 1.2(10^{-3})$

It is assumed that Cd and Te_2 behave ideally in the vapor phase. It is further assumed that the fugacity of Hg, f_{Hg} , is that extracted from the equation of state for Hg(g) given by Sugawara and Sato (10), i.e.

$$\mu(\text{Hg}(g)) = RT \ln f_{\text{Hg}} = RT \ln P_{\text{Hg}} + 4857.6P_{\text{Hg}} (-1.793/T + 251/T^2 + 0.001071) \quad [21]$$

where P_{Hg} is in atmospheres and μ in calories per gram atom. One then obtains the chemical potentials of HgTe and CdTe relative to the pure gas species Hg, Cd, and Te_2 ,

Fig. 2. Partial pressures of Te_2 along the Te-saturated three-phase curves for various x values of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}(s)$. Upper solid line labeled P_2^0 represents the vapor pressure of $\text{Te}(s,l)$. Symbols have the same meaning as indicated in the caption of Fig. 1. Solid lines are the calculated results from Ref. (4) for various x values.

Fig. 3. Partial pressures of Cd along the Te-saturated three-phase curves for various x values of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}(s)$. Symbols have the same meaning as in the caption of Fig. 1.

Fig. 4. Partial pressures of Hg over Te-rich ternary samples TER-1 (triangles) and TER-4 (inverted triangles) as a function of $10^3/T$. Liquidus points are indicated by X's.

Fig. 5. Partial pressures of Hg over Te-rich ternary samples TER-2 (triangles) and TER-3 (inverted triangles). Liquid points indicated by X's.

each at 1 atm, as

$$\bar{\mu}_{\text{HgTe}}^s(x, T) = RT \ln f_{\text{Hg}} P_2^{1/2} \quad [22]$$

$$\bar{\mu}_{\text{CdTe}}^s(x, T) = RT \ln P_{\text{Cd}} P_2^{1/2} \quad [23]$$

The chemical potential of HgTe in pure HgTe(s) was taken from a recent redetermination by Su *et al.* (11) as

$$\bar{\mu}_{\text{HgTe}}^{s,0}(\text{cal}) = -40642.4 + 41.6447T \quad [24]$$

The value of this chemical potential is claimed to be accurate to ± 70 cal at the 95% confidence limit. The quantity $W - VT$ was then calculated with Eq. [19], [22], and [24] for each measurement of the partial pressures over the 70 and 95 m/o CdTe solid solutions for which the composition of the condensed phase, x , was less than 0.71 and 0.96, respectively. The results are shown in Fig. 6 in which 54 points for $x = 0.70$ and 0.95 give experimental values for $W - VT$ that are represented within a standard deviation of 117 cal by the equation

$$W - VT = 4297.1 - 3.5750T(\text{cal}) \quad [25]$$

The variables formed by calculating $W - VT$ with Eq. [25] at each temperature can be transformed so that the marginal distribution for each of the transformed variables is the Student t distribution with 52 degrees of freedom (13). Based on this, one concludes that at each temperature, the value of $W - VT$ from Eq. [25] is within ± 10 cal of the true value at the 95% confidence limit.

The chemical potential of CdTe was not used to obtain $W - VT$ because of the following facts: (i) the chemical

Fig. 6. The quantity, $W - VT$, calculated using Eq. [19], [22], and [24] for $x = 0.70$ (triangles) and $x = 0.95$ (squares) in the formula $\text{Hg}_{1-x}\text{Cd}_x\text{Te}(s)$, as a function of T in Kelvin. Straight line is the least squares fit to these points.

potential of CdTe for pure CdTe(s), $\mu_{\text{CdTe}}^{s,0}$, is apparently uncertain by about 1 kcal [see Ref. (2)], (ii) the values of P_{Cd} are not as accurate as those of P_{Hg} , and (iii) in the process of calculating $W - VT$ one divides a small quantity, $\bar{\mu}_{\text{CdTe}}^s - \mu_{\text{CdTe}}^{s,0}$, by another small quantity, $(1 - x)^2$, magnifying the experimental error tremendously. [For $x = 0.70$ and 0.95, $(1 - x)^2$ is 0.09 and 0.0025, respectively.] The

chemical potentials of HgTe for the lower x values were also omitted for a reason analogous to (iii) above.

With Eq. [19], [20], and [25], one obtains

$$\Delta H_M \text{ (cal)} = (4297.1 \pm 49.9)x(1 - x) \quad [26]$$

and

$$\Delta S_M \text{ (cal/K)} = (3.5750 \pm 0.0539)x(1 - x) + 1.987 [x \ln x + (1 - x) \ln (1 - x)] \quad [27]$$

for the formation of the solid solution according to

The uncertainties given in Eq. [26] and [27] are calculated at the 95% confidence limit with a generalization of the Student t variable (13).

Discussion

The gross composition of the condensed phase or phases, x and y given in Table III-VIII, changes during the experiments due to the preferential vaporization or condensation of Hg. From the P_{Hg} and P_2 data, the 70 and 95 m/o CdTe solid solution samples appear to be Te-saturated even at the lowest sample temperatures measured. Therefore, the condensed phase was a mixture of liquid and solid phases and the partial pressures measured were those in equilibrium with a solid solution of unknown composition which can only be determined from the tie line at that temperature. However, since the value of y is very close to 1/2 for each run, the composition of the solid solution, x , coexisting with the sample should be very close to the gross x value of the condensed phases. Therefore, we set a criterion for the data and take all runs with an x value within 1% of the starting value, x_s , as acceptable data for the three-phase curve of the solid solution $\text{Hg}_{1-x_s}\text{Cd}_{x_s}\text{Te}$. Hence, those runs with $10^3/T$ lower than 1.0092 for HCT-70 and 0.8974 for HCT-95 were not accepted as the partial pressures of, respectively, $x = 0.70$ and 0.95 solid solutions and were not included in the analysis.

Numerous analyses (14) have been made to determine the interaction parameters of pseudobinary solid solutions. These were indirect in that the interaction parameters were obtained from a fit to the pseudobinary solidus and/or liquidus by assuming simple solution models for the liquid and solid phases. In this paper, these parameters are obtained more directly for $\text{Hg}_{1-x}\text{Cd}_x\text{Te(s)}$. Recently, Brebrick *et al.* (4) have fit the phase diagram and thermodynamic properties in the Hg-Cd-Te system, including the data reported here, by assuming an associated solution model for the liquid and a quasiregular model for the solid solution. Their result for $W - VT$ (cal) is given by

$$W - VT = 1385 - 0.8452T \quad [29]$$

Comparing this with Eq. [25], one finds the individual values for W and V are very different, but the value of $W - VT$ only differs 89 cal at 1100 K and 456 cal at 900 K.

The partial pressures for the ternary samples are listed in Table V-VIII. Those partial pressures with sample temperature lower than the liquidus temperature (given in Table IX) should be considered with care. They are the partial pressures over a liquid-solid, two-phase mixture, whose gross or overall composition is given by the x and y values in the tables. The individual compositions of the liquid and the solid have not been determined. For those runs with sample temperatures higher than the liquidus temperature, the composition of liquid phase is, of course, given by x and y , and these data have been used in the fit of the Hg-Cd-Te phase diagram (4).

The liquidus temperatures and tie-line data in the Te-rich portion of the phase diagram, *i.e.*, $y < 1/2$, have been determined experimentally by various techniques (15-17). The most complete and reliable liquidus temperatures were reported by Harman (15) using visual observation of the last-to-melt crystals. He also established the tie-line data by analyzing the composition of epitaxially grown films. Except for run TER-3, which is out of the composition range he covered and not so reliable as the others due to the "not so apparent" break in the slope of $\log(P_{\text{Hg}})$ vs. $10^3/T$ plot as shown in Fig. 5, our liquidus temperatures and tie-line data agree well with his results. The interested reader can make a more detailed comparison with the aid of Fig. 10 and 11 of Ref. (3). It is worth noting that the optical absorbance measurement used here is a static technique and so the possible error due to large supercooling effects for Te-rich melts is eliminated.

Measurements of Temperature Dependent Stress of Silicon Oxide Films Prepared by a Variety of CVD Methods

G. Smolinsky and T. P. H. F. Wendling*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We report the stress as a function of temperature of films of undoped and doped silicon oxide. These materials were prepared by chemical vapor deposition (CVD) from a variety of chemical reactions, under different physical conditions, and include DADBS (450°, 500°, and 550°C), TEOS (500° and 685°C), silane + oxygen (400°, 410°, and 440°C), wet oxygen (950°C), and plasma-enhanced (PECVD) silane + nitrous oxide (250°C). Data from each oxide were subjected to a linear least squares analysis and the first-order equation thus obtained was used to calculate the stress at 28°C and at the deposition temperature, the so-called intrinsic stress. From the slope of the line, we found the thermal coefficient of expansion of the oxides almost always to be less than that of <100> silicon. Dopants such as phosphorus and especially the combination boron and phosphorus lower the intrinsic stress of an oxide film relative to the undoped material and cause the rate of change of stress with temperature to be relatively flat. Except for 8% P- and 2.5% B,P-glass, oxides deposited below 500°C show a thermal hysteretic effect on heating to 450°C in air. Invariably the films become more tensile stressed, which must result from a shrinking and/or an extrusion of atoms from the matrix of the oxide. In contrast, thermally grown oxide exhibits a decided compressive stress that shows no hysteresis. No doubt this results from oxygen atoms intruding into the surface of the silicon lattice as the oxide layer grows.

Films of doped or undoped silicon oxide can be deposited on surfaces from a variety of chemical reactions and under different physical conditions. For example, SiO₂ is grown on a silicon surface at 950°C in a wet oxygen ambient, while a form of silicon oxide is deposited on a wafer maintained at 200°C from a plasma of silane and nitrous oxide. Furthermore, oxide films are deposited at 400°-450°C from the reaction of silane and oxygen. In addition, the decomposition of selected organosilicon esters and anhydrides at reduced pressure in the temperature range 400°-800°C can produce oxide films. Moreover, it is often possible to dope these films with several percent boron and phosphorus. Not too surprisingly, the physical properties of the oxides prepared in these different ways differ. In this report, we will be concerned with the stress induced in a <100> silicon wafer by a silicon oxide film. We will discuss the intrinsic stress, *i.e.*, the stress of the as-deposited film at its deposition temperature, and the rate of change of stress with temperature.

Experimental Technique

Materials.—The silicon wafers were of <100> orientation, either 3 or 4 in. in diameter and between 0.021 and 0.023 in. thick. Using standard low pressure chemical vapor deposition (LPCVD) or plasma-enhanced chemical vapor deposition (PECVD) techniques, silicon oxides were deposited on silicon wafers from a variety of chemical sources at a temperature appropriate for the method employed. These sources included diacetyoxyditertiarybutoxysilane (DADBS) (1); tetraethoxysilane (TEOS); silane, phosphine, and oxygen (P-glass); steam (FOX); silane and nitrous oxide (PECVD). Phosphine and trimethyl borate were used to incorporate the dopants phosphorus (P) and boron (B), respectively, in TEOS-oxide films. Phosphine, diborane, silane, and oxygen were used to prepare B,P-glass.

Measurement of stress.—Stress of deposited oxide films was measured using an optically leveraged laser beam apparatus (2). The method involves the determination of the change in the radius of curvature of a silicon wafer caused by a thin (~ 10,000Å) film of oxide. The stress, σ , is inversely proportional to the change in this radius and can be calculated if Young's modulus and Poisson's ratio of the substrate are known (2, 3). Using the appropriate values of the various coefficients given in Ref. (2 and 3), the stress of any wafer was calculated as

$$\sigma = 1.51 \times 10^7 (D^2/t) (\Delta d) \text{ dyne cm}^{-2} \quad [1]$$

where D is the thickness of the wafer in mils, t is the film

thickness in thousands of Angstroms, and Δd is the displacement of the laser beam spot in centimeters.

The apparatus can be used to determine the stress as a function of temperature (2, 4). The stress at a particular temperature, σ_t , can be expressed as (5)

$$\sigma_t = \sigma_i + (T_t - T_d) \frac{E_f}{1 - \nu_f} (\alpha_s - \alpha_f) \quad [2]$$

where E_f is Young's modulus of the film, ν_f is Poisson's ratio of the film, α_s and α_f are the coefficients of thermal expansion of the substrate and film, respectively, T_t is the temperature of interest, T_d is the deposition temperature, and σ_i is the so-called intrinsic stress. Equation [2] implies that the temperature dependence of the stress is related to the thermal expansion coefficients of the silicon wafer and the oxide film

$$\frac{d\sigma}{dT} = \frac{E_f}{1 - \nu_f} (\alpha_s - \alpha_f) \quad [3]$$

From the sign of $d\sigma/dT$, it is possible to determine the relative magnitudes of α_s and α_f .

Usually two wafers were used to measure the stress *vs.* temperature characteristics of any given deposited silicon oxide. First, the values for the laser beam spot displacement of the uncoated wafer, d_u , were measured at six temperatures close to 28°, 100°, 200°, 300°, 400°, and 450°C. The values for the beam displacement after application of the oxide film, d_c , were remeasured, and from the difference, $d_c - d_u$, a Δd was obtained that was used in Eq. [1] to calculate the stress at the temperature of the measurement. After allowing the coated wafer to cool to room temperature, the stress was remeasured over the same temperature range to determine the extent, if any, of a hysteresis. Data from each oxide were subjected to a linear least squares analysis, and the first-order equation thus obtained was used to compute the stress at 28°C and at the deposition temperature, the intrinsic stress, σ_i , and the value of $d\sigma/dT$. The assumption that the stress *vs.* temperature curve is linear within the temperature range investigated is supported by the findings of other work (3, 5).

Film shrinkage.—DADBS-oxide (1) was deposited on silicon wafers at 410°, 450°, 500°, 550°, and 600°C, respectively. The wafers were annealed in an argon atmosphere at 900°C for 1h. Film thickness before and after annealing was determined by an optical measurement.

Etching.—An optical method was used to determine the decrease of the thickness of silicon oxide on wafers that had been immersed for 1 min in 19°C, 7:1-buffered hydrofluoric acid. The stress/temperature relation had previously been determined for each of these wafers.

* Electrochemical Society Active Member.

Results and Discussion

Table I lists the silicon oxides investigated and the calculated values for the stress of each material determined at 28°C and at the deposition temperature and the rate of change of stress with temperature. Table I also gives the deposition method and temperature. A discussion of each material follows.

DADBS-oxide.—Stress measurements.—Three sets of two wafers each were coated with 9000-10,000Å of silicon oxide by the thermal decomposition of DADBS in a LPCVD (~ 0.7 torr) apparatus at 450°, 500°, and 550°C, respectively. The stress induced on the wafers is listed in Table I. Plots of measured stress vs. wafer temperature for the 450° and 550°C deposited oxides are shown in Fig. 1. The film deposited on wafers held at 450°C clearly exhibits hysteresis, while the 550°C film does not; it was unclear whether the film deposited on 500°C wafers did or did not. From Table I, it is seen that all three neat DADBS-oxides possess essentially the same degree of tensile intrinsic stress, σ_i , ($\sim 4.9 \times 10^9$ dyne cm^{-2}) and show almost the same stress at room temperature. Figure 2 shows plots of stress vs. wafer temperature of 500° DADBS-oxides prepared from neat DADBS or a 1.2:1 DADBS-oxygen mixture. Clearly the addition of oxygen results in a material with a smaller tensile intrinsic stress but which shows a marked hysteresis. Note that the calculated slope, $d\sigma/dT$, of the stress vs. temperature plot for each DADBS-oxide measured the first time is nearly the same ($\sim 8.3 \times 10^6$ dyne $\text{cm}^{-2}/^\circ\text{C}$). The incorporation of ~4% phosphorus (I) into the DADBS-oxide film lowers the intrinsic stress by a factor of ~ 0.4 and reduces the slope, $d\sigma/dT$, as well. The phosphorus-doped oxide exhibits a slight hysteretic effect.

Annealing and film shrinkage.—Wafers maintained at 410°, 450°, 500°, 550°, and 600°C, respectively, were coated with a DADBS-oxide film whose thickness was measured before and after a 1h anneal at 900°C in an argon atmosphere. Percent decrease in film thickness vs. deposition temperature is plotted in Fig. 3 along with a linear fit to the data. We see that the higher the deposition temperature, the less the film shrinks on annealing. In addition, it was observed that the higher the deposition temperature, the thicker a film could be deposited before cracking: DADBS-oxide deposited in the range 410°-550°C was found to crack at ~ 6500Å at the lower temperature but could be deposited to ~ 20,000Å at the higher temperature.

Summary.—The lower the deposition temperature of a DADBS-oxide, the less dense and the weaker the resulting film. At the time of deposition, these films possess a relatively high degree of tensile stress which, however, decreases on cooling to room temperature. From Eq. [3] and the positive value of the slope, $d\sigma/dT$, it is clear that the coefficient of thermal expansion of silicon, α_s , is greater than that of the oxide α_i . The values of the room temperature and intrinsic stress, as well as the slope of the stress/temperature line, are almost independent of the deposition temperature in the range 450°-550°C. This implies that if a more dense oxide could be produced at the lower temperature, it probably would not crack even if deposited to a thickness approaching that achieved at the higher temperature. The addition of oxygen to the DADBS or incorporation of phosphorus produces an oxide film with a lower tensile intrinsic stress. These films

Fig. 1. Plot of the measured stress as a function of temperature of two DADBS-oxide films, one deposited at 550°C and the other at 450°C. The dotted curve was obtained from a repeated measurement of the 450°C sample.

Fig. 2. Plot of the measured stress as a function of wafer temperature of two DADBS-oxide films, one prepared from neat DADBS and the other mixed with oxygen. The dotted curve is a repeated measurement.

must shrink on heating to 450°C, since the hysteretic effect results in a more tensile-stressed film at room temperature. However, note that the intrinsic stress is still less than that of the oxide prepared from neat DADBS. This may account for the observation that added oxygen enables deposition of a thicker crack-free film.

TEOS-oxide.—Stress measurements.—Duplicate 4 in. wafer were coated with about a micron of silicon oxide by the decomposition of TEOS at 685°C and a pressure of 0.3 torr, in a production facility LPCVD apparatus. Additionally, three sets of wafers were coated with an oxide doped with either phosphorus or both boron and phosphorus; a single wafer was coated at 500° with a boron-phosphorus-doped oxide. Table I lists the values for the stress and stress/temperature slope for these films. Figure 4 shows plots of the measured stress as a function of wafer tem-

Fig. 4. Plots of the measured stress as a function of temperature of three oxide films deposited at 685°C from TEOS: undoped, 5% phosphorus-doped, and 2% boron-5% phosphorus-doped oxide films.

perature in air for TEOS-oxide, 5% P-TEOS-oxide, and 2,5% B,P-TEOS-oxide films, respectively, deposited at 685°. Clearly the incorporation of a dopant such as phosphorus, and especially the combination boron and phosphorus, lowers the intrinsic stress and also affects the slope of the stress/temperature line. The values for the stress and slope as well as the stress/temperature line for the 5,4% B,P-TEOS-oxide are similar to those found for the 2,5% B,P-TEOS-oxide. In contrast, the 500° B,P-TEOS-oxide has a much higher measured tensile intrinsic stress than the other two B,P-TEOS-oxides that, moreover, becomes even greater as the wafer cools to room temperature (a negative $d\sigma/dT$).

Summary.—Chemically, TEOS and DADBS decompose to silicon oxide by an analogous mechanism (1), yet the calculated intrinsic stress of the 685° TEOS-oxide is 80% of the tensile intrinsic stress of the DADBS-oxides, while the slope of the stress/temperature line is only about 60% of that of the DADBS-oxide lines. An explanation for these observations would seem to be related to the difference in the deposition temperature of the two processes: a higher temperature results in a lower tensile-stressed material. This argument is supported by the values for the stress listed in Table I for the 500° and 685°C B,P-TEOS-oxides.

P-glass.—Stress measurements.—Three sets of two wafers were coated at 400°C, and one set at 440°C, with silicon oxide from the reaction of silane, phosphine, and oxygen at 0.45 torr. The amount of phosphorus incorporated in the oxide was made to vary between 0% and 8%. Figure 5 shows a plot of the measured stress induced by a 400°C-deposited, 0% P-glass film as a function of wafer temperature. Clearly the repeated measurement reveals a hysteresis, which is also observed for the 6% P-glass film but not for the 400° or 440°C, 8% P-glass coatings. Table I lists the values of the calculated room temperature, and intrinsic stress, and the slope of the stress/temperature line. In addition, these same calculated values for the repeated, i.e., hysteretic, line are given in Table I. For both the 0% and 6% P-glass films, the annealed material shows an increase in tensile stress and a decrease in the value of $d\sigma/dT$. Figure 6 shows data for as-deposited and after a 685°C anneal, 2,5% B,P-glass. The marked decrease in tensile stress and the relatively flat behavior of the stress with temperature can be rationalized if the oxide is assumed to have flowed during the annealing process.

Fig. 3. Plot of the decrease in film thickness vs. deposition temperature of DADBS-oxide films after annealing for 1h at 900°C in an argon atmosphere.

Fig. 5. Plot of the measured stress as a function of temperature of a 400°C deposited oxide from the reaction of $\text{SiH}_4 + \text{O}_2$.

Summary.—From the values listed in Table I for the two 8% P-glass oxides, the 40°C difference in their deposition temperatures is ineffectual. Surprisingly, a greater-than-6% phosphorus dopant is required in a P-glass oxide to achieve what at most a 5% phosphorus dopant does for a P-TEOS-oxide, *i.e.*, produce a material that exhibits a low tensile stress over the temperature range 28°C to the deposition temperature (compare the values listed in Table I). Again from Table I, we see that a 410°C B,P-silane glass is more tensile stressed than the B,P-TEOS glass. More provocative is the observation that the slopes of the stress/temperature lines for these two differently prepared doped oxides are disparate, indicating that the mechanical properties and/or the coefficients of expansion are markedly dissimilar. These disparities probably have their source in the 275°-285°C difference in the deposition temperatures employed to deposit the P-glass and P-TEOS, and B,P-glass and B,P-TEOS oxides, respectively. Indeed, following an anneal at 685°C, the stress/temperature curves for both B,P-doped glass and TEOS-oxide look similar (compare Fig. 4 and 6). Contrary to other oxides deposited at 450° or less, 8% P-glass and the B,P-glass show no hysteresis, indicating that these materials form an essentially homogeneous and relatively dense film.

The stress/temperature characteristics of CVD- $(\text{SiH}_4 + \text{O}_2)$ -oxide have been reported recently. In the first study

Fig. 6. Plots of the measured stress as a function of temperature of a 410°C, 2.5% B,P-glass. The solid line shows data for the as-deposited film, while the dotted line is for data from this film after a 0.5h anneal at 685°C.

(6), the oxide was deposited at a temperature of 415°C. The stress was measured in the temperature range 25°-450°C. It was decidedly compressive at 25°C ($\sim -2.8 \times 10^9$ dynes cm^{-2}) and increased steeply ($d\sigma/dT \sim 9 \times 10^6$ dynes $\text{cm}^{-2}/\text{deg}$) with temperature so that at 450°C the stress was tensile ($\sim 0.9 \times 10^9$). In the second study (7), the oxide was deposited at 250°C and found to be in tension at 20°C ($\sim 1.5 \times 10^9$ dyne cm^{-2}), which increased drastically ($d\sigma/dT = 10.7 \times 10^6$ dyne $\text{cm}^{-2}/\text{deg}$) in the temperature range 20°-125°C. Both of these silicon oxides exhibited thermal hysteresis, becoming more tensile stressed. The results from these two studies, while not in perfect agreement with each other or our work, show that a CVD- $(\text{SiH}_4 + \text{O}_2)$ -oxide deposited by three different systems exhibits similar stress/temperature behavior: a positive slope and a hysteretic effect.

FOX-oxide.—Stress measurement.—A layer of silicon dioxide was grown on two wafers that were maintained at 950°C in an ambient of wet oxygen at ~ 1 atm. Table I lists the values of the stress for this material, while Fig. 7 shows a plot of the measured stress at the indicated wafer temperatures. In addition, Fig. 7 shows the least squares linear fit to the data. The thermal oxide has a rather weak dependence of stress with temperature ($d\sigma/dT$); it deposits with a fairly high compressive stress ($= -1.82 \times 10^9$ dyne cm^{-2}) which becomes even more compressive at room temperature (-3.1×10^9).

Summary.—The compressive stress of thermal oxide no doubt results from oxygen atoms intruding into the surface of the silicon lattice as the oxide layer grows. Using Eq. [3] and the literature values for quartz (4) ($E/1 - \nu = 0.85 \times 10^{12}$ dyne cm^{-2} ; $\alpha_t = 0.55 \times 10^{-6}/\text{deg}$) and silicon (8) ($\alpha_s = 3.2 \times 10^{-6}/\text{deg}$), the slope, $d\sigma/dT$, was calculated to be $\sim 2.3 \times 10^6$ dyne $\text{cm}^{-2}/\text{deg}$. This is a factor of only 1.6 greater than that actually measured for the thermal oxide. This close agreement is a positive indication of the validity and accuracy of the method used in this study to determine the stress of the various silicon oxides.

The stress/temperature behavior of thermally grown silicon dioxide has been reported previously (6, 7). In the first study (6), the stress was measured in the temperature range 25°-900°C and was found to be in compression (from $\sim -2.2 \times 10^9$ to ~ 0 dyne cm^{-2}) with a rate of change of stress with temperature of about 0.3×10^6 dyne $\text{cm}^{-2}/\text{deg}$. The second study (7) measured the stress of the thermal oxide in the range -169°-300°C and also observed that the material was in compression (from ~ -3.8 to -3.2×10^9 dyne cm^{-2}) with a slope of about 1.7×10^6 dyne $\text{cm}^{-2}/\text{deg}$. These results are in moderately good agreement with our measurements on thermal oxide.

It should be noted that a relatively small value ($\sim 1 \times 10^6$) for the slope, $d\sigma/dT$, does not necessarily mean that the coefficient of expansion of the film, α_t , and substrate, α_s , are nearly equal. All that can be inferred is that the product $[E_f/(1 - \nu_f)] * [\alpha_s - \alpha_t]$ is a small number.

Fig. 7. Plot of the measured stress as a function of temperature of a 950°C steam-grown silicon dioxide film.

Fig. 8. Plot of the measured stress as a function of temperature of a 200°C PECVD grown oxide from the reaction of $\text{SiH}_4 + \text{N}_2\text{O}$. The dotted line is a repeated measurement.

PECVD-oxide.—Stress measurement.—Two wafers, maintained at 200°C, were coated with a silicon oxide layer by the plasma induced reaction of silane and nitrous oxide ($\text{SiH}_4 + \text{N}_2\text{O}$). The measured stress vs. temperature of this material is plotted in Fig. 8. At the deposition temperature, the stress is slightly compressive ($\sim -0.2 \times 10^9$), becoming somewhat more compressive at room temperature but remaining essentially flat in this temperature range. Heating the material above 200°C produces a decided change in the stress/temperature slope; it increases from a value of $\sim 1 \times 10^6$ to $\sim 10 \times 10^6$ dyne $\text{cm}^{-2}/\text{deg}$. In addition, this film exhibits a very pronounced hysteresis; the stress becomes tensile and increases slowly over the temperature range 28°–450°C from a value of $\sim 1.3 \times 10^9$ to $\sim 2.7 \times 10^9$ dyne $\text{cm}^{-2}/\text{deg}$.

Summary.—Properties such as etching rate (dilute HF), stress, and refractive index of PECVD-($\text{SiH}_4 - \text{N}_2\text{O}$)-oxide have been found to be a function of deposition temperature and to display a discontinuity at 200°C (9). PECVD-($\text{SiH}_4 + \text{N}_2\text{O}$)-oxide undergoes a marked change in stress on heating above 200°C in air. Because of the significant metamorphosis observed, this material would very likely change even if heated in an inert atmosphere. This marked increase in tensile stress, and its persistence on repeated measurement (see Fig. 8), a thermal hysteretic effect, can be rationalized by the loss of some material from the oxide film resulting in a decrease in volume with a concomitant increase in tension (6).

Aqueous HF etching rate.—Since both the stress and chemical reactivity of a silicon oxide should be a function of its physical and chemical nature, it was thought that there might be some correlation between hydrofluoric acid etching rate and measured stress of the various oxides. Table II lists the etching rate for several silicon ox-

ides. There does not appear to be a correlation between this rate and any of the stress properties listed in Table I.

Conclusions

In general, the thermal coefficient of expansion of the various silicon oxides investigated is less than that of silicon. This results in a decrease in tension in films deposited on silicon wafers as they cool to room temperature. Dopants such as phosphorus and especially the combination boron and phosphorus lower the intrinsic stress, σ_i , of a silicon oxide film and, in addition, cause the rate of change of stress with temperature, $d\sigma/dT$, to be relatively flat. Except for the 8% P-glass and 2,5% B,P-glass, oxides deposited at temperatures less than about 500°C show a thermal hysteretic effect on heating to 450°C in air. Invariably, these oxide films become more tensile stressed. This can result from a shrinking and/or an extrusion of atoms from the matrix of the film (6, 7). A complementary study (10) to our work reached similar conclusions.

Acknowledgments

We thank D. S. Williams for many helpful discussions about stress and how it relates to silicon oxides. We thank F. B. Alexander for preparing the PECVD-($\text{SiH}_4 + \text{N}_2\text{O}$)-oxide. We are grateful to T. F. Retajczyk for allowing us to use his laboratory.

Electrical Conductivity of Silicon Dioxide Thermally Grown on Silicon

J. K. Srivastava, M. Prasad, and J. B. Wagner, Jr.*

Center for Solid State Science, Departments of Physics, Chemistry, and Mechanical/Aerospace Engineering, Arizona State University, Tempe, Arizona 85281

ABSTRACT

DC and ac electrical conductivities of silicon dioxide thermally grown on p- (boron-doped) and n-type (phosphorous-doped) silicon have been measured in the temperature range of 25°-1100°C. Total dc conductivities varied from 10^{-9} to $10^{-16} \Omega^{-1}\text{cm}^{-1}$ in the temperature range of 25°-960°C. Arrhenius plots for total dc conductivities of SiO_2 grown on both the substrates exhibit two regions. Below 450°C, the conductivities were independent of temperature and are suggested to be governed by impurities. Above 450°C, the total dc conductivities increased with increase in temperature. The activation energies of conduction in the temperature range 500°-960°C were estimated to be 1.65 and 2.10 eV for SiO_2 grown on p- and n-type silicon, respectively. DC polarization measurements carried out in this temperature range suggest that conduction in SiO_2 is ionic as well as electronic. The ionic conduction is believed predominantly to be due to the transport of oxygen ions. AC conductivities were also measured in the temperature range of 550°-1100°C. The activation energies for the conduction in this temperature range were estimated to be 1.55 eV for SiO_2 on p-type silicon and 1.86 eV for SiO_2 on n-type silicon. These values are in close agreement with the values reported in the literature. AC conductivity of SiO_2 grown on n-type silicon was found to be lower than that of SiO_2 grown on p-type silicon.

In semiconductor and integrated circuit devices, silicon dioxide is grown thermally on silicon where it is used not only as an insulator, but also as a masking layer. The transport properties of SiO_2 thermally grown on silicon have therefore been studied by several investigators. Most of these studies have been restricted to a specific temperature region, depending on specific applications. Norton (1) and Sucof (2) independently studied the diffusion of oxygen in bulk fused silica. More recently, Irene (3) studied transport phenomena in thin SiO_2 films during oxidation of silicon. There is, however, considerable disagreement between the values of diffusivity determined directly and those estimated from the oxidation kinetics.

From marker studies (4-6), it is generally agreed that the inward migration of oxygen through the SiO_2 to the Si/ SiO_2 interface determines the kinetics of transport through SiO_2 . The mobile oxidant species in SiO_2 films has still not been uniquely determined. According to Revesz (7, 8), the oxygen migrating through SiO_2 during oxidation may not necessarily be a charged species. Neutral oxygen molecules may migrate through microheterogeneities, or the "channels" formed from $d\pi$ and $p\pi$ bonds (9) of silicon and lone pair electrons of the oxygen atom, respectively. Jorgensen's experiment (6) on the oxidation of silicon with and without applying an electric field, suggests that the oxygen diffusing through SiO_2 is negatively charged and that between 727° and 879°C SiO_2 is a mixed conductor with 0.4 as the value of ionic transference number (t_i). However, Raleigh (10) reported that Jorgensen's data could be equally well explained by electrolysis at each Si/ SiO_2 interface.

Mills and Kroger (11) measured electrical conductivity up to a temperature of 700°C to determine the mobile species in SiO_2 and concluded that the mobile species was charged oxygen. The extrapolated value of the total conductivity reported by Mills and Kroger (11) was several orders of magnitude higher than that reported by Raleigh (10) at 850°C and two orders of magnitude higher than the ac conductivity values of vitreous silica reported by Tripp *et al.* (12).

In spite of the large number of investigations, the exact nature of the transporting species through SiO_2 during oxidation is still unsettled. Similarly, there is considerable discrepancy between the data reported on the rate of oxidation of silicon, the diffusivities through the product layer, and the conductivity. Because of the inconsistencies in the reported data and the lack of conductivity data at higher temperatures, the present investigation was undertaken. Transport-number measurements were made

by electrical conductivity and open-circuit EMF methods on SiO_2 thermally grown on silicon substrates.

Experimental

1-5 kÅ thick SiO_2 films were grown thermally at one temperature, 1050°C, in dry oxygen on boron-doped p-type silicon <100> (14-22 $\Omega \text{ cm}$) and phosphorous-doped n-type silicon <100> (3.3 $\Omega \text{ cm}$) by Motorola, Incorporated. One side of these wafers was etched to provide a clean silicon surface. Platinum or molybdenum was sputtered thereon to provide an electrical contact. These oxidized wafers were cut into 1 × 1 cm square pieces and pressed together with oxide surface to oxide surface, to yield a symmetrical cell (A) in an oxygen activity corresponding to the Si/ SiO_2 equilibrium. For comparison, a 3 kÅ oxide thickness on p-type silicon was obtained, in this laboratory, by passing O_2 over hot water maintained at 95°C then over Si at 1100°C at a rate of 4 liter/min. AC conductivity of this SiO_2 was also measured using a cell, configuration (A). For polarization and open-circuit EMF measurements, 1 kÅ thick platinum or molybdenum was sputtered on the SiO_2 side and assembled as an asymmetrical cell (B).

The cell configurations were: for symmetrical cell (A), for total ac and dc conductivity

where M is Pt or W.

Asymmetrical cell (B) for polarization and EMF measurements

where M is Pt or W.

The apparatus consisted of a double-walled silica tube and a sample holder made of quartz with inlets and outlets for gases in each jacket, electrical circuits, and a Lindberg heavy duty furnace. Platinum or tungsten (~0.12 mm thick) in the form of disk or rectangular plate was used as electrode material. The tubular quartz furnace was electrically shielded by grounding a closely wound Kanthal wire around the tube. Shielded cables were used for external leads. Alumina disks were used in order to avoid any possible contact between the sample and the sample holder.

Each cell was positioned between platinum electrodes, and pure dry argon (oxygen less than 1 ppm) was allowed to circulate in each jacket of the silica tube. The argon in the outer jacket was used to eliminate the possible diffusion of H_2O through the quartz wall and into the sample. The samples were annealed at 600°C for about 12h prior to

*Electrochemical Society Active Member.

Fig. 1. Typical current vs. time curve at 860°C for SiO₂ grown on n-type Si in cell (A).

measurements. After such annealing, it was found that adjoining SiO₂ surfaces in cell (A) were bonded together.

DC conductivity was measured with cell (A) using 1000-3000Å thick SiO₂ by connecting the samples in series with a 10⁶-10¹¹Ω precision glass encapsulated standard carbon film HiMEG-Resifrom. 0.1-1.3V were applied using a Keithley 260 nV source. The voltage drop across the standard resistor was measured with a Keithley 604 differential electrometer.

Electronic conductivity was measured using the polarization technique described by Wagner (13, 14) using cell configuration (B), as suggested by Raleigh (10). In this experiment, positive potentials of 0.1-0.8V were applied on the SiO₂/Pt side using a Keithley 260 nV source and measuring the voltage drop across the standard resistor with an electrometer.

AC conductivity was measured using cell configuration (A) for different thicknesses of SiO₂ on silicon in the temperature range of 550°-1100°C, using a Wayne Kerr Model 211 conductivity bridge. The conductivities were also measured at different frequencies (50 Hz-1 kHz) at various temperatures.

Results and Discussion

Symmetrical cell (A).—The values of current (*I*) at different applied voltages (*V*) were obtained, initially in the temperature range 500°-960°C. The measurements were subsequently extended to temperatures between 500° and 25°C. At higher temperatures and higher applied voltages, the current was found to change with time for the same

Fig. 2. I-V curves for cell (A) consisting of SiO₂ on p-type Si

Fig. 3. I-V curves for cell (A) consisting of SiO₂ on p-type Si

applied voltage. A typical current time curve at 860°C for SiO₂ grown on n-type silicon is shown in Fig. 1. This behavior is indicative of ionic polarization. The initial current, however, varied linearly with applied voltage, exhibiting ohmic behavior, and, therefore, this was utilized to obtain the total dc conductivity. The slope of the I-V curve yielded the conductance and the total conductivity was computed from the relation $\sigma = m/lA$ where *m* is the slope of the I-V curve, *l* is the thickness, and *A* is the area of cross section of SiO₂. Because of the polarization, current reversal was not routinely carried out, but occasionally some measurements were obtained. The values thus obtained were found to be independent of the direction of the applied voltage.

Figures 2-5 show the typical current voltage plots at various temperatures. The behavior was ohmic at all the temperatures studied up to an applied EMF of ~0.3V. Higher voltages resulted in considerable damage to the platinum electrodes and the sample, probably because of

Fig. 4. I-V curves for cell (A) consisting of SiO₂ on n-type Si

Fig. 5. I-V curves for cell (A) consisting of SiO₂ on n-type Si

the formation of platinum silicide. In a few experiments, macroscopic holes as large as 1.5 mm diam were found in the electrodes. For this reason, the applied voltages were restricted to 1V and platinum electrodes were replaced by tungsten electrodes.

Assuming that these cells are in thermal and chemical equilibrium, the measured conductivity corresponds to

silica in equilibrium with the oxygen activity equivalent to the dissociation pressures of SiO₂-Si.

Figure 6 shows the Arrhenius plots for the total dc conductivity of SiO₂ grown on p- and n-type silicon. Each plot clearly indicates two regions. Below ~450°C, the total conductivity is almost independent of temperature within the experimental scatter. Above ~450°C, the conductivity rises sharply with temperature for SiO₂ grown on both p- and n-type silicon. The activation energies were 1.65 and 2.10 eV for SiO₂ grown on p- and n-type silicon, respectively.

The ac conductivity was measured in the temperature range of 500°-1100°C initially at 1 kHz and subsequently at frequencies down to 50 Hz. Below 500°C, the conductivity was too low to be measured accurately by the conductivity bridge used. Figures 7 and 8 show the plots of log σ (1 kHz) vs. reciprocal of temperature in the temperature range 500°-1100°C for SiO₂ grown on p- and n-type silicon, respectively. Both the plots yielded straight lines. The activation energies calculated from the slopes of these lines were 1.55 and 1.86 eV for SiO₂ grown on p- and n-type silicon respectively. Conductivity vs. frequency plots are shown in Fig. 9 for various temperatures. The conductivity of SiO₂ grown on n-type silicon decreases above 1000°C. The values of ac conductivity at a fixed temperature were found to be higher than the dc conductivity. However, after extrapolating the ac conductivity data to zero frequency, the values, although slightly higher, were very close to the dc conductivity values. The variation of conductivity with frequency was more pronounced in the SiO₂ grown on p-type silicon than the one grown on n-type Si. An activation energy for conduction (extrapolated to zero frequency) of SiO₂ grown on p-type silicon was estimated to be 1.73 eV (Fig. 10). This is in close agreement to that obtained from the dc conductivity (1.65 eV).

Figure 11 shows the temperature dependence of ac conductivity at 1 kHz for different thicknesses of SiO₂. The conductivity values fall on a single straight line within ex-

Fig. 6. Log σ vs. reciprocal temperature for cell (A) (SiO₂ on p-type Si; SiO₂ on n-type Si)

Fig. 7. Log σ vs. reciprocal temperature for SiO_2 on p-type Si measured in cell (A) (ac measurement 1 kHz).

perimental error, suggesting no dependence on oxide thickness. Figure 12 shows the Arrhenius plot for the conductivity of SiO_2 grown in wet oxygen. Analysis of this plot yields an activation energy of 1.2 eV. Comparison of this plot with that in Fig. 7 shows that the conductivity for the wet oxide is higher than for the dry oxide.

Asymmetric cell (B).—Polarization measurements.—DC polarization measurements were made using an asymmetric polarization cell configuration B. In this type of cell, the ionic conduction is blocked due to application of positive potential on SiO_2/Pt side. Under these conditions, for a mixed conductor a steady state current (I) for a given applied potential (V) is given by the following expressions (13, 14)

$$I = \frac{AkT}{Le} \sigma_n [1 - \exp(-eV/z_1kT)] + \sigma_p [\exp(eV/z_1kT) - 1] \quad [1]$$

Fig. 8. Log σ vs. $10^3/T$ for SiO_2 on n-type Si measured in cell (A) (ac measurements 1 kHz).

Fig. 9. σ vs. frequency for SiO_2 on p-type Si in cell (A) (solid line); and n-type Si (dashed line).

where A is the cross-sectional area, L is the thickness of the SiO_2 sample, e is the electronic charge, z_1 is the effective charge on an oxygen ion, and σ_n and σ_p are the electronic conductivities due to electrons and holes, respectively. In the limiting case when $V \gg kT/e$

$$I = \frac{AkT}{Le} [\sigma_n + \sigma_p \exp eV/kT] \quad [2]$$

thus the plot of I vs. $\exp(eV/z_1kT)$ yields a straight line. The slope and the intercept of this line gives σ_p and σ_n , respectively

$$\sigma_n = \frac{Le}{AkT} \text{ (intercept extrapolation of plateau)}$$

$$\sigma_p = \frac{Le}{AkT} \text{ (slope)}$$

Moreover, the shape of the current vs. polarization potential is indicative of the n or p character of the material (13).

Fig. 10. Log σ vs. $10^3/T$ for the data of Fig. 9 extrapolated to zero frequency.

Fig. 11. Conductivity vs. reciprocal temperature for different thicknesses of SiO₂ on p-type Si cell (A) (ac measurement 1 kHz).

Figures 13-16 show the current voltage plots for SiO₂ grown on n- and p-type silicon in the temperature range 545°-960°C. These plots show a plateau, indicating that the electronic conductivity is predominantly due to electrons. The partial conductivity due to electrons can be obtained from the extrapolation to zero applied voltages of the plateau in the above curves. The electronic transference number and total conductivity for SiO₂ grown on n-type substrate is found to be higher than for SiO₂ grown on p-type at higher temperatures. An Arrhenius plot for the conductivity due to the electrons is shown in Fig. 17.

Fig. 12. Log σ vs. reciprocal temperature for SiO₂ grown under wet condition on p-type Si cell (A) (ac measurement 1 kHz).

Fig. 13. Typical polarization curves for asymmetric cell (B) containing SiO₂ on p-type Si.

Open-circuit voltage measurement.—Open-circuit voltage measurements were made using cell B. In these measurements the oxygen activity varied on one side using Ar + O₂ mixtures, while oxygen activity at the other side was fixed by the Si-SiO₂ equilibrium.

The EMF of this cell is given by

$$E_{\text{theoretical}} = \frac{RT}{nF} \ln \frac{P_{\text{O}_2} \text{ (in argon)}}{P_{\text{O}_2} \text{ (Si/SiO}_2\text{)}}$$

and

$$t_i = \frac{E_{\text{measured}}}{E_{\text{theoretical}}}$$

where E is EMF in voltage, $E_{\text{theoretical}}$ is that calculated from the free energy of formation, F is Faraday, n is number of electrons per mole of oxygen involved in the transport. The partial pressure of oxygen in argon was con-

Fig. 14. Typical polarization curves for asymmetric cell (B) containing SiO₂ grown on p-type Si.

Fig. 15. Typical polarization curves for asymmetric cell (B) containing SiO_2 grown n-type Si.

trolled by passing argon over titanium chips kept at different temperatures. For higher oxygen pressures, pure Ar and oxygen were mixed in desired proportions. The oxygen pressures were measured using a zirconia probe. Figure 18 shows the plot of $\log P_{\text{O}_2}$ vs. $FE/2.303RT$. The slope of this plot yields t_i/n' over a given pressure range. The t_i for SiO_2 grown on n-type Si was calculated assuming $n = 4$ per mole of oxygen and was found to vary from 0.4 at low oxygen pressure to 0.76. These data are consistent with the observations made by Mills and Kroger (11).

The data obtained in the present investigation are compared with the data reported by other investigators in Fig. 19. It is clearly evident that below a certain critical temperature, the total conductivity is almost independent of

Fig. 16. Typical polarization curve for asymmetric cell (B) containing SiO_2 grown on n-type Si.

Fig. 17. $\log \sigma_n$ vs. $10^3/T$ for SiO_2 on p-type Si substrate.

temperature and above this temperature the conductivity increases in temperature with a higher activation energy. There is considerable discrepancy between various investigators regarding the temperature at which this transition occurs. Our data show a comparatively sharper transition. The temperature-independent conductivity below 450°C for our data is likely to be due to electronic contribution and is thought to be impurity controlled. Conduction in the higher temperature range $450^\circ\text{--}960^\circ\text{C}$ is mixed ionic and electronic.

Table I shows the available experimental, theoretical and extrapolated conductivity data at 850° and 25°C , and in Table II the corresponding activation energies have been summarized. The values of conductivity at 850°C calculated by Raleigh (10) from two independent ap-

proaches are $3.7 \times 10^{-11} \Omega^{-1}\text{cm}^{-1}$ and $3.5 \times 10^{-11} \Omega^{-1}\text{cm}^{-1}$. The former value is obtained from the experimental data of Jorgensen (6), whereas the latter value was estimated from the diffusion of oxygen in SiO₂ as measured by Sucov (2). These values may be compared with our dc conductivity values, viz., $10 \times 10^{-11} \Omega^{-1}\text{cm}^{-1}$ and 8×10^{-11}

$\Omega^{-1}\text{cm}^{-1}$ for SiO₂ grown on p- and n-type silicon, respectively.

Our dc conductivity data obtained for different thickness of SiO₂ are reproducible within an error limit of 30%-40% and are in good agreement with Raleigh's (10) calculated values. The absolute values of conductivity dif-

fer by 50%-60%, which is reasonable for such a highly insulating material. The extrapolated data of Tripp *et al.* (12) differ from our dc values by two orders of magnitude, while their data agree reasonably well with our ac values. The value of conductivity reported by Mills and Kroger (11) is greater by 4-5 orders of magnitude as compared to our dc values and 3 orders of magnitude as compared to our ac values.

To separate out the electronic conductivity from the total conductivity, we chose the dc total conductivity values. As discussed earlier, the ac conductivity values extrapolated to zero frequency are higher than dc conductivity values. This may be because of the contribution of the dielectric loss due to variation in the capacitance with frequency and temperature. The high conductivity of SiO₂ grown in wet oxygen conditions is suggested to be due to the presence of appreciable amount of OH (18) and probably more nonbridging oxygen (19).

Examination of the activation energy data reported in Table II reveals that our data agree closely with that of Law (16), who has obtained an activation energy value of 1.57 eV from oxidation data assuming the parabolic rate law. He suggested that this represents the energy of the transport of ions during thermal oxidation of silicon.

Considering only the electronic conductivity obtained from the measurements on the asymmetric cell, the activation energy is estimated to be 2.7 eV above ~700°C (see Fig. 17). Conductivity due to electrons is lower than that due to ions by more than one order of magnitude. Further evidence of mixed conductivity is found from the results obtained from polarization measurements. From the total conductivity data and the electronic conductivity data, ionic conductivity values were determined for different temperatures. The percentage of ionic conductivity has been plotted as a function of temperature in Fig. 20. As shown in this figure, the ionic conductivity is only 40% at 545°C, and rises with temperature to a maximum of ~95% in the case of SiO₂ on p-type silicon, and ~86% for SiO₂ grown on n-type silicon between 700° and 875°C. Above this temperature, the values drop steeply. The decrease in the ac conductivity of SiO₂ on n-type silicon above 1000°C suggests that either the charge carriers experience some kind of repulsive effect in SiO₂, or that some kind of trapping of charges occurs at the Si/SiO₂ interface.

The above data suggest that conduction in SiO₂ at an oxygen pressure corresponding to Si/SiO₂ equilibrium and at temperatures above 450°C takes place via charged oxygen species as well as electrons. Transport via charged oxygen species is likely to be either because of the presence of oxygen interstitials at higher oxygen pressures or due to oxygen vacancies at lower oxygen pressures. Since the oxygen pressures surrounding SiO₂ in our investigations is very low (Si/SiO₂ equilibria), the lat-

ter seems to be more favorable. Oxygen vacancies can be generated according to the following defect equilibrium

hence

$$K = [\text{V}_o] [e']^2 P_{\text{O}_2}$$

Thus, the effect of the decrease in oxygen pressure would be to increase the electronic as well as the ionic conductivity. In SiO₂, the electronic conductivity is mainly due to electrons. At temperatures below 450°C the electrons, which are generated with increase in temperature, either pair with holes or are being trapped by the impurities, and hence the electronic conductivity in this temperature range does not increase significantly. The above defect mechanism is in agreement with the experiments made by Folkes *et al.* (17). The above equilibrium will be strongly influenced by the presence of aliovalent impurities. It has been suggested in the literature that during oxidation of silicon doped with B or P, the oxide contains detectable amounts of B or P as a result of redistribution of impurities. Segregation coefficient suggests the incorporation of boron into SiO₂, with rejection of the phosphorous back into the silicon (20). The presence of B or P would affect the above equilibrium. If the trivalent boron dissolves substitutionally into the SiO₂ lattice, additional oxygen vacancies would be generated to satisfy the condition of electroneutrality. However, the number of oxygen ion vacancies would be decreased because of the presence of pentavalent phosphorous ions in the cation lattice.

The higher values of conductivities of SiO₂ grown on silicon containing B, as compared to those containing P, seems consistent with the increased concentration of oxygen vacancies due to such a mechanism during the transport through SiO₂ in this oxygen pressure range.

At high oxygen pressures, however, the presence of oxygen interstitials is more likely. The presence of pentavalent phosphorous will then increase the number of interstitial oxygen ions and the holes associated with it, while boron will have the opposite effect. Our measurements on the oxidation of silicon in 1 atm of oxygen (unpublished) show that phosphorous-doped silicon oxidizes faster than boron-doped silicon, suggesting the presence of interstitial silicon and holes at this oxygen pressure.

The transport number measurements show that the ionic transference number is a function of oxygen pressure and temperature. There appears to be a critical oxygen pressure at which a switchover of the predominant defect from oxygen interstitials to oxygen vacancies may occur. This can only be resolved by measuring the conductivities as a function of oxygen pressures over a wider pressure range.

Some Applications of Cold Crucible Technology for Silicon Photovoltaic Material Preparation

T. F. Cizsek*

Solar Energy Research Institute, Golden, Colorado 80401

ABSTRACT

Cold crucible melt confinement was used for four different silicon crystallization methods of interest in photovoltaic material preparation: directional solidification, Czochralski pulling, sheet growth, and continuous ingot casting. Large grained, multicrystalline ingots were directionally solidified in cold crucibles, and grain sizes up to 5 mm were observed. Dislocation-free crystals were pulled in [111] and [100] orientations, using semiconductor-grade silicon. The edge-supported pulling (ESP) growth method was employed for sheet growth. The sheets were solidified between quartz filaments. Continuous casting of square cross-sectional ingots with grain sizes of up to several millimeters was carried out. Material suitable for fabrication into solar cells was obtained by these methods. AM1 solar cell IV characteristics are presented for the different materials and for coprocessed cells made from conventional Czochralski crystals grown using quartz crucibles. Some purity and electrical property data for cold crucible crystals are also given. Dislocation-free cold crucible crystals had higher purity levels and photovoltaic conversion efficiencies than conventional Czochralski crystals.

The importance of high efficiency to viable photovoltaic systems is becoming progressively more recognized. With silicon, several researchers have already realized AM1 efficiencies above 18%. Because of its abundance, low material cost, salubrity, established technology base, and high theoretical conversion efficiency, silicon is an excellent candidate material for high efficiency PV systems. However, the minority carrier lifetime attainable in heavily doped (<0.5 Ω -cm) Czochralski-grown crystals from quartz crucibles may not be adequate for high efficiency solar cells. This paper explores some roles that cold crucible technology might play in silicon material preparation for both dislocation-free single-crystal cells and multicrystalline cells (including silicon sheets). Cold crucible growth shows a potential for less impurity incorporation than Czochralski growth because, in the former method, there are no hot reactive surfaces near the molten silicon. In addition, radio frequency (RF) repulsion tends to push the liquid silicon away from the finger-like water-cooled walls of the melt container.

Cold crucible melt confinement was used for four different silicon crystallization methods of interest in photovoltaic material preparation: directional solidification, Czochralski pulling, sheet growth, and continuous casting. Solar cells were fabricated from the crystallized silicon and compared with solar cells fabricated on conventional Czochralski-grown (CZ) wafers.

Experimental

Principles of cold crucible operation.—Heating and melt confinement with cold crucibles is provided via RF induction heating. In this study, a 65 mm diam RF coil with five turns was used at 470 kHz. The coil surrounds the cold crucible coaxially. The vertical walls of the crucible are composed of closely spaced, electrically isolated, water-cooled copper fingers that have approximately square cross sections. Each finger acts as an RF stepdown transformer, and the coil current induces RF currents to flow in the fingers. The finger currents, in

turn, induce a current to flow in the silicon charge. Heating and melting of the charge is caused by ohmic resistance to this current flow (I^2R heating). At the inside wall of the crucible, the instantaneous current directions in the fingers and in the charge are opposed (Fig. 1). Thus, a force arises due to magnetic repulsion and the silicon melt is pushed away from the fingers.

Directional solidification.—For directional solidification or Stockbarger-type growth of large grained, multicrystalline silicon, a commercial cold crucible with a 31 mm id, a 50 mm od, and a hemispherical bottom was used. The cross section of each water-cooled finger is a sector of a right cylindrical annulus, as shown in Fig. 1. The inner radii of the sectors decrease in the hemispherical bottom region until the cross section becomes a wedge at the very bottom. The crucible is made of copper with gold plating. A flared, cylindrical, fused-quartz sheath was placed between the cold crucible and the RF coil, with the flared portion extending outward over the top of the coil, to prevent arcing between the coil and crucible. The assembly was housed in a 38 cm diam, water-cooled, stainless-steel growth chamber. The crucible and coil were stationary.

A 55g charge of semiconductor-grade silicon along with sufficient boron dopant to yield approximately 2 Ω -cm resistivity was placed in the crucible. The growth chamber was evacuated before it was filled with 99.999% minimum-purity argon at 1.2 bar total pressure. The silicon charge was preheated with a graphite heater, inductively coupled to the top of the cold crucible, until it was hot enough to couple directly to the cold crucible. At this point, the preheater was moved away from the crucible region.

An RF power level of 19.5 kW (6.1 kV plate voltage and 3.2A plate current) was used to melt and stabilize the polycrystalline silicon. For directional solidification, the power was ramped down to 0 at a rate of approximately 0.5 kW/min. Figure 2 shows an etched cross section of an

Fig. 1. Operating principle of a cold crucible showing instantaneous current flows.

Fig. 2. Etched cross section of silicon directionally solidified in a cold crucible.

ingot solidified in this manner. Grain sizes of up to 5 mm can be seen.

Czochralski pulling.—While silicon crystals had previously been CZ pulled from a cold crucible (1), auxiliary radiant heating with a graphite heater was required for seeding. Auxiliary heating may compromise the purity of the grown crystals by increasing the carbon content, for example. In this study, both [100] and [111] dislocation-free crystals were grown without auxiliary heating from a cold crucible system similar to the one used for directional solidification of silicon.

Seeds with 4×4 mm square cross sections and either [111] or [100] orientation were used. At a generator power level of 20.5 kW (plate voltage = 6.2 kV, and plate current = 3.3A), a 60g charge of melted silicon in the cold crucible was sufficiently hot to allow good wetting on the rotating seed. When even wetting was achieved, the seed was pulled upward initially at 3 mm/min. Then the power was dropped to 19.2 kW, and the pulling speed was increased to approximately 20 mm/min in order to grow a thin-necked crystal of 1.3-2.5 mm diam and more than 2 cm long. Necks grown under these conditions were sufficient to eliminate dislocations generated in the seed attachment region and allowed subsequent growth to be dislocation-free. A rotation rate of 13 rpm was used.

After the neck was grown, the pulling speed and power were adjusted to widen the crystal to about 15 mm diam, and the rotation rate was reduced to around 5 rpm. Figure 3 shows the hot zone during the diameter transition. In addition to pushing the melt away from the cold crucible fingers, magnetic repulsion also causes the top of the melt to be nearly hemispherically domed in such a small crucible; therefore, growing crystals with diameters larger than about 15 mm is difficult. At full diameter, growth speeds from 0.2-2.8 mm/min were tried, and the power levels used ranged from 11 to 14 kW. Some crystals were doped with boron to approximately $2 \Omega\text{-cm}$ resistivity, for solar cell use.

Silicon sheet growth.—The edge-supported pulling (ESP) growth method (2-4) was employed for sheet growth, and, again, the crucible configuration was similar to that described for directional solidification. The silicon sheets were solidified between 0.5 mm diam quartz capillary filaments that had 0.02 mm wall thicknesses. The filaments were spaced 17 mm apart. Growth was initiated on a single-crystal seed sheet mounted between the filaments, and then the seed/filament assembly was moved upward at 15-30 mm/min to grow the sheet.

Fig. 3. Cold-crucible Czochralski pulling of dislocation-free silicon

A very high meniscus was observed, because the magnetic repulsion tends to create a mounded upper melt surface and also because there is a melt rise to the sheet's solid/liquid interface of 6-7 mm in addition to the RF effect. Under these harsh thermal gradients, the sheet quickly became multicrystalline. A larger crucible would be advantageous. Because the thin-walled quartz filaments are relatively weak, thermal expansion mismatch between them and the silicon sheet causes the filaments to break away from the sheet during cooldown and a straight sheet edge is left (Fig. 4).

Continuous casting.—The three crystallization methods described so far used a round cold crucible with a closed bottom. Continuous casting of silicon ingots was performed in an open-bottom crucible having a 26×26 mm square confinement cross section with slightly octahedral corners. The vertical water-cooled copper fingers were 6×6 mm in cross section and 104 mm high. A five-turn RF coil was used that had two outer turns with an 83 mm id and three inner turns with a 61 mm id. The coil was 38 mm high and was placed with its midplane 34 mm below the tops of the fingers. A cylindrical quartz arc shield was concentrically located between the cold crucible and the RF coil.

The casting process was started by inserting a 25×25 mm square graphite support into the bottom of the open crucible until it was at midcrucible height. 12g of silicon were placed on the support. The growth chamber was evacuated and purged with argon. Then the RF coil was energized to heat the graphite, which in turn heated the silicon, until the silicon was hot enough to couple directly to the cold crucible. An RF power level of 10.3 kW (at 464 kHz) was adequate to melt the silicon. At that point, the addition of new silicon material through the open top of the crucible was begun at a rate of 240 g/h, the RF power level was increased to 15.7 kW, and the graphite support was started downward at 2.5 mm/min. The liquid silicon solidified as it was slowly lowered out of the RF field, at a rate equal to the raw silicon addition rate. The process was operated for over an hour. Figure 5 is a schematic of the continuous casting process. Figure 6 shows a cast sili-

Fig. 5. Schematic diagram of a cold-crucible continuous casting process.

con ingot that is 17 cm long and has a square cross section. Grain sizes of up to several millimeters were observed.

Results

Properties measurements.—A number of characterization techniques were used to evaluate the CZ-pulled crystals. X-ray topography was used to examine the defect structure of the crystals. Molybdenum- $K_{\alpha-1}$ radiation from a line-focus tube operating at 40 kV and 30 mA was

Fig. 4. An ESP silicon sheet grown from a cold crucible using quartz filaments.

Fig. 6. A continuously cast cold crucible ingot, 17 cm long by 2.5 cm square.

used to image (220) scanning transmission topographs on Ilford L-4 photographic plates. It was verified that the neck growth procedure described in the Czochralski pulling section was sufficient to establish dislocation-free growth in both [111] and [100] orientations, and that the crystals remained dislocation-free at full diameter.

The feed-stock silicon for the cold crucible was semiconductor-grade material. An undoped [111] dislocation-free crystal was determined to be p-type with 90-200 Ω -cm resistivity, indicating an excess acceptor impurity content of approximately 1×10^{14} atom/cm³. The minority carrier bulk lifetime of this crystal, as measured by the ASTM photoconductive attenuation method, was 195 μ s. Some crystals were doped with boron, during growth, to between 2 and 3 Ω -cm p-type for solar cell evaluation. Infrared transmission spectroscopy analysis for carbon and oxygen impurities showed none above the levels in a vacuum float-zoned reference wafer. Neutron activation analysis for gold and copper in a [100], 2.5 Ω -cm, dislocation-free single crystal grown from the gold-plated copper cold crucible indicated a level of 0.14 ppb (weight) for gold and 15.0 ppb (weight) for copper.

Room temperature Hall mobility measurements were made on a polished wafer from one of the [100], dislocation-free, boron-doped crystals. Indium/tin alloy contacts were used with van der Pauw's method for disks of arbitrary shape (5). The measurements indicated a p-type carrier concentration of 8.3×10^{15} /cm³ and a resistivity of 2.55 Ω -cm. From three separate determinations, the average mobility was 295 cm²/V-s with a standard deviation of 4 cm²/V-s.

Solar cell characteristics.—Material suitable for fabrication into solar cells was obtained by three of the cold crucible methods. The continuously cast material was not doped, and no cells were fabricated. However, when properly doped, these ingots are expected to be similar in cell performance to the directionally solidified silicon.

Cold-crucible-grown silicon wafers were cut, lapped, machine polished with a colloidal silica slurry, and used to fabricate solar cells. Control cells, using commercial CZ-grown wafers of similar resistivity, were processed along with the cold-crucible-grown silicon. The cell fabrication process consisted of a phosphorus oxychloride diffusion at 850°C that created a 0.3 μ m deep junction with approximately 90 Ω/\square sheet resistance, an aluminum drive-in back contact, and photolithographically defined front metallization. A standard Ti/Pd/Ag evaporated grid deposition sequence was used for the front contact. The cell areas ranged from 0.1 to 3.0 cm². The smaller cells were mesa array cells fabricated simultaneously on a wafer. Individual cells in an array were isolated by an etched moat. Figure 7 shows the completed device array configuration. To better determine material effects on cell efficiency, antireflection (AR) coatings were generally not used.

Directionally solidified material ("Directional solidification" section, above) was large grained (see Fig. 2). Mesa-defined cells 1.61 cm² in area were cofabricated on both round directionally solidified wafers and commercial CZ controls of similar resistivity. Typical uncoated I/V characteristics under ELH lamp illumination at an intensity of 100 mW/cm² and a temperature of 25°C are shown in Fig. 8. Poorer performance in short-circuit current density (J_{sc}), open-circuit voltage (V_{oc}), and fill factor (FF) result in an efficiency of only 9.2% for the directionally solidified cell vs. 10.8% for the CZ control. AR coatings are expected to increase these values to approximately 13% and 15.4%, respectively.

Solar cell efficiencies for cold-crucible-pulled CZ crystals were observed to be higher than those of coprocessed, conventional CZ crystals. The characteristics of 0.1 cm² mesa array cells were again measured without an AR coating, so that any differences due to substrate material would not be masked by potential AR coating variations. Statistics on cell performance at 25°C under tungsten ELH lamp illumination, and at 28°C under filtered xenon solar simulator illumination, both at 100 mW/cm²

Fig. 7. An array of 0.10 cm² mesa cells on a [100] cold crucible Si wafer.

intensity, are given in Table I. Cell results from several wafers are included. In all cases, V_{oc} , J_{sc} , and cell efficiency were higher for the cold-crucible-grown material. The fill factors were nearly equal within the standard deviation (shown in parentheses) of the measurements. Under ELH illumination at 25°C, the average control efficiency was 10.9%; the cold crucible cells were 11.7% efficient. Under xenon solar simulator illumination at 28°C, the control cells were 10.2% efficient, and the cold-crucible cells had an average efficiency of 10.6%. Good AR coatings can increase the cell efficiency values by at least 43% and as much as 50% (6) if combined with surface passivation. Two larger cells were made from a CZ control wafer and a cold-crucible CZ wafer (3.04 and 0.64 cm² respective cell areas). These cells were fabricated using a relatively low efficiency base-line process, and a simple one-layer AR coating was applied. The comparative performance under 100 mW/cm² ELH illumination at 25°C is shown in Fig. 9 and indicates an 8% advantage for the cold-crucible cell under these processing and measurement conditions.

In Fig. 10, a comparison is made between several conventional CZ control cells and cold-crucible ESP sheet cells. Again, the cells are not AR-coated. In this case, a 0.1 cm² mesa array cell structure is used. The range of performance for the ESP cells correlates with the crystal structure (nearly single-crystal regions exhibit the best performance—up to 90% of the control efficiencies—while the smaller grained regions near the filaments have the lowest solar cell efficiency—as little as 68% of the control efficiencies).

Summary and Discussion

The cold-crucible method with RF heating has been successfully applied to the crystallization of silicon in

Table I. Solar cell current/voltage characteristics for some diffused-junction n/p devices of 0.10 cm² total area.

four different ways. Directional solidification yielded 30 mm diam, 55g ingots with grain sizes of up to 5 mm. This material was made into solar cells having efficiencies about 85% as good as those of conventional CZ control cells. Dislocation-free, 15 mm diam silicon crystals were pulled in both [111] and [100] orientations by a cold-crucible CZ technique. No auxiliary heating was required to grow the thin necks that are necessary to initiate dislocation-free crystals. X-ray topography verified that the crystals were dislocation-free. A number of electrical property measurements, and an analysis of solar cells made from the crystals, indicate that cold-crucible silicon may have some device efficiency advantages (4%-8%, depending on processing and illumination conditions) over conventional Czochralski-grown substrates for photovoltaic applications. Silicon sheets 17 mm wide were also pulled from a cold crucible melt using the ESP technique and quartz filaments. Pulling speeds of 15-30 mm/min were used. Solar cell efficiencies 68%-90% as good as those of conventional CZ control cells were observed. The efficiency was a function of sheet grain size, with larger grained areas having higher efficiencies.

A new continuous casting method using an open-bottom cold crucible was applied to silicon. Ingots 25 ×

Fig. 10. I/V curves for six ESP cold crucible cells and three CZ control cells.

25 mm in cross section and 17 cm long were cast at a linear rate of 2.5 mm/min and had grain sizes of up to several millimeters. This technique should be applicable to many other materials that are electrically conductive in the molten state. A variety of feedstock geometries such as liquid melts, solid bars, pellets, and powders could be used. The solid/liquid interface is submerged and hence slag formation that occurs in some solidification processes could be kept away from the interface. Contamination levels would also be lower than those in conventional casting processes. Long ingots with tailored cross-sectional shapes can be produced.

The main advantage that cold-crucible silicon melt confinement holds over conventional crucible techniques is freedom from high levels of impurities such as oxygen and carbon. Crystal purities appear to approach those of float-zoned crystals for C and O. Neutron activation analysis indicated that no significant contamination was introduced in the silicon crystals from the copper or gold cold-crucible material.

All of the work reported here was done with relatively small cold crucibles (approximately 30 mm diam). Considerable scale-up would be necessary for commercial application. This should not be a major problem, since cold crucibles up to 45 cm diam have been used in skull melting applications.

Acknowledgments

The assistance of the following three individuals is especially appreciated: M. Schietzelt, who provided help with the crystallization experiments; J. L. Hurd, who performed the infrared analysis and helped with design detailing and fabrication of the open-bottom cold crucible; T. Schuyler, who did the solar cell fabrication and testing. In addition, the author thanks C. Osterwald for carrying out the SERI solar simulator cell measurements. Support for this work was provided by the U.S. Department of Energy under Contract DE-AC02-83CH10093 and, in part, by JPL Contract WO8746-83.

Manuscript received Oct. 1, 1984. This was Paper 336 presented at the New Orleans, Louisiana, Meeting of the Society, Oct. 7-12, 1984.

Solar Energy Research Institute assisted in meeting the publication costs of this article.

A Study of UV Absorption Spectra and Photolysis of Some Group II and Group VI Alkyls

ABSTRACT

A preliminary study has been made of the UV photolysis of metal-organic compounds of Hg, Cd, and Te which could be used for low temperature, selective area deposition of cadmium mercury telluride (CMT). High resolution UV absorption spectra have been measured for dimethylcadmium (CdMe_2), dimethylmercury (HgMe_2), and diethyltelluride (TeEt_2). Possible modes for photodissociation are discussed in light of these results. The photodissociation of these alkyls was attempted in a hydrogen stream at atmospheric pressure using a mercury-xenon lamp, deposition being onto a silica reaction tube. Yields of Cd, Hg, and Te were measured under different deposition conditions to determine the dependence on UV intensity, alkyl concentration, and flow velocity.

Recent interest in low temperature growth of the infrared detector material cadmium mercury telluride (CMT) has stimulated research into new epitaxial growth techniques (1-3). The preliminary study of UV photolysis reported here is part of an investigation to use alkyls for the growth of CMT at temperatures where they are thermally stable (4, 5) and possibly achieve selective area growth.

The alkyl sources used for metal-organic vapor phase epitaxy (MOVPE) are dimethylcadmium (CdMe_2) and diethyltelluride (TeEt_2) with Hg vapor introduced from a liquid Hg source. Pyrolysis of these alkyls enables high growth rates of CMT at substrate temperatures above 400°C. In the present study, the UV absorption spectra of CdMe_2 , HgMe_2 , and TeEt_2 have been measured. Also, photolysis experiments have been attempted at room temperature using CdMe_2 , HgMe_2 , HgEt_2 , TeMe_2 , and TeEt_2 .

Room temperature photodeposition of Cd from CdMe_2 was achieved by Jonah *et al.* (6) using a 1 kW xenon-mercury lamp, and in more recent studies Ehrlich *et al.* (7) used CdMe_2 for localized deposition of Cd using a CW laser source at 257 nm. The latter authors have also measured the UV absorption spectra of CdMe_2 in the vapor phase and as an adsorbed layer (8, 9). Multiphoton absorption of CdMe_2 has been claimed by Rytz-Froidevaux *et al.* (10), who used longer wavelength radiation (above 300 nm) to initiate Cd deposition onto a quartz window; the deposition proceeds by heat generated in the photodeposited film. This technique involves a surface selective reaction and can produce Cd deposition to a resolution better than 1 μm .

Experimental

In order to investigate the UV absorption processes leading to photodissociation, the absorption spectra of the alkyls CdMe_2 , HgMe_2 , and TeEt_2 were measured at room temperature in a stainless steel gas cell. This cell had a path length of 5.1 cm and was fitted with UV transmitting Spectrosil A quartz windows. The absorption cross section at a particular wavelength can be estimated from the absorption coefficient using the relation

$$\alpha_\lambda = N\sigma_\lambda$$

For an ideal gas at STP, $N = 2.77 \times 10^{19}$ molecules cm^{-3}

*Electrochemical Society Active Member.

$$\therefore \sigma_\lambda \sim (0.27 \times 10^{-16}) \frac{\alpha_\lambda}{p} \text{ cm}^2$$

where p is the partial pressure of the alkyl measured in torr. In all the spectra given below, the broken line represents the absorption due to H_2 carrier gas only in the cell, and the solid line represents that of carrier gas with a small pressure p of the appropriate alkyl. The absorption coefficient α (cm^{-1}) for each alkyl is then given by the difference between these curves.

The spectral region of greatest interest is 200-300 nm. At longer wavelengths, the alkyls show negligible absorption, while at shorter wavelengths the Hg lamp used for dissociation emits negligible power. Absorption data in this spectral range have previously been obtained by Thompson and Linnett (11) using photographic techniques, but these spectra do not give the necessary information on relative strengths of transitions.

The photodeposition measurements were made using a continuous stream of H_2 plus alkyl vapor at a controlled flow rate and concentration and a constant total pressure of 1 atm. High purity hydrogen is supplied via flowmeters to two lines; one is fed to the bubbler containing the alkyl, the other line acts as a dilution stream to alter the partial pressure of alkyl vapor. The mixed stream is passed at ambient temperature through a 7 mm id silica tube. Radiation from a 1 kW Oriel mercury-xenon lamp was focused onto the silica tube. Waste gases from the reaction zone, predominantly hydrogen, are passed to a combustion chamber and burnt in a continuous flame. The whole system can be pumped out to test for leaks and purged with hydrogen. There were a number of additional features which were used in some of the experiments, such as back-reflecting mirror, masking, and a power meter. A laser power meter was used, with black body absorption characteristics to measure the radiation power density passing through the silica reaction tube.

The amounts of material deposited onto the wall of the silica tube as a consequence of photolysis were dissolved in acid and determined by atomic absorption analysis. The deposits were metallic in appearance and were not expected to contain large amounts of organic impurities, as subsequent secondary ion mass spectrometer (SIMS) experiments on epitaxial thin films only show small amounts of carbon contamination (18).

Fig. 1. Absorption coefficient vs. wavelength for CdMe_2 at a partial pressure of 0.8 torr; the zero phonon line is indicated (Z).

Absorption Spectra

The absorption spectrum of CdMe_2 at a partial pressure $p \sim 0.8$ torr is given in Fig. 1. The spectrum between 200 and 300 nm shows a discrete absorption band with well-resolved vibrational fine-structure peaking near 216 nm, together with a broad absorption continuum extending across the range of interest.

The ground state vibrational frequencies given by Bakke (12) for CdMe_2 and HgMe_2 are listed in Table I. Using these data, the vibrational progression in the CdMe_2 absorption band can be assigned as indicated in Table II, although it must be realized that there is some ambiguity in the possible assignments. Nevertheless, it seems clear from a comparison of Tables I and II that it is the totally symmetric (A_1) vibrational modes which are strongly excited in the transition. This is normally found for a strong symmetry-allowed electronic transition. We note that Thompson and Linnett (11) have discussed the fine structure in their sample of CdMe_2 as arising from CdEt_2 impurity. In view of the strength of absorption in our spectra, the known level of purity of the sample, and the agreement between hotband frequencies and Raman data for CdMe_2 , we do not consider this a credible explanation for our data.

The energies of the valence molecular orbitals (MO) in CdMe_2 have been calculated by Bancroft *et al.* (13) and compared with measured photoelectron spectra. The

electronic energies and orbital types are listed in Table III. The highest energy-filled MO (b_1) involves an antisymmetric linear combination of C_{σ} orbitals and is weakly bonding in the C—Cd—C chain by virtue of interaction with Cd 5p orbitals. The electronic transition giving rise to the discrete absorption band in Fig. 1 involves excitation of an electron from this b_1 MO to the first unfilled orbital, which is either nonbonding or antibonding. This electronic excitation therefore weakens the C—Cd—C bond, thereby promoting the photodissociation.

This weakening of the C—Cd bonds in the electronically excited state can be quantified from the analysis of the vibrational progression associated with the transition. The lines to low energy of the zero-phonon line (ZPL) Z in Table II are "hot bands," the transition originating from a vibrationally excited level of the ground electronic state. The ground vibrational frequency ν_2' deduced from the optical spectrum is $\nu_2' \sim 467 \text{ cm}^{-1}$, in good agreement with the Raman value listed in Table I. This mode represents a symmetric stretching of the C—Cd—C molecular chain. The lines to high energy of Z in Table II give the corresponding vibrational frequencies in the electronically excited state. From Table II, it can be seen that the C—Cd—C mode ν_2 in the excited state has a lower energy, $\nu_2 \sim 330 \text{ cm}^{-1}$, which indicates a weakening of the vibrational force constant, k . Since frequency $\propto k^{1/2}$, we obtain

$$\frac{k}{k'} \sim \left(\frac{330}{467} \right)^2 \sim 0.50$$

where k and k' are the Cd—C force constants in the excited and ground states, respectively. Thus, the UV absorption process giving rise to the discrete absorption band in Fig. 1 reduces the C—Cd—C bonding strength by a factor of ~ 2 .

Fig. 2. Configurational coordinate model for CdMe_2

The dissociation process for CdMe_2 appears to be asymmetric, with one CH_3 radical departing first with excess kinetic energy (14). Excitation of the symmetric C-Cd-C mode ν_2 in the optical transition could lead rapidly to excitation of the corresponding antisymmetric C-Cd-C mode ν_6 , which has a similar energy. This relaxation between modes is brought about by anharmonic terms in the molecular hamiltonian and usually proceeds very rapidly; in this case, the mode ν_6 may be the reaction coordinate for the dissociation. The discrete absorption band in Fig. 1 is overlapped by a broad continuum with a relatively low energy threshold. This continuum possibly represents absorption to an unbound electronic state which is purely dissociative. The situation is represented schematically in Fig. 2. Chen and Osgood (17) have also observed a long wavelength continuum for CdMe_2 vapor at 300 K. These authors attribute this absorption to a vibrationally allowed quadrupole transition which is dissociative.

The absorption spectrum of HgMe_2 at a partial pressure $p \sim 10$ torr is given in Fig. 3. The form of this spectrum is very similar to that for CdMe_2 , except that it is slightly shifted to higher energy. The vibrational progression can

be analyzed as for CdMe_2 , the probable assignments being listed in Table IV. Once again the progression is dominated by the symmetric A_1 modes, and particularly by the C-Hg-C stretching mode ν_2 . The similar bonding character for CdMe_2 and HgMe_2 is also reflected in the photoelectron spectra for these compounds (15).

From a comparison of ground and excited vibrational frequencies for the mode ν_2 , we obtain as a ratio of force constants for HgMe_2

$$\frac{k}{k'} \sim \left(\frac{370}{519} \right)^2 \sim 0.51$$

This is very close to the ratio obtained for CdMe_2 , and again indicates that electronic excitation into the discrete absorption band in Fig. 3 roughly halves the C-Hg-C bond strength.

Photodissociation mechanisms in HgMe_2 and CdMe_2 are presumably quite analogous. The Hg compound again shows a broad underlying dissociative continuum, but there is also evidence for the presence of free Hg atoms in the absorption cell from the weak Hg absorption line at 253.7 nm.

The absorption spectrum of TeEt_2 at a partial pressure $p \sim 1$ torr is given in Fig. 4. The form of this spectrum is

Fig. 4. Absorption coefficient vs. wavelength for TeEt_2 at a partial pressure of 1 torr.

Table V. Table of photodeposition results

Run no.	Alkyl	Exposure time (min)	Power intensity (W cm^{-2})	Partial pressure (torr)	Flow velocity (cm s^{-1})	Yield (mg)
9	CdMe_2	5	1.9	9.3	20	0.889
10	CdMe_2	5	2.0	2.3	20	0.704
11	CdMe_2	10	0.85	2.3	20	0.175 (1 cm mask)

7	TeEt_2	15	0.6	2.3	20	0.264
8	TeEt_2	15	1.79	2.3	20	0.662

quite different from those of the metal alkyls and shows a series of discrete absorption bands without well-resolved fine structure. There is also little evidence for any strong underlying absorption continuum. At the present stage, useful analysis of this spectrum would be difficult.

Photodeposition Results and Discussion

The results of the photodeposition measurements are summarized in Table V. In run 9, a smooth mirror deposit was formed on the silica reaction tube after 1 min exposure to a beam intensity of 1.9 W cm^{-2} with a partial pressure of CdMe_2 of 9.3 torr. A photograph of this reaction tube for run 9 is shown in Fig. 5. The experiment was performed with a power meter behind the reaction tube and with no back-reflecting mirror. The beam was completely attenuated by the deposit in the high intensity region after 1 min, and this coherent deposit extended in both directions into regions of lower beam intensity. The experiment was terminated after 5 min, leaving the cadmium deposit as shown in Fig. 5 extending for 12 cm almost symmetrically about the beam axis. The weight of Cd deposited was 0.889 mg; clearly, the weight would have been larger if the beam had not been attenuated. Run 10 was conducted under similar conditions to that of run 9, except for a reduction in CdMe_2 to 2.3 torr, achieved by adjusting the ratio of bubbler flow rate to dilution flow rate. The photograph of the reaction tube for run 10 in Fig. 5 is similar to run 9, with a coherent deposit extending for about 10 cm along the reaction tube. The period of exposure to the UV beam was 5 min, yielding a total Cd deposition of 0.704 mg. Following a pattern similar to run 9, the deposit formed initially in the high inten-

sity region and extended to regions of lower beam intensity.

For run 11, a lower power, 0.85 W cm^{-2} , was used, and the reaction tube was masked, except for a 1 cm gap to allow illumination. A photograph of the reaction tube is shown in Fig. 5, where only the illuminated region has a Cd deposit.

Photolysis of HgMe_2 was attempted under flow and beam power conditions similar to those of run 9 for CdMe_2 . In order to reduce loss of Hg from the reaction tube, a liquid nitrogen trap was placed downstream of the exposed region. Atomic absorption analysis determined the weight of Hg deposited to be 19.3 mg, a significantly higher yield than Cd from CdMe_2 .

Photolysis of HgEt_2 was unsuccessful using conditions similar to HgMe_2 photolysis. No mercury was visible after 15 min, and less than 0.01 mg of Hg was measured by atomic absorption analysis. No UV absorption spectra were measured for HgEt_2 , so it is not possible at this stage to explain the absence of photolysis using a mercury lamp or to predict under what conditions photolysis would occur.

The initial diethyltelluride (TeEt_2) photolysis experiment, run 1, used a back-reflecting mirror to increase the intensity in the reaction tube. In an exposure period of 15 min, 0.9 mg of Te was deposited with a TeEt_2 partial pressure of 2.3 torr. Although, in light of later experiments, the presence of the mirror did enhance photolysis, it was removed in subsequent experiments so that a power meter could be placed behind the reaction tube.

The deposition of Te onto the silica tube was not as smooth as the Cd deposit; some of the Te formed fine particles, which were carried out of the reaction tube, causing an error in the determination of weight of deposited Te. It was also observed that deposition did not occur in the region of high UV intensity; most of the deposit was downstream of this region.

The cause of this anomalous behavior was investigated using masks so that only part of the tube could be exposed to the UV radiation. Runs 4 and 5 were performed without masks to obtain a comparison with masked tubes. In both cases, the TeEt_2 partial pressure was 2.3 torr and the flow velocity was in the region of 20 cm s^{-1} . The power intensity in the central beam region was 0.6 W cm^{-2} . Run 4 yielded 0.668 mg of Te, while run 5 yielded 0.44 mg of Te; the difference in these values probably reflects the varying amount of Te lost from the tube as a fine dust.

Using a 1 cm mask in run 12 with a higher incident power intensity of 2.3 W cm^{-2} resulted in very little deposit in the window region of the mask; only fine lines of deposit resulted at each edge, as can be seen in Fig. 6. Run 12 displayed an unexpected feature of deposition occurring 10 cm downstream from the beam axis at a point where the tube emerges from the mask and is illu-

Fig. 5. Reaction tubes following photodeposition of CdMe_2 for runs 9 (1 cm mask), 10, and 11 (see text).

Fig. 6. Reaction tube following photodeposition of TeEt_2 ; the masked regions extend from 90 to 190 nm, and above 200 nm.

minated by a very low intensity of UV. This additional deposit can be seen in Fig. 6. It is also clear that there is little deposit within the 10 cm dark region.

In run 13, all conditions were the same except for the downstream portion of the mask being removed. A region of high intensity UV from the edge of the mask extending for about 2 cm has very little deposit, and most of the deposition is downstream of this where the UV illumination is weaker. The amount of Te deposited in run 13 was 0.36 mg, compared with 0.26 mg in run 12.

It can be concluded from these results that Te will not photodeposit onto silica in a region where the UV intensity is high, although this may not be the case for a different surface or in the presence of other species such as Cd. Te will deposit in a region where the UV intensity is lower and, as run 12 indicated, the intensity may be orders of magnitude lower than the peak intensity, but the amount of Te deposited is only a factor of 2 or 3 down from when the mask was not present. As will be discussed later, the photodeposition efficiency of TeEt_2 is a fairly simple function of the peak UV intensity. Therefore, a more complex process than simple photon absorption and dissociation of a C-Te bond is needed to explain the masking experiments. The relatively large amount of deposit occurring downstream of the mask in run 12 suggests that some TeEt_2 molecules have been pre-excited in the high intensity region. The mean time for a molecule to travel across the dark region is 0.5s, which rules out the possibility of an excited electronic state or vibrational state in the molecule. A possible mechanism is the formation of an intermediate species such as TeEt which then readily dissociates in a region of low photon flux.

The role of flow velocity of the $\text{H}_2 + \text{TeEt}_2$ stream was investigated, as it will influence the mean exposure of each TeEt_2 molecule to UV. In run 6, the flow velocity was reduced to one-third of the standard value, and the percentage yield was increased approximately three times (see Table V).

Changes in UV power intensity were investigated in runs 7 and 8, both runs being carried out without masks and flow velocities of 20 cm s^{-1} . In run 7, the beam power intensity was 0.60 W cm^{-2} , which deposited 0.264 mg of Te. In run 8, the power intensity was increased to 1.79 W cm^{-2} , depositing 0.662 mg of Te. For the concentrations used in these experiments and for photodeposition efficiencies in the region of 1%, it is likely that the weight of Te deposited would be proportional to the incident UV power intensity.

Successful photodeposition of TeMe_2 was achieved with a beam intensity of 1.3 W cm^{-2} and flow velocity around 20 cm s^{-1} . A total weight of 0.288 mg of Te was deposited in 15 min, which is approximately a factor of 2 lower than for TeEt_2 under equivalent conditions. The deposition mainly occurred downstream of the high UV intensity region, in agreement with the TeEt_2 experiments.

Conclusions

High resolution UV absorption spectra have been measured for a number of alkyl/ H_2 gas mixtures. For both CdMe_2 and HgMe_2 , there is an electronic transition from a weakly bonding to an antibonding MO in the energy range $43,000\text{--}47,000 \text{ cm}^{-1}$ which leads to significant weakening of the C-M-C molecular chain. This excitation can lead to photodissociation at room temperature. The mechanism may involve vibrational relaxation to the antisymmetric reaction coordinate of a bound state, or it may decay into the underlying continuum, which is probably dissociative. The spectrum of TeEt_2 cannot be easily analyzed to give evidence for analogous bond weakening in the excited state, although it is strongly absorbing in the part of the spectrum where the lamp emits a high UV intensity.

Photodeposition of Cd from CdMe_2 occurs readily when illuminated with a Hg lamp, although the absorption coefficient in the region of 254 nm is low ($\sim 0.05 \text{ cm}^{-1} \text{ torr}^{-1}$), in agreement with Ehrlich *et al.* (9). Similarly, HgMe_2 gives a good yield of Hg, but no significant photodissociation occurred with HgEt_2 ; the reason for this is not clear in the absence of absorption spectra for this alkyl.

The photodeposition of TeEt_2 and TeMe_2 does not appear to be first order in these experiments, as deposition did not occur in the region of high UV intensity but deposited downstream where the UV intensity was lower. Experiments by Connor *et al.* (16) on the flash photolysis of TeMe_2 indicated the formation of primary photoproducts of the type CH_3Te , although no indication was given of a delay in the production of Te photoproducts. The delay in deposition may be due to poor adsorption onto silica in a region of high UV intensity or to the formation of an intermediate compound which photodissociates further downstream in a region of low UV intensity.

Further experiments on using these alkyls for low temperature epitaxial growth are in progress.

The Photochemical Oxidation of GaAs

P. A. Bertrand

The Aerospace Corporation, Chemistry and Physics Laboratory, El Segundo, California 90245

ABSTRACT

The vacuum ultraviolet photochemical oxidation of GaAs by N_2O (wavelengths of 2537 and 1849Å) was studied by x-ray photoelectron spectroscopy. We believe the model most consistent with our data involves (i) adsorption of molecular N_2O , (ii) dissociation of the N_2O on the surface, and (iii) oxidation of the surface by the adsorbed O atoms. The temperature dependence of the overall reaction on the stoichiometric surface is dominated by the temperature dependence of adsorption of N_2O . An As-rich surface oxidizes more slowly, and the reaction saturates; in this case, the rate-limiting step and the cause of saturation is the oxidation of the surface by adsorbed O atoms. The As-covered surface does not present the proper sites (As atoms surrounded by Ga atoms) for fast, continued oxidation of GaAs.

Thermal, plasma, and anodic oxides of gallium arsenide (GaAs) have been heavily explored as insulating and passivating layers for this important semiconductor, with relatively little success. High trap density at the interface leads to poor electrical characteristics (1-3). Certain non-native insulators, such as silicon dioxide (SiO_2) and silicon nitride (Si_3N_4) deposited by various methods, also have high interface-state densities. In this case, the interface states seem to be related to the presence of an interfacial layer of oxidized GaAs, either native oxides present before deposition or oxides created during the deposition process (4-7).

For example, in the vacuum ultraviolet irradiation (VUV) assisted chemical vapor deposition of SiO_2 on GaAs, the "Photox" process developed by Hughes Aircraft Company, a GaAs photochemical oxide is found at the GaAs- SiO_2 interface, even when no initial GaAs native oxide is present before deposition (8). Knowledge of the mechanism of photochemical oxidation of GaAs is important for reducing or eliminating this layer, and for enhancing the usefulness of the "Photox" process in GaAs passivation. In the experiments reported here, the kinetics of the VUV photochemical oxidation of GaAs by nitrous oxide (N_2O) have been observed by x-ray photoelectron spectroscopy (XPS). A probable mechanism for the reaction is suggested in which molecular N_2O adsorbs on clean, stoichiometric GaAs prior to its dissociation. This model is suggested by the temperature dependence of the reaction: the reaction is less complete as the substrate temperature is raised.

Experimental

The GaAs coupons were polished <100> faces of p-type material, zinc-doped to a carrier concentration of $5 \times 10^{18} \text{ cm}^{-3}$. To produce the native oxides, coupons were cleaned with 2% bromine (Br) in methanol for 10s, rinsed in methanol, then placed in air at room temperature for several months.

For the photochemical oxidation experiments, the photochemical reactor was enclosed in a glove bag filled with flowing N_2 . The GaAs coupons were etched in the glove bag in either 2% Br_2 in methanol for 10s (to produce a stoichiometric surface) or in concentrated HCl for 15 min (to produce an As-rich surface) (9), rinsed in ethanol, and loaded into the reactor chamber. Since this procedure was carried out in the glove bag, the cleaned samples were never exposed to air. To the sensitivity of our XPS measurements, no oxidized Ga or As is present on the surface. In the reactor, the substrate was placed on a heated copper block where it would be illuminated from above by a low-pressure mercury (Hg) lamp. The photon flux of the lamp is about $1 \times 10^{15} \text{ photon/cm}^2 \text{ s}$, equally split between the 2537 and 1849Å lines. Both lines have sufficient energy for e^-h^+ pair production in GaAs, and the 1849Å line can dissociate N_2O to produce $N_2(^1\Sigma)$ and $O(^3P, ^1D)$. N_2O was introduced into the evacuated chamber at a flow rate of 60 standard cubic centimeters per minute (sccm), and the pumping speed was adjusted to establish a pressure of 6 torr in the chamber. These

conditions are similar to those used in the photochemical deposition of SiO_2 on GaAs. The chamber has been used with a Hg sensitizer, but Hg was not intentionally added to the N_2O in these experiments. After the flow of N_2O was established, the lamp was turned on for an arbitrarily chosen period of time. As a result of the geometry of the reactor, the Hg lamp illuminates both the gas and the substrate surface.

The coupons were removed from the reactor chamber, again in a N_2 environment, and placed in a desiccator. The desiccator was transferred to a N_2 -filled glove bag attached to a modified GCA-McPherson ESCA-36 XPS spectrometer that had a spherical-sector analyzer and a position-sensitive detector (10). The coupons were loaded into the spectrometer, also in a N_2 atmosphere, and the spectrometer was evacuated to 1×10^{-7} torr. The entire procedure, from the unloading of the reactor chamber to the XPS analysis, generally took less than 30 min.

Results

GaAs native oxides.—The compositions of GaAs native oxides have been measured many times (9, 11). The results of this study are in agreement with the literature: the oxide is 80% gallium trioxide (Ga_2O_3), with 20% arsenic trioxide (As_2O_3) and occasionally a small amount of arsenic pentoxide (As_2O_5), depending on preparation conditions (see Fig. 1). The oxidized As peak, separated by 3.8-4.2 eV from the more prominent peak as a result of GaAs in this study, is assigned to As_2O_3 by comparison to binding energy values for bulk As_2O_3 (12). Some workers have found smaller values for this separation for lightly oxidized GaAs (11), values that could be due to either oxygen deficiency of the oxides or band bending effects. There is elemental As present in the native oxide. The elemental As signal is unresolvable from the GaAs As signal in these experiments because of the signals ~ 0.5 eV separation. However, the full width at half maximum

Fig. 1. XPS spectrum of native-oxide-covered GaAs

Fig. 2. XPS spectrum of native-oxide-covered GaAs after exposure to VUV radiation for 30 min at 23°C.

(FWHM) of the As XPS peak in a native-oxide-covered surface is 1.9 eV, compared to 1.4 eV for a clean surface; this clearly indicates the presence of unresolved structure.

An additional form of oxidized As is present in the native oxide after exposure to VUV radiation (see Fig. 2). It is not as highly oxidized as As_2O_3 , as shown by its XPS peak position intermediate between those of GaAs and As_2O_3 . The As(metal)- As_2O_3 separation of approximately 3.6 eV for a change of 3 in As oxidation state (12) implies that the 2.8 eV separation between GaAs and partially oxidized As corresponds to a formal As oxidation state of about +2. This should not be taken as an indication of the presence of an actual compound "AsO." The +2 oxidation state of As is not stable. Instead, this separation means that one of the As-O bonds has been broken during VUV irradiation, and the oxide is oxygen deficient. There is also a pronounced shoulder on the most intense As peak; we attribute this to elemental As.

GaAs photochemical oxide.—The photochemical oxide grown under our reaction conditions on a stoichiometric Br_2 -etched GaAs surface has equal amounts of oxidized Ga and As and is not Ga_2O_3 rich, as is the native oxide (see Table I). The Ga oxide present is Ga_2O_3 , and the As oxides are As_2O_3 and the less oxidized "AsO"-like form mentioned above (see Fig. 3). Elemental As is present, as indicated by the FWHM of the GaAs As peak of 1.7 eV. The photochemical oxide grown on an As-rich, HCl-etched surface is As rich (see Table I and Fig. 4). In fact, for short reaction times, only oxidized As (predominantly AsO) is observed, and no oxidized Ga is present. Without VUV exposures, no oxide is formed on either type of surface.

The progress of the reaction can be monitored by calculating the fraction F of the total Ga and As in the analysis volume that is oxidized (see Table I, column 5, and Fig. 5). F is calculated by taking the sum of the peak intensities for Ga as, Ga_2O_3 , and As as As_2O_3 and "AsO" and dividing that quantity by the sum of the peak intensities for Ga and As in these forms as well as in oxidized GaAs. Peak heights rather than peak areas were used because of the difficulty of uniquely resolving overlapping peaks. The O (1s) spectra were not used in the analysis because they were very broad, indicating the presence of more than one type of O environment, and could not be resolved. The peak intensities have been corrected for the spectrometer sensitivity, but not for matrix effects (which are largely unknown), molar volumes (which are not well defined, especially for the oxygen-deficient oxide "AsO"), or depth into the sample of the emitting atom (since it is not known whether the layers are smooth or island-like). If the oxides are present as islands, the signal for the oxides will not rise as rapidly as it would if the oxides were smooth layers, and the signal for the substrate will not fall as rapidly. Thus F will depend less on reac-

tion time for an island-growth mode than for a smooth-layer growth mode, but will follow the same general trends.

For the native oxide, $F \approx 0.4$, or 40% of the Ga and As in the region sampled by XPS is oxidized (as discussed below, this can be thought of as an oxide $\sim 5\text{\AA}$ thick). For a 60 min reaction time, the photochemical oxides also have $F \approx 0.4$. On the Br_2 -etched surface for reaction temperatures of 70° and 100°C, the reaction does not appear to be nearing completion; F is still increasing at 60 min. Reactions were not run for longer periods of time, so the value of F at completion is not known. For lower temperatures, the reaction appears to slow after 30 min. Except for the 23°C case, the fraction of oxidation decreases with increasing temperature. On the HCl-etched surface, the reaction is clearly slowing after 30 min; it is probably complete at 60 min for all temperatures studied, and has no obvious temperature dependence.

Discussion

The observed temperature dependence of the photochemical oxidation (a decrease in the fraction of oxidation as temperature increases) of clean, stoichiometric GaAs by N_2O and VUV irradiation indicates that a gas adsorption step could be present in the reaction mechanism.

Fig. 3. XPS spectrum of Br_2 -etched GaAs after exposure to N_2O and VUV radiation for 60 min at 70°C.

Fig. 4. XPS spectrum of HCl-etched GaAs after exposure to N_2O and VUV radiation for 30 min at $40^\circ C$.

The photodissociation of N_2O , whether in the gas phase or on the surface, is temperature independent, and the rate of oxidation of GaAs by adsorbed oxygen (O) atoms produced by the dissociation of N_2O should increase slightly with increasing temperature. An adsorption step will have its equilibrium shifted toward reactants (unadsorbed gas and the clean surface) by increased temperature. Then, since there is less gas adsorbed at higher temperature, the overall reaction will be slower. Another possibility would be diffusion of Ga or As into the oxide layer (this will be discussed later).

Given the assumption that a gas adsorption step is responsible for the temperature dependence, the adsorption energy Q can be calculated from the temperature dependence of adsorption through the equation $F \propto \exp(Q/RT)$ (see Fig. 6a), and is 2 ± 1 kcal/mol, a value typical of physical adsorption. Oxygen atoms created on the surface by electron irradiation are known to adsorb strongly to GaAs (13), and the "excited oxygen" used in many oxidation studies to produce fast, heavy oxidation may also be atomic oxygen (14). The adsorbing species in the experiments described here is only physisorbed and, therefore, is probably N_2O . The O atoms produced in the gas phase may be quenched too quickly in our experimental conditions to live long enough to react with the surface, although this seems unlikely. Another possibility is that the oxygen atoms produced in these experiments are not as reactive as those produced by electron irradiation or by interaction with an ion-gauge filament; indeed, the states of these latter two forms of "excited oxygen" have not been characterized. Therefore, the photodissociation of N_2O occurs while it is adsorbed on the surface, either directly or through mediation by the excited surface. The adsorbed O atoms produced by this step then react with the GaAs surface to produce Ga and As oxides. The overall reaction can be pictured as

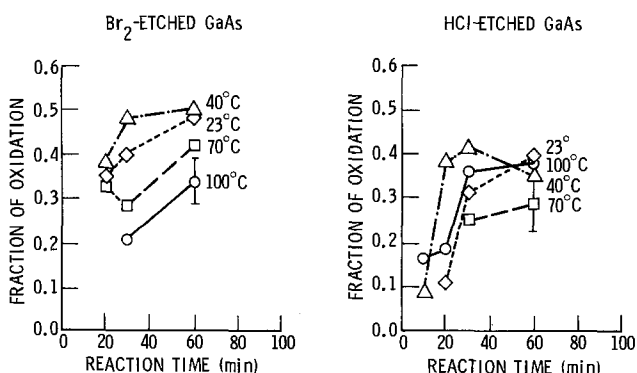

Fig. 5. Progress of photochemical oxidation of GaAs, illustrated by the fraction of oxidation as a function of time. Error bars represent the reproducibility expected in F as a result of the 15% reproducibility of XPS intensity measurements. (Left): Br_2 -etched surface. (Right): HCl-etched surface.

where $N_2O \cdot GaAs$ and $O \cdot GaAs$ represent adsorbed N_2O and O atoms, respectively.

Another possible explanation of the decreases in F with increasing temperature is that unoxidized Ga and/or As diffuses into the oxide layer, thus increasing the denominator of the fraction F . However, solid-state diffusion processes usually have activation energies of tens of kilocalories, many times greater than that observed here.

The thickness of the oxide layers can be calculated approximately (15) with two assumptions. First, the escape depth λ of the photoelectrons was taken to be 15\AA for both Ga and As. Second, the oxide layer is assumed to be a homogeneous film with an abrupt interface on top of the GaAs substrate. The thickness of the native oxide is calculated to be 5\AA , while the thickest photochemical oxide on a Br_2 -etched surface in these experiments is $\sim 8\text{\AA}$ thick.

The surface stoichiometry has a profound effect on the reaction. The As-covered surface does not oxidize as readily as the stoichiometric surface: the fraction of oxidation is less and saturates at ~ 30 min. The approximate thickness of the oxide layer at this point is only 6\AA . The reaction has no discernible temperature dependence, as a temperature-dependence plot shows (see Fig. 6b). The change in surface stoichiometry may eliminate or reduce the physisorption sites for N_2O , requiring gas-phase dissociation of N_2O and transport of O to the surface. The gas-phase production of O atoms and their transport to the surface is less probable than the adsorption and decomposition of N_2O for the previously considered case of a clean surface, which would account for the overall slowing of the reaction. However, it would not account for the saturation of oxidation after 30 min.

The final step of the photochemical oxidation reaction, the oxidation of GaAs by adsorbed O atoms, must be rate limiting in this case. This step should be very geometry- and composition-dependent. For example, room temperature adsorption of O_2 has been found to produce two adsorbed oxygen containing species on GaAs surfaces of various geometries and compositions: an adsorbed molecular form, bound predominantly to As, and an oxidic form, bound predominantly to Ga (13). Electron irradiation of the adsorbed molecular form converted it to the oxidic form. The mechanism of this reaction requires molecular adsorption sites in which the As atoms are surrounded by Ga atoms to enable subsequent reaction. An As-rich surface will have fewer such sites and should show reduced reaction with adsorbed O atoms. That is, the surface concentration of O in appropriate sites for reaction is rate limiting.

The limited oxidation of an As-rich surface has been used in the protection of GaAs from atmospheric effects, by creation of an As-rich layer on the surface by molecular beam epitaxy (MBE) (16) or electrochemical methods

(17). Layers of As 50-1000Å thick were found to oxidize only at their surfaces in air at room temperature and to prevent oxidation of the substrate GaAs. In the present experiments, the thickness of the As layer created by the HCl etch could not be measured, since its XPS signal was unresolvable from that of the substrate. It is probably much thinner than the MBE and electrochemical films, and may not be continuous. However, even in this case, the oxidation rate is decreased when the surface layers are As rich.

Conclusions

The photochemical oxidation of clean, stoichiometric GaAs probably proceeds by (i) adsorption of N₂O, (ii) dissociation of the N₂O on the VUV-excited surface, and (iii) oxidation of the surface by the adsorbed O atoms. The temperature dependence of the overall reaction is dominated by the temperature dependence of adsorption of N₂O. An As-rich surface oxidizes more slowly and the oxidation process saturates at 30 min. In this case, either gas-phase or surface dissociation of N₂O may occur; the rate-limiting step and cause of saturation is the oxidation of the surface by adsorbed O atoms. The As-covered surface does not present the proper sites (As atoms surrounded by Ga atoms) for fast, continued oxidation of GaAs.

High Field Ionic Conduction in Anodic Ta₂O₅ Formed in Oxalic and Phosphoric Electrolytes

I. Montero, J. M. Albella,* and J. M. Martínez-Duart

Instituto de Física del Estado Sólido, C.S.I.C. and Departamento de Física Aplicada, C-12 Universidad Autónoma, Cantoblanco, Madrid 34, Spain

In a recent paper (1), we have analyzed the anodization voltage-time curves of tantalum in terms of an avalanche model originally proposed by Ikonopisov (2). According to this analysis, the decrease of the slope of these curves during the anodization process at constant current (and hence at constant field) is brought about by the avalanche current originated in the electrolyte species incorporated into the oxide. Thus, incorporated impurities seem to play an important role in the control not only of the anodization rate but also of the avalanche electron current. This electron current turns out to be the direct cause of electrical breakdown during anodization.

Following our studies on the influence of the incorporated anions on the anodization and breakdown characteristics, new results are now presented here, concerning the anodization in oxalic acid at different current densities. They are also compared with our previous results in

*Electrochemical Society Active Member.

phosphoric acid (1). The oxalic acid is known to have low anion incorporation into the anodic Ta₂O₅ films since such cannot be detected by surface techniques such as Auger and ESCA spectroscopies (3). On the contrary, the incorporation of phosphate anions may amount up to 3% in anodization experiments in very diluted electrolytes (10⁻³M) (4). In addition, the oxalic acid along with other organic acids such as citric is widely used in the technology of tantalum thin film circuits (5).

Experimental

Tantalum samples of 99.96% nominal purity, supplied by Reframet-Hoboken, were anodized in a 0.01M solution of oxalic acid in water (1220 Ω-cm resistivity) at different constant current densities. The voltage-time curves, $V = V(t)$, as well as their time derivative, dV/dt , were recorded by means of a data acquisition system based on the HP 3497_A digital voltmeter (input impedance >10⁷ Ω) and the

Fig. 1. Experimental values of the derivative of the voltage-time curve per unit current density as a function of the anodization voltage. Solid lines represent the computed values according to the theoretical Eq. [1] and [2].

HP 85 microcomputer. The temperature of the sample was kept constant at $20 \pm 0.2^\circ\text{C}$ by using a thermostatic bath. Other experimental details have been described elsewhere (1).

Results and Discussion

Figure 1 shows the experimental results of the anodization rate per unit current density as a function of the anodization voltage at different current densities, within the range 0.89–10.34 mA cm⁻². As compared to the results obtained in phosphoric acid (1), we have observed that, all the anodizing conditions being the same, the oxalic acid gives, in general, lower values of the derivative and a lesser decrease of it with the anodization voltage.

Following the lines of our previous analysis of the anodization curves, we have obtained by the least squares method the parameters j_e and K , which give a best fit of the theoretical equation

$$\frac{dV}{dt} = K j_i = K(j_t - j_e) \quad [1]$$

to the experimental curves. In Eq. [1], K represents the unitary anodization rate, *i.e.*, the voltage rise per unit of ionic charge, and j_i the ionic current density, which is given by the difference between the total current density j_t supplied by the source and the avalanche electronic current j_e . This last magnitude is assumed to increase exponentially along the oxide thickness d in an avalanche mechanism according to the equation

$$j_e = j_0 \exp(\alpha d) = j_0 \exp(\alpha \beta V) \quad [2]$$

where j_0 is the primary electron current, α the impact ionization coefficient, and β the anodization constant which equals the inverse of the anodization field, E . For anodization experiments performed in phosphoric acid it has been demonstrated that j_0 is closely related to the relative concentration of the phosphorous species incorporated into the oxide (1). Thus the source of the primary electrons can be ascribed to these species acting similarly to donor levels in the bandgap.

For all the anodizing currents, the oxalic acid gives a constant value of the relative primary electron current, $j_0/j_i = 0.021 \pm 0.002$, this value being lower than that obtained in a diluted solution of phosphoric acid ($2.4 \times 10^{-3}M$) (1). In addition, no oxygen evolution was observed during the experiments except at voltages close to the breakdown voltage. This observation is in agreement with the measured efficiency at low voltages for the formation of Ta₂O₅, which is very close to 100% (6). A higher concentration of oxalic acid in the electrolyte gives similar values for j_0/j_i (7). This fact could be explained taking into account the low incorporation of the oxalic acid compared with the phosphoric acid, as it has been demon-

Fig. 2. Ionic current density vs. anodization field for oxalic (present work) and phosphoric acid electrolytes [previous work (1)]. The broken line has been drawn according to the work of Dell'Oca and Young (10).

strated by ESCA and AES measurements (3). The impact ionization coefficient results also in a nearly constant value, $\alpha = (1.96 \pm 0.02) \times 10^4 \text{ cm}^{-1}$. The constancy of α contrasts with its fair increase observed in phosphoric acid for increasing anodization currents (1) and can be a consequence of the different anodization fields found in each electrolyte. This effect is best appreciated in Fig. 2, where the ionic current density at low voltages, *i.e.*, $j_i \approx j_t - j_e$, has been plotted as a function of the electric field, for both the oxalic and phosphoric acid electrolytes. The value of E has been calculated from the constant K using the expression

$$K = \frac{ME}{10F\rho} \quad [3]$$

where M is the molecular weight of Ta₂O₅, F the Faraday constant, and ρ the oxide's density ($\rho = 8.03 \text{ g cm}^{-3}$).

In Fig. 2, the almost linearity of the logarithmic values of the ionic current density displayed by the oxalic acid is evident, in contrast to the curvature shown by the phosphoric acid (values taken from our previous work) (1). Also apparent in this figure are the higher electric fields needed to maintain a given ionic current for this last electrolyte. It is worth noting that the ionic conductivity values of the anodic Ta₂O₅ shown in the oxalic acid are very close to those obtained by Young and Zobel (8) in sulfuric acid, which is known to produce also a low proportion of incorporated anions. These authors measured the electric field directly from the quotient of the anodization voltage and the oxide thickness, this last magnitude being determined by ellipsometry.

The linear variation of the $\log j_i$ vs. E , within the studied range, is in agreement with the theoretical equation proposed for the ionic conduction mechanism at high fields (6)

$$j_i = j_i' \exp[-(W - qaE)/kT] \quad [4]$$

where j_i' is a constant. The exponent contains the field-dependent energy barrier in kT units found by the ions with charge q moving a distance $2a$ (the rest of the symbols have their conventional meanings). Assuming a charge of $5e$ for the ions and an energy barrier $W = 2.185 \text{ eV}$ from Young's work (9), the parameters of Eq. [4] would be $j_i' = 5.7 \times 10^{14} \text{ A cm}^{-2}$ and $a = 3.6 \text{ \AA}$.

A straightforward calculation shows that, for instance, with the above values of the parameters, a 3% change in the barrier height W results in a ten-fold variation of the current density. Thus, it seems reasonable to associate the lower ionic conductivity found for the H₃PO₄ electrolyte to a change either in the energy barrier or in the dis-

tance a as a consequence of the phosphorous incorporation. This assumption would also explain the nonlinear effects shown by the phosphoric acid in the $\log j_i$ vs. E curve. In this respect, from the work of Randall *et al.* (4) in anodization experiments with a 0.01M H_3PO_4 electrolyte, it can be inferred that the phosphorous content in the oxide may increase with current density so that it is 25% greater at 1 than at 0.1 mA cm^{-2} . More experiments in different electrolytes are now being conducted in order to obtain a deeper insight into the influence of the incorporated ions on the ionic conduction mechanism at high fields.

The Influence of Deposition Conditions on Hydrogen Bond Configuration and Trap Sites in Sputtered Si_3N_4

H. M. Anderson*

Department of Chemical and Nuclear Engineering, University of New Mexico, Albuquerque, New Mexico 87131

P. M. Martin

Pacific Northwest Laboratory,¹ Richland, Washington 99352

Considerable effort has been spent in defining the relationship between defect structure and charge characteristics in dielectric silicon nitride films used in microelectronic devices. The gap states of silicon nitride films are important, since they regulate memory properties of metal-nitride-oxide-semiconductor (MNOS) devices and electrical properties of thin film transistors. Gap states in silicon nitride arise from defects in the film and are attributed to Si and N dangling bond ($\equiv Si$ and $\equiv N$ units) formation during the deposition process (1-3). Hydrogen is known to passivate dangling bonds and remove the gap states of amorphous silicon (a-Si), and it is thought that hydrogen plays a similarly crucial role in determining the concentration of trap states in silicon nitride (3). The configuration in which hydrogen is chemically bonded in the nitride affects the concentration of Si and N dangling bonds in the film and, consequently, the reproducibility of device memory or conductive behavior.

In this technical note, we present some results showing the influence of deposition conditions on the partition of hydrogen bonding between Si and N in sputtered Si_3N_4 films. These results may prove useful in understanding the passivation Si and N dangling bonds and the location of trap sites in nitride films. Previous theoretical calculations based on the tight binding recursion method (4) have led to the conclusion that $\equiv Si$ centers are the long-term charge storage trap in CVD-deposited nitride as well as the center responsible for charge trapping instabilities in amorphous silicon-silicon nitride thin film transistors (3). The experimental results presented in this paper provide further evidence that hydrogen acts preferentially to passivate the $\equiv N$ dangling bonds of silicon nitride films.

Experimental

The RF diode sputtering system used to deposit Si_3N_4 has been described previously (5). An RF-induced dc bias of 1000-2000V was applied to the sputtering target in this experiment. A resistive heater was embedded in the substrate electrode to provide control over substrate temper-

ature. Both target and substrate RF networks were tuned by minimizing reflected power. The sputtering target was 99.999% pure Si, 15.24 cm diam. All sputtering gases were passed through a gas purifier, filtering H_2O , O_2 , and trace amounts of organics to <1 ppm. Deposition rates ranged from 120 to 260 Å/min, increasing with increased target power and decreasing with increased H_2 and N_2 . Power density to the target ranged from 1.10 to 3.30 W/cm². Substrate-target spacing was fixed at 3.18 cm.

Depositions were made with premixed electronic-grade $Ar+N_2+H_2$ on either 2.54 cm diam, 0.16 cm thick fused silica substrates for ultraviolet, visible, and near-infrared spectrophotometric and electrical measurements, or 2.54 cm diam, 0.4 cm thick germanium mirror for spectrophotometric measurements in the infrared. Gas pressure and particularly the partial pressures of H_2 and N_2 were varied for each of 14 nitride depositions, as shown in Table I. Deposits were characterized by index of refraction, film thickness, and spectral dependence of the absorption coefficient. A dual monochromatic UV-visible spectrophotometer was used to measure transmission spectra of films deposited on fused silica substrates from 200 to 2500 nm. A dual-beam infrared (IR) spectrophotometer was used to obtain by transmission spectrophotometry

Fig. 1. Vibrational spectra of sputtered $\text{Si}_3\text{N}_4\text{:H}$

complete IR vibrational absorption spectra of films deposited on Ge substrates in the region 2500-25,000 nm.

Results and Discussion

The chemical bonding configuration of hydrogen in silicon nitride films can be determined from IR absorption in the regions corresponding to vibrational stretching frequencies of Si-H (2150 cm^{-1}) and N-H (3350 cm^{-1}) (2). Previous measurements (2, 6, 7) have shown that for both plasma and CVD nitrides, IR absorption can be used to quantitatively estimate the partition of H between Si and N through a calibration of the IR absorption to absorption cross sections for Si-H and N-H from nuclear reaction analysis.

In this study, relative values for hydrogen bond concentration and the partition of hydrogen between Si and N were obtained for reactively sputtered nitride films. Hydrogen bond configuration was determined from IR vibrational absorption spectra using a method similar to that of Lanford (6) and Percy *et al.* (7). The absorption coefficients β of the Si-H and N-H stretching modes near 2150 and 3350 cm^{-1} , respectively, were calculated as a function of photon energy using the relation $T(\omega) = T_0(\omega) \exp -\beta t$, where t is the film thickness, $T_0(\omega)$ is the transmission of a nonabsorbing film, and $T(\omega)$ is the measured transmission for a frequency ω . Integrating over the distinct Si-H and N-H stretching frequency regions according to the relation $A_s = \int_{\omega_s} \beta(\omega) d\omega$ provides a relative measure of the H content in the film (8) due to either Si-H bonding [$A_{\text{Si-H}}$ (eV/cm)] or N-H bonding [$A_{\text{N-H}}$ (eV/cm)]. Figure 1 illustrates typical vibrational spectra as a function of wave number over the stretching modes 2150 and 3350 cm^{-1} for two $\text{Si}_3\text{N}_4\text{:H}$ films.

Fig. 2. Relative N-H bonding in $\text{Si}_3\text{N}_4\text{:H}$ Fig. 3. Relative Si-H bonding in $\text{Si}_3\text{N}_4\text{:H}$

Figures 2 and 3 illustrate the results for Si-H and N-H bonding vs. the H_2 and N_2 partial pressure deposition conditions depicted in Table I. Figure 2 illustrates increased N-H bonding in the nitride films with increased N_2 partial pressures in the deposition conditions. Simultaneous increases in the H_2 partial pressure appears to contribute to increased N-H bond formation until a leveling off occurs at high H_2 partial pressures. Figure 3, on the other hand, illustrates that, at high N_2 partial pressures, the formation of Si-H bonds in the nitride film is largely suppressed, regardless of the partial pressure of H_2 . Infrared absorption indicative of Si-H bond formation in the nitride film is observed when the deposition partial pressure of N_2 is small.

The results of varying the N_2 and H_2 deposition conditions indicate a preference for N-H bond formation in nitride films. For high N_2 partial pressures, a clear trend exists in the data toward greater N-H bond formation over Si-H bonding with increases in the H_2 partial pressure. It is only when the availability of nitrogen for incorporation into the film is low that Si-H bonding dominates over N-H bonding with increases in the H_2 partial pressure. Work by Fujita (1) using ESR also suggests that preferential N-H bonding occurs over Si-H bonding in CVD nitride. Their results suggest that the ESR signal originates mainly from silicon dangling bonds in CVD films. The pattern of N-H bonding observed in this study also strongly suggests that hydrogen will preferentially act to passivate N dangling bonds in nitride films.

Characterization of Boron-Implanted Silicon at Various Depths from the Surface by Raman Scattering

P. T. T. Wong

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, Canada K1A 0R6

M. Simard-Normandin

Northern Telecom Electronics Limited, Ottawa, Ontario, Canada K1Y 4H7

The preparation of a VLSI CMOS process implies the fabrication of p+n junctions with junction depths of the order of 0.25 μm . These junctions are usually fabricated by the implantation of boron or boron difluoride and annealed at high temperatures to activate the species and restore the implantation damage. Since boron diffuses very fast in silicon because of its light mass, the annealing times are shortened and new methods of annealing are implemented (laser, flashlamp, etc.). This can result in incompletely activated dopant if the annealing parameters have not been adequately chosen.

Raman scattering is an attractive method of characterizing boron-implanted silicon, allowing simultaneous measurement of the free-carrier concentration and the measurement of the number of impurities in substitutional position. It can also detect the presence of amorphous silicon, thus giving another measure of the effectiveness of the annealing cycle.

In this paper, we report Raman scattering measurements of low energy boron-implanted silicon at several depths from the surface and compare the results with the concentration profile obtained by secondary ion mass spectrometry (SIMS) techniques.

Experimental

The sample is a phosphorous-doped (3-7 $\Omega\text{ cm}$) n-type (100) CZ-grown 100 mm silicon wafer. Ions of $^{11}\text{B}^+$ with a fluence of $3 \times 10^{15}/\text{cm}^2$ were implanted at room temperature at an energy of 10 keV. The wafer subsequently received 100 nm of deposited SiO_2 at 450°C. Then furnace annealing was done in N_2 ambient at 925°C for 20 min. Finally, the wafer was coated with a 400 nm layer of deposited SiO_2 to serve as a mask for beveling.

For the Raman scattering experiment, three pieces were broken off the wafer. Half of each piece was covered with wax, and the oxide was stripped off the unmasked portion using HF. The implanted silicon was then etched in a mixture of acetic, nitric, and hydrofluoric acids using the oxide-covered side as a mask. Finally, the remaining oxide was removed to expose the surface. The height of the step was measured using an interference microscope. Samples etched 0.11, 0.18, and 0.35 μm below the surface were thus obtained. An unimplanted, unprocessed wafer of the same type was used for calibration. For the SIMS analysis, all oxide was removed from the wafer in HF. The SIMS analysis was done at the University of Western Ontario using a Cameca IMS 3-f ion microscope. A wafer implanted at the same dose and energy into bare silicon and otherwise unprocessed was used for SIMS calibration.

Raman spectra were measured with a Spex Model 14018 double monochromator equipped with 1800 line/nm holographic gratings and a cooled RCA C31034 photomultiplier. The Raman spectra, which were measured with a resolution of $\sim 2\text{ cm}^{-1}$, were excited with the 514.5 nm line with a CRL Model 12 argon-ion laser. This line had a power of 200 mW at the sample. A 90° scattering geometry was employed. The sample surface was slightly tilted with respect to the direction of the scattering so that the reflected laser beam was away from the entrance slit of the monochromator. The laser beam was linearly polarized and incident on the sample at the Brewster angle.

The absorption parameters of heavily doped silicon are given in Ref. (1). At $\lambda_0 = 514\text{ nm}$ and an angle of 75°, the penetration in the sample is of the order of 0.13 μm , which is comparable to the spacing of our data points. Using a parallel polarized beam further reduces the energy coupled into the depth of the sample, since most of this radiation is reflected. The perpendicularly polarized beam, which would normally penetrate and not be reflected, is not present in our case. Since the energy lost in the sample is exponential, we believe that only the first few molecular layers are detectable in the present experimental setup. To be precise, a small correction needs to be applied to each data point to take into account the penetration in the sample. Because the doping density is still very high ($> 10^{18}/\text{cm}^3$) at our deepest point and the absorption properties are not a very strong function of doping above that value, the correction is expected to be small and always in the same direction. In a relative analysis like the one performed here, it is safe to neglect this correction.

The data acquisition was performed by a Spex Model DM1 Datamate Processor and the resulting spectral data were transferred to a Nova IV Data General computer. Frequency and spectra sensitivity calibrations were applied to each spectrum. Frequencies, bandwidths, and integrated intensities were calculated.

Results and Discussion

Substitutional boron, with respect to its silicon neighbors, produces a local mode at a frequency higher than that of the optical phonon mode (520 cm^{-1}), i.e., at 620 cm^{-1} for boron-11. Shown in Fig. 1 are the Raman spectra of the optical phonon and the boron local mode at several depths of the sample. The top of the optical phonon

Fig. 1. Raman spectra of boron-11 implanted silicon at the depth of (a) 0.0, (b) 0.11, (c) 0.18, and (d) 0.35 μm from the surface.

Fig. 2. Depth dependence of normalized intensity ratio of the local mode between various depths (I_d) and the surface (I_0).

height so that the intensities of the local mode measured at different depths of the silicon sample can be compared visually. It is apparent from Fig. 1 that the local mode intensity decreases with increasing depth in the sample. Moreover, the asymmetry and the intensity of the wing on the high frequency side of the optical phonon band also decreases with increasing depth. The intensity of this wing, and thus the asymmetry of the phonon band, is due to the interaction between the optical phonon and the intervalence and interconduction-band electronic transitions which are enhanced with increasing substitutional boron concentration. Consequently, the changes in the intensity of the optical phonon wing at different depths of the sample agree with the changes in the intensity of the local mode and indicate that the concentration of substitutional boron decreases with depth in the sample.

There is a very weak two-phonon Raman band in the frequency region of the boron-11 local mode which is observed in a pure silicon sample (2). The intensity of this two-phonon mode normalized against that of the optical phonon was subtracted from the normalized intensities of the local mode measured at various depths of the sample. With these normalized intensities, the percentage decrease of the local mode intensity, and thus that of the

substitutional boron concentration as a function of the depth in the sample, can be calculated and is plotted against the depth in the sample in Fig. 2. In the normalization process, the intensity of the optical phonon of pure silicon being one-third lower than that of boron-implanted silicon (3) has been taken into account. To eliminate the interference of two-phonon scattering, one may replace boron-11 by boron-10 for implantation. The local mode of boron-10 shifts to $\sim 640 \text{ cm}^{-1}$, which is about 20 cm^{-1} higher than the frequency of the two-phonon mode.

The results shown in Fig. 2 are comparable with those obtained by SIMS shown in Fig. 3. The depth dependence of the boron concentration measured by Raman scattering is consistent with that by the SIMS technique, except at the surface. For instance, if the boron concentration at the depth of $0.11 \mu\text{m}$ from the surface is taken as 1, the boron concentrations at the depths of 0.18 and $0.35 \mu\text{m}$ decrease to 0.66 and 0.26 , respectively, measured by Raman scattering, and to 0.71 and 0.21 , respectively, by SIMS.

We cannot quote the boron concentration at the surface with any certainty using SIMS. In Fig. 3, the boron concentration is shown only from the point where the silicon profile (not plotted) is constant. Close to the surface, the oxygen content in the silicon varies and the count is lower. Using the same normalization as above, the Raman intensity is 1.20 at the surface. With this factor applied to the SIMS profile, the surface concentration would be $6.5 \times 10^{19} \text{ cm}^{-3}$, which is the value of the extrapolated diffused profile. The sharp peak is due to improper annealing where dislocations getter the boron. This peak disappears at higher annealing temperatures.

As shown in Fig. 1, the top portion of the local mode band in the spectrum measured on the surface of the sample is relatively narrower than in the spectrum measured at a depth of $0.11 \mu\text{m}$, and a very broad band is underneath the narrower band. This is consistent with the fact that, for this sample, the silicon is not perfectly crystalline at, or very near, the surface.

It has been shown that free carriers cause an increase in the phonon line width and a decrease in the phonon frequency as a result of "softening" of the crystal lattice through free-carrier redistribution (4). Figures 4 and 5 show the depth dependences of the phonon line width and the phonon frequency, respectively. Except for the surface, the phonon line width decreases, while the phonon frequency increases with increasing depth of the silicon sample. These results indicate that the free-carrier concentration in the sample decreases with increasing depth. With a calibration curve between the frequency shift and the free-carrier concentration, such as that in Fig. 1 of Ref. (5), the free-carrier concentrations at various depths of the sample can be calculated by the phonon frequency shifts at various depths with respect to the frequency of the pure silicon sample. Comparison between

Fig. 3. Boron concentration profile obtained by SIMS technique

Fig. 4. Depth dependence of the phonon line width at half-height

Fig. 5. Depth dependence of the phonon frequency

the depth dependence of the phonon frequency of the boron-implanted sample and the phonon frequency of a pure silicon sample is shown in Fig. 5. It indicates that the concentration of the free carrier in the boron-implanted sample reduces to 0 at the depth of about 0.39 μm from the surface.

Conclusion

The present work has demonstrated that Raman scattering is a useful technique for determining both the substitutional boron and free-carrier concentrations at different depths from the surface in boron-implanted silicon. Since Raman scattering techniques are nondestructive and do not require any electrical contact, they may be useful for industrial quality control of boron activation.

Acknowledgments

We wish to thank B. Loro for etching the samples and the Surface Science Western group for the SIMS analysis.

A Novel Processing Technique for the Fabrication of Thick Silicon Grids by Anisotropic Etching

B. Petit and J. Pelletier

Unité de Recherche Associée au CNRS no. 844, B.P. 98, CNS-CNET, 38243 Meylan Cedex, France

R. Molins

Institut National Polytechnique de Grenoble, B.P. 75, CMTC, 38402 St. Martin d'Herès, France

Novel procedures involving the anisotropic etching of silicon by aqueous solutions of pyrocatechol ethylene diamine or hydroxides of alkali metals have been reported over the past few years. Their purpose has been to achieve high precision patterns in silicon. Applications cover such diverse fields as the fabrication of mechanical devices (1) ranging from ink nozzles (2) to ion source extraction grids (3) and fine membranes (1) such as thinned transmission electron microscopy (TEM) specimens (4) and lithography masks (5). Among the above-mentioned etching techniques, some have the disadvantage of being lengthy and tedious, e.g., ethylene diamine etching (6, 7). Others, such as those involving hydroxides of alkali metals in water, are easier to use but etch SiO_2 (2, 8-10) at a rate which rules it out as a mask in many experiments (3). Varker and Chang have found that (100) silicon wafers masked on both sides with a plasma-deposited Si_3N_4 film can be successfully etched in a KOH solution (4). The equipment required for such plasma deposition and subsequent etching, however, and the long Si etching time involved (5 or 6 h for a wafer 300 μm thick) limit the application of this technique.

Our aim was to develop a simple and relatively rapid etch process that could be used to obtain both grids of the type found in ion sources and diaphragms of extremely fine aperture. In order to realize gains in Si etch time, the etchant would be heated to the highest temperature the mask could withstand. We therefore had to find a masking material that would be chemically inert in the

heated etchant. Moreover, the masking material had to be able to withstand these temperatures without coming

Fig. 2. SEM photomicrograph of a double-side etched grid 525 μm thick. Each base square is 390 μm on a side; and the orifices are 19 \times 19 μm^2 ; the center-to-center spacing is 740 μm .

Fig. 3. Single-side etching of a 500 μm deep hole starting from a base square of 730 \times 730 μm^2 . The underetching is emphasized by the white line surrounding the base square.

away from the substrate. NiCr was found to be suitable as the masking material in a solution of 10N NaOH at 363 K (9). As seen in our experiments, raising the temperature above 363 K led to damage in the NiCr layers, *i.e.*, resulted in an overly high NiCr etch rate with respect to an only slight increase in the silicon etch rate. For example, the NiCr etch rate of about 100 nm/h at even 368 K is incompatible with the etching of relatively thick Si substrates.

Our procedure consists mainly of steps used in conventional Si processing techniques. Single-crystal, (100)-oriented, 100 mm silicon wafers 525 μm thick and polished on both sides are used. The sequence of steps is shown in Fig. 1. An NiCr film about 350 nm thick is deposited on both sides of the samples by magnetron sputtering. The required window pattern is transferred through a photoresist layer onto the NiCr film either on one (case 1) or both surfaces (case 2), care being taken not to misorient the pattern with reference to the wafer's <110> flat edge. In the case of double-side etching, the square openings on both sides of the wafer must be carefully aligned. The NiCr film is then etched for a few minutes in an aqueous oxidizing solution containing ammonium cerium nitrate and acetic acid (with no observable effect on the silicon substrate). After removal of the photoresist layers, the wafers are immersed in a well-agitated 10N NaOH bath at 363 K for a total etching time of either 4.5h for case 1 or half that time for case 2. Towards the end of the etching step, the thickness of the re-

maining silicon is monitored by lowering the bath temperature a few degrees. Thus end-point detection is facilitated, especially in the more crucial case of single-side etching. At this point, the samples are ready for scanning electron microscopy (SEM) observations.

Using the technique described above, one can produce a great number of grids having orifices of only a few square micrometers, accurately defined by the pattern geometry (Fig. 2). An average etch rate of 120 $\mu\text{m}/\text{h}$ is obtained on the {100} planes at 363 K and is consistent with the results of Barycka *et al.* (9). The etch rate of the {111} planes is 3 $\mu\text{m}/\text{h}$, determined from underetching measurements of the base hole in the Si surface. Since the NiCr film remains intact, the size of the base holes after etching may only depend upon the lateral etch rate of the {111} planes. The SEM photomicrographs in Fig. 3 and 4 show the considerable depths etched, the good behavior of the masking layers even after a few hours of etching, as well as the well-defined, defect-free {111} sidewalls and (100) planes after NiCr removal. For case 2, the crystallographic planes revealed (see arrows in Fig. 4a and 4b) show a slight misorientation of the pattern from one side of the wafer to the other. The profile of the intersection of the two pyramidal shapes after anisotropic etching can also be seen.

In this very simple processing technique, the NiCr protective coating acts as a mask on both sides of the substrate; the 10N NaOH solution can thus be brought up to a temperature of 363 K, thereby allowing considerable gains in etch rates as compared to other procedures [see Table II of Ref. (1)]. Using this technique, fine mesh silicon grids suitable for mass spectrometry analysis, for instance, have been fabricated reproducibly by anisotropic etching of square-base holes through Si wafers of (100) orientation. The relatively short etching times involved, the ease of use, and good quality of the results obtained make this method an attractive tool for high precision diaphragm or grid fabrication.

Preparation and Conductivity Measurements of $\text{SiS}_2\text{-Li}_2\text{S-LiBr}$ Lithium Ion Conductive Glasses

Saeed Sahami,¹ Steven W. Shea, and John H. Kennedy*

Department of Chemistry, University of California, Santa Barbara, California 93106

We wish to report on the preparation and properties of new high lithium ion conductive glasses composed of $\text{SiS}_2\text{-Li}_2\text{S-LiBr}$. A number of conductive sulfide-based lithium glasses, which can be used as electrolytes in lithium solid state devices and batteries have been studied (1-7). The most widely studied are $\text{P}_2\text{S}_5\text{-Li}_2\text{S}$ glasses and their lithium iodide doped analogs, which show conductivity as high as $10^{-3} \text{ S-cm}^{-1}$ at 25°C . It was recently reported that since $\text{P}_2\text{S}_5\text{-Li}_2\text{S}$ (and $\text{B}_2\text{S}_3\text{-Li}_2\text{S}$) glasses require synthesis in sealed pressure quartz tubes, the $\text{SiS}_2\text{-Li}_2\text{S}$ glasses, which may be prepared under atmospheric pressure offer a viable commercial production alternative (8). The base glass, $\text{SiS}_2\text{:Li}_2\text{S}$ has a conductivity of at least $0.75 \times 10^{-4} \text{ S-cm}^{-1}$ at 25°C (8). Although the addition of LiI to $\text{SiS}_2\text{-Li}_2\text{S}$ base system increases the conductivity of these glasses up to $6.4 \times 10^{-4} \text{ S-cm}^{-1}$ (8), some oxidation of iodide to iodine may occur during synthesis (9). No investigation was reported on the effects of other lithium halides on the conductivities of these glasses.

We have investigated the effects of LiBr doping on the conductivity and the extent of glass formation of $\text{SiS}_2\text{-Li}_2\text{S}$ by varying the molar concentration of LiBr while holding the mole ratio of SiS_2 to Li_2S constant at 1:1.

The $\text{SiS}_2\text{-Li}_2\text{S}$ glasses were prepared by first mixing SiS_2 and Li_2S in a 1:1 mole ratio in a dry box with an oxygen and water level less than 2 ppm. The mixture was then placed in a vitreous carbon crucible, which in turn was positioned in a Vycor tube. The stoppered Vycor tube was taken outside the dry box and placed in a vertical furnace and heated for approximately one hour at 950°C under an argon gas blanket. The molten mixture was quickly quenched into a water bath at room temperature to form the vitreous

solid. To dope this base glass with LiBr, appropriate weights of LiBr and the vitreous glass were ground, mixed together, and the heating procedure described above was again followed. The quenched glasses were ground to a fine powder and a portion of the glass sample was uniaxially pressed into a 0.3 inch diameter rod with TiS_2 electrodes on both faces. This cell was subsequently isostatically pressed at ~ 45000 psi to achieve high density.

The ionic conductivity of each sample was measured by the complex impedance technique using a Solartron 1174 Frequency Response Analyzer interfaced to a Hewlett-Packard 9845B desktop computer and a General Radio 1435 Programmable decade resistance box. The signal applied across the sample was 25 to 100mV and the frequency varied from 0.1 to 10^5 Hz over the temperature range of 20° to 140°C .

Fig. 1. Complex impedance plot for 0.3 LiBr-0.35 SiS_2 -0.35 Li_2S using TiS_2 electrodes at 96°C and applied signal of 25 mV. Frequency varied from 1 to 10^5 Hz.

As is shown in Fig. 1, the complex impedance plots of glasses consisted of a straight line intersecting the real axis at approximately a 45° angle. The bulk resistance of the glass sample was obtained from the extrapolation of the straight line portion of the complex impedance plot to the real axis. In the temperature range studied here, the ionic conductivity of all the glasses was found to obey the Arrhenius law: $\sigma = \sigma^0 \exp(-E_a/KT)$. Values of ionic conductivity (σ) measured at 25°C and the activation energies (E_a) determined from the slopes of Arrhenius plots for $\text{SiS}_2\text{-Li}_2\text{S-LiBr}$ glasses are reported in Table I. Figure 2 shows a plot of $\log \sigma$ vs. mole % of LiBr added to the base glass. Here we see that the ionic conductivity increased linearly with LiBr up to 30 mole %, then it decreased sharply with the addition of more LiBr. Table I also indicates that the activation energy in the 0 to 30 mole % LiBr range remained relatively constant, but increased rapidly with higher concentrations of LiBr.

Table I. Conductivities and Activation Energies for Silicon Sulfide Glasses.

Glass Composition	σ (S-cm ⁻¹) at 25°C	E_a (Kcal/mole)
0.5 $\text{SiS}_2\text{-0.5 Li}_2\text{S}$	1.5×10^{-4}	7.8
0.1 $\text{LiBr-0.45 SiS}_2\text{-0.45 Li}_2\text{S}$	1.9×10^{-4}	7.0
0.2 $\text{LiBr-0.4 SiS}_2\text{-0.4 Li}_2\text{S}$	2.1×10^{-4}	7.5
0.25 $\text{LiBr-0.38 SiS}_2\text{-0.38 Li}_2\text{S}$	2.4×10^{-4}	7.1
0.3 $\text{LiBr-0.35 SiS}_2\text{-0.35 Li}_2\text{S}$	3.2×10^{-4}	7.5
0.35 $\text{LiBr-0.33 SiS}_2\text{-0.33 Li}_2\text{S}$	2.3×10^{-4}	8.7
0.4 $\text{LiBr-0.3 SiS}_2\text{-0.3 Li}_2\text{S}$	1.1×10^{-4}	9.6

Fig. 2. Logarithm of conductivity at 25°C. as a function of LiBr mole percent in $\text{LiBr-SiS}_2\text{-Li}_2\text{S}$.

The maximum conductivity in this work was observed for the 0.3 $\text{LiBr-0.35 SiS}_2\text{-0.35 Li}_2\text{S}$ glass. X-ray diffraction analyses of LiBr doped $\text{SiS}_2\text{-Li}_2\text{S}$ glasses showed that all samples with LiBr mole% of ≤ 30 formed uniform glasses while, samples with higher LiBr content indicated traces of LiBr crystals present in the glass matrix. These observations are in good agreement with the conductivity measurements, indicating that maximum LiBr solubility is achieved with the 30% LiBr base glass at least with the quench rates used in this initial study. Upon addition of more LiBr, the extent of glass formation decreased, resulting in a drop of ionic conductivity. Further studies of these glasses, including ^7Li NMR measurements of LiBr and LiCl doped glasses are in progress in our laboratories.

The Pourbaix Diagram for Cr With Fe and the Stress Corrosion Cracking of Stainless Steel

Daniel Cubicciotti*

Electric Power Research Institute, Palo Alto, California 94303

Lars Ljungberg

ASEA-ATOM, Västerås, Sweden

Hydrogen addition to the feedwater of boiling water nuclear reactors (BWR) is being used to avoid the problem of intergranular stress corrosion cracking (IGSCC) in weld sensitized regions of Type 304 stainless steel piping carrying coolant water. Hydrogen addition reduces the dissolved oxygen content of the coolant water and lowers the corrosion potential of stainless steel. The tests, mentioned below, have shown that IGSCC does not occur in sensitized stainless steel below a certain critical value of the corrosion potential. The reason for IGSCC mitigation below this critical potential has not yet been elucidated. In this note we report a correlation between the critical potential for IGSCC and the stable phase containing Cr. Above the critical potential where IGSCC can occur, the stable Cr-containing phase is Cr_2O_3 . Below the critical potential where IGSCC does not occur, the stable Cr-containing phase is FeCr_2O_4 . Our interpretation of this correlation is that a surface oxide phase of CrFe_2O_4 is protective against IGSCC while Cr_2O_3 is not. Further research is needed to define the mechanism of protection.

Thermodynamics of Cr-H₂O Systems. The equilibria for Cr between solid phases and solutions in the Cr-Fe-H₂O system at 300°C are shown in Fig. 1. Thermodynamic values for Cr were taken from Ref. 1. The only solid oxide containing both Fe and Cr, at least for which thermodynamic data are available, is FeCr_2O_4 . Its Gibbs energy of formation at 300°C was calculated from the data in Ref. 2 to be -336.5 Kcal per mole (referred to the elements at 25°C). The regions of stability of the solid Cr containing oxides depend on the activity of Fe, which in turn depends on which solid Fe compound is stable. The diagram indicates that

at the highest potentials (field A) the stable oxides are Cr_2O_3 and Fe_2O_3 and in the next lower adjacent field (B) FeCr_2O_4 and Fe_2O_3 . The change of stability of the Cr bearing oxide from Cr_2O_3 to FeCr_2O_4 is the region of interest to us.

Conditions in BWR.--During normal BWR operation the water recirculated through the reactor core contains (3) about 200 ppb (parts per billion) of dissolved oxygen and is approximately neutral (pH = 5.6). The corrosion potential of a Type 304 electrode in BWR water at about 300°C lies in the range of 0.0 to 0.1 volts, SHE, after some aging (4). This potential is still in the HCrO_4^- field, indicating that as the stainless steel recirculation piping corrodes, the Cr tends to dissolve out of the corrosion film. Examinations (5) of corrosion films on BWR piping confirm this analysis.

Mitigation of IGSCC by Low Corrosion Potential. Several series of tests (6,7) show that IGSCC of sensitized stainless steel does not occur in pure water if the potential of the steel is below a critical value in the range -0.2 to -0.3 volts SHE. In constant extension rate tests (CERT) in Ringhals-1 BWR (8) during hydrogen addition no IGSCC was observed when the corrosion potential was below -0.2 volts, when the water was pure. Tests in the Dresden-2 BWR have also shown such a critical potential.

During the tests in Ringhals-1 and in the Dresden-2 BWR with hydrogen added to the feedwater (equivalent to lowering the corrosion potential of stainless steel), it was observed that the concentration of Cr dissolved in the reactor water was decreased tenfold or more (8,9). That observation is

in accord with the increase in stability of the Cr-containing oxide when the potential is lowered (Fig. 1).

Correlation of Critical Potential with Pourbaix Diagram. The Pourbaix diagram shows that for neutral water (pH=5.6), there is a change of phase at about -0.2 volts--i.e., at about the critical potential. Below that potential the stable Cr-containing oxide is FeCr_2O_4 and above it Cr_2O_3 . Thus, at about the critical potential for IGSCC, observed in CERT, there is a change in the stable Cr containing phase.

This correlation indicates that formation of a surface oxide of FeCr_2O_4 may be the process that provides protection against IGSCC for stainless steel. The correlation is significant in that it provides a basis for predicting the influence on IGSCC of changes in environmental conditions. Critical potentials were found to be related to the solute for 0.01 molal solution of various salts in Ref. 10.

Diffusion of Sb in (111) Silicon during N₂ Heat-Treatment

T. Kook* and R. J. Jaccodine*

Sherman Fairchild Center for Solid State Studies, Lehigh University, Bethlehem, Pennsylvania 18015

Recently thermal nitridation of silicon has been investigated and its effect on dopant diffusion has been reported(1,2). Mizuo et al. (1) found retarded B and P diffusion and enhanced Sb diffusion during N₂ and NH₃ heat treatments of the bare (100) and (111) silicon at 1100°C. They also investigated the effect of the SiO₂ capping and found that N₂ heat treatment had little effect while NH₃ heat treatment resulted in enhanced B and P diffusion and retarded Sb diffusion. Fahey et al. (2) also reported similar results. In this note we report the anomalous junction motion of Sb diffused specimens during N₂ heat treatment and the effect of the SiO₂ capping after prolonged heat treatments.

Czochralski-grown, lightly-doped, p-type (111) silicon wafers were implanted with Sb to a dose of 1.0 X 10¹⁴/cm² at 80 keV. In addition, two groups of specimens were prepared by implanting B into n-type wafers to a dose of 2.1 X 10¹⁴/cm² and P into p-type wafers to a dose of 1.0 X 10¹⁴/cm² at 100 keV and 80 keV, respectively. These were run concurrently with the Sb implanted ones. After annealing at 900°C for 30 min, all wafers were oxidized at 900°C in steam to grow 2000-Å-thick pad oxide. 1200-Å-thick silicon nitride was deposited by the low pressure chemical vapor deposition process over the oxide. Then drive-in heat treatments were performed to obtain 1-micron-deep initial junctions. P implanted specimens required 1 hr and for Sb specimens 13 h were required. B implanted specimens did not undergo the drive-in step because their junction depth was already about 1 micron after annealing and oxidation steps. Subsequent lithography and plasma etching were done to fabricate a specimen structure consisting of the SiO₂ capped silicon, the Si₃N₄ capped silicon, the SiO₂ + Si₃N₄ capped silicon, and the bare silicon. N₂ heat treatments were done in a conventional single wall quartz tube at 1100°C up to 24 h. Heat treated specimens were angle-lapped and stained to measure the

junction depths by interferometry. The junction depths after heat treatment were measured as X_{JS} in the bare silicon, X_{J0} in the SiO₂ capped silicon, X_{JN} in the Si₃N₄ capped silicon, and X_{JON} in the SiO₂ + Si₃N₄ capped silicon.

In Fig. 1, X_{JS}/X_{JON} for B, P, and Sb diffused specimens after N₂ heat treatments are plotted along with X_{J0}/X_{JON} for Sb diffused specimens. The junction motion of the Sb diffused specimens in the bare silicon is retarded after prolonged heat treatments, which is quite contradictory to the result of Mizuo et al.(1). On the other hand, the retarded junction motion of B and P diffused specimens is in good agreement with previous work(1,2). The junction motion in the SiO₂ capped silicon is enhanced after prolonged heat treatments while the Si₃N₄ capping has little effect. To rationalize the discrepancy between our study and the previous Sb studies (1,2) we made an extensive use of a precision angle-lapping and a spreading resistance probe. Fig. 2 shows the concentration profiles of Sb in the bare silicon and in the SiO₂ + Si₃N₄ capped silicon after 2 h N₂ heat treatment. It can be clearly seen that even though both regions have the same junction depths, the actual concentration profiles are quite different due to the severe out-diffusion loss

Fig. 1. X_{JS}/X_{JON} for B, P, and Sb diffused specimens and X_{J0}/X_{JON} for Sb diffused specimens after N₂ heat treatment at 1100°C.

*Electrochemical Society Active Member.

key word: thermal nitridation, Sb diffusion

of Sb atoms from the bare silicon surface during N₂ heat treatment. By integrating the concentration profiles the out-diffusion loss of Sb atoms after 2 h N₂ heat treatment was calculated to be about 25 %. Those of B and P were less than 8 %.

The concentration profiles in Fig. 2 strongly suggest that Sb diffusion is indeed enhanced during thermal nitridation of silicon in N₂. We developed a model to test the above observation by modifying the conventional drive-in model of a Gaussian distribution considering the time-averaged out-diffusion loss of dopant atoms. The time-averaged diffusivity ratio, $\langle D_S \rangle / \langle D_{ON} \rangle$ can be expressed as

$$\langle D_S \rangle / \langle D_{ON} \rangle = [(C_{SON} / C_{SS}) (\langle Q_S \rangle / \langle Q_{ON} \rangle)]^2$$

where C_{SS} and C_{SON} are the surface concentrations in the bare silicon and in the SiO₂ + Si₃N₄ capped silicon after heat treatment and $\langle Q_S \rangle$ and $\langle Q_{ON} \rangle$ are the time-averaged total dopant concentrations in each region. The changes of X_{JS}/X_{JON}, $\langle Q_S \rangle / \langle Q_{ON} \rangle$, and $\langle D_S \rangle / \langle D_{ON} \rangle$ with N₂ heat treatment time are plotted in Fig. 3. Above all, Sb diffusion was indeed enhanced by thermal nitridation of silicon. Initially $\langle Q_S \rangle / \langle Q_{ON} \rangle$ decreases rapidly but it decreases slowly as thermal nitridation proceeds. $\langle D_S \rangle / \langle D_{ON} \rangle$ increases initially up to 2 h and then decreases as thermal nitridation slows down. As a combined result of the time-dependent $\langle Q_S \rangle / \langle Q_{ON} \rangle$ and $\langle D_S \rangle / \langle D_{ON} \rangle$, X_{JS}/X_{JON} decreases after prolonged heat treatments. We also calculated $\langle D_S \rangle / \langle D_{ON} \rangle$ for B and P and found that both B and P diffusion were retarded during thermal nitridation of silicon in N₂. This favors a mechanism of silicon interstitial depletion in the surface region(2,3). The

Fig. 2. Sb concentration profiles after 2 h N₂ heat treatment at 1100 °C.

undersaturation of interstitials in turn causes vacancy supersaturation and the diffusion of Sb atoms, which are considered to move almost exclusively by vacancies(4), is enhanced. The apparently retarded Sb junction motion is due to the severe out-diffusion loss of Sb atoms during N₂ heat treatment.

The SiO₂ capping resulted in enhanced Sb diffusion(see Fig. 1). This suggests a slower nitridation of substrate silicon under the oxide capping. The apparent difference from the NH₃ ambient case is the lower activity of N₂ with SiO₂. We conclude that N₂ should diffuse through SiO₂ without reaction and nitrify the substrate silicon. NH₃ is considered to react with SiO₂ and generate oxygen atoms which oxidize the substrate silicon.

In summary, the out-diffusion of Sb atoms during N₂ heat treatment and its effect upon shallow junction were investigated. It was clearly seen that the conventional angle-lapping and staining alone is not appropriate for this kind of study.

Graphite Aluminum- and Silicon Carbide-Coated Current Collectors for Sodium-Sulfur Cells

M. Mikkor

Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The electrical performance and corrosion of current collectors made from graphite foil bonded to aluminum and from stainless steel protected by silicon carbide coating are compared to current collectors protected by chromium coatings. The testing is done in corrosion cells operated under dynamic conditions in Na_2S melts at 350°C . The cells are operated under both cathodic and anodic potentials of 100-300 mV measured with respect to carbon reference electrodes. The current collectors made from graphite foil, $127\ \mu\text{m}$ thick, bonded to aluminum have lowest total impedances (ohmic plus polarization) of 2.0 and $5.4\ \Omega\text{-cm}^2$ under cathodic and anodic potential of 300 mV. The corresponding values for silicon carbide coatings, 1.8-2.0 μm thick, are 2.9 and $19.0\ \Omega\text{-cm}^2$, and, for chromium coatings $\sim 50\ \mu\text{m}$ thick, 3.2 and $10.7\ \Omega\text{-cm}^2$. No, or very little, corrosion is observed on the graphite/aluminum samples or on the silicon carbide-coated samples over a period of 2-3 months.

An open issue in developing a sodium-sulfur battery with a long life is the corrosion of the metal sulfur-electrode current collector. For load leveling application by the electric utility industry, the goal for a battery life is 10 yr.

In current development programs, chromium-plated stainless steel has been used as a sulfur container and a current collector (1). Alternative container materials with improved sodium polysulfide corrosion resistance are being explored as part of the sodium-sulfur battery development program (2-4). In the present study, the electrical performance and corrosion resistance of two new current collector materials are compared to chromium-coated steel. These materials are graphite foil bonded to aluminum- and chromium-plated stainless steel covered with sputtered silicon carbide layer.

The protective coating on the current collectors has to meet several criteria: the coating has to be electrically conductive and chemically inert to the sodium polysulfides that are formed in sodium-sulfur cells. In addition, the coating has to adhere well to the metal substrate, and be capable of withstanding thermal cycling from room temperature up to the operating temperature of the cells, $300^\circ\text{-}400^\circ\text{C}$, without peeling or flaking. The coating should also be self-healing or repairable to prevent the corrosion of the substrate from starting at pinholes or defects in the coating. Both graphite/aluminum- and silicon carbide-coated current collectors have the potential for meeting these criteria.

The composite structure of graphite layer bonded to an aluminum substrate makes a good current collector. Graphite is chemically inert to sodium polysulfides under the operating conditions of the sodium-sulfur cells (5) and is sufficiently conductive electrically ($\sigma \sim 1.0 \times 10^3\ \Omega^{-1}\text{cm}^{-1}$) to be used as a thin protective layer without introducing large ohmic losses. The use of current collectors solely made from graphite in practically sized sodium-sulfur cells results in high ohmic losses that seriously degrade the cell performance (6, 7). Aluminum is an excellent substrate. A protective nonconductive aluminum sulfide layer is formed on aluminum when it is exposed to polysulfide melt. This prevents corrosion from starting at coating defects and also allows greater flexi-

bility in current collector designs, since only selected areas need to be covered with graphite. In addition, aluminum is an excellent lightweight conductor.

Silicon carbide has an electrical conductivity of $0.001\text{-}100\ \Omega^{-1}\text{cm}^{-1}$ (8-10). It is also chemically inert to sodium polysulfide melts under the operating conditions of sodium-sulfur cells (11, 12). Sodium-sulfur cells built with sintered silicon carbide sulfur containers have shown no corrosion under testing (11). However, these containers are expensive and bulky. On the other hand, a thin conductive well-adherent silicon carbide layer applied to a steel container can protect the steel from corrosion by sodium polysulfides and, at the same time, retain the advantages of a metal container: high strength, ductility, and electrical conductivity. A system of bonding silicon carbide coatings to chromium-plated stainless steels is described in Ref. (13). The chromium forms a base to which the silicon carbide adheres well. In addition, any chromium exposed by defects within the silicon carbide layer can be protected from corrosion by the sodium polysulfides by oxidizing the exposed chromium before the current collectors are immersed into the polysulfide melt or built into the sodium-sulfur cells. The nonconductive chromium oxide formed during oxidation is inert to sodium polysulfides.

Experimental Technique

Graphite aluminum bonding.—The graphite is used in the form of foil or paper that is bonded to an aluminum substrate. In the test samples, GTA grade Grafoil, $127\ \mu\text{m}$ thick, manufactured by Union Carbide is used. The Grafoil composition is 99.9% graphite, with ash content of less than 0.1%. The nominal ash composition is 25% Al_2O_3 , 50% SiO_2 , 20% Fe_2O_3 , and 5% mixed oxides. No organic binders are used in Grafoil. The aluminum substrates, aluminum 1100 or 5 nines pure aluminum, consist of 0.5 in. wide strips, $3/2$ in. long and $\sim 1/16$ in. thick. The bonding process consists of evaporating or sputtering an aluminum layer about $1\ \mu\text{m}$ thick onto the side of Grafoil to be bonded to the aluminum substrate. This step is critical for a good bond. It allows the aluminum to come into direct contact with graphite with, at most, a very thin inter-

vening aluminum oxide layer present at the interface. The bond between the thin aluminum layer on Grafoil and the aluminum substrate is achieved by pressing the two pieces together in a hot press at 615°-620°C under a pressure of 2000 psi. The samples are kept in the hot press under argon atmosphere, at temperature, for 6-8h. During this time, a bond is formed at the aluminum/aluminum interface and the mechanical bond between the evaporated aluminum layer and graphite is strengthened by probable formation of a thin layer of aluminum carbide (Al_3C_4). Aluminum and graphite can react at temperatures as low as 400°C if no oxides are present at the interface (14, 15). The bond between aluminum and Grafoil formed by this procedure is stronger than the tear strength of Grafoil, which tends to peel off in layers. Although aluminum carbide is unstable in moist air, forming methane, no deterioration of the bond is observed in samples left in room air for weeks. Within a sodium-sulfur cell, there is little if any moisture, and the potential problem of moisture reacting with the aluminum carbide does not occur.

Slightly modified procedures from that discussed in the above for the bonding of aluminum and Grafoil were also tried. Pressing an unaluminized Grafoil sheet directly against an aluminum substrate in the hot press produced very poor bonding. The ever-present aluminum oxide on aluminum prevents the graphite from coming into direct contact with aluminum and, thus, inhibits the formation of an aluminum carbide bonding layer. However, a good bond between aluminum and Grafoil is achieved if a thin layer of cryolite/alcohol slurry is spread on the surface of aluminum before the Grafoil is hot pressed against the aluminum. The cryolite (Na_3AlF_6) is used as a wetting agent (16); it tends to break up the aluminum oxide layer and allows the chemical reaction between the aluminum and Grafoil to proceed. Cryolite can also be used to facilitate the bond formation at the aluminum/aluminum interface. This step was not found to be necessary.

Silicon carbide coating.—The silicon carbide coating is deposited on a chromium-plated stainless steel substrate. The chromium layer, 25-50 μm thick, provides a good adhesive base for the silicon carbide and allows the use of silicon carbide coatings with defects, e.g., pinholes. The chromium underlayer exposed by the defects can be oxidized to form chromium oxide, which is chemically inert in sodium polysulfide melts and thus prevents corrosion of the chromium underlayer. The silicon carbide is deposited by RF sputtering or by chemical vapor deposition (17). The adhesion of a silicon carbide layer to chromium on stainless steel can be improved by heat-treatment in an inert atmosphere above 1100°C. Through a high temperature diffusion process, tertiary compounds (13, 18) of chromium and silicon carbide can form at the interface.

The samples that are tested were not heat-treated to form tertiary compounds at the SiC/Cr interface. The silicon carbide is deposited by sputtering in a high purity argon (99%)-nitrogen (1%) gas mixture using a 6 in. sintered SiC target. Nitrogen, which acts as an n-type dopant (19) in SiC, is introduced into the system to increase the conductivity of the films. Before film deposition, the substrates are cleaned by an RF (13.6 MHz) gas discharge. The deposition rate is $\sim 60 \text{ \AA}/\text{min}$ at unheated substrate placed 52 mm from the target, at RF power of 200-300W, anode voltage of 1.3-1.6 kV, and gas pressure of 2.7×10^{-3} torr. The resistivity measurements are done on films deposited on quartz substrates, and the corrosion tests are done on films deposited on chromium-plated E-Brite (Fe-26Cr-1Mo) substrates.

Sodium polysulfide.—The sodium polysulfide (Na_2S_5) used in the tests is prepared from J. T. Baker (no. 3910) sodium monosulfide, 9 hydrate ($\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$) crystals by drying the crystals under hydrogen/helium (1:1) gas flow at 700°-800°C to form Na_2S . The monosulfide and appropriate amount of resublimed sulfur (Mallinckrodt no. 8420) are sealed under forepump vacuum into glass ampuls, slowly heated to 450°C to form Na_2S_5 , and then

cooled to room temperature. The transfer of polysulfide to the test cell is done in a helium dry box.

Measurements.—The testing of samples is done in corrosion cells, as shown in Fig. 1, under constant cathodic and anodic potentials in sodium polysulfide (Na_2S_5) melt at 350°C. The cell consists of a Pyrex "test tube," partially filled with sodium polysulfide (Na_2S_5), usually covering only part of the sample surface to be tested. The current and reference voltage leads, either chromel or aluminum wires, are welded to the sample substrate at the top. This area is above the sodium polysulfide melt level. In a case of a chromium-plated E-Brite substrate, the sample (5/4 \times 1/2 in.) is first coated with an insulating glass on all sides except for a rectangular window left for deposition of SiC. The glass prevents the E-Brite from coming into contact with sodium polysulfides. The counter and reference electrodes are graphite rods, threaded and cemented (with alcohol-based graphite cement) to molybdenum rods above the melt level. The molybdenum rods are brought to the outside through a silicon rubber stopper. The cells are leak-tight to better than 10^{-8} standard cubic centimeters per second (sccs). Graphite leads are not brought out directly because leak-tight seals cannot be made to the porous graphite. The temperature of the cell is monitored by a thermocouple inserted into a closed-end glass tube that extends into the melt. The cells are evacuated and then backfilled with argon to a pressure of 2-3 in. of water.

The samples are tested at constant potentials with respect to a carbon reference electrode, either anodically or cathodically at 350°C. The tests are usually done at 300 mV, the maximum cathodic potential expected at the sulfur container wall. This potential corresponds to the open-circuit potential difference between Na_2S_5 and Na_2S_3 melts. Currents through the samples are monitored continuously. At periodic intervals, current-interrupt data are taken from which the change in resistance of the sample, and ohmic and polarization contributions to the resistance, are determined. The measurements are made 2 μs after the start of the current interruption pulse of 10 μs duration using an Electrosynthesis Company (East Amherst, New York) Model 800 IR interrupter. The sample surfaces are examined after the tests.

The resistivity of sputtered amorphous silicon carbide films (1.5-2 μm thick) on quartz substrates is measured by a standard four-probe method. The layout is shown in Fig. 2. Sputtered platinum contacts are used for the current and voltage leads. The resistivity measurements as function of temperature are done in an argon atmosphere.

Results

Graphite/aluminum.—The current carried by a Grafoil/aluminum sample as a function of time under anodic and cathodic polarization of 200 mV is shown in Fig. 3. These polarizations correspond to the charging and discharging of a sodium-sulfur cell. In both cases, the current reached a steady state and then remained constant for approximately 70 days. The current then started to decline in a gradual and steady manner. The one sharp drop in current on sample GA-1 is unexplained. Post-test examination of the samples showed the presence of sulfur/sodium polysulfide in isolated spots at the Grafoil-aluminum interface. The steady decrease in current is most likely associated with loss of contact area between Grafoil and aluminum due to slow seepage of melt through the Grafoil.

The initial decrease of current under anodic conditions is due to the buildup of sulfur at the Grafoil-melt interface. Sulfur, which is nonconductive and immiscible in a sodium polysulfide melt, tends to block the electrode. The current decreases until an equilibrium is reached between the rate of oxidation of sulfur ions to sulfur and the rate of chemical reaction of sulfur to form soluble sulfide ions, *i.e.*

and

If the cell is left at open circuit for several days, the sulfur film at the Grafoil-melt interface is removed; if the cell is turned back on, a similar decay in current is observed as the sulfur film builds up again as shown by the data in Fig. 3 for days 87-94.

Under cathodic polarization an electrochemical reduction of sulfide ions occurs at the electrode

The initial currents are high, on the order of 130 mA/cm². The decline in current is likely caused by the partial formation of a Na₂S₂ layer at the melt-electrode interface, which partially blocks the access of Na₂S₄ and Na₂S₅ to the electrode. Steady state is reached when the electrochemical reactions reach equilibrium with the diffusion and convection of reactants at the interface. The steady-state current under cathodic polarization is higher than under anodic polarization, ~80 mA/cm² compared to 50 mA/cm², because no blocking sulfur film is formed. The voltage-current dependence is shown in Fig. 4. The data are taken under conditions where the variation of current with time has stabilized. This corresponds to days 49-50 in Fig. 3 for samples GA-1 and GA-2.

Silicon carbide.—The temperature dependence of resistivity of amorphous SiC films up to 400°C is shown in Fig. 5. A resistance change occurs during the initial heating of the films to ~400°C. On subsequent temperature cycles, the resistance changes seem to be reversible. The initial activation energy is 3.45 kcal/mol; on subsequent cycles, the activation energy is higher, 9.4 kcal/mol. The resistivity of the 1.5-2.5 μm thick films averaged around 140 Ω-cm at 350°C, the operating temperature of sodium-sulfur cells.

Similar resistance changes in amorphous SiC films have been reported by Wasa and co-workers (20). They found the resistance change with temperature to be reversible if the substrate temperature during deposition of the SiC films is higher than the temperature range of the resistivity measurements. The mechanism of resistance change in amorphous SiC films is not understood, but is thought to be associated with changes in the structure of sputtered films caused by thermally activated processes. The changes are not caused by surface oxidation of SiC films which takes place at temperatures higher than 1000°C (20, 21).

The currents carried by amorphous SiC coatings sputtered on chromium-plated E-Brite substrates as a function of time under cathodic and anodic polarizations in a sodium polysulfide melt (Na₂S₅) are shown in Fig. 6. The current under cathodic conditions across the SiC coatings is high. Initial values for the other samples ranged from 150 to 120 mA/cm² at cathodic polarization of 300 mV. The current decreases as a function of time, but tends to stabilize after ~20 days of operation. The current across sample SiC-C stabilized at ~85 mA/cm² and then slowly increased to 100 mA/cm² near the end of the test period of 84 days. The current under anodic polarization is much lower than under cathodic polarization. The current across sample SiC-B remained constant at ~32 mA/cm² until the test was terminated after 57 days.

The surfaces of the silicon carbide coatings were examined with a scanning electron microscope (SEM) before and after testing of the samples in sodium polysulfide

Fig. 3. Current vs. time of Grafoil/aluminum samples in Na₂S₅ melt under cathodic and anodic potentials of 200 mV.

Fig. 5. Temperature dependence of resistivity of thin amorphous silicon carbide films.

melts. The surface morphology of freshly sputtered silicon carbide coating on chromium-plated E-Brite is shown in Fig. 7. The surfaces of samples tested under cathodic polarization of 300 mV for 22 days (sample SiC-A) and 84 days (sample SiC-C) are shown in Fig. 8 and 9, respectively. The surface of an anodically tested sample, SiC-B, tested for 57 days at 300 mV polarization is shown in Fig. 10.

The overall surface morphology of a sample tested cathodically for 22 days is similar to the surface of silicon carbide coating unexposed to sodium-polysulfide melt, Fig. 7. However, the exposed silicon carbide surfaces, both above (no current passing through the SiC coating) and below the sodium polysulfide melt level, Fig. 8 (current passing through the coating), are covered with small light-colored chromium sulfide crystals. More crystals are found on the coating below the melt level. Some of the crystals have a platelike hexagonal structure that is similar to Cr_2S_3 crystals found on chromium-plated sulfur containers used in sodium-sulfur cells (22). Cross-sectional analysis of samples examined with SEM showed no

indication of the presence of chromium sulfides, sulfur, or sodium polysulfides at the chromium/silicon carbide interface. The growth of chromium sulfide crystals

Fig. 10. Surface of SiC coating below Na_2S_3 melt level of sample SiC-B after 57 days at anodic potential of 300 mV. Small white particles are chromium sulfide crystals. Surface morphology is similar to an untested sample shown in Fig. 7.

seems to occur via transport of chromium and sulfur through the pores in the amorphous silicon carbide coating.

The amorphous silicon carbide coating exposed to the sodium polysulfide melt for 84 days shows substantial change from the initial surface morphology. The coating surface, both above and below the polysulfide melt level, is covered with numerous chromium sulfide crystals. In addition, the SiC surface morphology is no longer hilly and smooth (Fig. 7), but is "worn," especially in some areas below the sodium polysulfide melt level, Fig. 9. In other areas, the worn pattern is not as deep. The mechanism causing the changes in the morphology of the silicon carbide coating has not been determined. The changes could be due to slow chemical reactions or to dissolution, or, more likely, due to small-scale flaking at the pores within the silicon carbide coating, caused by the transport of chromium and sulfur.

The surface morphology of the sample tested anodically has not changed much from the untested sample. Figure 10 shows the surface features below the polysulfide melt level. Chromium sulfide crystals on the surfaces are still present, but are fewer in number than on the cathodically tested samples.

Comparison with chromium.—The electrical performance of Grafoil/aluminum- and silicon carbide-coated current collectors is compared to chromium-coated current collectors. The data taken under cathodic and anodic conditions are summarized in Tables I and II, respectively. The measured losses occurring at the substrate/coating/melt interface are separated into ohmic and polarization losses and are normalized to a unit area of the current collector. The summarized data are for test periods when the currents remained stable (refer to Fig. 3, 6, and 11). The electrical performance of a well-adhered Gra-

Fig. 11. Current vs. time of chromium-coated sample under different cathodic potentials. The envelope of shaded areas corresponds to the magnitude of current oscillations.

foil/aluminum current collector is superior to that of a chromium-coated current collector. It has lower overall resistance both under cathodic and anodic potentials. At a polarization of 300 mV, the resistance values are 2.0 and $5.4 \Omega\text{-cm}^2$, respectively. The comparable values for a chromium-coated current collector are 3.2 and $10.7 \Omega\text{-cm}^2$. Consequently, the Grafoil/aluminum current collectors have lower power losses and carry substantially higher currents for a given potential.

The silicon carbide-coated current collectors have comparable resistances to the chromium-coated samples under cathodic potentials. The resistances under anodic conditions are higher. However, the current carrying capability as a function of time of the silicon carbide-coated samples is better than that of chromium-coated samples; the current in the case of silicon carbide samples increased slightly during 84 days, while the current decreased from 96 to 80 mA/cm^2 in 30 days for the chromium sample (Fig. 11). Under anodic potentials, the currents are lower than under cathodic potentials because of the formation of a blocking sulfur film at the electrode surface. For the chromium- and silicon carbide-coated samples, the steady-state currents under anodic conditions are independent of potential (Table II). The current increases with voltage only for the Grafoil/aluminum samples. The polarization resistance increases rapidly with voltage, while the ohmic resistance remains constant. Under cathodic conditions, the polarization resistance is, within experimental error, also independent of voltage.

Current oscillations observed with chromium sample.—The current vs. time of the chromium-coated sample is shown in Fig. 11. Typical current oscillations and variations in cell resistance during oscillations are shown in Fig. 12 for a sample polarized cathodically at 300 mV.

The amplitude of oscillations can build up to quite high values, as indicated by the shaded regions on Fig. 11. The

	100	14.1	0.85	6.2	25		

oscillations can suddenly decrease or disappear and then build up again. The onset depends on the cathodic potential and on the previous operating history of the sample. No oscillations are observed at cathodic polarization below 200 mV. The periods of oscillation are variable; at 300 mV, the period ranged from 1.9 to 2.4 min, and at 250 mV, from 3 to 9 min. During the oscillations, the ohmic contribution to the resistance remains constant, while the polarization contribution changes inversely with current (Fig. 12).

Post-test analysis of the sample shows the chromium plating to be covered with various thicknesses of chromium sulfide layers. These layers can be more than 10 μ m thick (22). Surface peeling and flaking of chromium sulfide layers are observed over large areas of a sample as shown in Fig. 13 and 14. The surface of chromium sulfide layers at higher magnification showing crystals and partially dissolved crystals are shown in Fig. 15 and 16.

The chromium sulfide layers are probably porous enough to be penetrated by the sodium polysulfide melt, yet restrictive enough to inhibit greatly the transport of the polysulfides through this layer. Under high enough cathodic potential, a concentration gradient of sodium polysulfides ranging from Na_2S_x (perhaps as low as Na_2S_2) near the chromium surface to Na_2S_5 near the outermost part of the chromium sulfide layer can be formed. This gradient gives rise to high concentration polarization. The formation of lower polysulfides within the chromium sulfide layer sets up high stresses causing the layers to flake and, thus, decreases the impedance due to polarization. As the chromium sulfide layer builds up again, the polarization impedance increases and current decreases. The rate of growth and flaking of the chromium sulfide layer is dependent on many variables, e.g., potential, porosity of the layer, and convection and diffusion near a sample surface.

Discussion

Coating processing (Grafoil/aluminum).—The mechanism of degradation of the bonding between the Grafoil and aluminum is due to the slow penetration of sodium polysulfide and sulfur through the Grafoil sheet to the Grafoil-aluminum interface. However, Grafoil can be made impervious to sodium polysulfides and sulfur by deposition of a coating of glassy or pyrolytic carbon.¹ This offers a possible method of preventing the sulfur and sodium polysulfides from reaching the carbon/aluminum interface, by modifying the bonding process, by depositing the aluminum on Grafoil coated with glassy carbon rather than on Grafoil directly. The layer of glassy carbon would not affect the bond to the aluminum.

The glassy coatings from a few mils up to 10 mil thick can be applied in a gas flow reactor using methane and inert carrier gas such as argon or nitrogen at temperatures of 2000°–2300°C (24, 25). Some reactors are up to 19 in. in diameter and 50 in. long, which would allow for batch processing of Grafoil sheets in appropriate shapes.

¹Graphite cylinders and current collectors used in glass cells have been made impervious by this process at Ford Motor Company (23).

Silicon carbide.—The amorphous coatings of silicon carbide that were tested have adequate electrical conductivity for use as a coating for the current collectors in sodium-sulfur cells. The adhesions of the coating to the substrate has been good during tests lasting up to three months. The coatings that were tested are porous; the transport of chromium and sulfur through the pores leads to the formation of chromium sulfide crystallites on the surface of a silicon carbide coating. However, the total surface area covered by these crystallites is small, and their effect on electrical performance seems to be minimal. Examination of the surface indicates some "wear" of surface, most likely due to the transport of materials through the porous coating.

Fig. 12. Typical current oscillations and sample resistance changes observed on chromium-plated sample polarized cathodically at 300 mV. The ohmic impedance remains constant; polarization impedance is out of phase with current.

Fig. 13. Overall picture of cracked and flaking chromium sulfide layers on chromium-plated E-brite sample tested for 36 days at cathodic potential.

Fig. 14. A cracked and flaking chromium sulfide layer

The process parameters for depositing the silicon carbide coatings were not optimized to achieve maximum density. Although high film density is desirable, one can work with porous films by oxidizing the chromium exposed by the pores in the film (13) prior to exposure to sodium polysulfide melt. The chromium oxide is chemically inert to sodium polysulfide melts and has shown no effects of corrosion under cathodic and anodic cycling (26).

The resistivity of the tested silicon carbide films, 1.5-2.5 μm thick, of 140 $\Omega\text{-cm}$ at 350°C is adequate for coating current collectors used in sodium-sulfur cells. However, these films were not optimized to have minimum resistance. The resistivity of the films can be decreased by at least an order of magnitude by increasing the carrier concentration with optimized nitrogen doping and by crystallization of amorphous films by annealing. Crystalline films can also be formed by sputtering the silicon carbide on heated substrates. Resistivities as low as 0.13 $\Omega\text{-cm}$ have been reported at 350°C (19).

Corrosion cells and sodium-sulfur cells.—The resistance values measured in the corrosion cells, both under cathodic and anodic conditions, are much higher than the total cell resistances measured in sodium-sulfur cells. In the corrosion cells, all the current is carried by ionic conduction through the sodium polysulfide melt and all the electrochemical reactions occur at the sample surface. In sodium-sulfur cells, the current is carried from the electrolyte by electronic conduction through the graphite felt and by ionic conduction through the melt to the metal

Fig. 15. Platelike chromium sulfide crystals, Cr_2S_5 , in area slightly above the Na_2S_5 melt level.

Fig. 16. Partially dissolved chromium sulfide crystals below Na_2S_5 melt level.

sulfur container. Also, most of the reactions take place at the graphite felt/electrolyte interface region and not at the sulfur container wall. For instance, during charging under an anodic potential of 300 mV, the resistance of a chromium/melt interface is 10.7 $\Omega\text{-cm}^2$ in the corrosion cell (Table II). In the sodium-sulfur cells, the total cell resistance (which includes the resistances of electrolyte, graphite felt/electrolyte contact, graphite felt electrode in a parallel circuit with ionically conductive sodium polysulfide melt, graphite felt/container contact, and the chromium sulfide/chromium layer on the sulfur container) during charging is much lower, $\sim 1.4 \Omega\text{-cm}^2$. The contact resistance at the container wall is less than one-third of cell resistance, *i.e.*, $< 0.5 \Omega\text{-cm}^2$, as compared to 10.7 $\Omega\text{-cm}^2$ measured in the corrosion cell. The resistance data obtained from corrosion cells are much higher and are not expected to correspond to values observed in sodium-sulfur cells.

The corrosion test cell offers an accelerated means, under well-controlled conditions, to test the corrosion of materials for use as sulfur-electrode current collectors in sodium-sulfur cells. The conditions in the test cell are more severe than the conditions at the sulfur container (current collector)/electrode interface in a sodium-sulfur cell. In the test cell, the 300 mV test potential is across the sample/polysulfide melt interface, while in the sodium-sulfur cell the potential across the container/electrode interface is considerably less during most of the charge-discharge cycle. Most of the chemical reactions in the sodium-sulfur cell take place away from the container wall near the graphite felt electrode/electrolyte interface. Although a direct quantitative correlation of corrosion of samples in test cells with corrosion of current collectors in sodium-sulfur cells has not been made, qualitative data indicate a much faster corrosion in the test cells. A chromium-plated E-Brite sample tested continuously for 36 days under cathodic potential of 300 mV showed severe corrosion with flaking, peeling, and some dissolution of the chromium sulfide layer that is formed on chromium (Fig. 13 and 14). In contrast, many chromium-plated E-Brite sulfur containers of sodium-sulfur cells cycled continuously for 1-2 years (1) have shown less corrosion of the chromium plate than occurred on the sample in the test cell during one month.

Summary

Both Grafoil/aluminum- and silicon carbide-coated current collectors performed well for short times. The current carrying capacity of Grafoil/aluminum collectors in sodium polysulfide melt is higher than that of chromium-plated collectors by a factor of ~ 1.5 under cathodic potentials and by a factor of ~ 2.0 under anodic potentials. The bonding between Grafoil and aluminum is stronger

than the tear strength of Grafoil. No corrosion of Grafoil was observed for samples tested for more than 90 days. A deterioration of a Grafoil/aluminum bond occurred after 70 days due to slow seepage of sodium polysulfides through the Grafoil. Presealing of the Grafoil with glassy carbon prior to aluminum bonding should alleviate this problem.

The current carrying capacity of amorphous silicon carbide covering a chromium-plated E-Brite sample is comparable to that of chromium-plated samples under cathodic potentials and lower by a factor of 0.6 under anodic conditions. No increase in resistance of the silicon carbide sample is observed over a period of 84 days, while large changes are observed with a chromium-plated sample. In addition, the adhesion of the silicon carbide coating is very good; there were no indications of peeling or flaking. The corrosion observed on the 1.8 μm thick film tested for three months is minimal and may be due to transport of reactants within the porous coating. The porosity of present coatings, while not ruling out their application in sodium-sulfur cells, can be greatly minimized by optimizing the sputtering conditions.

Investigation of Li/SO₂ Cell Hazards

II. Thermal Decomposition Studies of Cell Discharge Products

William P. Kilroy*

Naval Surface Weapons Center, Silver Spring, Maryland 20903-5000

ABSTRACT

Lithium dithionite undergoes rapid adiabatic exothermic decomposition leading to large rates of self-heating and pressure generation. Lithium-lithium dithionite mixtures, which can form during overdischarge, were found to be very hazardous. Such mixtures are capable of causing explosive venting in Li/SO₂ cells. Carbon black substantially lowers the initiation temperatures required for sustained self-heating to occur and alters the mechanism of both the adiabatic and nonadiabatic dithionite decompositions. The rate of heating and the amount of electrolyte present in discharged Li/SO₂ cathodes appears to alter the overall distribution of decomposition products and the cells' thermal behavior.

In a recent paper, accelerating rate calorimetry (ARC) was used to define the thermal and pressure behavior of Li/SO₂ cells during overdischarge (1). Cells containing lithium at the end of cell life were found to undergo thermal runaway when overdischarged at ambient temperatures. The thermal runaway resulted from a series of coupled exothermic chemical reactions. Two of these reactions,

occurring in the 100°-150°C temperature region, involved the reaction of lithium with the battery electrolyte and the decomposition of lithium dithionite. These reactions are critical to Li/SO₂ safety since they provide the pathway for the propagation of a thermal runaway to the melting point of lithium. It was postulated that the initiation temperature and kinetics of each of these exothermic reactions may be interdependent and could also be affected by the amount of electrolyte present. Lithium

* Electrochemical Society Active Member.

dithionite will generate SO₂ upon decomposition (2), thereby affecting the lithium-electrolyte reaction which has been shown to be dependent on SO₂ concentration (3). In turn, the thermal stability of lithium dithionite was not fully explored, and its decomposition appeared to be a function of its degree of wetness with the electrolyte.

Other factors may influence the thermal stability of lithium dithionite. Although lithium dithionite is the product formed upon discharging a Li/SO₂ cell at 1 mA/cm² at -30° or 25°C, a more complex chemistry was observed at 71°C (4-6). Apparently, higher temperatures either change the reduction mechanism or cause some of the lithium dithionite to decompose. The question of whether the additional chemicals produced in the high temperature discharge can affect the dithionite decomposition needs to be examined.

Since carbon black has been shown to be a catalyst in Li/SO₂ cells (7), it may also catalyze the decomposition of the lithium dithionite. The surface area of the carbon black was cited as the most important factor in enhancing catalytic activity. Consequently, the sample configuration, that is, the distribution of lithium dithionite on the carbon black, brought about by changes in current density, may also be a factor in the stability of the dithionite.

Previous investigations have shown that sample configuration was a factor in the thermal decomposition of the sodium salt, Na₂S₂O₄ (8). Thin layers of this salt decomposed slowly when heated isothermally, whereas large samples generally decomposed at higher temperatures and with greater rapidity. The major products that formed were attributed to the following reactions

Thin layer

Thick layer

The lithium salt has been shown to undergo a different high temperature decomposition (2) according to the reaction

The objective of this investigation was to examine the thermal stability of lithium dithionite, particularly in its relation to Li/SO₂ cell components such as carbon, electrolyte, etc., and other factors that might influence its stability and ultimately lead to Li/SO₂ battery safety hazards.

Experimental

Lithium dithionite was synthesized by the method previously reported (2). Analysis confirmed it was 88% pure, containing primarily lithium sulfite as an impurity (9).

Commercial Li/SO₂ cells were discharged at constant temperature in a Tenny Jr. Environmental Chamber using constant current controlled by a PAR Model 173 or 371 galvanostat. The discharged cells were opened in a helium-filled glove box.

All differential scanning calorimetry (DSC) studies were performed under nitrogen atmosphere using a Perkin Elmer Model 2 DSC. All dry samples were weighed before and after each DSC analysis. Samples were prepared in a dry room of less than 0.4% relative humidity. All the discharged cathode samples were sealed in DSC cells under helium. After DSC analysis, the DSC cells were immediately and rapidly cooled to ambient temperature under nitrogen.

Infrared analyses were performed using Perkin Elmer Model 683 and 1500 IR spectrometers. Samples were prepared as KBr pellets in the dry room.

Mass spectroscopic studies were performed using a Finnigan Model 4000 GC chemical ionization electron impact mass spectrometer.

Samples used in the ARC studies were loaded and sealed in an 8.6 ml titanium bomb while under a helium atmosphere. The ARC analyses were performed under nitrogen in a Columbia Scientific Instruments calorimeter.

Shock sensitivity tests were performed on samples of Li₂S₂O₄ and on 1:1 mixtures of lithium and lithium dithionite using a drop-weight-impact apparatus used in U.S. Navy explosive testing. This instrument employed a microphone noise meter calibrated using the drop hammer with and without known explosive samples. The impact distance necessary to give positive tests results on 50% of the samples was determined. This distance was then compared to data giving similar results on known explosive materials.

Accelerating rate calorimetry.—The ARC is a micro-processor-controlled adiabatic calorimeter that heats a sample to a desired starting temperature, waits for thermal equilibrium to be achieved, and then checks for a self-heating rate exceeding a preselected threshold. This cycle continues in fixed temperature increments until an exotherm is detected. The instrument then maintains the sample under adiabatic conditions and continuously monitors the time, temperature, and pressure relationship until the exothermic reaction is complete.

An exothermic reaction may proceed as a slowly decelerating reaction (low activation energy) or as a rapidly self-accelerating reaction (high activation energy). In the latter case, the heat of reaction is available to continuously heat the reactants to higher temperatures and thereby increases the rate of reaction until it accelerates exponentially with temperature. Thermal runaway occurs when rapid increases in temperature and reaction rates are realized. Safety hazards occur if the temperature rise causes an uncontrolled pressure increase as a result of an increase in vapor pressure or the formation of gaseous products.

The ARC thermal data have been presented as a log rate of self-heating vs. 1/T (K) plot. The 1/T (K) temperature axis is labeled in degrees centigrade for convenience. This is essentially an Arrhenius plot of the data, and each exothermic reaction will appear as a separate peak. A heat/search mode of operation where self-heating was not observed shows up as a discontinuity in the ARC thermal curves. Additional details concerning the theory and operation of the ARC have been reported (10, 11).

Results and Discussion

Adiabatic ARC studies.—ARC studies on commercial 2/3 A and D size Li/SO₂ cells overdischarged at ambient temperature exhibited an exothermic reaction beginning near 100°C. Similar low activation energy reactions occurred near 90°C on cathodes taken from 2/3 A and D size cells discharged to 2.0V at 25°C. The D cell cathodes displayed two distinct regions of exothermicity similar to the ARC behavior found in lithium-limited cells. However, the cathodes from the 2/3 A cells had an additional exotherm starting near 116°C and exhibited coupled exothermic reactions similar to those observed on all resistively overdischarged excess lithium cells (1).

The 2/3 A and D cells were discharged to 2.0V at 1 and 10 mA/cm², respectively. Conceivably, this rate difference could alter the discharge products and in turn affect the thermal behavior. This possibility was investigated by mass spectroscopy and ARC experiments.

Portions of the cathodes from the same 2/3 A and D cells were vacuum dried and heated in turn at 3°C/min in a mass spectrometer. Both cathodes evolved sulfur and SO₂ near 100°C. Since the only product formed in 2/3 A cells under these conditions is lithium dithionite (4), the sulfur and SO₂ are attributed to the thermal decomposition of lithium dithionite. This similar chemical and temperature behavior observed for the 2/3 A and D cell cathodes indicates that the differences in their ARC behavior cannot be readily explained by differences in discharge products. This was confirmed by discharging a 2/3 A cell at 71°C where a complex array of sulfur discharge products form (5). The ion intensity vs. temperature data obtained upon heating this cathode in the mass spectrometer (Fig. 1) are similar to those obtained with the cathode containing only dithionite. Again, the major evolution of S and SO₂ begins near 110°C. The sulfur observed near

Fig. 1. Mass spectra upon heating a cathode from a 2/3 A size Li/SO₂ cell discharged at 1 mA/cm² at 71°C. Masses 64, 128, 256, total ion intensity.

60°C is consistent with the free sulfur found under these discharge conditions.

Figure 2 compares the ARC thermal and pressure data observed on cathodes taken from 2/3 A cells discharged at 1 mA/cm² at -30° and 71°C. The similar ARC behavior observed for cathodes containing only dithionite (-30°C) and cathodes with a complex discharge chemistry (71°C)

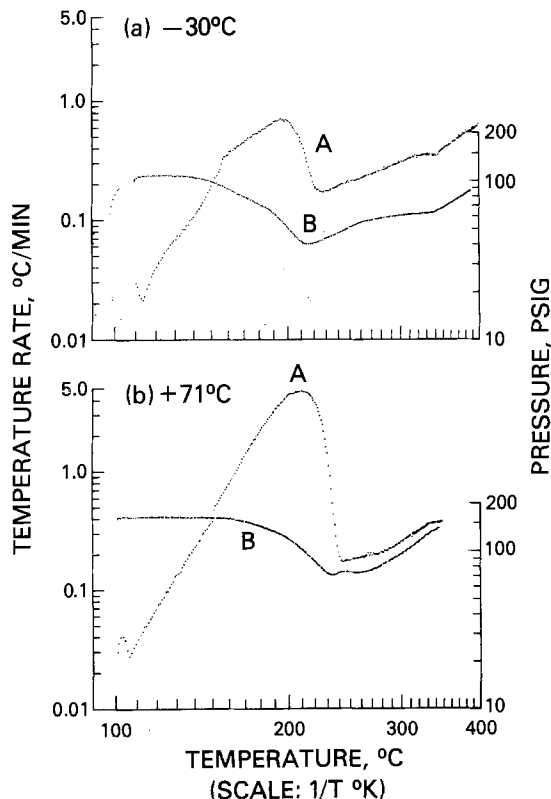

Fig. 2. ARC thermal (curve A) and pressure (curve B) behavior for cathodes from 2/3 A size Li/SO₂ cells discharged at 1 mA/cm² to 2.0V at (a) -30°C and (b) +71°C.

confirms that differences in the cathode chemistry do not account for the differences in ARC behavior reported previously (1).

Several other factors need to be considered. The D cathodes were wet with electrolyte, whereas the 2/3 A cathodes had the bulk electrolyte removed by vacuum pumping. Additionally, the differences in discharge rates alter the spatial distribution of the dithionite in the carbon black matrix. Thus, the spatial configuration of the dithionite (8) and the catalytic activity of carbon black (7) may combine to influence the ARC behavior and may account for the lower decomposition temperature of lithium dithionite than previously reported (2).

Thermal decomposition of dithionite.—ARC thermal data for samples of lithium dithionite (curve A), a mixture of lithium and lithium dithionite (curve B), and sodium dithionite (curve C) are illustrated in Fig. 3. The corresponding ARC pressure data are shown in Fig. 4.

The ARC thermal behavior of a 2.0g sample of laboratory-synthesized lithium dithionite is given in Fig. 3, curve A. Starting at about 140°C, lithium dithionite undergoes adiabatic decomposition, proceeds through two rapid exothermic reactions, and attains a self-heating rate of 85.5°C/min. The sample had an adiabatic temperature increase of 352°C to reach a final adiabatic temperature of 500°C. The corresponding ARC pressure behavior (Fig. 4, curve A) shows the sample generates 340 psig of pressure. The rate of pressure generation exceeded 60 psi/min.

ARC analysis was performed on a large sample (5.0g) of the sodium salt. The thermal behavior, illustrated by the solid line, curve C in Fig. 3, shows two distinct exotherms beginning at 122° and 230°C. During the first exotherm, the sample proceeds through a series of continuous exothermic reactions and attains a maximum self-heating rate of 137.5°C/min upon reaching a temperature of 190°C. The samples adiabatic temperature increased 250°C, reaching a final temperature of 372°C. The ARC pressure behavior is shown in Fig. 4, curve C. The sudden rise in pressure at 140°C coincides with initiation of the final reaction of the first exotherm.

These ARC data indicate the potential for safety hazards in Li/SO₂ cells. The amount of lithium dithionite used in this study was much less than that present in a fully discharged D cell. Despite this, the magnitude of the

Fig. 3. ARC thermal behavior. A: Li₂S₂O₄ (2.0g). B: Li₂S₂O₄ (2.48g) + lithium metal (0.53g). C: Na₂S₂O₄ (4.9g, 98%).

Fig. 4. ARC pressure behavior. A: Li₂S₂O₄. B: Li₂S₂O₄ + lithium. C: Na₂S₂O₄.

overall pressure rise was significant enough to cause venting in some commercial cells.

Infrared analysis on the residue from the ARC experiment on Li₂S₂O₄ is shown in Fig. 5, curve A. Several products including sulfite and sulfate can be identified. Qualitative tests with naphthol yellow S showed no dithionite remaining. Some sulfur was present.

Fig. 5. Infrared spectra. A: Li₂S₂O₄ adiabatically decomposed in the ARC. B: Residue of the lithium-Li₂S₂O₄ reaction in the ARC.

Due to the rapidity of the Li₂S₂O₄ adiabatic decomposition, one plausible reaction may involve a radical chain mechanism, with one pathway given SO₃²⁻ with S and SO₂ forming through an SO intermediate

Lithium-lithium dithionite.—Safety hazards in overdischarged Li/SO₂ cells have often been attributed to the reaction of lithium with acetonitrile after depletion of the SO₂. However, even more serious hazards were observed on overdischarge at low temperatures (1) when residual SO₂ electrolyte was present. The cell capacity was limited by the saturation of the carbon current collector. The residual SO₂ passivates the lithium which deposits during overdischarge to form a lithium-carbon-lithium dithionite matrix.

The ARC thermal and pressure data for a mixture of lithium dithionite and excess lithium are illustrated by curve B in Fig. 3 and 4, respectively. A large exothermic reaction again begins near 140°C and proceeds through a series of reactions. The lithium melts at 180°C, indicated by the endotherm (dotted depression) in curve B, Fig. 3, which causes a sudden rise in the pressure, curve B, Fig. 4. This is attributed to the reaction of lithium with lithium dithionite

Heat from this reaction triggers gas producing reactions including (i) rapid decomposition of any residual dithionite to form SO₂ and (ii) reaction of the carbon with the S and SO₂ decomposition products of the dithionite. Upon reaching a self-heating rate exceeding 60°C/min and a pressure exceeding 400 psi, the calorimeter bomb shattered. A second mixture, containing a 10:1 mole ratio of 0.6g lithium and 1.2g Li₂S₂O₄, behaved similarly. The pressure was generated at a rate exceeding 340 psi/min at 200°C when the vessel again shattered.

Infrared analysis of the residue from the lithium-lithium dithionite reaction is shown in Fig. 5, curve B. Comparison of the two IR spectra in Fig. 5 reveals that lithium alters the decomposition mechanism significantly. The large broad bands at 1480, 1425, 500 cm⁻¹ and the strong sharp band at 865 cm⁻¹ correspond to the IR spectra obtained from lithium oxide. Qualitative spot tests confirmed the presence of sulfide. The additional IR bands of the spectra indicate that other products form, presumably from the reaction of SO₂ gas generated during the decomposition of the dithionite. The IR band at 1000 cm⁻¹ and shoulder at 1250 cm⁻¹ indicate some dithionate may have formed. Conceivably, the SO₂ may also react with the sulfite decomposition product to form metabisulfite, S₂O₃²⁻, giving rise to bands near 1160, 1088, 990, and shoulder near 650 cm⁻¹ (12).

Lithium dithionite-carbon.—The ARC thermal data for lithium dithionite appear appreciably different from those of the discharged cathodes. The ARC data on the discharged cathodes were characterized by the generation of pressure arising from the low temperature exotherm observed near 90°C (Fig. 2). This pressure, measured at 110°C, accounted for only 60% of that expected for complete dithionite decomposition. This was determined by using weighed cathodes, containing known amounts of carbon and dithionite determined from coulometric-iodometric analyses, placed in a fixed volume of the ARC bomb. The residual electrolyte precluded an exact determination of the percent decomposition.

After the initial decomposition of the dithionite, multiple exothermic reactions begin near 116°C, as shown by the variation in slope of the self-heating curves. The ARC

pressure data, curve B in Fig. 2, show the pressure decreasing, which indicates the SO₂ gas is consumed by a reaction during the latter part of this exothermic behavior.

A second exothermic reaction that generates additional gas pressure begins near 220°C.

The effect of carbon black on the decomposition of dithionite was investigated. A mixture, simulating the relatively moisture-laden cathodes taken from discharged D cells (1), was prepared by mixing 1.2g Li₂S₂O₄ with 0.18g undried Shawinigan carbon black under a helium atmosphere. Figure 6, curve A shows the ARC thermal behavior of this sample after two months storage in a desiccator. Sustained multiple reactions begin at 61°C. The mixture attains a self-heating rate of 11°C/min and an adiabatic temperature rise of 291°C, reaching an adiabatic temperature of 352°C.

A second mixture, simulating cathodes from the relatively moisture-free 2/3 A cells (1), was prepared under helium by grinding together lithium dithionite with Shawinigan carbon black that was vacuum dried several days at 250°C. The ARC thermal data, shown in Fig. 6, curve B, has characteristics common to both the discharged cathodes and the lithium dithionite. Although the self-heating process begins near 90°C as observed with the discharged cathodes, the rapid decomposition and pressure generation (Fig. 6, curve C) occurs near 145°C as found in the case of the lithium dithionite.

Adiabatic decomposition mechanisms.—Lithium dithionite-carbon.—Since undischarged cathodes exhibited no exothermic behavior, the low temperature exotherms are attributed to the carbon catalyzed decomposition of lithium dithionite, given by the reaction

Studies in which lithium dithionite was heated to 140°C under N₂ support this reaction. The dithionite loses mass slowly over several days, producing SO₂ gas. Infrared analysis of the residue showed only lithium sulfite and

residual dithionite. DSC analysis showed endotherms at 113° and 119°C, indicating the presence of sulfur. It should be noted that Li₂S₂O₃ undergoes endothermic decomposition into sulfur and sulfite beginning near 116°C (3).

The exotherm starting near 220°C is attributed to the decomposition of the residual dithionite according to the reaction

Upon completion of the ARC analysis, the residues were weighed. The mass loss was 23% consistent with the theoretical loss expected from an overall process represented by Eq. [7].

Lithium dithionite.—In the absence of carbon, the adiabatic decomposition of lithium dithionite may follow a different mechanism, as indicated by the more rapid rise in self-heating rates. Sample size may be a factor. The large samples had still higher self-heating rates and greater rates of pressure generation. The ARC data indicate two principal processes occur (with or without carbon). The proposal mechanism is given by Eq. [4], which accounts for the sulfate and sulfite products. High temperatures appear to favor formation of the sulfite, as indicated by the previous nonadiabatic studies (2). Additional studies are in progress.

Lithium-carbon-lithium dithionite.—A cathode taken from a 2/3 A size SO₂ cell overdischarged 30% at 1 mA/cm² at 25°C was vacuum dried and placed in a helium-filled combustion bomb. The bomb was evacuated and heated to 200°C. Infrared analysis on the collected gas revealed that, in addition to SO₂, some carbonaceous gases were present, primarily CS₂ and CO₂.

The ARC data indicate that the heat generated from the carbon-catalyzed Li₂S₂O₄ decomposition can trigger very exothermic reactions involving lithium. In addition to the reaction represented by Eq. [5], the lithium may also react with the sulfur present from decomposed dithionite. The heat generated apparently causes the carbon black to react according to the reaction

Mechanism for overdischarge hazards.—During forced overdischarge, especially during low temperature operation where the SO₂ electrolyte is least likely to be consumed, lithium can accumulate in the carbon cathode together with the lithium dithionite discharge product. Polarization of the carbon due to loss of some electrolyte and saturation of the carbon generates heat. Localized heating (hot spots) causes the carbon-catalyzed decomposition of Li₂S₂O₄ to generate a large adiabatic temperature increase. This heat can trigger an extremely rapid and very exothermic lithium-lithium dithionite reaction. In addition to the sudden gaseous pressure generation, the heat causes carbon to react almost synchronously with the SO₂ and S decomposition products, creating additional pressure by the formation of carbonaceous gases.

Nonadiabatic DSC-IR study of Li₂S₂O₄ decomposition.—Lithium dithionite was weighed in sealed DSC cells under nitrogen prior to heating. After heating, the DSC cell was opened and the residue was weighed and examined

Fig. 7. Infrared spectra. A: Li₂S₂O₄ heated 20°C/min to 190°C in a DSC. B: Li₂S₂O₄ heated to 240°C at 20°C/min or at 0.62°C/min to 220°C in a DSC.

by IR analysis. Table I summarizes the DSC-IR data. The extent of dithionite decomposition was influenced by (i) the rate of heating and the final temperature and (ii) the presence of carbon black.

Infrared analysis on the residue from sample 1, shown in Fig. 7, curve A, indicates little decomposition has occurred at 190°C when the sample is heated at 20°C/min. The IR bands at 505, 545, 910, 1032, and 1082 cm⁻¹ are due to Li₂S₂O₄. Characteristic of DSC analysis, decomposition occurred sooner and to a greater degree if the sample is heated slower, 0.62°C/min. As cited earlier, isothermal heating at 140°C over several days enabled extensive decomposition to occur. The IR spectra of samples heated in the DSC to higher temperatures, as cited in Table I, resemble hydrated sulfite and are illustrated in Fig. 7, curve B. The lithium dithionite typically lost 24 ± 2% mass.

Samples 4, 5, and 6 are ground mixtures of Li₂S₂O₄ and carbon Shawinigan black. Prior to heating, such mixtures show no change in the IR spectra from that of Li₂S₂O₄. However, Fig. 8, curve A shows the IR spectra of sample 4 after heating. Comparison of samples 1 (Fig. 7, curve A) and 4 (Fig. 8, curve A) under identical heating conditions reveals that carbon black catalyzes the decomposition of Li₂S₂O₄. In the presence of carbon black, some mass loss occurs and new IR bands form. More extensive heating (samples 5 and 6) gives rise to the FTIR spectra shown in Fig. 8, curve B. Comparison of curve B in Fig. 7 and 8 reveals carbon black has altered the decomposition of dithionite as evidenced by the spectral changes, most notably at 1209 cm⁻¹ and perhaps near the 500 cm⁻¹ region.

Discharged cathodes.—A 2/3 A size commercial Li/SO₂ cell, discharge at 25°C to 2.0V at 40 mA constant current,

Fig. 8. A: IR spectra of a ground mixture of Li₂S₂O₄ and carbon Shawinigan black heated 20°C/min to 190°C. B: IR spectra of ground mixture of Li₂S₂O₄ and carbon Shawinigan black heated to 0.62°C/min to 220°C. C: IR spectra of a cathode from a 2/3 A size Li/SO₂ cell discharged at 25°C at 15 mA/cm² or C size cell at 71°C at 10 mA/cm².

known to contain only Li₂S₂O₄ as a discharge product (4), was opened in a helium glove box. Samples of the cathode were immediately hermetically sealed in DSC cells while still wet with electrolyte. Additional samples of this cathode were placed in a desiccator in the glove box, vacuum dried, and sealed in DSC cells. The cathode samples were analyzed by DSC at various rates of heating.

DSC and subsequent IR analyses on the residue indicated that the thermal behavior and the chemistry of discharged cathodes may be influenced by their rate of heating and to some extent their degree of wetness with electrolyte.

Figure 9 shows the temperature at the peak of the major exothermic reaction in the DSC vs. log of the DSC heating rate of the cathodes wet with electrolyte. The break in the curve indicates a change in the chemistry occurred at the higher heating rates. At slow DSC heating rates, only a single exotherm appears. A new exothermic transition begins at about 10°C/min preceding the original exotherm. As the heating rate increases, this first exotherm intensifies until, at 80°C/min, a sudden endotherm occurs between the two exotherms. Replicate analyses, performed at each heating rate, gave identical thermal behavior.

The IR spectra of the residues obtained at heating rates of 1.25° and 20°C/min are compared in Fig. 10. The 1209, 1155, and 1125 cm⁻¹ IR bands that appear at the higher heating rate confirm a change in chemistry has occurred.

Fig. 9. Log DSC heating rate vs. peak temperature of principal exothermic reaction of a cathode still wet with electrolyte from a Li/SO₂ cell discharged at 1 mA/cm², 25°C.

DSC analyses on portions of the dried discharged cathode were performed in replicate at various rates. The samples gave rise to unexpected endothermic behavior. This generally occurred after a slowly occurring exotherm had begun.

Infrared analyses on the residues typically gave rise to the IR spectra shown in Fig. 10, curve C. The IR bands at 1209, 1153, and 1125 are similar to the IR bands observed on rapidly heating cathodes containing electrolyte (Fig. 10, curve B). The dried cathodes gave rise to a more intense 1209, 1153, and 1125 cm⁻¹ bands, relative to the other IR bands of the spectra. Whenever the 1153 and 1125 cm⁻¹ bands were prominent, endothermic behavior was consistently observed.

DSC-IR analyses permit the examination of chemical changes introduced by heating the discharged cathodes outside of the normal cell environment. To study the chemical changes induced by heat within a pressurized cell, both 2/3 A and C size cells were discharged at high rates and/or high temperatures. The cathodes were compared using IR analyses. The IR spectra for a C size cell discharged at 71°C and 10 mA/cm² is shown in Fig. 8, curve C. An identical IR spectra was obtained for a 2/3 A size cell discharged at 25°C at 15 mA/cm² where the external cell temperature reached 88°C. In addition to the five dithionite bands, new bands appear at 1240, 1165, and 970 cm⁻¹ and several small bands appear near 650 cm⁻¹. This contrasts with the 1209, 1153, and 1125 cm⁻¹ bands that form upon heating vacuum-dried cathodes or on rapidly heating the electrolyte-wet cathodes outside of the cell environment.

A 2/3 A size cell discharged at 25°C at 1 mA/cm², so as to produce only Li₂S₂O₄, was placed in an oven for two days at 71°C. Subsequently IR analysis on the cathode revealed little dithionite decomposition had occurred. This data suggests that the reduction process and/or the SO₂ electrolyte plays a role in the high rate or high temperature discharge chemistry. Additionally, the 1240 cm⁻¹ band, indicative of thionate formation, which is formed during high rate or high temperature discharges, was not found upon heating discharged cathodes in the low pressure environment of the DSC cells.

Fig. 10. IR spectra of a cathode from a 2/3 A size Li/SO₂ cell discharged at 1 mA/cm² at 25°C to 2V. A: Cathode wet with electrolyte heated 1.25°C/min to 240°C. B: Cathode wet with electrolyte heated 20°C/min to 240°C. C: Cathode vacuum dried 1 day, heated 20°C/min to 240°C.

Shock sensitivity testing.—Samples of lithium dithionite subjected to impact testing showed no evidence of any shock sensitivity. However, the tests performed on mixtures of lithium and lithium dithionite gave positive results. Sensitivity was determined from the impact distance required to give positive tests on 50% of the test samples. These data were then compared with data on known explosives that gave similar test results. The lithium-lithium dithionite samples had a sensitivity equivalent to plastic bomb explosives. During the runs when no shock sensitivity was detected, the sample ignited upon impact.

Summary and Conclusions

ARC, DSC, and IR data indicate several parameters may alter the chemistry of Li/SO₂ cells. These include the spatial distribution of products on the carbon during adiabatic heating, the amount of electrolyte at the end of cell life, and the rates of heating or discharge.

Discharged cathodes still wet with electrolyte and known to contain only dithionite gave rise to IR bands at 1209, 1153, and 1125 cm⁻¹ upon being rapidly heated in a DSC. Slow heating did not give rise to these bands. Similar but more intense bands were found after heating cathodes depleted of electrolyte in the DSC. IR studies on cathodes taken from Li/SO₂ cells discharged at high temperatures or high rates showed different IR bands at 1240, 1165, etc., cm⁻¹, indicating the effects of heat in a pressur-

Optical Etch-Rate Monitoring Using Active Device Areas: Lateral Interference Effects

P. A. Heimann*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The technique of optical (laser) etch-rate monitoring is proving useful for integrated circuit manufacture and process development. This technique detects the change in film thickness during etching by monitoring the reflectance of the film on the integrated circuit wafer. When the reflectance is monitored over a region of the wafer containing both etched and unetched areas, the results are affected by lateral interference, which is interference between the light reflected from the different regions. This lateral interference has only a minor effect when less than 30% of the region being monitored is covered by an etch-resistant layer (typical for metal-type lithography levels), but it can cause severe distortions when a larger fraction of the region is covered by the resist. The effects of lateral interference have been examined using numerical simulations. The results are in good agreement with experimental etch-rate monitor signals from the etching of patterns with resist coverage ranging from 10 to 80% of the total area.

As integrated circuit dimensions become smaller and as the various conducting or insulating films used in these circuits become thinner, the tolerances on the etch processes for these films become more severe. The need for careful monitoring of these etch processes can be met by detecting changes in the optical reflectance of the film structures.

Originally (1, 2), the reflectance of a large area (greater than 2 mm²) was monitored while the entire area was being etched. The reflectance change was caused by the interference of light reflected from the interfaces between the various film layers ("vertical" interference), since this interference is affected by the changing thickness of the top etched layer. However, there are cases where it is undesirable or impossible to monitor the reflectance from a large area. First, a narrow beam is required, and the etch-machine operator must be able to place the beam only upon this large test area. Second, in step-and-repeat lithography, a separate reticle might be needed to produce this large area for etch-rate monitoring. Finally, etch-rate monitoring techniques have been described (3, 4) which require that the area being monitored contains both regions that are etched and regions that are covered with a photoresist or other etch-resistant layer. Therefore, it is necessary to understand what happens when this combination of etched and unetched regions is being monitored.

Whenever a patterned area is monitored, there is interference between the light reflected from the different regions (lateral interference) as well as the vertical interference described above. Lateral interference always occurs, unless the patterned wafer is imaged onto the detector. This will not happen with a simple laser system. The lateral interference is affected by the difference in height (layer thicknesses) between the etched and unetched regions. Since the light that is reflected from any one region will vary in both amplitude and phase during the etch, the resulting signal is a complicated function of the layer thicknesses, and modeling is needed to understand these signals.

Effects of Lateral Interference

As an example of the effects of lateral interference, consider the reflectance of a thermal oxide on silicon when the oxide is partially covered by resist (Fig. 1). The (complex) ratio r_e of reflected to incident amplitude of light from the etched area is given by (5)

$$r_e = \frac{r_1 + r_2 e^{-2i\delta_1}}{1 + r_1 r_2 e^{-2i\delta_1}} e^{-2i\delta_0} \quad [1]$$

where r_1 and r_2 are Fresnel reflection coefficients, computed from the oxide and silicon indexes of refraction, n_1 and n_2

* Electrochemical Society Active Member.

$$r_1 = \frac{1 - n_1}{1 + n_1}; r_2 = \frac{n_1 - n_2}{n_1 + n_2} \quad [2]$$

and δ_0 and δ_1 are phase shifts, given by

$$\delta_0 = 2\pi d_0/\lambda; \delta_1 = 2\pi n_1 d_1/\lambda \quad [3]$$

for light of wavelength λ , an oxide thickness d_1 , and a step height d_0 between the top surfaces of the oxide and the resist. The term $e^{-2i\delta_0}$ accounts for the phase change of the light as it travels down and back up the step-height distance.

If the light beam is confined only to the etched area, then the detected intensity is proportional to $|r_e|^2$, which, from Eq. [1], is equal to

$$|r_e|^2 = \frac{r_1^2 + r_2^2 + 2r_1 r_2 \cos(2\delta_1)}{1 + r_1^2 r_2^2 + 2r_1 r_2 \cos(2\delta_1)} \quad [4]$$

It can be shown that the detected intensity here is a periodic function of the oxide thickness d_1 , with a period of $\lambda/2n_1$. Note that this intensity is independent of the phase term $e^{-2i\delta_0}$ of Eq. [1]. Note also that the periodic function is not purely sinusoidal, although it can be shown that it approaches a sinusoid as n_1 approaches 1.

If the light is reflected from both etched and unetched areas, then lateral interference will cause the amplitudes, not the intensities, of the reflected light to be added together. If there is no resist erosion, then the ratio of reflected to incident amplitude of light from the unetched area will have a constant (complex) value r_u . The detected intensity I is then given by

$$I = I_0 |f_e r_e + f_u r_u|^2 \quad [5]$$

where I_0 is the incident intensity, and f_e and f_u are the

Fig. 1. Film structure partially covered by resist

etched and unetched fractions, respectively, of the total area. At this point, the algebra gets very complicated, since the amplitude and phase of r_e are oscillating, with different periods, as the oxide thickness d_i is changed. The detected intensity is no longer independent of the phase term, since the two complex reflectances are added algebraically. The resulting intensity is the sum of functions that oscillate at periods with $\lambda/2$, $\lambda/2n_i$, $(\lambda/2 + \lambda/2n_i)$, and $(\lambda/2 - \lambda/2n_i)$. This is very messy, and well suited to computer simulation (6). If there is resist erosion, then r_u is also a periodic function of resist thickness, and the resulting etch-rate monitor curves are even more complicated.

From this example, one probably gets the impression that lateral interference is undesirable. This is not necessarily so, especially for two cases of practical interest. When the etched area is a large fraction of the total area, which is typical for metal-type lithographic levels, the lateral interference causes only a minor distortion to the signal that would occur if only the etched area were being monitored, and therefore it can be ignored. Furthermore, the etch-rate monitor techniques described in Ref. (3) and (4) would not work at all without lateral interference.

Simulations and Experimental Results

For optical etch-rate monitoring of active device areas, there are two limiting cases of interest. Lithography levels such as metal and poly usually have most of the wafer area unmasked, so the optical etch-rate monitor signal for this type of level is similar to the signal for a large unpatterned area. Lithography levels such as window and polycon have only a small portion of the wafer unmasked, and therefore the signal is dominated by the resist-covered portion of the wafer. A third case of interest is the intermediate case which occurs in experimental structures such as meander patterns, in which roughly half of the wafer area is etched.

The calculated (6) etch-rate monitor curve (632.8 nm laser) for etching polysilicon on top of field oxide, with no resist present, is shown in Fig. 2. The signal is periodic, except for a slight increase in maximum reflectivity as the slightly absorbing polysilicon gets thinner. Figures 3a-3c show the calculated signals when 10, 30, and 50% of the polysilicon area is covered by resist, although it is unlikely that more than 30% of the area would be covered in a metal-type lithography level of an actual device. The solid curves correspond to the case where there is no resist erosion, and the dashed curves correspond to a resist that erodes one-fifth as fast as the polysilicon. One can see that the lateral interference does not make the curve unintelligible unless one approaches 50% coverage. In general, therefore, for a metal-type lithography levels, there is only a slight difference between the etch-rate

Fig. 2. Calculated etch-rate monitor curve for 3500Å polysilicon on top of 3200Å thermal oxide on silicon, for 632.8 nm light and 100% exposed area (no resist coverage). Arrow shows point of etching completely through the polysilicon layer.

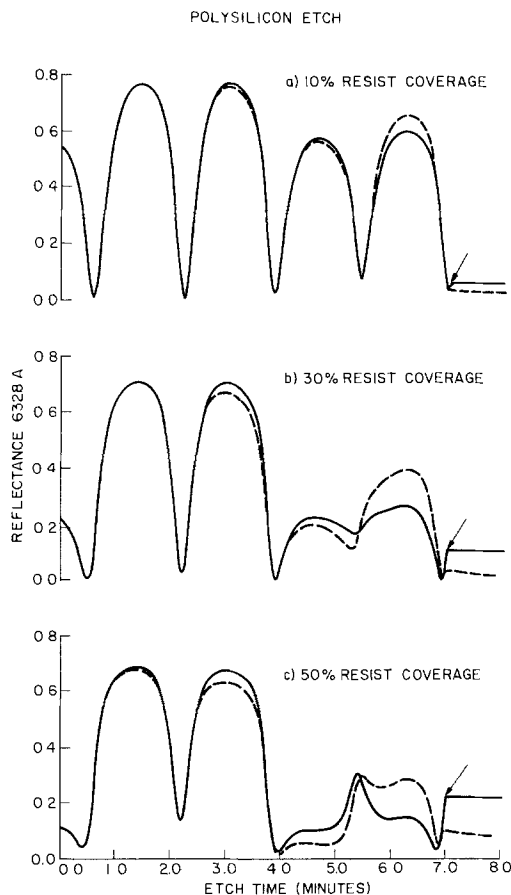

Fig. 3. Calculated etch-rate monitor curves, using 632.8 nm light, for polysilicon partially covered with resist. These fractions are typical for metal-type lithography levels. Solid curves are for no resist erosion, dashed curves are for 5:1 selectivity of polysilicon to resist. Arrows show points of etching completely through the polysilicon layer.

monitor curves from large test areas and from active device areas.

For window-type levels, the exposed area is only a small fraction, typically 1%, of the total area. Therefore, the reflectance change caused by etching these exposed areas is small, and can be masked by reflectance changes of the resist-covered areas. This effect can be minimized by selecting a light wavelength for which the resist is opaque, since then the resist reflectance will be small and constant. A 253.7 nm low pressure mercury arc is an excellent source of such light. One could also use a 632.8 nm laser and add a dye to the resist, provided that this dye does not affect the resist exposure or development, that it can withstand resist baking, and that it does not contaminate the devices below the resist. However, even when the effects of resist erosion are minimized, one is still plagued by a very low signal-to-noise ratio, since the overall reflection is quite low, and since windows, bonding pads, and "streets" between chips usually cover only about 1% of the total wafer area. Figure 4 shows simulations of window etch-rate monitor curves, using 253.7 nm light, when 95 or 99% of the area is covered with resist, along with the curve calculated for the case where there is no resist present. Again, the dashed lines indicate the curves for a 1:5 ratio of resist vs. oxide etch rates. Note that the maximum reflectance is only about 0.08, since most of the area is covered by an absorbing resist. An artifact of lateral interference is that there appears to be fewer periods of oscillation for the resist-covered samples than for the sample without resist. For instance, the dashed curve in Fig. 4b appears to have four and one-half periods, corresponding to 368 nm ($\lambda = 253.7$ nm, $n_1 = 1.55$) of oxide etched, when actually 1000 nm of oxide has been etched in this simulation. Therefore, it is impractical to determine the etch rate in real time of a window etch

Fig. 4. Calculated etch-rate monitor curves, using 253.7 nm light, for unpatterned oxide (a) and for oxide partially covered with resist. The unetched portions cover 95% (b) and 99% (c) of the wafer area. These fractions are typical for window-type lithography levels. Solid curves are for no resist erosion; dashed curves are for 5:1 selectivity of oxide to resist. Note expanded scale for reflectance. Arrows show points of etching completely through the oxide layer.

from the structure of these curves. However, if a slight overetch can be tolerated, then the end point of the window etch can be detected easily (provided that signal-to-noise problems can be overcome) by looking for a change in the periodicity of the signal.

Experimental curves for reflectance at 632.8 and 253.7 nm from an oxide on silicon, 80% covered by resist, are shown in Fig. 5. The structure of the reflectance at 632.8 nm is determined mainly by resist erosion, which is slow. The reflectance in the ultraviolet (253.7 nm) shows a complicated structure similar to that of Fig. 4. The overall drop in intensity is believed to be caused by the buildup during etching of an ultraviolet absorbing polymer on the view port of the reactive ion-etch machine. The oxide in this sample was 1800 nm thick, which corresponds to 22 periods of oscillation. As with the simulation, there appears to be far fewer periods in the experimental curve, due to distortions caused by lateral interference. The arrow in Fig. 5 indicates the point where the structure of the curve becomes much smoother. This is the end point of the oxide etch, which is evident from the curve after only a slight overetch.

One instance where the 50% coverage is beneficial is the interferometric technique of Sternheim *et al.* (3) for monitoring either the etching of opaque layers or the etching of trenches into the silicon substrate. In these cases, there is no vertical interference because there is only one reflecting interface at any lateral position. However, if only part of the area is being etched, one can make use of lateral interference to monitor the step height between etched and unetched areas. Figures 6a and 6b show the calculated reflectance for a case presented by Sternheim *et al.*: silicon, with half of the area covered by

Fig. 5. Experimental etch-rate monitor curves at 253.7 nm and 632.8 nm for etching 1800 nm oxide on silicon, with 80% of the area covered by resist.

an etch-resistant thermal oxide, so that lateral interference causes the reflectance to oscillate. In Fig. 6a, the oxide is assumed to have no erosion. Using arguments similar to those of the Effects of Lateral Interference section, one can show that here a curve with N periods corresponds to an etching depth d given by

$$d = N\lambda/2 \quad [6]$$

since the index of refraction of air or vacuum is 1.0. In Fig. 6a, we have 4.1 periods using 632.8 nm light, which corresponds to 1.3 μm etching. Figure 6b models the experimental data from Sternheim *et al.*, where the oxide erodes at one-fifth of the silicon etch rate. The ampli-

Fig. 6. Calculated etch-rate monitor curves using 632.8 nm light for etching silicon with 50% of the area covered by a masking oxide (4150Å thick). Dashed line corresponds to 1.30 μm etch depth.

tudes of the oscillation are no longer uniform. Furthermore, we now have 4.4 periods. If Eq. [6] is used for calculating the step height, one would get a value of $1.39 \mu\text{m}$, which is larger by 7% than the correct value. Sternheim *et al.* observed a 6% error for this case, with the error being in the same direction: the optical etch-rate monitor yielded a larger step than a stylus measurement. The structure of their etch-rate monitor signal [Fig. 5 of Ref. (3)] does not agree exactly with the calculated curve of Fig. 6b here. The model cannot predict the structure of the curve unless the masking oxide thickness is known precisely, but it can predict the error in step height as found by the etch-rate monitor. Figure 6c shows the calculated etch-rate monitor curve when the masking oxide is 500\AA thicker than in Fig. 6b. The structure of the curve again is different, but the $1.3 \mu\text{m}$ etch with the same erosion ratio of 1:5 still yields about 4.4 periods of oscillation. The calculated error in step height is not a simple function of oxide (or resist) erosion rate, but the calculated error is always less than 10% for erosion ratios of 1:5 or less, and always in the direction that the optical etch-rate monitor value will be too large.

Conclusions

Optical etch-rate monitor signals have been modeled for patterns that are usually found in integrated circuit manufacturing. For metal-type lithography levels, lateral interference causes a slight distortion in the shape of the etch-rate monitor curve, and may lead to a slight error in determining the etch rate. For meander-type patterns, the distortion can be serious enough to make the curves unintelligible. For window-type lithography levels, the etched area is usually too small to produce a useful etch-rate monitor signal, unless the signal from the etched

areas can be enhanced. Lateral interference can be employed for monitoring the etching of opaque or bulk materials, with a predicted error in depth value of less than about 10% for resist erosion at less than one-fifth of the film etch rate.

Acknowledgments

I would like to thank M. Feldman and A. D. White for many stimulating discussions about the lateral interference in various optical systems. The challenge of explaining experimental data supplied by R. J. Schutz and J. E. Olsen provided the inspiration and direction for this project. I would also like to thank J. M. Moran and H. J. Levinstein for their support and suggestions.

Drastic Changes in the Electrical Resistance of Gold-Doped Silicon Produced by a Hydrogen Plasma

A. Mogro-Campero,* R. P. Love, and R. Schubert¹

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

High resistivity silicon samples were prepared by gold doping and subjected to a hydrogen plasma for various times (0-4h) and temperatures (130°-450°C). Spreading resistance profiles show that the resistance decreases to values close to those of the original wafers with no gold doping up to a depth defined as the penetration depth. This behavior is consistent with the neutralization of the compensating property of gold in silicon. The derived effective diffusion coefficient $D = 9 \times 10^{-7} \exp(-0.45/kT) \text{ cm}^2\text{s}^{-1}$, with kT in electronvolts for the temperature range 130°-275°C, is in reasonable agreement with an extrapolation of the diffusion coefficient reported by others for tritium in silicon at 400°-500°C. The penetration depth seems to be related to the diffusion of hydrogen, primarily in atomic form. The implied high solubility of hydrogen in our samples ($\geq 10^{15} \text{ cm}^{-3}$) is probably determined by defects and impurities. The results of annealing experiments on plasma-treated samples are compatible with further diffusion of the neutralizing agent at the annealing temperatures. Reduced resistivities persist even after a 500°C anneal in nitrogen for 1h.

Analysis by deep-level transient spectroscopy (DLTS) has recently revealed that the concentration of the gold-related deep levels in silicon can be significantly reduced up to depths of several micrometers by exposing heated crystalline samples to a hydrogen plasma (1, 2). This paper reports on the first work on changes in resistance of gold-doped silicon samples due to exposure to hydrogen plasma. The probing depth of the DLTS technique is limited by avalanche breakdown in the silicon, whereas the depth limitation in resistance profiling is determined only by sample thickness. The changes in resistance we observe imply the neutralization of the compensating property of gold in silicon, and are consistent with obser-

vations of the reduction of the concentration of gold-related deep levels by DLTS (1, 2). Gold in silicon introduces both a donor and an acceptor deep level. When the concentration of gold becomes comparable to or greater than the shallow dopant concentration, the compensating action of the gold levels leads to drastic resistivity increases (3). Silicon wafers (n-type) had gold diffused from their back surfaces, and the resulting high resistivity samples were used in the experiments reported here. The samples were heated to various temperatures while being subjected to a hydrogen plasma for periods of 0-4h. Samples with an oxide cap and with an oxide and aluminum layer were also exposed. Spreading resistance profiles were used to measure the depths to which the neutralization of the compensating property of gold was present. The results are consistent with the diffusion of atomic hydrogen.

Procedure

The starting wafers were n-type CZ silicon, 4-10 Ω -cm, and orientation (111). Gold was evaporated onto the back of the 350 μ m thick samples, and diffused in nitrogen at 1000°C for 30 min. The solid solubility of gold in silicon at this temperature [10^{16} cm $^{-3}$ (3)] is about an order of magnitude higher than the shallow dopant (phosphorus) concentration ($\sim 10^{15}$ cm $^{-3}$) of the starting wafers. Figure 1 (curve a) shows that the resistivity of a gold-doped sample is much higher than that of the starting wafers. The resistivity gradient is consistent with a higher gold concentration near the surface, as observed also by others (4). In cases where samples were used with a thermally grown oxide layer, oxidation preceded gold diffusion; if an aluminum layer was evaporated on top of the oxide, the evaporation was performed after gold diffusion.

Samples were placed on the lower plate of a parallel-plate system, heated to a given temperature, and subjected to a hydrogen RF plasma (13.56 MHz and 100W) at 0.5 torr. The walls of the chamber are electrically grounded, and the lower plate with the sample is isolated and thus at a floating potential. Before removing the sample, the temperature was allowed to decrease to 80°C while the sample was still subjected to the plasma. A portion of the sample was angle lapped, and spreading resistance was measured vs. depth from the top silicon surface. No change in resistance profile was observed for a starting sample (prior to gold doping) subjected to a hydrogen plasma at 200°C for 1h.

Results and Discussion

Figure 1 (curves b and c) shows spreading resistance vs. depth for gold-doped samples which have been subjected to a hydrogen plasma for 1h at 200°C. We observe that the compensating property of gold has been largely neutralized in the first few micrometers from the surface, as shown by the decrease in resistance to values close to those of the starting wafers prior to gold doping. No evidence for neutralization was observed for a gold-doped sample subjected to the hydrogen ambient for 1h at 200°C, but with no RF power applied. Since curves b and c in Fig. 1 correspond to different portions of the same sample, the differences can be ascribed to experimental variability. The depth to which a substantial decrease in resistance persists is defined as x_p (penetration depth), and was evaluated graphically from the spreading resistance plots. The penetration depth was estimated by approximating the resistance curve with two straight line segments in the region of interest and finding their inter-

Fig. 1. Spreading resistance vs. depth; the bar indicates the range of resistance values of the starting wafers (prior to gold doping). Curve a: Gold-doped sample. Curve b: Gold-doped sample subjected to a hydrogen plasma at 200°C for 1h. Curve c: Another portion of the sample in b.

section. One line approximates the region of rapid rise in resistance, and the other the slower decrease in resistance at greater depth. For curves b and c of Fig. 1, the values of x_p are 7 and 9 μ m, respectively. Figure 2 shows that, for high temperatures and long exposure times, the penetration depth can only be determined as a lower limit value for the gold-doped samples used here because the region of high resistance values ends at depths ≥ 60 μ m.

Figure 3 shows the penetration depth vs. the square root of time for a constant temperature of 200°C. A linear relationship is consistent with a diffusion process if the diffusion coefficient is constant with depth. Within experimental variability, a linear relationship is observed at times ≥ 1 h.

It has been usually presumed that effects similar to those reported here after hydrogen plasma exposure, such as the neutralization of gold levels in silicon (1, 2) and resistivity changes in boron-doped silicon (5), are due to the diffusion of atomic hydrogen into the sample. However, unresolved questions about the actual incorporation depth of hydrogen in silicon (6-8) have kept this an open question. The high concentration of hydrogen residing near the surface may facilitate defect generation via local strain (8), and the particular defect distribution due to hydrogen bombardment (9) may also play a role in the neutralization observed. The relative importance of these mechanisms can be expected to be different in a sample with a substantial top layer of thermal oxide. A plasma-exposure experiment for 1h at 200°C was performed on a sample with 0.1 μ m of thermal oxide. The resulting spreading resistance profile was similar to those obtained from samples without the thick oxide layer. The diffusion coefficient of deuterium molecules in vitreous silica at 200°C is 8×10^{-9} cm 2 -s $^{-1}$ (10), which is sufficiently high to make the oxide appear as an ineffective barrier to hydrogen. The experiment is, therefore, consistent with hydrogen diffusion's being the primary agent responsible for the observed neutralization. Recent indirect evidence (11, 12) also points strongly toward hydrogen diffusion, particularly results showing the neutralization of gold levels by electrolytic doping (12), in which case the effects of particle bombardment are absent.

In another experiment, we subjected a gold-doped sample with 0.1 μ m of oxide and an additional 1 μ m of evaporated aluminum to the hydrogen plasma for 2h at 200°C. There was no effect on the resistance profile com-

Fig. 3. Penetration depth vs. square root of time for samples subjected to a hydrogen plasma at 200°C. Dashes above and below some data points indicate values obtained on separate portions of the same sample and serve to illustrate experimental variability. A finite penetration depth is observed even for $t = 0$ because of the cooling sequence. This artifact is most significant for short times. The line shows that within experimental variability, a linear relationship is approximately obeyed for times ≥ 1 h.

pared to a gold-doped sample which had not been exposed to plasma. The diffusion coefficient of hydrogen in the aluminum layer would have to be $\leq 10^{-13} \text{ cm}^2\text{-s}^{-1}$ for the $1 \mu\text{m}$ layer to be an effective barrier. The reported values for the diffusion coefficient of hydrogen in aluminum are a strong function of purity (13, 14) and are spread over many orders of magnitude when extrapolated to the lower temperatures of our experiments. Although the starting material used in the evaporator is highly pure aluminum, we have not analyzed the purity of the deposited aluminum layer. However, the effective low diffusivity implied by our experiment may be related to the oxide layer which will inevitably form on the aluminum after exposure to air. The extrapolated diffusivity of atomic hydrogen in sapphire (15) is extremely low, so that a thin layer of, say, 10 nm would be sufficient to act as a barrier for the hydrogen at the temperature of our experiment.

In order to obtain diffusion coefficients D from the observed penetration depths x_p , we assume a constant surface concentration solution to the diffusion equation (16), from which we use the approximate expression $x_p = 5.4 (Dt)^{1/2}$, where t is time. The calculated diffusion coefficient vs. temperature is shown in Fig. 4. In terms of the simple expression $D = D_0 \exp(-E_a/kT)$, the activation energy E_a seems to increase at the higher temperatures, although we do not have sufficient data to establish this trend. By linear least squares fitting, we obtain $D = 9 \times 10^{-7} \exp(-0.45/kT) \text{ cm}^2\text{-s}^{-1}$ with kT in electronvolts. Two experimental points obtained in a similar manner by others from the neutralization of gold levels by a hydrogen plasma using deep level transient spectroscopy (17) are also shown in Fig. 4. They are in reasonable agreement with our data. Extrapolations from direct measurements of atomic hydrogen diffusion in silicon at 1100°-1200°C (18) and tritium diffusion in silicon at 400°-500°C

Fig. 4. Diffusion coefficient (derived from penetration depth) vs. temperature. Solid circles and lower limits are from the present work. The data point for 200°C is an average of five independent measurements. The solid line is a least squares linear fit to our data points. The open circles are data reported by others (17). The dashed line and dash-dot line are for atomic hydrogen diffusion (18) and tritium diffusion (19) in silicon.

(19) are also shown in Fig. 4. The activation energies obtained in those studies were 0.48 and 0.56 eV, respectively.

An important matter to consider is the relative roles of molecular or atomic diffusion in a given experiment. Three states of hydrogen in silicon have been suggested (20): atomic, molecular, and one in which hydrogen bonds with a silicon atom. When considering other impurities and defects, other combinations such as a gold-hydrogen association suggested by our experiment will probably come into play. The gold density being neutralized in our experiments is $\geq 10^{15} \text{ cm}^{-3}$ (the doping density before gold doping). The hydrogen solubility data at 1 atm (18) extrapolated to the temperature of our measurements (say, 250°C) is $2 \times 10^3 \text{ cm}^{-3}$. We believe this discrepancy is an indication of the importance of defects and impurities in our case.

Figure 5 shows the effect of isochromal annealing on plasma-treated samples. In general, resistance increases near the surface and decreases at depths greater than the original penetration depth with increasing temperature. This is consistent with a diffusion of the neutralizing agent both toward the surface and into the bulk. The somewhat irregular behavior, such as for the 450°C anneal, may be a measure of experimental variability.

Summary and Conclusions

Samples of high resistivity silicon prepared by gold doping were subjected to hydrogen plasma at various temperatures and times. The resistance is found to decrease to values close to those of the original wafers with no gold doping for a depth (called the penetration depth) which varies approximately as the square root of time. Results from samples covered with thermally grown oxide and with an additional aluminum layer, as well as indications from similar work by others using deep level transient spectroscopy, point to hydrogen diffusion as the mechanism most likely responsible for the observed depths of neutralization. Over the temperature range of 130°-275°C, we obtain $D = 9 \times 10^{-7} \exp(-0.45/kT) \text{ cm}^2\text{-s}^{-1}$,

Fig. 5. Spreading resistance vs. depth. The bar indicates the range of resistance values for the starting wafers. All curves correspond to gold-doped samples. Curve a: No plasma exposure, no annealing treatment. Curve b: Exposed to a hydrogen plasma for 1h at 250°C. Curves c-f: Treated as sample in curve b, and then annealed in nitrogen for 1h at 300° c, 400° d, 450° e, and 500° f.

with kT in electronvolts. The activation energy is close to that obtained for atomic hydrogen diffusion in silicon (18) at 1100°-1200°C (0.48 eV) and to that reported for tritium diffusion in silicon (19) at 400°-500°C (0.56 eV). The activation energy for diffusion of molecular hydrogen in silicon has been estimated as 2.7 eV (20). The absolute values of diffusivity in the temperature range of our experiments can be compared with extrapolations of the higher temperature data. The extrapolation of atomic hydrogen (18) gives values a few orders of magnitude higher than ours, but the extrapolation of the tritium data results in comparable values. Extrapolation of solubility data for hydrogen in silicon (18) gives values which are significantly lower than those which our results imply. We take this as an indication that in our case solubility is dominated by defects and impurities. In conclusion, we believe that the neutralization of gold we observe is related to the diffusion of hydrogen, in which the atomic species is most likely dominant, and that the consequent effective diffusion coefficient and solubility are influenced by defects and impurities which trap hydrogen.

Annealing of samples after plasma exposure shows that the neutralizing effect is diminished near the surface, but increased at depths greater than the original penetration depth with increasing temperature, which is consistent with diffusion of the neutralizing agent in both directions.

The sample does not recover the resistivity profile which was present before plasma exposure even after an anneal of 500°C for 1h.

Ion Beam-Assisted Etching of Aluminum with Chlorine

L. Y. Tsou¹

AT&T Technologies, Incorporated, Princeton, New Jersey 08540

ABSTRACT

Ion beam-assisted etching of aluminum, in which an inert gas ion beam and a reactive gas are simultaneously applied to a substrate, was investigated for its fine line etching capability. As a result of the collimated nature of the ion beam, extremely high resolution, anisotropic etching of aluminum samples patterned with trilevel photoresist was demonstrated. Etch rates of 2000 Å/min were routinely achieved in this ion beam-assisted etching mode. In addition, etching behavior as a function of ion energy, ion flux, and reactive gas intensity was also examined.

Plasma etching and, in particular, reactive ion etching are essential to the fine line pattern transfer in current fine line semiconductor processes (1). The directionality of ions through the plasma sheath is responsible for the anisotropic profile of the etch. This ion-enhanced gas-surface interaction plays an important role in the etching process. However, it is difficult to control the behavior of the ion, its energy, or its intensity in the plasma.

On the other hand, the ion energy, current density, and the direction of the ion can be independently controlled in ion milling, in which an inert gas ion beam is employed to physically sputter off the unmasked material. The collimated ion beam has extremely high resolution. Feature sizes as small as 100 Å have been produced (2). However, the low etch rate and the lack of selectivity for different materials limit its application.

The replacement of the inert gas with a reactive gas in a conventional ion milling machine, reactive ion beam etching (RIBE) (3-6), has been recently reported to be able to enhance the etch rate and selectivity due to the chemical nature of the reactive ion, while it still preserves the inherent anisotropy. Moreover, the independent control of the process parameters will help to elucidate the basic mechanism and kinetics of the etching, and will be useful to our understanding of the complicated plasma etching process.

In another approach, a separate supply of reactive gas coupled with an inert gas ion beam (7) has an etching behavior similar to RIBE, while the corrosive attack of the ion gun is minimized. Furthermore, the reactive species and inert gas can be independently controlled in this arrangement. This setup (8) was employed to quantitatively illustrate the role that ions play in plasma etching. Here, we report the results of aluminum etching in this ion beam-assisted etching mode (IBAE). Etch rate as a function of ion flux, ion energy, and chlorine pressure was extensively investigated. The anisotropic wall profile and higher etch rate demonstrates directly that etching is enhanced by the ion bombardment. The independent control of the etching parameters, as opposed to the process parameters in the plasma etching, simplifies the interpretation of the experiment data, and quantitative information about the gas-surface interaction is derived.

Experimental

The apparatus setup is schematically shown in Fig. 1. A hot filament ion gun with permanent magnets, manufactured by Ion Tech, Incorporated, was employed as the ion beam source. This 2.5 cm diam source is capable of delivering the beam current density up to 1 mA/cm² at 500 eV. Inert gas was injected directly into the gun. The vacuum chamber equipped with a 6 in. diffusion pump and a water-cooled baffle could be pumped down to 5×10^{-7} torr. The pressure in the main chamber was 1×10^{-4} torr when a discharge was maintained with the xenon flow of 1 sccm. Both the inert gas and the reactive gas were regulated through the mass flow controllers, and the Cl₂ pressure measurement was calibrated with an MKS manometer. The beam current was measured by a Faraday cup

¹ Present address: Philips Laboratories, Briarcliff Manor, New York 10510.

that could be moved out of the way during etching. The sample was placed on a water-cooled holder, which was 10 cm from the ion extraction grid, and was electrically grounded in this study. Low energy electrons were provided by a tungsten filament to neutralize the charge on the substrate.

Results and Discussion

Etching profile.—Anisotropic etching was consistently demonstrated in this study. This indicates that the lateral etch rate of aluminum by Cl₂ alone is very slow and the vertical etching is enhanced by the directional ion beam. It has been reported (9) that Cl₂ could spontaneously react with pure aluminum at a rate independent of ion bombardment. However, anisotropic etching can also be accomplished if the sidewall of the etched feature is passivated to suppress lateral reaction (10). Since the background pressure of the system was about 1×10^{-6} torr, the rate of oxide formation was less than one monolayer per second. In this study, as the removal rate of aluminum was as high as 20 monolayers per second, the observed anisotropic etching cannot be simply described as the result of sidewall passivation by the oxide. It is conceivable that the photoresist species sputtered by the ion beam might protect the sidewall against lateral etching as well. In a separate RIE study of polysilicon with Cl₂ plasma, we found that it was more difficult to achieve an anisotropic wall profile for the wafer patterned with SiO₂ mask than that with the photoresist mask.

An SEM micrograph of a typical etched sample with 1 μm thick aluminum patterned with HPR photoresists is shown in Fig. 2. The linewidth loss measured by the Vicker's image shearing microscope is about 0.9 μm due to the erosion of the round-shaped photoresist. The high

Fig. 1. Schematic diagram of the IBAE machine

Fig. 2. SEM cross section of the etched aluminum tester patterned with single-layer resist.

resolution capability of the directed ion beam is illustrated in Fig. 3, where an aluminum sample patterned with trilevel resist was etched by IBAE. The structure consists of a 0.75 μm wide line and space with 1.5 μm thick resist on top of 1 μm thick aluminum. There is no measurable linewidth loss after etching through this hard-baked, planarizing photoresist.

Effect of reactive gas.—At a xenon ion energy of 500 eV and the beam current density of 0.75 mA/cm², the aluminum etch rate was studied as a function of Cl₂ pressure. A strong atomic aluminum optical emission line, 396 nm or 309 nm, was monitored during the run. As in reactive ion etching, this time evolution curve determines the induction period to clear the native oxide and the end point of aluminum etching. Figure 4 shows the aluminum etch rate at various Cl₂ background pressures. Etch rates up to 2000 Å/min were obtained at a Cl₂ pressure of 5 × 10⁻⁴ torr. The ion current density monitored by the Faraday cup was only increased by 10% after that amount of Cl₂ was introduced into the system, indicating some backstreaming of Cl₂ into the ion source. Pressures above this limit resulted in an unstable ion beam. A localized high flux of chlorine gas was obtained by supplying the gas through a 0.03 cm diam nozzle about 2.5 cm above the wafer at a 45° angle, while a low background pressure was still maintained in the chamber. Figure 5 illustrates the etch rate vs. gas flow through the nozzle. Etch rates of 4000 Å/min were demonstrated in this configuration. This indicates that the supply of the reactive gas is a rate-

Fig. 3. SEM cross section of the etched aluminum tester patterned with trilevel resist.

Fig. 4. Aluminum etch rate vs. chlorine pressure

determining step in ion beam-assisted etching of aluminum.

Effect of the ion beam.—The effect of the ion current density on etching was investigated with a fixed ion energy of 500 eV and a constant Cl₂ pressure of 4 × 10⁻⁴ torr. From the time evolution curve of Al optical emission, the total etch time can be divided into two parts, the induction time for native oxide etch and the real etch time for pure aluminum. Since the major mechanism to clear the oxide is by physical sputtering, it was not surprising to find that the induction time was increased as the ion density was decreased. However, the real etch rate for pure aluminum was nearly independent of the current density in the range of 0.40-0.80 mA/cm². (Note that this current

Fig. 5. Aluminum etch rate vs. chlorine flow through nozzle

density corresponds to an ion impact rate of 2-4 ions per aluminum atom per second.)

Etch rate dependence on ion energy in the range of 300-500 eV was measured at a current density of 0.40 mA/cm² and a Cl₂ pressure of 4×10^{-4} torr. Again it is interesting to observe that the etch rate of pure aluminum is insensitive to ion energy in this study. In addition, the etch rate of aluminum assisted by an argon ion is similar to that assisted by a xenon ion in our typical operating condition.

It is well established (11) in the nonreactive ion sputtering that the sputtering rate increases with ion energy initially and then reaches a plateau around 1-5 keV. A recent report (12) on the reactive ion beam etching of aluminum showed that the etch rate increases rapidly with energy in the range of 300-600 eV and starts reaching a plateau after 600 eV. Our observation that etch rate is a weak function of ion energy from 300 to 500 eV in the ion-assisted etching of aluminum may imply that 300 eV is in the plateau region of the sputtering yield curve. Future investigation to extend the ion beam capability to the lower energy side will provide more information.

Reaction probability.—The composition of the etching species in the IBAE configuration can be accurately measured. Considered in this study are the flux of the xenon ion and chlorine molecule. The actual etch rate can be obtained from the emission intensity-time curve. For an ion energy of 500 eV, a current density of 0.4 mA/cm², and a Cl₂ pressure of 4×10^{-4} torr, the aluminum removal rate is 12 monolayers per second. While in the absence of the reactive gas, Cl₂, the physical sputtering yield was measured to be 0.5 atom/ion. From the Cl₂ pressure which was measured by a capacitance manometer with an accuracy of $\pm 5 \times 10^{-5}$ torr, we can estimate the collision rate between Cl₂ and aluminum substrate, and subsequently derive the reaction probability for Al₂Cl₆ formation. The result is (23 \pm 3)% in this IBAE study. Similar value is estimated from Ref. (9), in which Cl₂ flux was low (1/20 of that in this work), but the rate was independent of the ion bombardment energy. However, it was reported recently (13) that without ion bombardment the reaction probability in the same low flux condition was only a few percent. The discrepancy among these data warrants the need of further investigation.

Conclusion

An inert gas ion beam coupled with a reactive gas, Cl₂, was applied to investigate its etching behavior on pat-

terned aluminum. Extremely high resolution, anisotropic etching of the aluminum patterned with trilevel resist was accomplished. An etch rate of 2000 Å/min has been routinely achieved. A high etch rate, 4000 Å/min, was demonstrated when a nozzle jet was employed to supply the reactive gas. As a result of the collimated nature of the ion beam, features with a high aspect ratio (0.75 μ m wide, 2.5 μ m deep) were etched.

The etch rate of aluminum was found to be independent of the ion energy and current density, in the region of 300-500 eV and 0.4-0.8 mA/cm², respectively. However, it was shown that the aluminum etch rate was increased by increasing the Cl₂ pressure. Finally, the reaction probability for AlCl₃ formation was estimated to be 23%.

The Composition and Properties of PECVD Silicon Oxide Films

P. Pan,* L. A. Nesbit, R. W. Douse, and R. T. Gleason

IBM General Technology Division, Essex Junction, Vermont 05452

ABSTRACT

Plasma-enhanced chemical vapor-deposited (PECVD) silicon oxide films were prepared by the reaction of SiH₄ and O₂. The deposition rate as a function of O₂ flow rate, RF power, and total pressure was obtained. The film composition and properties for samples deposited with different O₂ flow rates were measured. Si-rich films were obtained for the deposition with O₂:SiH₄ flow rate ratio of < 3.5. The refractive index increased and film thickness decreased after samples were annealed. Etch rate in a solution containing ten parts of ammonium fluoride and one part hydrofluoric acid (10:1 BHF) and refractive index decreased by increasing the Si:O ratio in samples. The SiH_n bonds were found for all Si-rich films. Both Si-OH and H-OH bonds were observed for all samples. The phases Si, SiO₂, and SiO_x were found for Si-rich films. At a constant field, the film conductivity increased with increasing Si:O ratio. Evidence of electron traps was observed for PECVD SiO₂ and Si-rich Si-O films.

The PECVD technique is widely used in the semiconductor industry for the deposition of inorganic thin films (1). The advantages of this process are good step coverage and low deposition temperature. The substrate tempera-

ture, RF power, ratio of reactant gases, and total gas pressure are the critical deposition parameters which will affect the composition and properties of the PECVD film (2, 3).

PECVD silicon oxide can be produced by the reaction of silane gas SiH₄ with an oxidizer, such as O₂, N₂O, CO₂,

* Electrochemical Society Active Member.

etc. (4, 5). The ratio of SiH_4 to oxidizer that forms a stoichiometric PECVD SiO_2 film depends on the dissociation energy of the oxidizer gas. The preparation and properties of stoichiometric PECVD SiO_2 films have been reported by many authors (4-9). The physical properties of slightly off-stoichiometric PECVD SiO_x films ($1.5 < x < 2$) also have been reported (10). The deposition and properties of PECVD SiO_2 and Si-rich SiO_x films, using SiH_4 and O_2 as reactant gases, have not been reported.

Recently, the Si-rich oxide film (*i.e.*, the so-called semi-insulating polycrystalline silicon, SIPOS), which was deposited by the conventional chemical vapor deposition (CVD) or low pressure chemical vapor deposition (LPCVD) methods, has been reported to be an excellent material for the passivation of high field transistors (10). The formation and properties of CVD or LPCVD Si-rich oxide have also been studied intensively by many authors (11-14).

The purpose of our work was to study and understand the relationship between the film composition and properties of PECVD SiO_2 and Si-rich PECVD SiO_x films ($0.48 < x < 2$) as a function of deposition parameters. In this paper, the deposition rate as a function of O_2 flow rate, RF power, and total pressure is reported. The film composition and physical and electrical properties for samples deposited with different O_2 flow rates were measured and related to the Si:O ratio in films.

Experimental

PECVD silicon oxide film was deposited in a LFE Model 301 reactor. The system was described in detail in Ref. (3). The reactant gases were SiH_4 (1.5% in Ar) and O_2 (1% in Ar). The RF frequency was 13.562 MHz. After the pressure was reduced to about 20 mtorr, the chamber was backfilled with reactant gases. The SiH_4 gas flow rate was maintained at 0.3 sccm, and samples with different compositions were obtained by varying the O_2 flow rate. Except for the results of deposition rate as a function of deposition conditions, all data reported in this paper are for samples deposited at a temperature of 350°C, with a power of 50W and a total pressure of 1.5 torr.

The Si, O, N, and C concentrations in the PECVD samples were analyzed using an electron microprobe and Auger electron spectroscopy (AES). An ~800 nm thick film was used for electron microprobe analysis. A thick (~700 nm) thermal SiO_2 film was used as the standard to determine the Si and O concentrations. A thin layer of carbon was deposited simultaneously on the standard and the unknown to reduce charging effects. Both the standard and the unknown were peaked during all measurements. The Si K_α and O K_α x-ray intensities were observed for 40s counting time. By using the MAGIC IV computer program (15), the average row counts for at least six points were corrected and converted into atomic percent. A scanning Auger microscope was used to analyze the ~50 nm thick films. The primary electron-beam voltage was 5 kV, and the beam current was 1 μA . Thin thermal SiO_2 , LPCVD Si_3N_4 ($n = 2.01$), and evaporated carbon films were used as the standards for determining the Si, O, N, and C concentrations, respectively.

For thick samples of about 800 nm deposited on bare Si, the infrared (IR) spectra were taken on a Fourier transform infrared (FTIR) spectrometer. For all measurements, the total number of scans was set at 200, and the resolution was 4 cm^{-1} for all measurements.

The refractive index and the relative film thickness, before and after annealing, were measured using an automatic ellipsometer ($\lambda = 632.8 \text{ nm}$). The etch rates in 10:1 BHF at room temperature were measured for both the as-deposited and annealed samples. In this study, all annealing was done at 1000°C in N_2 for 30 min. The film density was obtained by measuring the weight:volume ratio for a film about 800 nm thick. This film thickness was determined by using a Talystep.

Samples for transmission electron microscope (TEM) studies were prepared by etching from the back side of the silicon wafer with a nitric-hydrofluoric acid solution.

The samples were then examined with the electron beam normal to the surface plane with a TEM operated at 120 kV.

Integrated Auger spectra and x-ray photoelectron spectroscopy (XPS) data were taken in a double-pass CMA. The primary electron-beam voltage was 5 kV and the beam current was 0.5 μA . The x-ray used was the Mg K_α line of 1253.6 eV.

I-V data were measured by using a picoampere meter. Current was measured 3s after a step voltage was applied. A voltage source with linear ramping rate of 20 V/s was used for the measurements of dielectric breakdown voltage, which was defined as the applied voltage that induced a current density of $5 \times 10^{-4} \text{ A/cm}^2$ through the film.

Results and Discussion

As shown in Fig. 1, the deposition rate increased rapidly from 17.5 to 38.5 nm/min as O_2 flow rate (R) increased from 0.5 to 1.25 sccm. It also increased slowly for $R > 1.25$ sccm. This can be explained by the strong chemical reaction between Si and O radicals. The increase in O radical concentration will enhance reaction at the surface and/or in the plasma due to the formation of Si-O bonds. When the deposited film is close to the stoichiometry of SiO_2 , the enhancement of this reaction at the surface will be reduced and the deposition rate will tend to level off. The data in Fig. 1 and the film composition as a function of O_2 flow rate (Fig. 3) support this explanation. The dependence of deposition rate on RF power and total pressure is shown in Fig. 2. The increase of RF power increased the electron temperature, which results in increased concentrations of reactant radicals and in turn increases the deposition rate. The increase in total pressure increases the concentrations of reactant gases, but decreases the electron temperature. The deposition rate increased with increasing total pressure, indicating that the concentrations of reactant radicals increased with increasing total pressure. The deviation of film thickness across the wafer was found to be within 8% for samples deposited with a RF power of 50W and a total pressure of 1.5 torr. For other deposition conditions, the deviation was found to be within 15%. From data shown in Fig. 1 and Fig. 2, it is clear that the desired deposition rate can be obtained by using a proper combination of O_2 flow rate, RF power, and total pressure.

Fig. 1. Deposition rate of PECVD silicon oxide as a function of O_2 gas flow rate.

Fig. 2. Deposition rate of PECVD silicon oxide as a function of RF power and total pressure.

The Si and O concentrations in the layer as a function of O_2 gas flow rate (R) are plotted in Fig. 3. The 2σ deviation of the data is ~ 0.4 atom percent (a/o) for oxygen and ~ 0.7 a/o for silicon. Within experimental error, the Si and O concentrations for both as-deposited and annealed samples were found to be identical. From Fig. 3, it is observed that the Si and O concentrations change significantly for $R < 1$ sccm ($O_2:SiH_4 < 3.3$), and approach the stoichiometric values (Si = 33.3 a/o, O = 66.7 a/o) for $R > 1$ sccm. This indicates that a stoichiometric PECVD SiO_2 film can be obtained by using SiH_4 and O_2 as reactant gases. Films deposited on Al-coated wafers were also analyzed. No evidence of Al signal was detected, implying that the penetrating depth of the incident beam is less than the film thickness. This evidence also indicates that the observed Si concentration resulted entirely from deposited mate-

Fig. 3. Si and O atomic percent as a function of the O_2 gas flow rate (R) for both as-deposited and annealed PECVD silicon oxide films.

rial. Because of high background noise, nitrogen was not detectable in any of the samples by electron microprobe analysis.

Auger analysis for thin films, which were deposited under the same conditions as those for thick films, showed that the nitrogen and carbon concentrations are ~ 1 a/o for all Si-rich samples and are undetectable (< 0.1 a/o) in the PECVD SiO_2 samples. Because the chemical reaction between Si and O is stronger than that between Si and N or Si and C, the observation of less contamination in the stoichiometric SiO_2 film, which was deposited with a high O_2 gas flow rate, is expected. Auger depth profiling data for thin samples showed that the film composition as a function of depth is uniform. The oxygen concentration obtained by Auger analysis agrees with that obtained by electron microprobe analysis within 1.7 a/o.

The IR transmission spectra, ranging from 400 to 4000 cm^{-1} , were obtained for all samples. Typical spectra for a Si-rich sample (Si:O = 1.19) are shown in Fig. 4. The O-H ($3600-3400$ cm^{-1}), Si-H ($2250-2120$ cm^{-1}), and Si-O (~ 1053 cm^{-1}) bonds were clearly observed in the as-deposited sample. No Si-H and O-H bonds were found in the annealed sample. The wave number of the main Si-O stretching bond was found to be ~ 1080 cm^{-1} for the PECVD SiO_2 film, and between 1045 and 1060 cm^{-1} for the PECVD Si-rich films. After annealing, the wave number of the Si-O bond was found to increase to ~ 1095 cm^{-1} for all samples. For PECVD SiO_2 , the other Si-O stretching bond was found to decrease from 820 to 810 cm^{-1} and the symmetric O-Si-O bond was found to increase from 450 to 465 cm^{-1} after annealing. The full width at half maximum (FWHM) of the Si-O stretching bond was found to be ~ 100 cm^{-1} for PECVD SiO_2 , and between 120 and 150 cm^{-1} for the PECVD Si-rich sample. After annealing, the FWHM value was reduced by about 10-30 cm^{-1} . Compared with results for thermal SiO_2 (16) and CVD Si-rich SiO_x (17), we found that the wave number of Si-O stretching bonds was lower, the FWHM value was larger, and the change in both wave number and FWHM value upon annealing was larger for PECVD Si-O films. The change in degree of oxygen deficiency, film density, and/or strain in materials will result in a shift in IR stretching bonds. The presence of larger amounts of hydrogen in PECVD oxide films will result in oxygen deficiency and lower film density. The wave number and FWHM values before and after annealing are listed in Table I.

Typical IR spectra from 1700 to 4000 cm^{-1} for three Si-rich samples of different Si:O ratios are shown in Fig. 5. Two peaks in the Si-H stretching region are clearly observed. The high wave number peak is at 2250 cm^{-1} and

^a Annealed films.

is attributed to the Si-H group in amorphous SiO₂ (a-SiO₂). This peak is close to the SiH₂ peak with two oxygens bonded to the Si atom as reported by Lucovsky (18). The low wave number peak was found to shift from 2150 to 2120 cm⁻¹ as the Si:O ratio increased from 0.8 to 2.05. This peak is attributed to the Si-H group in amorphous Si (a-Si). Compared to the results of Brodsky *et al.* (19) on a-Si deposited by the glow discharge method one finds that the candidates attributed to these peaks are SiH₃ and SiH₂. The ratio of the intensity of the low wave number peak to that of the high wave number peak was found to increase from 0.6 to 1.2 with increasing Si:O ratio. These results also suggest that the high and low wave number peak should be attributed to the Si-H group in a-SiO₂ and a-Si, respectively. This observation of SiH_x ($x = 2$ or 3) in the deposited films suggests the deposition of major radicals in SiH₄ plasma (SiH₃ or SiH₂). Two peaks were also clearly observed in the O-H region. Following the results of Pliskin (16), the peak at 3640 cm⁻¹ was attributed to the Si-OH bond and the peak at 3400 cm⁻¹ was attributed to H-OH. The intensities per micrometer of the Si-H and O-H bonds for all samples are shown in Fig. 6. The relative concentrations of Si-H and O-H bonds from sample to sample can be obtained by comparing the relative optical densities.

As reported by Brodsky *et al.* (19), the concentration of Si-H bonds (N) can be written as

$$N = \frac{(1 + 2\epsilon_m^2)(\epsilon_m)^{1/2}}{9\epsilon_m} \cdot \frac{N_A}{(\Gamma/\xi)} \int \frac{\alpha(\omega)}{\omega} d\omega \quad [1]$$

where ϵ_m is the dielectric constant of the matrix, N_A is Avogadro's number, Γ is the absorption strength of the Si-H bond (cm²/m-mol) and ξ is the number of SiH_x bonds contributing to the absorption process. The value of (Γ/ξ) was reported (19) to be nearly equal to 3.5 for all SiH_x groups. By using Eq. [1], the Si-H concentrations in the a-SiO₂ and a-Si matrices were found to be about 3.4×10^{21} and 7×10^{21} cm⁻³, respectively, for the sample with Si:O

Fig. 5. IR transmission spectra from 1700 to 4000 cm⁻¹ for three samples with different film compositions.

Fig. 6. Intensity per micrometer of Si-H (a-SiO₂), Si-H (a-Si), Si-OH, and H-OH peaks vs. the Si:O ratio for PECVD oxide films.

= 2.1. These values were found to be at least 100 times larger than that for CVD Si-rich oxides reported by Hartstein *et al.* (20).

Pliskin (16) showed that the concentrations of Si-OH and H-OH bonds can be written as

$$W = (-14A + 89B)(2.2/\rho) \quad [2]$$

$$S = (179A - 41B)(2.2/\rho) \quad [3]$$

where W is the weight of H-OH (including H₂O in the easily removed silanol) and S is the atom percent of OH as silanol. A and B are the optical density per micrometer for the Si-OH and H-OH bonds, respectively, and ρ is the film density. From Eq. [2] and [3], and the measured film density listed in Table II, the concentrations of H-OH and Si-OH bonds for the sample with Si:O = 1.19 were found to be 9.8×10^{19} and 4.9×10^{20} cm⁻³, respectively. These values also were found to be about 100 times larger than that for the CVD Si-rich oxide (20). An increase in deposition temperature or RF power will reduce the amount of hydrogen in as-deposited films.

Comparing the IR transmission spectra for different film thickness, one finds that Si-H and O-H bonds were clearly observed in thick samples (~800 nm), but were not detected in thin (50 nm) samples. Since the intensities of the Si-H and O-H bonds depend on the film thickness, the Si-H and O-H bonds must exist in the bulk of the film and are not a property of the film surface.

^a Annealed films.

Fig. 7. Refractive index, before and after annealing, and relative film thickness (d_A/d) as a function of Si:O ratios.

The refractive index (n) of as-deposited and annealed samples and the relative film thickness (d_A/d) as a function of the Si:O ratio are shown in Fig. 7. The quantities d and d_A are the film thicknesses before and after annealing, respectively. From this figure, it is clear that d_A/d decreases with increasing Si:O ratio. Because contamination in the Si-rich films is only 1.0 a/o, and the refractive index of the CVD Si_3N_4 film is only 2.01, the observation of a higher n value for higher Si:O ratios is believed to be due mainly to the presence of excess Si in the Si-rich samples. The refractive index was also found to increase after annealing. The increase in film density after annealing could be responsible for this result. The behavior of the denser film having a higher refractive index was also reported in the literature (5, 16).

Comparing the difference in refractive index (Δn) before and after annealing, one finds that Δn of the Si-rich sample is larger than that of PECVD SiO_2 . The d_A/d values for all samples were found to be less than 0.93, which also implies a densifying effect after annealing. The observation of a larger Δn value and smaller d_A/d value for Si-rich samples strongly suggests that the change in film density before and after annealing for the Si-rich film is larger than that of the PECVD SiO_2 film. The presence of higher amounts of hydrogen discussed earlier in the as-deposited films is believed to be one of the causes of this behavior.

The etch rate as a function of Si:O ratio for as-deposited and as-annealed samples is shown in Fig. 8. The etch rate of thermal SiO_2 and annealed PECVD SiO_2 films are comparable, and the etch rate for the unannealed PECVD SiO_2 film is about 1.7 times that of thermal SiO_2 . This result indicates that the film density plays an important role in etch rate; the denser the film, the lower the etch rate. The presence of weaker Si-H bonds is another reason for the higher etch rate for the as-deposited samples. Due to the presence of excess Si in the Si-rich film, a decrease in etch rate with increasing Si:O ratio for the annealed samples is expected. The random fluctuation of the etch rate with respect to the Si:O ratio for the as-deposited films is believed to be due to the complex effects of film density and film composition.

SEM pictures for the etched surfaces of six samples are shown in Fig. 9. All of the pictures were taken after the samples had been dipped in 10:1 BHF for 1 min. It is clear from this figure that the etched surface of the unannealed Si-rich sample is much rougher than the others, possibly as a result of porosity. No roughness was

Fig. 8. Etch rate for as-deposited and for annealed samples vs. Si:O ratio.

observed on the surface of the PECVD SiO_2 films (Si:O = 0.88), and only slight roughness was found on the annealed Si-rich samples.

Two as-deposited Si-rich films of differing oxygen concentrations (~ 11.8 and 36.4 a/o) were analyzed via TEM. The film containing ~ 36.4 a/o oxygen had an electron diffraction pattern similar to, but more diffuse than, that of thermal SiO_2 , indicating a fundamental structural difference between the Si-rich film and thermal SiO_2 . By imaging a portion of the first diffuse diffraction ring near the Si (111) position, small precipitates about 1 nm in diameter were observed in dark field. Because the AES and XPS data show the presence of excess Si in this sample, the precipitates are probably clusters of amorphous Si. No such clusters or precipitates were observed in thermal SiO_2 .

The Si-rich film with an oxygen concentration of ~ 11.8 a/o yields an electron diffraction pattern similar to that of PECVD Si. For both the Si-rich oxide and PECVD Si films, the first diffuse diffraction ring is at the same position as the (111) polysilicon ring. The second diffuse ring has an intensity maxima between the (220) and (311) polysilicon ring positions. Hamasaki *et al.* (11) have demonstrated that silicon crystals with a mean diameter less than or equal to 2 nm show overlapping (220) and (311) Si diffraction peaks. Darkfield microscopy of the first dif-

Fig. 9. SEM pictures of etched surface of six samples

fuse ring produced by the Si-rich film and by a PECVD Si film shows 1 nm precipitates, which is consistent with the calculation of Hamasaki *et al.* (11). These results indicate the presence of Si clusters in PECVD Si-rich Si-O films.

The Si grain diameters of annealed films, measured in dark field by imaging the Si (111) ring, were 10, 5, and 1 nm for samples with oxygen concentrations of 7.8, 22.8, and 36.4 at%, respectively. The two films with lower oxygen concentrations have distinct diffraction rings which are characteristic of polycrystalline silicon. However, the diffraction patterns of the film with an oxygen concentration of ~36.4 at%, before and after annealing, are nearly identical. Plots of the Si cluster size as a function of oxygen concentration for the as-deposited and annealed films are shown in Fig. 10. From this figure, one finds that the Si grain size decreases with increasing oxygen concentration for a constant annealing time and temperature, and the Si grain size for the Si-rich sample is nearly constant. These results, which are similar to those reported on CVD Si-rich oxide (11) and LPCVD Si-rich oxide (13), indicate that the presence of oxygen inhibits the growth of Si grains during annealing.

Figure 11 shows the integrated Auger Si LVV spectra for clean Si, the PECVD Si-rich oxide, and thermal SiO₂. An intermediate peak at ~83 eV, similar to those observed for the CVD Si-rich samples (21), was observed for the PECVD Si-rich oxide film. This peak has also been observed at the SiO₂/Si interface (22) and on the Si surface during the initial oxidation stage (23). Following the report of Helms (22), this intermediate peak was attributed to the presence of the transition phase SiO_r in the Si-rich film. The peak at ~90 eV for the Si-rich film corresponds to the main peak for clean Si. The AES data thus establish the presence of Si, SiO₂, and SiO_r phases in the PECVD Si-rich Si-O film.

The Si 2P XPS for a PECVD Si-rich oxide film is shown in Fig. 12. The binding energies of the two peaks are at ~103 and 99 eV attributed to the Si 2P peaks in the matrices of SiO₂ and free Si, respectively. Because of the unsymmetrical shape of the peaks, more than two gaussian curves are necessary to fit these data. This observation is similar to results reported on CVD and LPCVD Si-rich oxide (24, 25). The presence of an intermediate gaussian curve suggest the presence of the transition phase SiO_r. Based on similar observations of SiO_r at the SiO₂/Si interface (22, 26), the presence of SiO_r at the boundary of a Si cluster and the SiO₂ region is expected. The observation of Si, SiO₂, and SiO_r phases by XPS for PECVD Si-rich Si-O films is consistent with results obtained by TEM and AES analysis. No difference in the integrated Auger Si LVV spectra and the XPS data for both the PECVD SiO₂ and thermal SiO₂ samples was observed.

Fig. 11. Integrated Auger Si LVV spectra $N(\epsilon)$ for clean Si, PECVD Si-rich oxide, and thermal SiO₂.

I-V data for three Si-rich samples about 190 nm thick are shown in Fig. 13. The Al/Si-rich Si-O/Si structure was used. From these data, one finds that the conductivity is lower for samples deposited with high O₂ flow rate (*R*). In other words, the conductivity increases with the Si:O ratio in Si-rich films. This result is similar to that for CVD Si-rich Si-O (12) and is caused by electron tunneling between Si islands (27). The behavior of electron trapping during conduction can also be seen from these data. The applied field to reach a current of 1×10^{-9} A (current density = 2.2×10^{-7} A/cm²) across samples deposited with different *R* values is shown in Fig. 14. This field decreases sharply as the *R* value decreases from 0.95 to 0.75 and further decreases slowly as the *R* value decreases from 0.75 to 0.5. Figure 14 can be used as a guideline for the choice of deposition conditions when a PECVD Si-rich Si-O is used as an injector in EEROM applications (28, 29).

A typical distribution of dielectric breakdown strength for PECVD SiO₂ is shown in Fig. 15. Two hundred metal/SiO₂/Si (MOS) devices were tested for films depos-

Fig. 10. Size of silicon grain as a function of oxygen atomic percent for as-deposited and annealed samples.

Fig. 12. Si 2P XPS data for PECVD Si-rich oxide

Fig. 13. I-V data for PECVD Si-rich Si-O films (190 nm) deposited with different O_2 flow rates (R).

ited with $R = 3$ sccm. About 11% of the devices have breakdown strengths of ≤ 6 MV/cm, which indicated the presence of defects in the films (e.g., pinholes). About 85% of the devices tested show catastrophic breakdown, and the rest ($\sim 15\%$) show only I-V conduction. Two typical I-V data for PECVD SiO_2 are shown in Fig. 16. The conduction of these films follows the Fowler-Nordheim (F-N) mechanism (30). The slope of the F-N plot is high, possibly due to trapping of negative charges which results in a decrease of the actual field across the SiO_2 films. A ledge on the I-V curve is observed for some samples as the result of trap generation at high fields (31). The breakdown distribution and I-V data for PECVD SiO_2 studied here, which are worse than that for thermal SiO_2 , indicate the limitations of applying PECVD SiO_2 films to an active IC device. A positive flatband voltage (~ 0.6 V) is observed for Al/PECVD SiO_2/Si devices. This is about 1.2 V higher than the flatband voltage for Al/thermal SiO_2/Si devices. The presence of negative

Fig. 14. Applied field, resulting in current density of 2.2×10^{-7} A/cm², across PECVD Si-rich Si-O films as a function of O_2 flow rates.

Fig. 15. Distribution of dielectric breakdown strength for PECVD SiO_2 films deposited with $R = 3$ sccm.

charges, as observed in the I-V data, is one of the causes of this positive flatband voltage.

Summary

PECVD silicon oxide films, with a range in Si:O concentration of 0.88 to 3.6, were prepared by the reaction of a constant SiH_4 gas source with varying O_2 gas flow rates. The N and C concentrations were found to be < 1.5 a/o in the Si-rich film and undetectable in the PECVD SiO_2 film. From the IR spectra of the unannealed Si-rich films, we found that the wave number of the main Si-O stretching bonds is low and their FWHM value is high. After annealing, the wave number was found to increase to ~ 1095 cm^{-1} and the FWHM values were reduced by at least 10%. These results suggest either an oxygen deficiency or porosity in the as-deposited PECVD Si-rich films. Si-H_n bonds (either in a- SiO_2 or a-Si) were found in the as-deposited Si-rich films, but were not observed in the PECVD SiO_2 film. The Si-OH and H-OH bonds were found in all unannealed films. No Si-H or O-H bonds were detected in the annealed films. The concentrations

Fig. 16. Fowler-Nordheim plot for two typical PECVD SiO_2 films deposited with $R = 3$ sccm.

of Si-H and O-H bonds in the PECVD Si-rich films were found to be in the order of 10^{20} and 10^{21} cm^{-3} , respectively. These concentrations are at least 100 times greater than those in CVD Si-rich oxide films.

The refractive index was found to increase with increasing Si:O ratio, film density, or N contamination. The difference in refractive index before and after annealing was also found to be greater for the Si-rich oxide films. These results, and the smaller d_s/d value, indicate that the density of the Si-rich films is less than that of the PECVD SiO_2 film. This is consistent with the results showing higher amounts of hydrogen in Si-rich films. For the annealed films, the etch rate decreases with increasing Si:O ratio, but for the as-deposited films, the distribution of etch rate with respect to the Si:O ratio was random. This implies that the etch rate depends primarily on film composition and film density.

The presence of Si, SiO_2 , and the transition phase SiO_x was identified by TEM, AES, and XPS. The size of the Si cluster was found to be ~ 1 nm for all as-deposited samples, and was found to decrease with increasing oxygen concentration for the annealed samples. No difference in the integrated Auger Si LVV spectra and the XPS data was observed for PECVD and thermal SiO_2 .

I-V data for Si-rich Si-O films indicate that the film conductivity increases with increasing Si:O ratio. The injecting field decreases sharply as the O_2 flow rate decreases from 0.95 to 0.75 sccm. A fair dielectric breakdown distribution was observed for PECVD SiO_2 films. Trapping of negative charges and trap generation at high field for both PECVD SiO_2 and Si-rich films were found.

Based on properties studied here, we believe that the annealed PECVD Si-rich Si-O films have the potential of being used as an injector in EEROM and as passivation films for high field transistors. Annealing at low temperature ($\sim 500^\circ\text{C}$) for long times ($\sim 1\text{h}$) was found to be effective in improving the yield of PECVD SiO_2 films, which may increase the possibility of using these films as insulators in active devices.

ABSTRACT

Nearly stoichiometric CuInS_2 films have been deposited on alumina and graphite substrates at $650^\circ\text{--}700^\circ\text{C}$ by the close spacing chemical vapor transport technique. The source material was synthesized from the elements in a sealed fused silica tube, and a mixture of hydrogen and iodine or hydrogen and hydrogen iodide was used as the transport agent. The composition, microstructure, crystallographic, and electrical properties of the CuInS_2 films were investigated.

Ternary chalcopyrites are promising optoelectronic materials. The potential of several I-II-VI₂ compounds, such as copper indium diselenide, CuInSe_2 , for photovoltaic detectors and solar cells, light emitting diodes, etc., has been demonstrated (1-3). Similar to CuInSe_2 , copper indium disulfide, CuInS_2 , crystallizes in the chalcopyrite structure and is also a direct-gap semiconductor. CuInS_2 has a room temperature bandgap of 1.5 eV and is a promising thin film photovoltaic material.

Thin films of CuInS_2 have been deposited by several techniques: vacuum evaporation, spray pyrolysis, chemical vapor deposition, electrodeposition, etc. In the evaporation technique, the use of dual sources of CuInS_2 and S has produced p-type films with a carrier concentration of $(7\text{--}9) \times 10^{15} \text{ cm}^{-3}$ and a grain size of 1-2 μm (4). In the spray pyrolysis technique, aqueous solutions of cupric acetate, indium trichloride, and thiourea were sprayed onto substrates at $200^\circ\text{--}500^\circ\text{C}$; the electrical resistivity of the film was found to be affected strongly by the Cu/In molar ratio in the solution (5). The chemical vapor deposition technique utilizes the reaction of $\text{CuCl}(\text{NCCH}_3)_n$, $\text{InCl}_3(\text{NCCH}_3)_n$, and hydrogen sulfide on the surface of gallium phosphide substrates at 850°C or above (6). The electro-codeposition of Cu, In, and S from an aqueous solution followed by annealing in H_2S has produced CuInS_2 films on Ti substrates (7). In addition, CuInS_2 films have been prepared by treating (i) sputtered Cu-In alloy with hydrogen sulfide at $300^\circ\text{--}400^\circ\text{C}$ (8) or (ii) molecular beam deposited Cu-In alloy on glass substrates with sulfur or hydrogen sulfide at $300^\circ\text{--}400^\circ\text{C}$ (9).

In this work, CuInS_2 films have been deposited on foreign substrates by the close spacing chemical vapor transport (CSCVT) technique. Their composition, microstructure, crystallographic, and electrical properties have been investigated. The experimental procedures and results are summarized in this paper.

Close Spacing Chemical Vapor Transport of CuInS_2

The chemical transport technique has been widely used for the crystal growth and film deposition of electronic materials. This technique is applicable to solid-state materials which react reversibly with a gaseous reagent (the transport agent) to form volatile products. Since the equilibrium constant of most reactions is temperature dependent, the transport can be brought about by the presence of a temperature gradient. CuInS_2 reacts reversibly with iodine according to the equation

The chemical equilibrium of this reaction shifts to the left at lower temperatures. Iodine may thus be used to transport CuInS_2 source material from a high temperature zone to regions of lower temperatures. Hydrogen iodide

decomposes into its elements at high temperatures and may also be used as a transport agent. Hydrogen chloride and hydrogen bromide are inert toward CuInS_2 and are not suitable as transport agents. CuInS_2 crystals have been grown in a closed tube by using iodine as a transport agent (10). The conventional chemical transport technique, however, is not suitable for the deposition of CuInS_2 films on foreign substrates due to the nature of the nucleation and growth processes. Once CuInS_2 nuclei are formed on the substrate surface, further transport tends to deposit CuInS_2 on the existing crystallites rather than on the substrate surface. Thus, continuous films cannot be obtained until the crystallites coalesce, and this may require the transport of a considerable amount of CuInS_2 in the form of very thick films. The nucleation process may be greatly facilitated by using the CSCVT technique (11), where the source material and the substrates are separated by only about 1 mm. Under this condition, the deposition process is diffusion limited, and each component of the source material is directly transported across the space to the substrate.

The source material, polycrystalline plates of CuInS_2 , was synthesized from the elements (all of 99.999% purity, purchased from ASARCO, Incorporated, New York, New York) in a carbon-coated fused silica reaction tube about 30 cm long. One side of the reaction tube was of rectangular cross section ($2.5 \times 1.8 \text{ cm}$), about 15 cm long, and was attached to a circular cross section tube. Elemental copper and indium in stoichiometric quantities were placed in the rectangular cross section of the tube, evacuated, and heated to form an alloy, which adhered to the wall of the reaction tube. Sulfur, 0.2-0.4% excess over the stoichiometric ratio, was then introduced into the reaction tube, which was again evacuated and sealed while under evacuation. The reaction tube was placed in a two-zone furnace with each zone separately heated and independently controlled. Initially, the rectangular section of the tube (Cu-In) was maintained at 650°C (the mp of 1:1 Cu:In alloy is about 630°C), and the sulfur zone was heated at 450°C . The temperatures of both zones were gradually increased until all sulfur was consumed. The CuInS_2 zone was then increased to 1150°C (the mp of CuInS_2 is about 1090°C) and the reaction tube gradually pulled out of the furnace to allow the unidirectional solidification of the melt. The CuInS_2 ingots obtained in this manner are single-phase polycrystalline, p-type with room temperature resistivities of 200-500 $\Omega\text{-cm}$ as measured by the four-point probe technique.

Because of the chemical reactivity of I_2 at high temperatures, the selection of the substrates for the deposition of CuInS_2 films by CSCVT is rather limited. Alumina, graphite, and carbon-coated graphite substrates were used (carbon was deposited on graphite by the pyrolysis of propane at 1200°C in a He atmosphere, and this carbon

Fig. 1. Schematic diagram of the vertical apparatus for the deposition of CuInS_2 films by CSCVT.

coating eliminates the pits on the graphite surface due to its porosity). The CSCVT process was carried out in a vertical or horizontal fused silica reaction tube, as shown in Fig. 1 and 2, respectively. The heater material for maintaining the substrate and the source material at the desired temperatures is an important consideration. It should be chemically inert and introduces no impurities into the deposited films. Single-crystalline silicon was first used as heaters; however, it reacts with sulfur to form silicon sulfide which hydrolyzes in air, liberating hydrogen sulfide. Silicon dioxide- or silicon nitride-coated silicon blocks are also unsuitable because of the pinholes in the insulator. Graphite is porous, and the coating of high density graphite with about $50 \mu\text{m}$ of pyrolytic carbon is more satisfactory than that of others. Fused silica rods of 0.1 cm diam were used as spacers between the source material and the substrate. The entire assembly was enclosed in a fused silica tube provided with gas inlet and outlet tubes. Thermocouples were used to monitor the temperatures of the substrate and the source material.

The important process parameters in the CSCVT technique are the substrate temperature, the temperature difference between the source and the substrate (fixed at 0.1 cm), and the pressure of the transport agent. Many CSCVT experiments have been carried out to determine the range of process parameters required for the deposition of uniform CuInS_2 films. The use of the vertical or horizontal reaction tube and the use of iodine or hydrogen iodide as the transport agent have produced essentially the same results. The source temperature and the concentration of the transport agent are important in that they determine the reaction rate between the source material and the transport agent. Source temperatures in the range of 650°C - 700°C and an iodine or hydrogen iodide partial pressure of 200-400 torr were found to be suitable. At low source temperatures, such as 500°C , the reaction rate is too low to obtain any reasonable rates of deposition. At too high temperatures, such as 800°C , the sulfur dissociation pressure becomes appreciable. The deposited films were sulfur deficient (very high resistivity p-type or n-type). The substrate temperature determines the rate of

Fig. 2. Schematic diagram of the horizontal apparatus for the deposition of CuInS_2 films by CSCVT.

Fig. 3. Scanning electron micrographs of the surface and vertical cross section of a CuInS_2 /graphite specimen prepared at 675°C .

nucleation and the grain size in CuInS_2 films. The use of low substrate temperatures favors the nucleation process and the formation of small grains in the films. The nucleation rate is reduced and the grain size is increased at high substrate temperatures; however, the film may not become continuous until a large thickness is deposited. The temperature difference between the source and the substrate also determines the deposition rate of CuInS_2 films, and a 20°C - 30°C temperature difference was used in most experiments. By using experimental conditions in the range mentioned above, deposition rates of 10-25 $\mu\text{m}/\text{h}$ may be obtained.

Properties of CuInS_2 Films

Adherent and uniform CuInS_2 films have been deposited on alumina and graphite and carbon-coated graphite substrates over the temperature range of 650°C - 700°C by the CSCVT technique. The microstructure of the deposited films depends strongly on substrate temperature; the grain size increases with increasing temperature. An as-deposited surface of a CuInS_2 film deposited on a graphite substrate at 675°C and the vertical cross section of the specimen are shown in Fig. 3. The crystallites, though of random size ranging from $2\text{-}3 \mu\text{m}$ to larger than $10 \mu\text{m}$, show well-developed faces. Figure 4 shows the scanning electron micrograph of the surface of a CuInS_2 film on an alumina substrate. The crystallites in the CuInS_2 film on alumina substrate appear to be more densely packed than those on graphite or C/graphite substrates.

The chemical composition of several CuInS_2 films deposited on graphite substrates in the temperature range 650°C - 700°C has been analyzed by the electron microprobe technique. The results are summarized in Table I, where the data obtained by using a 20 keV electron beam of $1 \mu\text{m}$ diam indicate that the transported films are stoichiometric within the experimental error.

The crystallographic properties of transported CuInS_2 films have been determined by the x-ray diffraction tech-

Fig. 4. Scanning electron micrograph of the surface of a CuInS_2 film on an alumina substrate.

nique using CuK_α radiation. Figure 5 shows a typical spectrum of a transported CuInS_2 film, where the " 2θ " values are in good agreement with the published structural data (12).

Using p-type CuInS_2 plates of 100-500 $\Omega\text{-cm}$ resistivity as the source material, the transported films are of p-type conductivity. The electrical resistivity of CuInS_2 films on alumina substrates, measured by the four-point probe technique, is always much higher than that of the source material. Resistivities of several thousand ohm-centimeters have frequently been observed. This high resistivity is due to sulfur deficiency in the transported CuInS_2 film, since the resistivity of the films can be reduced significantly by heating in a $\text{H}_2\text{-S}$ or $\text{H}_2\text{-H}_2\text{S}$ atmosphere at 700°-800°C. This heat-treatment may be used to control the resistivity of CuInS_2 films.

Summary

Single-phase polycrystalline CuInS_2 ingots have been synthesized from the elements of 99.999% purity in a carbon-coated, sealed, fused silica tube at about 1150°C. Using CuInS_2 ingot as the source material, adherent and nearly stoichiometric CuInSe_2 films have been deposited on alumina, graphite, and carbon-coated graphite substrates by the CSCVT technique using a hydrogen-hydrogen iodide or a hydrogen-iodine mixture as the transport agent. The substrate temperature and the partial pressure of the transport agent are the most important process parameters of the transport process. The composition of CuInS_2 films deposited at 650°-700°C has been confirmed by electron microprobe and x-ray diffraction. The electrical resistivity of CuInS_2 films is usually very high, several thousand ohm-centimeters; however, it may be reduced significantly by heating in $\text{H}_2\text{-S}$ or $\text{H}_2\text{-H}_2\text{S}$ at 700°-800°C.

Table I. Composition of transported CuInS_2 films on graphite substrates by electron microprobe analysis

Deposition temperature (°C)	Cu (a/o)	In (a/o)	S (a/o)
650	24.23 ± 1.77	24.37 ± 1.78	51.40 ± 3.75

Formation Process of $Y_2O_2S:Eu^{3+}$ in a Preparation with Flux

Osam Kanehisa, Tsuyoshi Kano, and Hajime Yamamoto

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

The formation process of a red emitting phosphor, $Y_2O_2S:Eu^{3+}$, has been clarified in a reaction

Sulfuration of Y_2O_3 and Eu_2O_3 is completed at a firing temperature as low as 700°C and at a firing period of 2h. Diffusion of Eu^{3+} follows the sulfuration, and grain growth begins when lattice disorder of Y_2O_2S decreases to a minimum at 1050°C. Larger particles are obtained when a part of Y_2O_3 is replaced with YPO_4 .

A red emitting phosphor, $Y_2O_2S:Eu$, is widely used in color picture tubes because of its high efficiency and appropriate color under cathode-ray excitation. For the preparation of such rare earth oxysulfides, several methods are known: (i) reduction of rare earth sulfate by H_2 or CO (1); (ii) reduction of rare earth sulfite by CO (2); (iii) sulfuration of rare earth oxide by H_2S or CS_2 (3); (iv) sulfuration of rare earth oxide in the atmosphere of $N_2 + H_2O + H_2S$ (4); (v) reaction between an oxide and a sulfide (5); and (vi) sulfuration of rare earth oxide in the flux of $S + Na_2CO_3 + K_3PO_4$ (6).

Among these methods, the last one is most important, since it has come to be used for production of commercial phosphors. This is because the method has good productivity. As such, there have been many papers on $Y_2O_2S:Eu$ prepared in this way, mostly concerning its optical properties (7). In contrast, little has been known on the formation process of $Y_2O_2S:Eu$ in the flux method. To our best knowledge, only Ozawa reported the growth mechanism of $Y_2O_2S:Eu$ microcrystallines (8). Accordingly, in the present paper we describe the results of our investigations into the sulfuration reaction, Eu^{3+} diffusion, and grain growth using different firing times and temperatures. Examinations of the brightness and color of the phosphors prepared under the various firing conditions will be discussed.

Experimental Procedures

Samples were prepared according to the method reported by Royce *et al.* (6). A mixture of Y_2O_3 and Eu_2O_3 with a molar ratio of 0.957:0.043 was mixed with the flux, which was a mixture of S, Na_2CO_3 , and K_3PO_4 at a molar ratio of 3:1:0.1. The mixture was then charged in an alumina crucible with an alumina lid and fired. Of the starting materials, Y_2O_3 was at 99.99% purity and Eu_2O_3 at 99.9%. A small amount of Tb (14 ppm in atomic ratio) was added to the Y_2O_3 to enhance the luminescent efficiency (9). The other starting materials were of reagent grade. The standard sample was fired at 1180°C for 2h. Fired products were yellow solids with the shape of the crucible. Samples for brightness and color measurements were washed with deionized water and dil-HCl and dried at 120°C for 4h. However, samples for x-ray diffraction analysis and luminescence spectra measurements were washed only with deionized water to make the existence of Y_2O_3 in the products detectable, because Y_2O_3 is soluble in dil-HCl. Instead of Y_2O_3 , a mixture of Y_2O_3 and YPO_4 , or only YPO_4 , was also used as yttrium starting materials, because partial substitution of Y_2O_3 with YPO_4 increases grain size.

The mean particle size of the samples was obtained using the Blaine method. The principle underlying this method is to obtain the specific surface area of the sample by measuring the time it takes for air to pass through a powder bed. This method gives a better estimation of the mean size of primary particles than the sedimentation method, which tends to measure aggregated particle size.

Relative cathodoluminescence (CL) brightness was obtained using a United Detector Technology photocell de-

tektor with a photometric filter at a 10 kV accelerating voltage and $1 \mu A/cm^2$ current density. Samples were mounted on stainless steel holders having a screen weight of 100 mg/cm². Resulting data were calculated as a percentage of the value for the standard sample.

As a measure of color, the ratio between CL brightnesses with and without the use of VR-60 Toshiba filter was defined. For convenience, we call this value the red color component ratio, or R_c , which can be expressed as $R_c = (\text{CL brightness with VR-60 filter} / \text{CL brightness without VR-60 filter})$.

The value for the standard sample is 0.926. With the increase in Eu^{3+} concentration, R_c increases. CL spectra were measured with a Nikon P-250 monochromator, the dispersion of which is 6 nm/mm, and an RCA-7102 photomultiplier. Correction of spectral sensitivity was made using a data acquisition system, the Hewlett-Packard 9825A. For linewidth measurements, a Spex 1400 monochromator with a dispersion of 1 nm/mm was used.

Decay characteristics under 337 nm N_2 laser excitation were obtained using a Biomation waveform recorder, Model-1010, combined with a Toyotsusho averager, Model 1010SA. They were analyzed using the HP9825A. Scanning electron microscopy (SEM) images were obtained with a Hitachi SEM (HHS-2R) at a 25 kV accelerating voltage and $5 \times 10^{-1} \mu A$ beam current. Thermoluminescence (TL) glow curves were measured in a conventional way; a sample was irradiated by 254 nm light from a low pressure mercury lamp at 80 K for 10 min, kept at 80 K until the afterglow disappeared, and then warmed up to about 470 K at a rate of 10-15 deg/min.

Results and Discussion

Dependence on firing time.—To facilitate investigation of the sulfuration reaction, the firing time was changed from 0 to 150 min at 1180°C. When starting materials packed in an alumina crucible were set in a furnace kept at 1180°C, the furnace temperature first went down to around 900°C and then recovered to 1180°C in less than 10 min. Firing time is defined here as the period during which the sample is kept at 1180°C. Firing for 0 min means pulling the sample out of the furnace just after the furnace temperature reaches 1180°C.

The sulfuration reaction occurs very quickly for firing at 1180°C. All the samples were found to be Y_2O_2S as a result of x-ray diffraction analysis. Figure 1 shows the SEM images and Fig. 2 mean particle sizes for these samples. With a firing of 0 min, the mean particle size is 1.5 μm . However, in the SEM images, such small particles can barely be observed. The average size of a unit grain, though, is 8-10 μm , and these grains are apparently groups of coagulated primary particles. With an increase in the firing time, this aggregation decreases, primary particles grow, and the mean particle size obtained by the Blaine method comes to show good coincidence with SEM imaging unit grains.

Figure 3 shows the relative CL brightness and R_c against firing time. With firing of 0 min duration, CL brightness is only 23% of the standard sample. With an in-

Fig. 1. SEM images of samples fired at 1180°C for different periods of time.

crease in firing time, the brightness increases drastically and reaches a standard level with 30 min firing.

For 0 min firing, R_c is already 0.900; it keeps its value for 20 min, and reaches 0.926 (= standard level) for 30 min firing. This shows that diffusion of Eu^{3+} is completed for 0 min firing, and the R_c increase from 0.900 to 0.926 is attributed to the lattice rearrangement by crystal growth.

A sample with a standard level of brightness and R_c was obtained with 30 min firing. Its mean particle size was about 2.9 μm .

Dependence on firing temperature.—As was mentioned above, the sulfuration reaction at 1180°C proceeds too fast for proper investigations of the first stage. Then firing temperature was lowered with the firing time being kept at 2h. Three starting materials for the yttrium component were examined: Y_2O_3 , YPO_4 , and Y_2O_3 (92 mole percent [m/o]) + YPO_4 (8 m/o). Each case will be described in detail below.

Y_2O_3 as a starting material.—X-ray powder diffraction analysis has shown that all products fired at 700°C and above are $\text{Y}_2\text{O}_2\text{S}$, but those fired at 500° or 600°C are a mixture of $\text{Y}_2\text{O}_2\text{S}$ and Y_2O_3 . The main-peak ratio of the x-ray diffraction between $\text{Y}_2\text{O}_2\text{S}$ and Y_2O_3 is 7:1 for firing at 600°C and 1:1 at 500°C.

In contrast to x-ray diffraction data, CL spectra show only $\text{Y}_2\text{O}_2\text{S}:\text{Eu}^{3+}$ for all samples, and not a trace of $\text{Y}_2\text{O}_3:\text{Eu}^{3+}$ was observed even for samples fired at 600°C and below. The result indicates that Eu^{3+} diffuses into $\text{Y}_2\text{O}_2\text{S}$ more easily than into Y_2O_3 . In fact, in the preparation of $\text{Y}_2\text{O}_3:\text{Eu}^{3+}$ phosphor, a higher firing temperature is needed for the diffusion than is the case for $\text{Y}_2\text{O}_2\text{S}:\text{Eu}^{3+}$.

Fig. 2. Mean particle size change of samples fired at 1180°C for different periods of time.

Fig. 3. CL brightness and R_c changes for samples fired at 1180°C over different periods of time.

Figure 4 shows SEM images for the Y_2O_3 starting material and fired products. Figure 5, on the other hand, presents firing temperature dependence of the mean particle size of the phosphors. Although the mean particle size of Y_2O_3 is 1.5 μm , there are no grains of this size in the SEM image, which indicates that primary Y_2O_3 particles aggregate and form coagulated grains of about 8-10 μm in size. In the initial stage of reaction, $\text{Y}_2\text{O}_2\text{S}:\text{Eu}^{3+}$ prepared at 700°C for 2h have a size and morphology similar to those for the Y_2O_3 starting material. This same similarity was also observed in $\text{Y}_2\text{O}_2\text{S}:\text{Eu}^{3+}$ prepared at 1200°C for 0 min.

This shows that mass transport is not remarkable in the initial stage of the reaction. As the sulfurizing reagent, liquid Na_2S_x or evaporated Na_2S_x , S_x gases can be assumed. Here, the melting point of Na_2S_x is 920°C, when $x = 1$. It decreases with an increase in x . It would be more difficult for liquid Na_2S_x to wet all of the fine pores and thin gaps in Y_2O_3 particles having a very low surface tension than for Na_2S_x , S_x gases. So it can be assumed that a gas-solid reaction is the predominant mechanism in the initial stage. It is confirmed that Y_2O_3 can be sulfurized into $\text{Y}_2\text{O}_2\text{S}$ with the reaction of gas components in the flux by the following experiment, though it is not direct evidence for the predominance of gas-solid reaction. Y_2O_3 in a small alumina crucible without lid was set in a larger alumina crucible with lid containing only flux component.

Fig. 4. SEM images of Y_2O_3 and $\text{Y}_2\text{O}_2\text{S}$ samples fired at different temperatures for 2h.

Fig. 5. Mean particle size change with increase in firing temperature. 1: Y₂O₃ was used. 2: 0.92 Y₂O₃ and 0.16 YPO₄ were used.

The ratio of the amount of charged Y₂O₃ and flux component is the same as that of the standard sample. They were fired at 900°C for 2h. In the small crucible, a certain amount of Y₂O₂S was confirmed to be prepared. Mass transport by liquid-solid contact will certainly work at high firing temperatures or over long periods, where grain growth is recognized.

The mean particle size of Y₂O₂S:Eu³⁺ fired at 900°C is about 0.9 µm, and the SEM image shows that small primary particles will most likely separate from the coagulated grains. The SEM image of Y₂O₂S:Eu³⁺ fired at 1050°C shows many small, well-crystallized particles. With firing above 1050°C, grain growth is accelerated, aggregation of particles decreases, and the unit grain size in the SEM image shows good coincidence with the mean particle size measured by the Blaine method.

Fig. 6. Brightness and R_c changes for samples fired at different temperatures for 2h. 1: Y₂O₃ was used. 2: 0.92 Y₂O₃ and 0.16 YPO₄ were used.

Table I. Impurity analysis using atomic absorption techniques

Firing temperature (°C)	Ca (ppm)	Na (ppm)	K (ppm)
600	1.46	730	23.75
1200	0.56	8	0.70

Relative luminescence brightness and R_c under cathode ray excitation are shown in Fig. 6. As the measurement was made after treatment with dil-HCl, all Y₂O₃ was eliminated in a sample prepared at 600°C. With the increase in firing temperature from 600° to 1100°C, however, relative CL brightness increases monotonously until it reaches the standard level for firing at 1100°C. Above 1100°C, it retains the same highest value.

The red color component ratio (R_c) in the emission spectra is around 0.7 for a sample fired at 700°C. With the increase in firing temperature, R_c increases and reaches 0.900 for a sample fired at 850°C. It keeps its value for the firing in the range 850°-1000°C. These results correspond to those of firing time dependence and show that Eu³⁺ diffusion is completed for the firing at 850°C.

A sample having the standard level in brightness and R_c was obtained with firing at 1050°C. Its mean particle size was 3.0 µm and nearly equal to that of the sample fired at 1180°C for 30 min.

Table I shows the results of atomic absorption analysis of impurities in the samples fired at 600° and 1200°C. Examined elements were Ca, known as a quencher for Y₂O₂S:Eu, and the flux components Na and K. Clearly, the sample fired at 1200°C includes fewer impurities than the sample fired at 600°C. This is because impurities are segregated from the particles as lattice rearrangement proceeds with an increase in firing temperature.

The lifetime of the ⁵D₀ (Eu³⁺) emitting level and the half width for the ⁵D₀ → ⁷F₀ emission lines at LNT are shown in Fig. 7. The lifetime is analyzed as a single exponential curve. The samples fired at 1100°C and above showed a single exponential decay curve, with a lifetime of 440 µs. When the firing temperature was 1050°C and below, decay curves deviated from a single exponential form. This indicates the existence of more than one Eu³⁺ luminescence center, probably caused by the lattice disorder.

The half-width for ⁵D₀ → ⁷F₀ transition decreases monotonously with firing temperature, again showing lattice disorder at low temperatures.

The effects of lattice disorder can also be seen in the TL glow curves shown in Fig. 8. The sample fired at 1160°C

Fig. 7. Half-line width and lifetime shown in relation to firing temperature.

On the basis of the above results, formation processes can be summarized as follows.

1. Sulfuration is completed instantly for 1180°C firing and in 2h for 700°C firing. As the products of the initial stages retain the morphology of the starting material Y₂O₃, it can be considered that the sulfuration reaction is dominated by gas-solid reaction.

2. Eu³⁺ diffusion into Y₂O₂S proceeds promptly after the sulfuration reaction. When Y₂O₂S coexists with Y₂O₃ or YPO₄, Eu³⁺ diffuses into Y₂O₂S preferentially. In the Y₂O₃ and Y₂O₄ + YPO₄ cases, R_c reaches 0.900 and 0.935, respectively, for firing at 850°C. It maintains its value until brightness increases to the standard value. This R_c value of 0.900 is also obtained in the products fired at 1180°C for 0-20 min. This indicates that the diffusion of Eu³⁺ into Y₂O₂S is completed when R_c reaches 0.900 in 2h at 850°C firing or instantly at 1180°C firing. This rapid Eu³⁺ diffusion is explained by the great lattice disorder in the initial stage of the reaction.

3. Compared to Eu³⁺ diffusion, grain growth is dependent upon longer firing time and higher temperatures. Even when Eu³⁺ diffusion is completed, the product retains a morphology similar to that for starting material Y₂O₃. Nucleation can be clearly observed in Fig. 4 for firing at 900°C. It is to be emphasized that grain growth is accelerated when brightness and R_c are already at the standard level and grains are about 3 μm in size.

4. The role of YPO₄ in the grain growth is considered to be as follows. In the Y₂O₃ + YPO₄ case, R_c decreases with firing at 1050°C. This indicates that, at this temperature, YPO₄ is completely sulfurized into Y₂O₂S. As the average size of YPO₄ is smaller than that of Y₂O₃, the size of Y₂O₂S obtained from YPO₄ sulfuration is smaller than that from Y₂O₃ sulfuration. These small Y₂O₂S particles promoted grain growth in the solid-liquid reaction.

Conclusions

The formation process of Y₂O₂S:Eu in a preparation with flux has been clarified. The sulfuration reaction Y₂O₃ + Eu₂O₃ + flux(S + Na₂CO₃ + K₃PO₄) → Y₂O₂S:Eu³⁺ + flux is completed in 2h with firing at 700°C or < 10 min with firing at 1180°C firings. In this reaction, it can

be assumed that a gas-solid reaction is a predominant mechanism. Eu³⁺ diffusion proceeds promptly after the sulfuration reaction, while the host lattice still has much disorder with many impurities. Diffusion is completed in 2h with firing at 800°C or < 10 min with firing at 1180°C. When Y₂O₂S exists with Y₂O₃ or YPO₄, Eu³⁺ diffuses into Y₂O₂S preferentially. The sulfuration reaction 2YPO₄ + Na₂S_r → Y₂O₂S + flux proceeds at about 900°C, and ends at 1000°C with 2h firing. It has become clear that the grain growth is accelerated, when Eu³⁺ diffusion is completed, the brightness reaches the highest level, and the mean particle size is about 3 μm. Larger particles are obtained with partial substitution for Y₂O₃ of YPO₄. The reason for this phenomenon is not clear yet, but it may be related to the fact that YPO₄ sulfurizes into Y₂O₂S later than Y₂O₃.

Technical Notes

Highly Selective Dry Etching of Polysilicon Using Chlorinated Gas Mixtures for VLSI Applications

E. Degenkolb,* K. O. Park,^{†1} J. B. Shorter, and M. Tabasky

GTE Laboratories, Waltham, Massachusetts 02254

With scaled-down silicon-gate MOS devices, dry etching to pattern polycrystalline silicon over thin gate oxide must meet two stringent requirements: anisotropy and high selectivity. Specifically, for gate polysilicon thicknesses of 0.6 μm, a suitable etching process should be able to produce etched gates of length 1 μm without removing more than 5 nm of underlying SiO₂. Etching of polysilicon can be made highly selective with respect to SiO₂ in plasmas of fluorine containing gases such as SF₆, but anisotropy is normally sacrificed for high selectivity (1).

*Electrochemical Society Active Member.

^{†1}Present address: Intel Corporation, Livermore, California 94550.

It was shown by Forget *et al.* (2) that the addition of Cl₂ to SF₆ improves selectivity over SF₆ alone, but in our experience this combination is not ideal because anisotropy is critically dependent on the relative concentrations of SF₆ and Cl₂. Cabral and Horwitz (3) used SiCl₄ + O₂ to etch silicon with greater than 10:1 selectivity over SiO₂. Molecular chlorine combined with argon was used for silicon etching by Schwartz and Schaible (4) and shown by Pogge *et al.* (5) to give Si:SiO₂ selectivity of approximately 20:1. Recently, Park and Rock (6) have shown that SiCl₄ + Cl₂ also gives a residue-free anisotropic silicon etch with high selectivity. In this paper, we describe the capabilities of this combination for gate polysilicon etching.

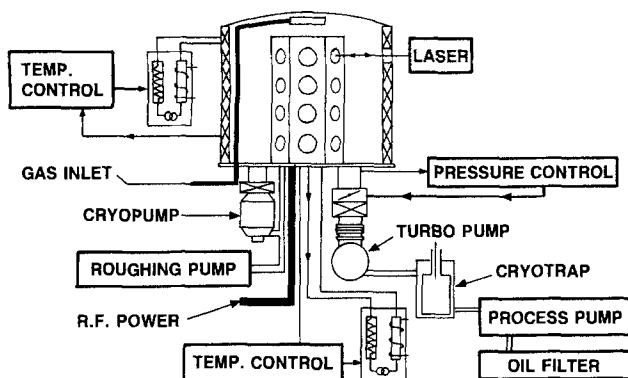

Fig. 1. Schematic of Hex-cathode reactive ion etching system

Experimental

Gate etching test samples were prepared by depositing 600 nm LPCVD polysilicon onto thermally oxidized silicon wafers. The polysilicon was implanted with 5×10^{15} cm^{-2} phosphorus at 50 keV and then cleaned by exposure to O_2 plasma. After a 15 min anneal at 800°C in O_2 , the wafers were patterned with positive AZ1400 series photoresist. Just prior to polysilicon etching, the wafers were dipped for 15s in buffered HF solution ($\text{NH}_4\text{F}:\text{HF} = 7:1$), rinsed, and baked at 90°C for 30 min.

Reactive ion etching (RIE) of polysilicon was conducted in a 24-wafer Hex-cathode reactor (Plasma-Therm 640, shown in Fig. 1), which is an asymmetric diode system using the bell jar itself as the anode (anode-to-cathode area ratio 3:1), and is equipped with a turbomolecular pump and cold trap. One to four wafers were etched at a time; bare SiO_2 -coated wafers occupied the other positions. To obtain reproducible etch rates, it was found necessary to precondition the etch chamber (before loading samples to be etched) with an O_2 plasma at 40 mtorr and 400W RF. During this treatment, the discharge color changes from blue to greenish-yellow and dc self-bias changes from -170 to -220V . The O_2 plasma may be reacting with adsorbed chlorides left from the previous etching cycle.

Polysilicon samples were loaded on Al_2O_3 -coated platens and the reactor was pumped to a background pressure of 5×10^{-5} torr before admitting reactive gases. Electrode temperature was 37°C ; chamber wall temperature was 39°C . The total flow rate of $\text{SiCl}_4 + \text{Cl}_2$ was main-

Fig. 2. Etch rate and selectivity of polysilicon to thermal oxide as a function of reactant gas composition in Hexetch 640 at 36 sccm total flow, 28 mtorr pressure, and 400W RF power.

Fig. 3. Polysilicon ($0.6 \mu\text{m}$ thick) etched at 400W RF, 28 mtorr, 33 sccm Cl_2 , and 3 sccm SiCl_4 in Hexetch 640. Photoresist mask ($1.5 \mu\text{m}$ thick) is still in place.

tained at 36 sccm at a chamber pressure of 28 mtorr with RF power of 400W at 13.56 MHz. The relative concentrations of Cl_2 and SiCl_4 were controlled by varying the individual gas flows, and etch rates were measured with a Nanometrics Film Thickness Computer. Optical emission from a plasma of $\text{SiCl}_4 + \text{Cl}_2$ was recorded using an Instruments S-A scanning monochromator of focal length 0.2m and a photomultiplier of S-5 spectral sensitivity.

Results and Discussion

Figure 2 shows etch rates and Si/SiO_2 selectivity as a function of Cl_2 concentration in SiCl_4 . Since the polysilicon is covered by native SiO_2 , our measurements yield the etch rate for the composite film. From 0 to 85% Cl_2 , the polysilicon etch rate increases while the SiO_2 etch rate remains nearly constant. Beyond 85% Cl_2 , both etch rates decline, yet selectivity continues to improve and anisotropy remains high. In this region, the plasma color changes from violet to blue and the dc self-bias changes from -120 to -80V . The result of these changes is a dramatic drop in the SiO_2 etching rate, which accounts for the increase in selectivity.

Figure 3 shows polysilicon on SiO_2 which was etched with greater than 30:1 selectivity using 90% $\text{Cl}_2 + 10\%$ SiCl_4 . Anisotropy is characteristic of this gas combination, which etches without residue as long as the reactor has good vacuum integrity. Selectivity of polysilicon over photoresist is about 2:1 under these conditions and drops as RF power is increased. Anisotropic etching is also obtained using sputtered silicon nitride as a less erodible mask which can be removed with hot H_3PO_4 . Figure 4

Fig. 4. Polysilicon etched as in Fig. 3, after removal of silicon nitride mask. SiO_2 step heights are $0.4 \mu\text{m}$.

POLYSILICON ETCHING WITH Cl₂ + SiCl₄

Fig. 5. Polysilicon etching signal from laser reflectometer. Arrow shows approximate end point.

shows an example of polysilicon gate structures over 0.4 μm SiO₂ steps which were etched with the same gas mixture using a 0.15 μm thick silicon nitride mask.

Polysilicon etch monitoring by laser reflectance is shown in Fig. 5 using 90% Cl₂ in SiCl₄. A delay is evident between plasma ignition and onset of polysilicon etching, which is in part due to the need to etch off native SiO₂ covering the polysilicon. The presence of residual water vapor may also contribute to the delay. Approximate end point is shown by the arrow, and the process can be terminated with less than 5 nm gate SiO₂ removal.

Alternative etch monitoring can be done using the 307 nm emission of Cl₂^{*}, as shown in Fig. 6. In this case, we see that the plasma is depleted of Cl₂^{*} until polysilicon etching is complete. The initial dip in Cl₂^{*} intensity could be due to reaction with residual water vapor. The gradual approach to end point is a reflection of slower etching near the center of the wafers. The near-ultraviolet plasma emission spectrum is shown in Fig. 7 as a function of inlet gas composition. Between the Cl₂^{*} peaks is a sharp sequence of lines due to SiCl, which disappears rapidly as

POLYSILICON ETCHING WITH Cl₂ + SiCl₄

Fig. 6. Polysilicon etching signal from Cl₂^{*} optical emission. Arrow shows approximate end point.

Fig. 7. Dependence of optical emission spectrum on etching gas composition.

the chlorine content is increased. A much broader emission peaked at 327 nm becomes weaker gradually as Cl₂ concentration is increased. This broad band may be due to emission from a SiCl_x species such as SiCl₂. SiCl₂ is energetically favored to form (7) and has been observed to be a major component in SiCl₄ discharges (8).

Figure 8 shows normalized emission intensities and etch rates as a function of inlet gas composition. The peak in polysilicon etch rate corresponds more closely with Cl₂^{*} than with SiCl_x^{*} or SiCl^{*} emission. From this, we conclude that Cl₂^{*} may be a primary silicon etchant species. These data are consistent with earlier results by Park and Rock (6) indicating that the function of silicon chlorides is etching SiO₂. The polysilicon etch rate decline can be interpreted by recalling that it has a native oxide, which takes longer to penetrate at higher Cl₂ content.

Fig. 8. Comparison of etch rates with optical emission intensities

Conclusions

Highly selective, clean and anisotropic gate polysilicon etching can be achieved in RIE reactors using a $\text{Cl}_2 + \text{SiCl}_4$ gas mixture. Sputtered silicon nitride is a more desirable etch mask than photoresist because it is less erodible and more easily removed following RIE processing. This etching process can be monitored by laser reflectance or Cl_2^* optical emission, so that less than 5 nm gate SiO_2 is removed during overetch.

Acknowledgments

Technical assistance for these experiments was provided by H. A. MacLean. We are grateful to N. J. Lewis for SEM photos, to P. E. Poppert, F. C. Rock, W. Lapatovich, and J. Kramer for helpful discussions, and to D. Casey for management support. This work is dedicated to the memory of Jeremiah McCarthy, whose fairness and courage inspired us all.

An Anodic Oxidation Technique for the Growth of Transparent Conducting Layers of SnO_2

S. Dhar,* Susanta Sen, and Dipanker Biswas

Institute of Radiophysics and Electronics, Calcutta 700 009, India

Transparent conducting layers of SnO_2 (1, 2) are currently of interest because of their widespread use in a number of devices. Available techniques for growing this material are thermal oxidation, reactive evaporation, reactive sputtering, sputtering of oxide targets, chemical vapor deposition, and spray pyrolysis. Sputtering techniques are known for high quality yields, but their use is limited by high costs and experimental complexities. Spray pyrolysis, however, provides a comparatively simpler and cheaper method for depositing large area layers. However, this is essentially a high temperature technique, and the film quality achieved is not as good as that obtained for the sputtered layers.

For a long time, anodization has been used as a simple and efficient method for converting metals into their oxides. However, attempts to anodically oxidize tin have been only partially successful (3-6). Giany and Kelly (7) were apparently able to grow SnO_2 from tin sheet using an ethylene glycol-based bath but did not present data on the electrical conductivity and optical transparency of the grown layers. Two of the present authors (S. D. and D. B.) recently presented a preliminary report (8) on a new anodic oxidation technique for converting vacuum-deposited tin coatings to highly transparent and conducting SnO_2 . The purpose of this paper is to give a more detailed description of the process and of the results obtained.

Microscopic glass slides were used as substrates for the SnO_2 layers. They were degreased by boiling in liquid detergent, followed by 1/2h standing in chromic acid. The slides were then leached in aqua regia and finally washed in deionized water and dried in filtered air. Analytical-grade tin was then evaporated at a pressure of 2×10^{-5} torr onto the substrates to form layers of up to 1 μm thick.

The bath used for tin anodization contained 1.5g of the Na salt of EDTA in 100 ml of CH_3OH (Analar) and 100 ml of distilled water. Anodization was carried out at 30°C.

In the anodization cell, the tin layer on glass was employed as the anode, and a nickel plate as the cathode.

These electrodes were tilted such that the distance between them was smallest at the lower edges. Thus, oxide film formation was initiated at the lower edge of the anode, where the current density was highest. An average current density of 3 mA/cm^2 was found to be satisfactory for the conversion of Sn to SnO_2 , yielding a completely transparent layer. At higher current densities instead of being transparent, the tin layer is converted to a brownish mass, probably of SnO . The same effect is again observed when the concentration of EDTA in the bath is lowered. Before testing, the anodized layers were washed and dried in warm air. No heat-treatment was used.

The resistivity of the anodically grown SnO_2 layers, measured by the usual two probe technique (9), was found to be of the order of $10^{-2} \Omega\text{-cm}$. Transmittance of a 400Å thick SnO_2 layer on glass measured with a Cary 17D spectrophotometer in the automatic scan mode (bare glass sheet as reference), is presented in Fig. 1. The film is seen to be practically transparent over the wavelength range 350-700 nm.

A typical scanning electron micrograph of a 3000Å layer is presented in Fig. 2, which shows the grain structure.

Fig. 1. Transmittance vs. incident wavelength curve for a 400Å thick anodically grown SnO_2 layer.

*Electrochemical Society Active Member.

Fig. 2. Surface microstructure of an anodically grown SnO₂ layer, as revealed by scanning electron microscopy (markers correspond to 1 μm length).

An anodic oxidation procedure for growing SnO₂ layers on glass is described. Since the procedure is performed at

room temperature, it may be used to form transparent SnO₂ coatings on various substrates, including polymers. On conducting substrates, it may be possible to deposit the tin electrochemically instead of from the vacuum. Work is in progress to investigate anodic growth of SnO₂ films on substrates other than glass and to more thoroughly characterize the electrical and optical properties of such films.

Acknowledgment

The authors are indebted to Professor B. R. Nag for some valuable discussions and comments on the work.

The Role of Chlorine in the Gettering of Metallic Impurities from Silicon

Thomas A. Baginski*

Department of Electrical Engineering, Auburn University, Auburn, Alabama 36849

Joseph R. Monkowski*

Radio Semiconductor, Incorporated, State College, Pennsylvania 16801

Semiconductor device fabrication processes have been directed at developing and further refining MOS technologies. The oxides used in these devices must be of the highest quality to insure optimal device performance. Therefore, considerable effort has been devoted to improving the electrical characteristics of these oxides.

The presence of chlorine during silicon oxidation has been found many times to play a significant role in improving the minority carrier lifetime in the underlying silicon. Sometimes this improvement has been by a factor of two to three orders of magnitude (1, 2). However, at other times, very little effect has been seen. Since the lifetime improvement is believed to originate from the gettering of metallic impurities, this investigation was undertaken to determine if these discrepancies could be understood in terms of discrepancies in the gettering behavior of chlorinated oxides.

In this investigation, silicon wafers were contaminated with gold or copper. Chlorinated oxides were then grown at a variety of temperatures and HCl concentrations. Metallic impurity concentration profiles were measured. The results provide a quantitative description of the contaminant's movement during oxidation.

Experimental Procedure

Starting materials for all oxidations were (100)-oriented, 20 $\Omega\text{-cm}$, n-type, 2 in. diam. silicon wafers approximately 150 μm thick. Both before the contamination and before

* Electrochemical Society Active Member.

the subsequent oxidation, all wafers were cleaned in a standard manner using an ammonium hydroxide/hydrogen peroxide solution, a diluted hydrofluoric acid dip, a hydrochloric acid/hydrogen peroxide solution, and several deionized water rinses.

The wafers had a spin-on contamination source applied to the back side and were spun at 2000 rpm for 30s to form a source layer of uniform thickness.

The spin-on source consisted of SiO₂ plus either gold or copper in an alcohol suspension. The solution concentration exceeded 10²⁰ metal atom/g, thus insuring that the applied layer acted as an infinite source of metal atoms. After deposition of the doped oxide, the wafers were annealed for 10 min at 373 K in an N₂ ambient to bake out the alcohol, thus forming a glass layer saturated with the desired impurity.

The samples were then placed in a furnace to allow for diffusion of the metal. Copper was diffused at 1353 K. The diffusion temperature of Cu was chosen as slightly below the eutectic point in order to inhibit the formation of Cu-Si alloys while insuring a high solubility limit. The literature shows the solid solubility of Cu to be 6 $\times 10^{17}$ atom/cm³ at a temperature of 1353 K with a diffusion coefficient of 8 $\times 10^{-3}$ cm²/s. A 4h diffusion was performed in an electronic-grade nitrogen atmosphere.

Au was diffused at 1473 K for 15-30 min. Au has a solid solubility 8 $\times 10^{16}$ atom/cm³ and a diffusion coefficient of 10⁻³ cm²/s at this temperature (3). It is noted that both metals have extremely high diffusion coefficients. Setting

Fig. 1. Copper profiles for wafers oxidized in dry O_2 for 30 min at $900^\circ C$ with various amounts of HCl added.

Fig. 2. Copper profiles for wafers oxidized in dry O_2 for 30 min at $1100^\circ C$ with various amounts of HCl added.

the thickness of the wafer equal to the diffusion length yields times in the range of minutes for either a copper or gold atom to travel from one side of the wafer to the other. Diffusion times were chosen between one and two orders of magnitude greater than these merely for processing convenience.

The samples were then oxidized at 1173, 1373, and 1473 K for 30 min in 0, 3, and 10% HCl/ O_2 gas mixtures.

For determination of the concentration profiles of the metals, layers of silicon were sequentially removed by etching in an ultrapure mixture of 1:20 HF:HNO₃. These solutions were then analyzed using dc plasma-excited emission spectroscopy. The layers were either 2.5 or 5 μm thick. In order to insure that only the front surface of the wafer was etched, the back side was protected with a wax inert to the etchant. In all cases, blanks were run to insure that extraneous contamination levels were below 1 ppb.

Results and Discussion

Figure 1 shows the results of oxidation at 1173 K. The reference is for a wafer profile immediately after the contamination with no further processing. Note that, in the reference profile, most of the contamination is located within several micrometers of the surface, the critical area where the device structures are located. This characteristic profile has been described elsewhere (4).

Oxidation in dry O_2 tends to redistribute the impurities to some extent, but there is clearly very little gettering. Additions of either 3 or 10% HCl to the O_2 getters the copper to below the detectability limit. Analysis of the silicon oxide grown with HCl showed no trace of copper, indicating that the copper was removed from the wafer into the HCl ambient.

The behavior of copper at 1373 K with 0, 3, 10% HCl in O_2 (Fig. 2) and at 1473 K with 0, 3, 10% HCl in O_2 (Fig. 3) is similar. In the case of $1100^\circ C$, 2.5 μm slices of Si were

Fig. 3. Copper profiles for wafers oxidized in dry O_2 for 30 min at $1200^\circ C$ with various amounts of HCl added.

Fig. 4. Gold profiles for wafers oxidized in dry O_2 for 30 min at $1100^\circ C$ with various amounts of HCl added.

etched away to provide a finer depth resolution. The reference profile shows a high concentration of Cu within the first 2.5 μm of the wafer surface, showing clearly that the Cu segregates to the most critical region of device performance. During subsequent dry O_2 oxidation, the impurity shows little tendency to redistribute through the sample. Oxidation with 3 or 10% HCl again drops the impurity profile to below the detection limit. The oxide layer was also analyzed and was found to contain no copper. For this particular set, the wafers were etched to 50 μm from the surface, then a 2.5 μm slice was removed, and again the wafers were etched down to 100 μm and another slice removed. No Cu was detected in any part of the sample. The detection limit of the technique was approximately 10^{16} Cu atom/cm³ and 5×10^{15} Au atom/cm³.

Figure 4 shows the results with gold after the exposures. None of the treatments shows any appreciable influence on the redistribution of the gold. This behavior is in clear contrast to that of the copper, and indicates that there are indeed differences in the ability of chlorine to getter different metals. These differences are believed to stem from differences in the thermodynamic stability of the metal chloride.

For example, copper chloride is stable in a vapor phase at temperatures used during oxidation. Gold chloride decomposes at temperatures below 573 K (5).

Conclusions

In this investigation, silicon wafers were contaminated with copper and gold. Oxidations were then carried out at temperatures of 1173-1473 K using additions of 0-10% HCl to dry O_2 gas. In all cases, the metallic impurity concentration profiles were established to better than 1 ppm using atomic emission spectroscopy of solutions containing dissolved samples.

Copper is easily removed by the addition of HCl to the oxidizing ambient, but gold is not affected. The observed behavior is attributed to the existence of a volatile copper chloride and the lack of any stable gold chloride at the temperatures used.

Cathodoluminescence of MgS:RE Phosphors

R. P. Rao

Materials Science Centre, Indian Institute of Technology, Kharagpur 721-302, India

Alkaline earth sulfides (AES) has been known for a long time to be excellent and versatile phosphor material (1). These are traditionally known as Lenard phosphors. Luminescence and electronic properties of sulfides like ZnS and CdS, belonging to (II-IV) group, have been widely studied (2). However, systematic investigations have not been made in detail on alkaline earth sulfides of the same group (II-VI) because of their chemical instability with atmospheric moisture and poor reproducibility. After Lehmann's extensive study (3-7), these sulfides have gained in importance as efficient phosphors, particularly in cathodoluminescence because of their low current saturation. When doped with certain impurities such as rare earths (RE), they produce emission from the UV to the near-IR regions. In the past, many workers have doped the phosphors with impurities in the presence of flux in order to reduce the doping temperature as well as to create a media for incorporation of impurities into the lattice.

Most of the earlier work on these sulfides has been carried out only on the studies of phosphorescence (8), photo-, thermo-, and electroluminescence (9-12). Recently, Kasano *et al.* (13) have reported the preparation and cathodoluminescence properties of Eu²⁺- or Ce³⁺-activated MgS and Ca_{1-x}Mg_xS phosphors. In this paper, the preparation and cathodoluminescence (CL) of MgS:RE (RE = Eu, Sm, Ce) are reported. From these results, the emissions of Eu²⁺, Ce³⁺, and Sm²⁺ are explained by considering their transitions.

Experimental

Polycrystalline MgS was prepared by reducing pure MgSO₄ (E. Merck, Germany) with pure CS₂ in an argon atmosphere. A good yield of MgS in the final product was obtained by passing CS₂ at 900°C for 1.5h. MgS phosphors were prepared by doping with different quantities of the rare earth elements Eu, Sm, and Ce. In the process of doping, MgS and MgSO₄ (4:1 by weight) were mixed with

the required amounts of respective rare earth oxides and fired at 900°C for 1.5h in the presence of CS₂. In the past, MgS:Ce films were prepared by firing MgO:Ce films in H₂S atmosphere at 950°C (14). In this investigation, films of different thicknesses were prepared by depositing fine grains of average particle sizes on well-cleaned glass substrates in an aqueous medium at room temperature (300 K) by sedimentation technique. The samples were dried and then protected from atmospheric moisture by coating with a polymer binder (Dow Corning 805). The texture of the films was studied with scanning electron microscopy.

The phosphor films were excited by 10 kV electrons at approximately 0.5 mA/cm² in a demountable cathode ray tube at 300 K. The emission from the excited samples was recorded with the help of a Bausch and Lomb monochromator and photomultiplier (PM) (XP1117) tube. All spectra presented in this paper were corrected for monochromator and PM tube response.

Results

In the process of materials preparation, the firing temperature (900°C) and the duration of firing (1.5h) were fixed at optimum values from a few trials at different temperatures and durations and from a consideration of other data such as DTA, TGA, DTC, etc. (15). To avoid the complications with residual flux left in the final product as well as the incorporation of unwanted impurities, MgS and MgSO₄ were taken as starting materials in the ratio 4:1. Moreover, MgS is highly hygroscopic, and it is difficult to separate the flux from the final product (16). As the melting temperature of MgSO₄ is well below the melting point of MgS, the firing temperature of the mixture would be reduced moderately.

X-ray diffraction spectra of these films exhibited the prominent lines of MgS, and no lines corresponding either to MgSO₄ or MgO were observed. Figure 1 shows the scanning electron micrographs of MgS doped with RE.

Fig. 1. Scanning electron micrographs of polycrystalline films. a (left): MgS:Eu. b (right): MgS:Ce phosphors.

Fig. 2. Cathodoluminescence of MgS:Sm phosphor

From the photographs, it is clear that the films formed by the sedimentation technique used in this study are uniform.

Though many samples were prepared with different concentrations of impurities, only results on typical concentrations are presented in this paper. The cathodoluminescence spectrum of MgS:Eu (0.1% by weight) is observed in the red region with a band maximum at 590 nm. Two emission bands were observed in the green (525 nm) and red (590 nm) regions in the case of MgS:Ce (0.1% by weight) phosphors. As shown in Fig. 2, three emission bands are observed at 575 (green), 610 (red), and 660 nm (deep red) in the cathodoluminescence spectrum of MgS doped with Sm (0.1% by weight). The above results are explained by considering the possible transitions proposed by various workers in similar type of materials.

Discussion

The chemicals used in the preparation of MgS:RE were of 99.99% purity. The only possible activators doped were rare earths, and there was no coactivator since there was no flux material. The emission bands observed in this study are due only to rare earth ions. The Eu^{2+} ion is known as a broad-band $4f^65d \rightarrow 4f^7$ emitter. The ground state is $^6S(4f^7)$, and the lowest excited state is $4f^65d$. From the results of this investigation, the emission can also be interpreted as allowed transitions to the ground state $^6S_{7/2}$ from the excited states of $4f^65d$ configuration. Nakao (17) has observed the emission bands at 592, 652, and 594 nm for MgS, CaS, and CaSe, respectively, doped with Eu at 300 K. It was also reported (17) that sharp spiked lines (phonon lines) appeared on the shorter wavelength side at low temperatures (80 and 6 K), as observed by others in the case of alkali halides doped with Eu. From this extensive study, it was concluded that these bands are due to Eu^{2+} ion centers.

The emission of the Ce^{3+} ion corresponds to a $5d-4f$ transition. Since the configurational coordinate curves of these two levels are different, the emission has a broad-band character. The band has a doublet due to the ground-state splitting, $^2F_{5/2}$ and $^2F_{7/2}$ (18). Gilliland (14) has reported that the emission band (second peak) at 610 nm

with higher concentrations of Ce becomes dominant with the Ce to Mg ratio was 1:1 in case of MgS:Ce phosphors. The emission observed in this investigation is exactly the same as that observed by Asano *et al.* (19). They reported that the emission bands $^2T_{2g}(5d) \rightarrow ^2F_{7/2}$, $^2F_{5/2}(4f)$ originating from the intraionic transitions of Ce^{3+} . The band maxima are at 2.36 and 2.1 eV with an energy difference of 0.26 eV, which corresponds nearly to the difference between the energy levels of $^2F_{5/2}$ and $^2F_{7/2}$ of 4f electrons of Ce^{3+} ion. Lehmann has observed three bands in the yellow, red, and deep red for the same type of phosphors. Data on Sm^{3+} -doped alkaline earth sulfides are few. Also, the possible transitions are not discussed anywhere. The Sm^{3+} rare earth ion is one possessing a complex nature with a total number of 1994 levels and 306,604 possible transitions (20), it will only be speculative to propose any possible allowed transitions from the above results. However, from the bands at 17,452, 16,393, and 15,152 cm^{-1} , the transitions like $^4G_{5/2} \rightarrow ^6H_{5/2}$, $^4G_{5/2} \rightarrow ^6H_{7/2}$, and $^4G_{5/2} \rightarrow ^6H_{9/2}$ may be proposed. It needs further detailed investigations to find out the exact transitions of Sm^{3+} involved.

It is concluded from these studies that these MgS phosphors can be prepared in a simple way and used as CL phosphors. Further experiments are required to understand the role of RE impurities on the emission characteristics in these phosphors. The efficiency could be determined by comparing with standard CL phosphors.

Enhanced Diffusion in Boron Implanted Silicon

L. C. Hopkins, T. E. Seidel,¹ J. S. Williams,² and J. C. Bean*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

INTRODUCTION

When boron is implanted into crystalline silicon the dopant distribution includes a deeply penetrating tail due to ion channeling (1,2). This channeling tail is an unavoidable consequence of large angle scattering events occurring during implantation. When such samples are annealed it has been observed (3-6) that boron in the tail region diffuses anomalously fast. This occurs for both long (~30 min) furnace anneals at low temperatures (700-800°C) (3) or rapid (~10 sec) higher temperature anneals (1050-1100°C) (4-6).

The cause of this enhanced diffusion has been the subject of considerable discussion (7,8). One possibility, proposed by Fair (7), is that point defects created by the implantation (e.g., vacancies and/or self-interstitials) enhance the tail diffusivity. Because such defects are created primarily near the peak of the boron implantation distribution, this model must involve migration of such defects from the peak damaged region inward to the deeper channeling tail. In this paper we report an experimental test of this "non-local" diffusion model. Samples are annealed with and without the heavily damaged surface region and profiled by SIMS. Preliminary results show similar diffusion in both sample lots in contradiction to the Fair proposal, implying that the enhanced tail diffusion is a "local" phenomenon.

EXPERIMENTAL

Boron was implanted with two batches of 4" <100> 10 Ω cm P-type silicon wafers (#A and #B) using an Extrinsic DF4 implanter. The wafers were tilted ~7° off-normal, in an arbitrary rotational direction and implanted at room temperature. Boron energy was 40.0 keV and swept beam current was kept low (~100 μA) to avoid beam heating. After implantation wafers in each batch were divided and adjacent pieces were etched in an HF-HNO₃ solution to remove ~2000Å (as verified by Dektak profilometer measurement). This 2000Å region contained the peaks of both the boron and damage distributions. Adjacent unetched and etched portions of the B wafers were then annealed together in a rapid thermal annealing furnace at ~1100°C for ~10 sec. This yielded the following sample matrix

Table I. Sample Matrix

#	Implanted	Etched	Annealed
A	X		
A'	X	X	
B	X		X
B'	X	X	X

Boron profiles were measured using an Atomika A-DIDA-3000-30 ion microprobe. An O₂⁺ primary beam was selected to enhance boron sensitivity. The O₂⁺ beam was incident 2° off-normal at an energy of 10.0 keV. The 300 μA analysis beam was focused to ~100 μm and scanned over a 1/2 mm × 1/2 mm crater yielding an etch rate of ~1/2 μm/hr. Samples were analyzed back-to-back in a vacuum of 2 × 10⁻⁹ torr. Signal was collected only over the center 30% of the analysis crater to ensure adequate depth resolution.

Because the experiment depended on discrimination of subtle differences in diffusion profiles, two means were used to monitor and confirm stable SIMS operation. First, both boron and silicon ¹⁴Si⁺⁺ profiles were measured. Drift in the analysis beam current or detection sensitivity would then be revealed by drift of the ¹⁴Si⁺⁺ signal. Second, the depth integral of the ¹⁴Si⁺⁺ signal was compared to the measured volume of the analysis crater. Data was only used if both the ¹⁴Si⁺⁺ signal was constant during the run (within ±5%) and if the integrated silicon count to volume ratio was constant sample to sample (within ±10%).

Typical raw SIMS data is shown for samples #A in Fig. 1. Data for runs satisfying the two above tests were then converted to concentration vs depth profiles via the following processing. To generate a concentration scale, the ¹¹B⁺ count was first divided, point by point, by the ¹⁴Si⁺⁺ count. This would normalize out any residual drift in SIMS sensitivity. Second, the SIMS boron background signal (as indicated by the flat base count at the deep end of the distribution) was subtracted from the normalized boron count. Finally, the depth integral of the normalized boron count for samples A and B was compared to the stated implant dose of 2 × 10¹⁵/cm² yielding calibration constants for each sample. The calibration constants for the A and B samples were then transferred to the A' and B' samples respectively. (A and B samples were calibrated separately to account for a slight discrepancy between implantation doses to the wafers.)

Fig. 1 Raw (unprocessed) data for control boron implanted sample (#A: unetched and unannealed).

The depth scale was established by setting the total sputter time equal to the total crater depth, sample by sample. Given that the samples were composed only of Si and trace B and that the $^{14}\text{Si}^{++}$ reference counts were constant during profiling, it can be safely assumed that the sputter rate was constant. Intermediate depth points were therefore established by linear interpolation of the total analysis depth.

RESULTS

Processed data are shown in Figs. 2 and 3. Figure 2 compares unannealed and annealed boron distributions in unetched samples (A and B). Figure 3 compares unannealed and annealed distributions in etched samples (A' and B'). In both figures the channeling tail falls at a rate of $\sim 6.1 \times 10^{15}/\text{cm}^3/\text{\AA}$ in unannealed samples vs $\sim 4.5 \times 10^{15}/\text{cm}^3/\text{\AA}$ in annealed samples. Within our experimental accuracy, the presence or absence of the maximally damaged near-surface region has no effect on the enhanced diffusion of channeled boron tail. Because samples were implanted at room temperature and subjected to no high temperature processing prior to etching, point defects created

Fig. 2 Processed (calibrated) data for unetched samples with (#B) and without (#A) post implantation anneal.

near the peak of the boron distribution should have been frozen in place and thus removed by the etch. The near identical diffusion of etched and unetched samples therefore indicates that these defects are not responsible for the enhanced channeling tail diffusion.

Fig. 3 Processed (calibrated) data for $\sim 2000\text{\AA}$ etched samples with (#B) and without (#A') post implantation anneal.

To summarize, SIMS profiling experiments on boron implanted silicon samples indicate that radiation damage created near the peak of the boron profile cannot be the dominant agent producing anomalous diffusion. Alternate models are therefore required to explain and predict the annealing behavior in this technologically important process.

A Performance Improvement for High Temperature Stabilized-Zirconia pH Sensors

Mike J. Danielson* and Oscar H. Koski

Pacific Northwest Laboratory, Richland, Washington 99352

Jonathan Myers

Rockwell Hanford Operations, Richland, Washington 99352

In a recent paper, Danielson, Koski, and Myers (1) reviewed the literature on high temperature pH sensors constructed from yttria-stabilized zirconia. They also reported their own work in which sensors demonstrated excellent pH response in the range of 100 to 300°C. Danielson et al. (1) recognized from their potential measurements that the sensors acted reversibly to oxygen (on their internal surface) by the following equilibria:

This observation has great importance for simplifying the calibration procedure. Previously, all the metallic fills studied (Cu/Cu₂O, Ag, Au) by the authors required a preliminary autoclaving to 250 to 300°C before their potential was that predicted by Eq. [4], and this is very inconvenient for pH studies between 100 to 250°C. This note discusses a platinum fill which results in the sensors acting reversibly to oxygen at 100 to 300°C without the need for initial autoclaving at 250 to 300°C.

The metallic platinum is applied as a thin coating to the inside of the sensor (Figure 1). The Pt coated sensors will start out at 100°C being poised by oxygen from the air, and it is our experience that sensors which have good pH response at 100°C will operate even better at higher temperatures. The 8 wt% yttria sensors were evaluated in a silica-carbonate buffer (F⁻, 17.6 mg/l; Cl⁻, 335 mg/l; SO₄²⁻, 2.4 mg/l; Ca²⁺, 1.3 mg/l; K⁺, 10 mg/l; Na⁺, 399 mg/l; Si, 43.4 mg/l; CO₃²⁻, 67 mg/l; HCO₃, 32 mg/l; pH = 9.77 @ 25°C) sparged with hydrogen at

one atmosphere. A platinized-platinum hydrogen electrode and external Ag, AgCl reference electrode (0.100 M KCl) were used in the experiments carried out at 100, 150, and 200°C. Corrections were made for the thermal liquid junction potential of the external reference to place the potentials on the Standard Hydrogen Electrode scale. All the zirconia sensors had a Pt fill. Table I shows the calculated pH for the hydrogen electrode and the zirconia sensors. The old zirconia sensors had a varied autoclave history including about 30 days of autoclaving before this test. Sensor 1 is defective (doesn't give full Nernstian response at 100°C) and is included for comparison. We have observed that sensors will develop a degraded pH response (when evaluated at 100°) when subjected to 300°C conditions for a week or more.

Table I. pH Measurement Data

Sensor	Description	pH (Calculated)		
		100°C	150°C	200°C
H ₂	Hydrogen electrode	8.77	8.29	7.99
1	ZrO ₂ /old	8.39	8.36	7.71
2	ZrO ₂ /old	8.73	8.29	7.91
3	ZrO ₂ /new	8.69	8.35	7.92
4	ZrO ₂ /new	8.97	8.41	8.11

The pH values were calculated by using the E° (Table II) of Eq. [4], the measured voltage of the sensors on the hydrogen scale, and the Nernst equation (taking account that fO₂ = 0.2). This is an especially severe test of the pH performance of the zirconia sensors since pH sensors are normally standardized in a known buffer and their pH response measured relative to this value. Except for the response of Sensor 1 at 100°C, the measured pH is within 0.2 pH units of the value measured using the

* Electrochemical Society Active Member.

hydrogen electrode, and the agreement improves as the temperature increases. Though this data only goes to 200°C, it is our experience that even better performance would be expected at 250 and 300°C.

Table II. E° Data

T	E°
100°C	1.167 V
150°C	1.127 V
200°C	1.088 V
250°C	1.050 V
300°C	1.013 V

The following procedure is used to coat the sensors:

- 1) Coat inside of sensor (depth of 2.5 cm) with Englehard Pt ink (No. A-4338).
- 2) Dry at 120°C for one hour to harden the coating.
- 3) Wind piano wire around mandrel to make a spring which is a little larger in diameter than the sensor I.D. Coat spring with Pt ink and insert.

Figure 1. pH Electrode

- 4) Fire in air to 400°C for 18 hours.
- 5) Epoxy ceramic collar to upper portion of sensor after cooldown.

This development demonstrates a significant simplification in the calibration process which should assist in the practical application of the sensors for temperatures of 100 to 300°C. More accuracy can be obtained by using a buffer of known pH to standardize the sensors as is currently done with glass pH sensors at ambient conditions.

A Discussion of the Mechanism of Cadmium Migration in Sealed Nickel-Cadmium Cells

David H. Fritts* and Ross E. Dueber*

Air Force Wright Aeronautical Laboratories, Wright-Patterson Air Force Base, Ohio 45433

ABSTRACT

Cadmium migration in sealed nickel-cadmium cells was studied in order to explain the occurrence of premature cell failure due to internal shorting. Time lapse microphotography of the cadmium surface revealed numerous migration regions growing during the life of a single cell. The dominant transport mechanism of the active material was hydrodynamic in nature and was due to molar volume changes occurring in the electrode. Migration occurred "en masse" with the migration regions charging and discharging with the electrode. Individual migration regions were analyzed under the SEM and were shown to consist of both crystalline and amorphous forms of active material. It was determined that the amorphous active material contained metallic cadmium which allowed for an electronic connection to the negative electrode. Growth of the migration regions occurred through a precipitation/dissolution mechanism of the active material until a short circuit developed between the two electrodes.

Failure analyses of sealed nickel-cadmium cells indicate that cadmium migration is a major cause of premature cell failure (1-4). Several theories exist explaining the mechanism by which the active material traverses the separator region from the cadmium electrode (4-6). Through the use of time-lapse microphotography, we have observed that the migration occurs "en masse" at selected positions on the surface of the electrode (7). These migration regions are not dendrites in the true sense, but are rather mound-like structures protruding into the separator. We believe the migration regions consist of both metallic cadmium and cadmium hydroxide. Our films show the regions of active material growing in size as the number of cycles increases. Eventual failure of the cell occurs by the formation of numerous "soft shorts."

Experimental

Four types of test cells were constructed for defining a mechanistic model of cadmium migration. The various cell types were fabricated to answer questions that occurred to us as the investigation progressed. The first type of test cell, cell 1, was constructed for filming under the microscope. It consisted of one cadmium and one nickel electrode, each cut $28.0 \times 18.0 \times 0.8$ mm from commercially manufactured, chemically impregnated plates, placed in a Plexiglas case equipped with a Teflon gasket and a removable Plexiglas top. One layer of nylon mat served as the separator (Fig. 1). In order to avoid interference of the electrode surface, a minimal amount of electrolyte was used (0.3 ml of 32 weight percent [w/o] KOH *vs.* a calculated 0.45 ml cell void volume). Current was drawn at the 1C rate, based on a $\text{Ni}(\text{OH})_2$ electrode capacity of 121 mAh, using a Hewlett-Packard Model 6177 dc current source. Depth of discharge progressed from 20 to 40 to 80%. Cell failure occurred at cycle 1728. All testing was performed at room temperature.

Filming of the cell was performed at $75\times$ magnification using a Bolex 16 mm movie camera attached to an Olympus Model BH10 metallurgical microscope with a time lapse control unit.

Cell 2 was designed to minimize the interactions between the nickel and cadmium electrodes by separating

the two in different compartments with a common electrolyte reservoir (Fig. 2). The electrodes were identical to those used in the first cell. Holes were drilled into the side of the cadmium electrode compartment to control electrolyte flow. A thin layer of paraffin oil was placed on the electrolyte surface to prevent the formation of carbonates in solution. The cell was given a full charge and then cycled at the 0.67C rate to a 20% depth.

In addition to the above, two other cells were also constructed for specific testing purposes. Cell 3 was constructed using nickel and cadmium electrodes cut from the above-mentioned plates without utilization of a separator. The electrodes, with dimensions $36.0 \times 12.0 \times 0.8$ mm, were placed in a Plexiglas box 6 mm apart. The space between the two electrodes was filled with 0, 10, and 20 w/o cadmium metal (Alfa-Ventron, M6N, 200

Fig. 1. Time lapse microphotography cell, cell 1

*Electrochemical Society Active Member.

Fig. 2. Cell for isolating electrode interactions, cell 2 (inset depicts estimated electrolyte flow pattern).

mesh) with the balance of the mixture being cadmium-hydroxide (Alfa-Ventron ultrapuriss.). A constant current of 50 mA was used to charge and discharge the cell between voltage limits of 1.8 and 0.4V. The electrolyte was again 32 w/o aqueous KOH.

The fourth cell, cell 4, was constructed using a standard sintered nickel electrode with the dimensions of $15.0 \times 30.0 \times 0.8$ mm. The counterelectrode was a coiled cadmium wire of 1 mm diam. The length of the wire submerged in electrolyte was 16 cm. The cell was cycled between 1.93 (peak voltage on charge) and 0.65V. A constant current of 600 μ A was kept using the Hewlett-Packard Model 6177C dc current source. The parameters measured were cell capacity and voltage.

Analyses of the cadmium electrode surfaces and cell separators were performed with an ISI scanning electron microscope equipped with a Kevex dispersive x-ray spectrometer.

Results

Our initial viewing of the films provided us with a great deal of insight into the environment of a nickel-cadmium cell during cycling. Readily apparent from the beginning are the hydrodynamic forces present throughout the cell. In both starved and flooded cells, electrolyte could be seen constantly moving back and forth between the electrodes and the separator. Small particles of active material and sinter were detached from the electrodes by the hydrodynamic forces and subsequently distributed randomly throughout the separator region. The severity of electrolyte pumping action could be increased and decreased by proportionally varying the current rate.

Several migration regions formed on the electrode surface near the top of cell 1 and were able to be filmed. We focused upon one rather large migration region (0.63×10^{-2} cm across at base) which we found after the eight hundredth cycle. For the remainder of the cell's life, the camera filmed the behavior of this region which consisted of mossy active material. It was obvious after a few hundred cycles that the migration area indeed was growing. Measurements from the film estimated the migration region to be 1.3×10^{-2} - 2.0×10^{-2} cm at the base and 2.0×10^{-2} cm from base to peak when the cell finally failed. Another migration region similar to this one, however, was the ultimate cause of cell shorting.

A more careful viewing of the films showed other interesting phenomena occurring inside the cell. Several rather large pieces of active material, which apparently had broken off the cadmium electrode, were found moving randomly throughout the separator region. No agglomeration of these pieces was found forming a bridge between the two electrodes.

A patterned color change in the migration region was also noticed with each charge and discharge. Color changes in the migration region began at the peak and progressively moved towards the base during both charge and discharge. The color change was seen to be much faster during discharge than during charge.

In cell 2, we again observed numerous migration regions on the surface of the cadmium electrode, although they were much smaller in size than in the previous cell. Specific details of the growth of these regions was obscured due to the flooded state of the cell and the paraffin oil layer. After completing 1400 cycles, the cell was disassembled and the surface of the cadmium electrode rinsed, dried, and examined. Without the aid of magnification we were able to see four very large, distinct migration regions. The positions and size of these regions corresponded to the holes in the Plexiglas case where the electrolyte entered. Micrographs taken by the SEM revealed three distinct areas in each migration region. Figure 3 depicts an overall view of one migration region. There is the central migration area where buildup of active material is the greatest. A more detailed micrograph (Fig. 4) shows the central migration area to be a combination of both crystalline and mossy active material. Immediately surrounding the central area is a second area that is relatively clear of active material (Fig. 5). The roller tracks on the sintered substrate are even exposed. Farthest from the central area is the outer or peripheral area, which is representative of the morphology of the majority of the cadmium electrode surface (Fig. 6).

Each of the three separator mixtures used in cell 3 completed more than 100 cycles without a failure. The only change observed in the separator mixture was a gradual darkening of the originally white cadmium hydroxide with time.

The cadmium wire cell, cell 4, was deep discharged 92 cycles. The maximum capacity of the wire on discharge, between the previously stated potentials, was 1.97C. In Fig. 7, an SEM micrograph of the wire surface is shown. Generally speaking, the surface is characterized by a mossy structure which is strewn with β -Cd(OH)₂ crystals. This is very similar to our structural observations noted with sintered electrodes.

Discussion

Ordinary vented aircraft nickel-cadmium cells employ gas-impermeable separators which act as barriers to active material. Sealed nickel-cadmium cells, on the other hand, utilize nylon mat separators which allow for gas recombination to take place. Unfortunately, this permeability is a detriment to the inhibition of the migration of active material. As cycle life increases, active material from the cadmium electrode forces its way through the separator and eventually contacts the nickel electrode. These "short circuits" lead to decreased cell performance and subsequent cell failure.

Several models exist for the mechanism by which active material migrates into the separator. Mayer (8) had suggested that negatively charged Cd(OH)₂ could be transported electrophoretically away from the cadmium

Fig. 3. Migration region on cadmium electrode from cell 2

Fig. 4. Central migration area from cell 2

Fig. 6. Peripheral area of cadmium electrode from cell 2

electrode. Discrepancies with this model were brought forth by several other researchers in the field, including Barnard *et al.* (9) and James (10, 11); therefore, we chose not to consider it as a viable model at this time.

The remaining two models suppose Cd(OH)_2 is initially deposited in the separator and then converted to metallic cadmium. The difference between the two models lies in the method of reduction of Cd(OH)_2 . Several authors believe the reduction of Cd(OH)_2 occurs through a solid phase reaction (12-14). For failure to happen through such a process, Cd(OH)_2 would have to become detached from the electrode and in turn agglomerate in the separator to form a connection between the cadmium and nickel electrodes. Cadmium hydroxide would then be reduced to metallic cadmium, which results in the formation of what is termed a "soft short."

In contrast to solid-state reduction of Cd(OH)_2 , the precipitation/dissolution model advocates reduction through the formation of soluble intermediate phases (15). Rotating disk electrode studies by Okinaka (16) provided evidence for the existence of both solid and solution phase transport of cadmium species. During anodic oxidation, the mechanism appears to be a predominantly solution phase. The intermediate species formed on both charge and discharge is Cd(OH)_3^- (16-17). The Cd(OH)_3^- could, according to the model, recrystallize in the separator and provide paths for shorting to occur (18). Shorting paths could occur according to the following possible reactions as represented by McDermott (19)

Discharge

or

Charge

or

The solubility of the intermediate species is well established. Its transport is dominated by the pumping action of the electrolyte as viewed in the film of cell 1. This pumping is due to specific volume changes in the electrodes. During discharge, cadmium is converted to cadmium hydroxide, resulting in an increase in the electrode's specific volume and the accompanying displacement of electrolyte into the separator. Such convective currents as McDermott suggests (19) could carry the solvated cadmate species outwards from the electrode interior. We have found that precipitation of Cd(OH)_3^- occurs at selected nucleation sites on the cadmium electrode surface, rather than in the separator, thus forming the migration regions we observed (Fig. 8). We do not

Fig. 5. Area of electrode surrounding the central migration area from cell 2.

Fig. 7. Surface of cycled cadmium wire

Fig. 8. Migration region filmed in cell 1 (Cd at top, Ni at bottom)

know at this time why some nucleation sites on the electrode surface are more active than others. This is quite difficult to determine in light of the fact that the micromorphology of the surface is so complex and varying. These migration regions do, however, grow in size with cycle life as increasing amounts of $\text{Cd}(\text{OH})_2$ are precipitated.

Attempts were made to study the individual migration regions in cell 1 with the SEM, but failed because of our inability to preserve an intact region upon separating the electrode and the separator. After several hundred cycles, the separator and the electrode surface meld together and become somewhat indistinguishable. We do not believe this behavior is strongly related to the degree of electrolyte starvation in our test cell. The amount of cadmate ion transported is proportional to the volume of electrolyte "pumped" from the electrodes. This pumping occurs during charge/discharge when the electrodes undergo molar volume changes. Therefore, the dominant parameter affecting migration is thought to be depth of discharge.

A micrograph was taken of a cross section of the separator (Fig. 9), and dispersive x-ray elemental mapping of the cross section verifies that active material is pushing through the separator in the form of a migration region. This would account for the presence of active material in the separator, which was previously thought to have precipitated out on nucleation sites within the separator itself. No evidence was found to support a precipitation mechanism within the separator region. Active material in the separator is the result of either intact migration re-

Fig. 9. Cross section of separator from cell 1 (Cd side at top, Ni side at bottom).

gions or pieces of migration regions detached from the electrode by the hydrodynamic forces of the electrolyte.

In order to study cadmium migration behavior without hindrance from either the separator or the nickel electrode, cell 2 was designed and built. The nickel electrode was positioned at a great enough distance from the cadmium electrode to negate the effects of gassing and specific volume change. The result was much the same as before, only this time the migration regions were smaller in size. The occurrence agrees with what Will and Hess (17) stated about the extent of migration being directly related to the rate of discharging and the number of cycles. The lower discharge rate would in fact decrease the hydrodynamic force of the electrolyte and lessen the amount of dissolved cadmium carried to the electrode surface for precipitation.

Except for the four migration regions, the dominant morphology of the electrode surface is as shown in Fig. 6. These "boulders" are $\beta\text{-Cd}(\text{OH})_2$ which have predominantly formed through the dissolution/precipitation mechanism. They have been observed by Ritterman (20), and are akin to the classical hexagonal platelets (Fig. 10).

In contrast to the well-defined $\beta\text{-Cd}(\text{OH})_2$ of the peripheral area, there are the smaller crystals and mossy material of the central migration area. Figure 4 shows the small $\beta\text{-Cd}(\text{OH})_2$ crystals covered by the mossy active material. What appears to have happened is that active material surrounding the central migration area has been swept from the substrate and deposited at its current position by the flow of electrolyte into and out of the electrode compartment. As before, the electrolyte flow is caused by specific volume changes in the cadmium electrode. The dissolved cadmate species is transported by the electrolyte flow to the central migration area, where it randomly precipitates as mossy material.

Our comparison of the structure of the mossy material to the structure of the migration region filmed in cell 1 revealed a striking similarity between the two. Others have observed the presence of this particular structure of active material as well (21, 22). Judging from the charge/discharge behavior of the migration region in cell 1 and the growth of the migration region in cell 2, we believe that this mossy active material, and not the highly crystalline structure, is responsible for the eventual short circuit. Crystalline $\text{Cd}(\text{OH})_2$, especially the large $\beta\text{-Cd}(\text{OH})_2$ crystal, is supposedly difficult to recharge (17, 20). Our films of cell 1 show the migration region is charging and discharging in unison with the cadmium electrode. The change in the color of the migration region is due to the absorption and expulsion of electrolyte caused by the specific volume change of the electrode. It is quite important to note the direction of the color change of the migration region upon current reversal. On both charge and discharge the color change begins at the

Fig. 10. Cadmium electrode from cycled cell

peak, implying that the electronic attachment to the nickel sinter is not broken.

Unlike cell 1 where the active migration regions were random throughout the electrode surface, in cell 2 we were able to select the position where migration occurs by controlling the electrolyte flow. The presence of the mossy material again implies some sort of solid-state connection to the nickel sinter. Chua found this same mossy material on the surface of cadmium electrodes which had been cycled at 1C discharge rates (22). Using the energy dispersive system, he determined the material to be cadmium. We were unable to determine the exact composition of the mossy material using the same technique owing to the elemental limitations of the instrument.

The evidence presented so far strongly suggests the growth of the migration region occurs through the precipitation of the dissolved cadmate species as $\text{Cd}(\text{OH})_2$. Electronic connection to the nickel sinter is maintained by underlying, unconvertible metallic cadmium which exists in the migration region. As the migration region grows, additional $\text{Cd}(\text{OH})_2$ is precipitated and converted to Cd until the short circuit between the two electrodes is complete.

Attempts were made to approximate both the composition and behavior of a migration region. Metallic cadmium was interspersed throughout cadmium hydroxide and placed between two electrodes in cell 3. We tried to convert the $\text{Cd}(\text{OH})_2$ to Cd with the help of the interspersed metallic Cd powder, thus creating a short circuit. Our failure to accomplish this suggests that an electronic connection with the nickel sinter begins at the electrode surface and cannot be formed through the agglomeration of migration material in the separator that comes in contact with the electrode.

The basic migration structure we have developed through the course of this paper is one that is dominated by a composite of three material forms: metallic cadmium, a finely divided $\text{Cd}(\text{OH})_2$, and $\beta\text{-Cd}(\text{OH})_2$. The $\beta\text{-Cd}(\text{OH})_2$ plays a passive role in that it is electronically isolated [continuous growth occurs through precipitation of $\text{Cd}(\text{OH})_3^-$ ions]. The portion of the structure that is capable of causing cell shorting is a mossy mixture of Cd/Cd(OH)₂. This statement implies that metallic cadmium is always present in the migration region and that it is electronically connected to the substrate. Confirming these contentions beyond a doubt is extremely difficult, and we did not develop a successful technique here, but certain questions do arise, given that the model is correct, that can be answered.

A necessary condition for the model to be correct is the migration region cannot be totally converted to $\text{Cd}(\text{OH})_2$; otherwise, it would become electronically isolated. This implies that the metallic cadmium present can only be partially converted and self-passivation by $\text{Cd}(\text{OH})_2$ occurs. To test this contention, the cadmium wire cell was built. If passivation did not occur, the wire could be discharged until it was totally converted or isolated by fracture. Our results indicate that the wire does indeed passivate. The maximum capacity achieved was 1.97C. The corresponding volume of material discharged is $1.33 \times 10^{-4} \text{ cm}^3$ as given by

$$V = CM/2\rho e$$

where C is the capacity, M the mass of cadmium atom, ρ the density of cadmium, and e an electronic charge. The value of V is approximately $8.7 \times 10^{-2}\%$ of the total wire volume.

An estimate for the thickness of the discharge layer (dr) can be obtained by dividing V by the surface area of the wire. If it is assumed that the wire surface remains smooth (area = $2\pi rl$), then the estimated discharge thickness from the capacity measurements is $3.5 \times 10^{-5} \text{ cm}$, which is three orders of magnitude smaller than a characteristic dimension of a developed migration region. It should be noted that the surface of the wire is not smooth (Fig. 7), and therefore the area is larger than the $2\pi rl$ and the dr from V is less than $3.5 \times 10^{-5} \text{ cm}$. Thus, only a small fraction of the available cadmium could be dis-

charged prior to self-passivation, making it quite possible for metallic cadmium to permanently exist in the migration region.

Conclusions

In aqueous cells with cadmium electrodes, various cadmium species are transported throughout the cells. The dominant transport mechanism is forced convection of the electrolyte caused by molar volume changes in the electrode active materials as they are charged and discharged. The species transported are soluble cadmium ions, such as $\text{Cd}(\text{OH})_3^-$ and/or particulate material such as $\beta\text{-Cd}(\text{OH})_2$ crystals.

The failure of sealed nickel-cadmium cells is often due to a phenomenon called "soft shorting." Soft-short failures are associated with the penetration of the separator by material transported from the cadmium electrode. In this paper, we have described the nature of the separator penetration that causes soft shorting.

We have chosen the terminology of migration region for these areas, as indeed they appear to be a slow migration of active material that starts from the interior of the electrode and does not terminate until it has grown through the separator and shorted the cell. Time lapse microphotography of these growth regions has shown that they are characterized by a mossy material that charges and discharges with the cadmium electrode. The structure may contain $\beta\text{-Cd}(\text{OH})_2$ crystals, but we have concluded that these are electronically inactive and do not contribute to the short. The mossy portion of the migration region consists of both metallic cadmium filaments that extend from the electrode substrate to the tip of the region and finely divided cadmium hydroxide. The metallic portion of the region can survive successive discharges, as the discharge process is self-passivating, with the average physical depth of discharge estimated to be less than $3.5 \times 10^{-5} \text{ cm}$.

We have also shown that metallic cadmium particles mixed with finely divided cadmium hydroxide will not short a cell, leading to the conclusion that random deposition of cadmium species within the separator will not cause a short. It is a necessary prerequisite for shorting that metallic cadmium filaments be grown from the electrode substrate.

Relationships Between Carbon Black Cathode Material Characteristics and Lithium/Oxyhalide Cell Performance

K. A. Klinedinst*

GTE Laboratories, Incorporated, Waltham, Massachusetts 02254

ABSTRACT

Nine carbon blacks with iodine surface areas ranging between 60 and 1222 m^2/gm and with dibutyl phthalate absorption numbers ranging between 125 and 420 $\text{cm}^3/100 \text{ gm}$ have been evaluated as lithium/oxyhalide cell cathode materials. Two criteria have been considered: their ability to serve as heterogeneous catalysts for the cathodic half-cell reaction (a function of both internal surface area and specific activity), and their ability to accommodate the continuous deposition of solid discharge products with minimal internal resistance losses (a function of both the porosity and pore size distribution of the agglomerated carbon particle aggregates). For carbons with surface areas of at least 250 m^2/gm , overvoltages for SOCl_2 reduction are practically independent of carbon black surface area. Furthermore, cathode porosities and Li/SOCl_2 cell discharge capacities both correlate with the DBP absorptometer numbers characteristic of the high surface area carbon blacks themselves. If the activity of a low surface area carbon is augmented via a catalytic additive (e.g., supported platinum), overvoltages similar to those obtained with high surface area carbons and complete utilization of the cathode's internal pore volume are achieved. The use of cathode "pore formers" may also lead to improved performance characteristics, particularly at very high current densities where pore former particle diameters averaging about 200 μm yield optimal performance results. Of the commercially available carbon blacks examined, Ketjenblack EC and Black Pearls 2000 function best as Li/SOCl_2 cell cathode materials, greatly outperforming the standard carbon, Shawinigan acetylene black.

Shawinigan acetylene black (containing 5-10% PTFE as a binder) is the commonly used cathode material for lithium/oxyhalide electrochemical cells. However, a variety of other carbon blacks have been examined as alternatives. Dey investigated 12 different carbon blacks as Li/SOCl_2 cell cathode materials and concluded that, overall, Shawinigan acetylene black was superior to all of the others (1). However, Gilman and Wade showed that improved $\text{Li/SO}_2\text{Cl}_2$ load voltages may be achieved with a carbon black possessing a higher surface area than that of Shawinigan black (2). More recently, this observation was confirmed by Wade *et al.*, who also showed that treating the cathode material with acetone may markedly improve $\text{Li/SO}_2\text{Cl}_2$ cell load voltages and capacities (3). Conclusions similar to those of Wade *et al.* have also been reported by Reddy and Thurston, who evaluated a variety of high surface area and chemically treated carbons as Li/SO_2 cell cathode materials (4).

All of these studies were motivated by the belief that there should be demonstrable relationships between cell performance characteristics, on the one hand, and the physical and/or chemical characteristics of the carbon black cathode materials, on the other. The work reported here was performed in order to seek broadly based experimental evidence substantiating this widely held belief (5).

Experimental

Nine carbon blacks were examined. Shawinigan acetylene black (50% compressed) was obtained from Gulf Oil Canada Limited. The furnace black specified as Conductex 40-220 was supplied by the Columbian Chemicals Company. Ketjenblack EC, another furnace-type black, was supplied by the Armak Company. Finally, several other blacks were supplied by Cabot Corporation. These included Vulcan XC-72, Black Pearls 2000, CSX 99, CSX 150A2, CSX 179B, and CSX 174. These carbons are listed in Table I along with the surface areas (by iodine adsorption, m^2/gm) and dibutyl phthalate absorptometer numbers (ASTM no. D-2414-70, $\text{cm}^3/100 \text{ gm}$) reported by the manufacturers. As indicated, of the carbons investigated, Shawinigan acetylene black possesses both the lowest

surface area (60 m^2/gm) and the highest DBP absorption (460 $\text{cm}^3/100 \text{ gm}$).

PTFE-bonded cathodes were fabricated from each of the carbons as well as from Shawinigan acetylene black containing 10% supported platinum. Each carbon was dispersed in a 50:50 water:isopropanol mixture to which was added enough du Pont TFE-30 to bring the PTFE loading to 10 weight percent (w/o). The resulting PTFE-bonded carbon mixtures were dried and subsequently applied to both sides of nickel Exmet screen current collectors so as to form 1 mm cathode sheets. Cathode porosities were determined from measured weights and volumes. Cathode-limited Li/SOCl_2 cells containing 1 $\text{cm}^2 \times 1 \text{ mm}$ cathodes (cut from these cathode sheets) were constructed within Pyrex containers with ground glass joints and glass-to-metal feedthroughs for the lead wires (6). The electrolyte was a 1.8M solution of LiAlCl_4 in SOCl_2 . The anodes, supported upon nickel Exmet screen current collectors, were cut from 0.76 mm thick lithium foil. Nonwoven glass fiber paper 0.127 mm thick was used as the separator material. These cells were discharged fully through constant loads ranging between 20 and 1000 Ω at +25°, -20°, and -40°C.

PTFE-bonded cathodes were also prepared using finely divided $(\text{NH}_4)_2\text{CO}_3$ and NH_4HCO_3 as "pore formers." $(\text{NH}_4)_2\text{CO}_3$ was mixed in equal proportions with Shawinigan acetylene black containing 10% supported platinum. In these experiments, $(\text{NH}_4)_2\text{CO}_3$ particles rang-

ing between 18 and 30 mesh (0.59 and 0.99 mm) and >100 mesh (<0.15 mm) were used. In a second set of experiments, 60-80 mesh NH₄HCO₃ particles were mixed with carbon black, the ratio of pore former to cathode material ranging between 1:4 and 4:1. In each case, the pore former was removed from the finished cathode by heating in the air at a temperature between 100° and 200°C. Then, Li/SOCl₂ cells of the type described above containing these cathodes were discharged at 25°C through 20Ω constant loads in order to determine the relationships between high rate cell performance and pore former particle size and concentration.

Results

Correlations between carbon black characteristics and cathode performance.—The porosities of cathodes formed from the nine carbon blacks are listed in Table II along with the average plateau current densities, average load voltages, and capacities obtained with Li/SOCl₂ cells containing these cathodes discharged through 100Ω loads. The cathode porosities are plotted vs. the DBP absorptions characteristic of the carbon blacks themselves in Fig. 1. With the single exception of Shawinigan acetylene black, the porosities of the PTFE-bonded cathodes formed from the various carbon blacks correlate with the DBP absorption values. The Li/SOCl₂ cell capacities are similarly plotted vs. the DBP absorptions characteristic of the carbon blacks in Fig. 2. Again, with the single exception of Shawinigan acetylene black, the discharge capacities correlate with the DBP absorption values and, therefore, with the porosities of the PTFE-bonded carbon cathodes.

The corresponding Li/SOCl₂ cell plateau load voltages (at 30-33 mA/cm²) are plotted vs. the iodine surface areas of the carbon black cathode materials in Fig. 3. As indica-

Fig. 1. Cathode porosity vs. dibutyl phthalate absorption of carbon black.

Fig. 2. Li/SOCl₂ cell capacity vs. dibutyl phthalate absorption of carbon black.

ted, with the single exception of the lowest surface area carbon (Shawinigan acetylene black), the full cell polarization data are practically independent of carbon black surface area ($E_{avg} = 3.23 \pm 0.05V$).

Of the commercially available carbon blacks examined, Ketjenblack EC and Black Pearls 2000 possess both high surface areas (1000 and 1050 m²/gm, respectively) and high DBP absorptions (340 and 330 cm³/100 gm, respectively). Furthermore, they both perform well as Li/SOCl₂ cathode materials. In fact, of the carbons examined, only CSX 174 (characterized by a 1222 m²/gm surface area and a 420 cm³/100 gm DBP absorption) outperformed Ketjenblack EC and Black Pearls 2000 in Li/SOCl₂ cell tests. Li/SOCl₂ cell polarization curves obtained at +25°C with Shawinigan black and Ketjenblack EC cathodes are compared in Fig. 4, while typical ambient temperature discharge curves are compared in Fig. 5 and 6 (corresponding to current densities of 15-16 and 30-32 mA/cm², respectively). Polarization curves obtained at -20°C are compared in Fig. 7, while typical -20°C discharge curves are compared in Fig. 8 and 9 (corresponding to current densities of 3 and 15 mA/cm², respectively). Finally, -40°C polarization curves are compared in Fig. 10, with typical discharge curves being compared in Fig. 11 and 12 (corresponding to current densities of 3 and 5.5 mA/cm², respectively). Ratios of discharge capacities achieved at +25°, -20°, and -40°C with the two cathode materials (Ketjenblack EC and Shawinigan acetylene black) are compared in Table III.

Activity enhancing additives.—It is well known that substantial improvements in Li/oxyhalide cell cathode efficiency may be achieved by incorporating various catalytic additives into the standard PTFE-bonded Shawinigan acetylene black cathode. The proven

oxyhalide reduction catalysts may be classified as belonging to one of four different types: precious metals like metallic platinum (7, 8), nonprecious metals and metal halides like copper and cupric chloride (9-11), organometallics such as iron or cobalt phthalocyanine (12-15), and halogens (Cl₂ or Br₂) (16-18). In the work reported here, the Shawinigan black cathode material was modified by supporting finely divided metallic platinum upon its surface, the total platinum loading being about 10 w/o. Li/SOCl₂ cells containing PTFE-bonded cathodes fabricated from this modified acetylene black were fully

discharged through 100Ω loads. In Table IV, the resulting discharge characteristics are compared with those obtained in the absence of supported platinum (from Table II). As shown, the addition of the electrocatalyst resulted in a 240 mV reduction in cathodic overvoltage and a 140% increase in capacity.

The range of load voltages *vs.* iodine surface area determined by all of the carbon blacks examined with the exception of Shawinigan acetylene black (from Fig. 3) is

tics that correlate well with those of the higher surface area furnace-type blacks.

Structure enhancing additives.—There is another class of cathode additives which act to modify the structure of the PTFE-bonded carbon cathode rather than its specific activity for a particular chemical reaction. Such cathode additives, broadly classified as pore formers, have been used most successfully in the fabrication of controlled-porosity fuel cell electrodes, and they are widely used in the manufacture of porous materials (19). In the general procedure, the pore forming material, possessing a well-defined particle size distribution, is mixed with the standard electrode ingredients. The electrode is formed, and subsequently, the pore former is removed via thermal decomposition, dissolution in an appropriate solvent, etc.

In the work performed here, finely divided (NH₄)₂CO₃ and NH₄HCO₃ were used as pore forming materials in conjunction with Shawinigan acetylene black containing 10% supported platinum. Thus, PTFE-bonded electrodes

Fig. 12. Li/SOCl₂ cell discharge curves at -40°C with 5.5 mA/cm^2 current density.

Fig. 13. Li/SOCl₂ cell load voltage vs. surface area of carbon black

Fig. 14. Li/SOCl₂ cell capacity vs. dibutyl phthalate absorption of carbon black.

were prepared using a 50:50 mixture of (NH₄)₂CO₃ and 10% platinum on Shawinigan black, the (NH₄)₂CO₃ being subsequently removed via thermal decomposition. Prior to mixing with the carbon black, the pore former was sieved using standard mesh screens so as to produce fractions ranging in particle diameter from 0.59-0.99 mm to below 0.15 mm. Li/SOCl₂ cells containing cathodes formed from the various (NH₄)₂CO₃ fractions were discharged through 20Ω loads ($I_{avg} \approx 140$ mA/cm²) to yield the performance characteristics listed in Table V. (The high discharge rate conditions used to evaluate the pore formers are more demanding than the lower rate conditions employed elsewhere in this study and, therefore, are more likely to reveal significant performance variations that result from structurally related diffusional limitations.)

The average cell load voltages and capacities are plotted vs. (NH₄)₂CO₃ particle size (standard mesh) in Fig. 15 and 16, respectively. Optimal high rate performance characteristics are obtained with cathodes formed via the use of 60-80 mesh particles. Thus, enriching the cathode with pores approximately 200 μm in diameter [using 50% (NH₄)₂CO₃ in the cathode blend] results in a 160 mV reduction in cathodic polarization and in a 30% increase in cathode utilization efficiency at the 140 mA/cm² rate.

Next, another series of PTFE-bonded cathodes was fabricated using 60-80 mesh NH₄HCO₃ as the pore former. The amount of NH₄HCO₃ mixed with the 10% platinum on Shawinigan acetylene black cathode material ranged between 0 and 80 w/o. As before, Li/SOCl₂ cells containing these cathodes were discharged through 20Ω loads ($I_{avg} \approx 140$ mA/cm²) to yield the performance characteristics listed in Table VI. The average load voltages and capacities are plotted vs. pore former concentration in Fig. 17 and 18, respectively. Optimal high rate performance characteristics are obtained with cathodes formed from a blend containing about 40% NH₄HCO₃ (60-80

mesh). Thus, enriching the cathode with pores approximately 200 μm in diameter (using 40% NH₄HCO₃ in the cathode blend) results in a 45% increase in cathode utilization efficiency along with a modest reduction in cathodic overvoltage.

Discussion

Broadly speaking, the porous carbon black cathode in a lithium/oxyhalide or lithium/sulfur dioxide cell must perform two important functions in addition to its obvious role as a current collector. On the one hand, its internal surface must function as a heterogeneous catalyst for the cathodic half-cell reaction. On the other hand, its pores must be able to accommodate the continuous deposition of solid discharge products without becoming so severely narrowed that internal resistance losses lead to premature failure. In the case of the Li/SOCl₂ system, LiCl is the primary solid discharge product. Additionally, elemental

sulfur may precipitate within the porous cathode and separator once its solubility in the oxyhalide electrolyte is exceeded (20)

The full cell polarization data (Fig. 3) obtained with the various carbons suggest that a surface area of 250 m²/gm is sufficient to effectively catalyze the electroreduction of SOCl₂ at a 30 mA/cm² rate (at ambient temperature and with a 1 mm cathode thickness). However, a 200-300 mV polarization penalty is incurred with a carbon having a surface area as low as 60 m²/gm. However, as shown in Fig. 13, when the activity of a low surface area carbon is augmented via a catalytic additive (*e.g.*, supported platinum), overvoltages similar to those achieved with high surface area carbons are obtained.

The cathode porosity and Li/SOCl₂ cell capacity data (Fig. 1 and 2) obtained with the various carbons indicate that, for carbons with surface areas of at least 250 m²/gm, the cathode utilization efficiency (capacity per unit cathode volume) increases linearly with increasing cathode porosity. Indeed, it would be surprising if this were not the case since, as shown in Eq. [1] above, insoluble LiCl is produced stoichiometrically during the discharge of a Li/SOCl₂ cell. Furthermore, virtually all of the LiCl so produced deposits within the porous cathode. Thus, the greater the cathode porosity, the longer a cathode-limited cell should be able to discharge at a given rate and at a particular operating temperature.

Equally significant, however, is the fact that both the porosity of a PTFE-bonded carbon cathode and the discharge capacity of a Li/SOCl₂ cell containing this cathode correlate with the dibutyl phthalate absorptometer number characteristic of the high surface area carbon black itself. DBP absorption is a measure of the "structure" of the carbon black, *i.e.*, the average number of particles fused together to form an aggregate. In an important paper concerning the morphology of carbon black aggregates, Medalia reported that, for eight carbon blacks of various structure levels and particle sizes, the void volume between agglomerated carbon black aggregates calculated from electron microscopic data was in good agreement with the experimentally measured DBP absorption (21). Furthermore, the analysis presented can be applied to calculate the effective volumes of carbon black aggregates in systems of arbitrary concentration from DBP absorption values. There is, therefore, ample experimental and theoretical evidence suggesting that the capacity of a cathode-limited cell should be a function of the DBP absorptometer number characteristic of the carbon black cathode material. It must be remembered, however, that the carbon black must possess a sufficiently high specific activity for the cathodic reaction in order that its full capacity may be realized in practice. As shown in Fig. 14, the activity of a low surface area/high

structure carbon may be augmented via a catalytic additive (*e.g.*, supported platinum) so as to enable the complete utilization of the porous cathode.

Finally, as noted recently by Ohsaki *et al.*, the efficiency of a given carbon black as a lithium/oxyhalide cell cathode material will be a function not only of the porosity of the PTFE-bonded cathode, but also of its pore size distribution (22). Thus, the experiments with cathode pore formers reported here were performed in order to gauge the sensitivity of Li/SOCl₂ cell high rate discharge characteristics to the distribution of pores within the PTFE-bonded cathode. Interestingly, while Ohsaki *et al.* concluded that pores having a diameter greater than 0.2 μm are not used effectively (at a 20 mA/cm² rate), the results of the present study suggest that enrichment of the cathode with pores approximately 200 μm in diameter (using 40% NH₄HCO₃ in the cathode blend) results in the most significant performance gains (at a 140 mA/cm² rate).

Summary and Conclusions

Nine carbon blacks with iodine surface areas ranging between 60 and 1222 m²/gm and with dibutyl phthalate absorptometer numbers ranging between 125 and 420 cm³/100 gm have been evaluated as lithium/oxyhalide cell cathode materials. Two criteria have been considered: their ability to serve as heterogeneous catalysts for the cathodic half-cell reaction (a function of both internal surface area and specific activity), and their ability to accommodate the continuous deposition of solid discharge products with minimal internal resistance losses (a function of both the porosity and pore size distribution of the agglomerated carbon particle aggregates).

Li/SOCl₂ cell polarization measurements indicate that a surface area of 250 m²/gm is sufficient to effectively catalyze the electroreduction of SOCl₂ at a 30 mA/cm² rate (at ambient temperature and with a 1 mm cathode thickness). However, a 200-300 mV polarization penalty is incurred with a carbon having a surface area as low as 60 m²/gm. However, if the activity of a low surface area carbon is augmented via a catalytic additive (*e.g.*, supported platinum), overvoltages similar to those characteristic of high surface area carbons may be achieved.

With carbon black cathode materials having surface areas of at least 250 m²/gm, the discharge capacities of cathode-limited Li/SOCl₂ cells increase with increasing cathode porosity. Furthermore, cathode porosity and discharge capacity both correlate with the dibutyl phthalate absorptometer number characteristic of the high surface area carbon black itself (a measure of the structure of the carbon black). In practice, however, a given high structure carbon must possess either a high surface area or a very high specific activity in order to fully utilize its internal pore volume. In general, the activity of a low surface area/high structure carbon may be augmented via a

catalytic additive so as to enable the complete utilization of a PTFE-bonded cathode formed from that carbon.

Additional experiments with cathode formers have shown that significant improvements in high rate Li/SOCl₂ cell performance may be achieved by incorporating such pore formers into the cathode blend. Thus, optimal high rate performance characteristics are obtained with cathodes formed via the use of 40% NH₄HCO₃ or (NH₄)₂CO₃ having particle sizes in the 60-80 mesh range (corresponding to a 200 μm average particle diameter).

Of the commercially available carbon blacks examined, Ketjenblack EC and Black Pearls 2000 possess both high surface areas (1000 and 1050 m²/gm, respectively) and high DBP absorptions (340 and 330 cm³/100 gm, respectively). Furthermore, as Li/SOCl₂ cell cathode materials and without the use of special catalytic additives or pore formers, they both greatly outperform the standard carbon, Shawinigan acetylene black (at temperatures between +25° and -40°C and at current densities ranging between 2 and 200 mA/cm²).

Composition of Surface Layers on Li Electrodes in PC, LiClO₄ of Very Low Water Content

Gholamabbas Nazri* and Rolf H. Muller*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT

Surface layers formed on Li in PC, LiClO₄ with less than 1 ppm of water have been analyzed by use of IR spectroscopy, SIMS, ESCA, low angle x-ray diffraction, and SEM. Electrodeposited Li showed a highly porous micromorphology with surface layers containing primarily a partially chlorinated hydrocarbon polymer and lithium carbonate. The carbonate is mostly present in the inner film regions, the polymer in the outer. Perchlorate decomposes to chlorine compounds of lower valences, with higher-valent chlorine found in the outer film regions and lower-valent in the inner.

The electrochemistry of the alkali and alkaline earth metals in ambient temperature nonaqueous electrolytes has been reviewed by several authors (1-6). The electrolytic deposition and dissolution of Li from aprotic electrolytes with high efficiency is of interest for the operation of ambient temperature high energy-density rechargeable Li batteries. Surface layers which spontaneously form on the metal protect it to varying degrees from corrosion, but they are mainly responsible for the poor rechargeability of the lithium electrodes (7, 8).

Great efforts have been made during the last decade to prevent or minimize the formation of surface layers. Improvements have been achieved by the molecular modification of solvents (9, 10) and the use of lithium alloys as anodes (11-14), while the effectiveness of solvent purification to improve electrode performance has not been uniform. In some cases, trace amounts of water or reactive

gases such as SO₂, O₂, and N₂ have been found to improve the cycling efficiency of the lithium anodes (6). Reaction products of Li with solvent have been reported to be more detrimental to the Li morphology and cycle life than the products formed by Li-protic reactions (15). Dey and Sullivan showed that propylene carbonate (PC) decomposes on a graphite electrode below + 0.6V vs. Li (16). Rauh and Brummer claim that one of the reasons for the poor rechargeability of Li electrodes is the corrosion of the lithium anode at grain boundaries, resulting in an electrical isolation of lithium particles from the substrate by corrosion products. This isolated metal is not available for stripping during the next anodic cycle (17). Dey also showed that a lithium electrode after charge and discharge had a porous structure. Epelboin *et al.* (13) found that surface layers are formed on Li electrodes in PC, 1M LiClO₄ during charge, during discharge, and at open circuit. Yen *et al.* (18) carried out ESCA studies of the surface layer on lithium which had been cycled in a 2Me-

* Electrochemical Society Active Member.

THF, 1.5M LiAsF₆ electrolyte. They found Li, C, O, As, and F on the surface of discharged Li. A polymerization of AsOF on the surface has been proposed (13). The effect of light on the polarization on lithium electrodes in PC has been studied by Povarov and Sitnina (19). They found that the anodic current of Li decreases and the cathodic current increases during exposure of the electrode to visible light. They concluded that a passive film formed on Li in PC possesses semiconducting properties. The sign of the effect indicates a p-type semiconductor. Although the electrons and holes are formed under the influence of light, the main carrier of current through the passive film is Li ions (19).

Understanding the structure and composition of surface layers on lithium is important for further progress in the development of rechargeable ambient temperature Li batteries. The objective of this work was to elucidate the nature of the films on lithium and their role during charge and discharge of Li electrodes by use of different experimental techniques, in particular IR spectroscopy, x-ray diffraction, ESCA, SIMS, and SEM.

Experimental

Propylene carbonate (PC) (Burdick and Jackson) has been used as a solvent. After vacuum distillation, GC analysis usually showed a water content of 20-30 ppm (Propac column, 110°C injection temperature). Treatment of the distilled solvent with Li amalgam resulted in a water content which was below the detection limit of GC (1 ppm).

The LiClO₄ (G. Frederick Smith) used for the experiments has been recrystallized three times from ultrapure water and dried under vacuum at 240°C for 12h. The water content of LiClO₄ before and after vacuum drying has been measured by use of a vacuum oven with differential pressure change equipment, a digital pressure gauge, and a mass spectrometer. The sample was placed in the vacuum oven in a ceramic crucible with a thermocouple in its center. The temperature of the oven was scanned from 25° to 800°C at 3 deg/min. After each sudden change in pressure, the mass spectrum of the released gas was monitored to determine its chemical composition. Thus, the water content of vacuum-dried LiClO₄ (10⁻⁴ torr, 160°C) was found to be much below 1 ppm. Cyclic voltammetry in the PC, LiClO₄ electrolyte with Pt electrodes also showed a water content below 1 ppm.

Cyclic voltammetry with platinum electrodes of 1.0 and 1.5M LiClO₄ solutions with PC solvent prepared as described above indicated a water content of less than 1 ppm for the solutions. Before each experiment, two auxiliary electrodes of Li (2 × 2 × 0.3 cm), placed in the same cell, were used to further purify the solutions by potentiostatically cycling these electrodes between ±2V vs. a Li reference electrode at 50 mV/s for 15-20 cycles. The resulting electrolyte has been used for the experiments reported here.

Electrochemical experiments have been performed in a dry box (Vacuum Atmospheres) equipped for removal and analysis of oxygen, water, and nitrogen. The O₂ and H₂O content of the He in the inert atmosphere box was measured continuously with a calibrated O₂ fuel cell sensor (Vacuum Atmospheres A O 316-H) and a solid-state moisture sensor (Vacuum Atmospheres AM-2), both of them sensitive to < 0.1 ppm. These components, in addition to N₂, were also measured with a calibrated gas chromatograph (Vacuum Atmospheres AN-1). Concentrations of about 10 ppm of O₂ and H₂O and 50 ppm of N₂, normally achieved, were lowered to less than 1 ppm by use of a stirred pool of lithium amalgam exposed to the dry box atmosphere (He). Li sheet of 3 mm thickness (Foote Mineral 99.99%) has been used for the preparation of electrodes, unless the metal was cathodically deposited on Cu or Ni substrates. Reference and counterelectrodes were always made of solid Li.

The composition of surface layers on bulk or electrode-deposited Li has been analyzed by transmission IR spectroscopy after removal from the surface with a glass rod.

Surface layers on electrochemically deposited Li have been characterized by ESCA, SIMS, AES, and SEM. For these studies, the electrode was washed with dry PC after formation of the surface layer. The electrode was then entered into a He-filled transfer chamber which had been placed inside the dry box. After connection to the pre-evacuation chamber of the ESCA/SAM/SIMS system, the transfer chamber was purged three to four times with ultrapure Ar for removal of He, and evacuated for transfer of the specimen to the main vacuum chamber with a magnetic transfer rod. XPS spectra for Li, O, C, and Cl have been collected after different times of Ar ion bombardment. The Li and O spectra were broad and are not shown here. The sputtered area was chosen to be much (about eight times) larger than the observed area in order to minimize redeposition and surface diffusion of sputter products. X-ray diffraction also has been employed for the analysis of surface layers. The morphology of the Li deposit and the electrode after cycling has been studied by SEM.

Results and Discussion

Li amalgam (approximately 2%) has been used to investigate the behavior of PC in contact with film-free lithium before and after removal of water. The formation of a solid, black material on the amalgam surface, and a transparent material with a scale-type structure on top of it, was observed. A viscous material was present at the interface of scales and electrolyte. Spectrum C in Fig. 1 represents the scale-type material, spectrum D the dark solid material. Comparison with spectra A and B of Li₂CO₃ and PC included in Fig. 1 shows that most of the functional groups of PC, in particular covalent CO₃ (1030, 1170, 1790 cm⁻¹) and CH₃ (3000 cm⁻¹), are preserved in the precipitate. A small amount of Li₂CO₃ is possibly indicated in spectrum D by absorption at 500 and 860 cm⁻¹. The presence of residual PC in the film is not a likely cause of the observed spectral features because the procedure used for removing the solvent from the film material involved heating in vacuum. The sample chamber of the IR spectrometer was purged with Ar during the measurements.

An IR spectrum of the surface layer formed on a Li electrode in PC, 1M LiClO₄ during cathodic deposition at 1 mA/cm² on a Cu substrate is shown in Fig. 2, curve B. The spectrum of this material differs from those of the precipitate formed on the amalgam (Fig. 1) in that many of the functional groups of PC are no longer present, such as covalent CO₃ (700, 760, 1030 cm⁻¹). Comparison with the two calibration spectra for PC and Li₂CO₃ (A and C) indicates the formation of Li₂CO₃ by the presence of ionic CO₃ peaks (500, 860, 1430, and 1500 cm⁻¹). Additional peaks around 600 and 1600 cm⁻¹ and the special feature of the spectrum at around 200 cm⁻¹ show formation of other materials. The band at 620 cm⁻¹ may show the presence of a carbon-chlorine bond.

Previous studies (20) on the effect of residual water on film formation during charge and discharge of Li electrodes have shown a peak at 3560 cm⁻¹ due to lithium oxide in addition to the peaks due to Li₂CO₃ and polymer found here. The formation of oxidic and polymeric films

on bulk lithium at open circuit had been postulated earlier (21). Those layers are probably too thin for observation by the present techniques.

The composition of the surface layer has also been investigated by use of ESCA with Li deposited electrochemically from PC, 1M LiClO₄ on a Cu substrate. After deposition, the electrode has been washed with dry PC and evacuated. Without exposure of the electrode to air, it was inserted in the vacuum chamber of the ESCA equipment with a transfer rod (High Vacuum Apparatus Manufacturing). Two different carbon 1s peaks have been observed, one at 290 eV related to Li₂CO₃ and another at 284 eV typical of polymeric carbon (Fig. 3). The latter peak is often seen as a result of surface contamination, and it rapidly disappears upon sputtering (after about 10Å removal). However, the depth profiling of the surface layer showed the peak at 284 eV decreasing only gradually, while that at 290 eV increased with sputter time. It can be concluded that Li₂CO₃ is mostly present in the inner film regions, polymer in the outer, although the large internal surface of the porous deposit makes it difficult to distinguish inner and outer regions and does not allow us to derive film thicknesses from sputter times. The slight shift of the peaks in Fig. 3 at different sputter times is probably due to charging of the film and change in its thickness. The ESCA spectrum for chlorine 2p (Fig. 4) showed the presence of five different chlorine compounds in the film, indicating that LiClO₄ decomposes during electrochemical deposition of Li. Literature data given in Table I have been used for identifying the peaks. Depth profiling showed that chlorine of higher valence, such as perchlorate, is mostly present in the outer regions of the film, while chloride and chlorinated polymeric compounds are present in the inner regions. The mechanism of polymer formation from PC or some of its decomposition products and the chlorination of the polymer are not clear. Since propylene had been identified as a reaction product of PC with Li (16), it is a likely participant in polymerization

Fig. 3. XPS spectra of carbon 1s in the surface layer formed on a Li electrode, electrochemically deposited on Cu from PC, 1M LiClO₄. A: Top surface. B: After 10 min sputtering. C: After 20 min sputtering. Sputtering rate: 8 Å/min.

Fig. 4. XPS spectra of Cl 2p in the surface layer formed on Li, electrochemically deposited from PC, 1M LiClO₄ indicating the decomposition of ClO₄ ions. A: Top surface. B: After 10 min sputtering. C: After 20 min sputtering. Sputtering rate: 8 Å/min.

reactions. Epelboin *et al.* concluded that LiCl exists in the film (13). It is also possible that Cl ions are formed by the decomposition of ClO₄, ClO₃, ClO₂, or ClO ions due to the sputtering.

The surface layer formed on electrochemically deposited Li on Cu has been studied using SIMS. A complex spectrum was obtained, which was difficult to fully interpret. In the low mass range (Fig. 5), fragments of PC can be recognized. They include among hydrocarbons CH (13) and CH₂ (14), C₂ (24), (CH₂)₂ (28), CH₃CH₂ (29), CH₃CH₃ (30), propylene or (CH₂)₃ (42), and propane (44). Possible oxygen compounds are CO (28), CO₂ (44), and ethylene oxide (44). Chlorine appears as fragments of residual perchlorate, such as HCl (36), LiCl (42), and ClO (51), but also as chlorinated organic compounds such as CHCl (48), CH₂Cl (49), possibly CH₃Cl (51), and (not shown in the figure) CH₃CH₂Cl (64). Small amounts of water may be indicated by OH₃ (19), LiOH (24), LiO (or Na) (23), Li₃O (30), and Li₂OH (31). Other lithium compounds are possibly LiC (19) and LiCH₂CH₂ (49). After Ar ion bombardment of the surface layer, the residual gas analysis of the SIMS chamber always showed a strong Li (7) and a Li₂ (14) peak, which indicates the presence of occluded metallic Li in the film. Most of the low mass SIMS spectrum had also been observed previously from surface layers on bulk Li (21). In the high mass range (Fig. 6), fragments with mass higher than that of PC (102) were observed. These are indicative of the presence of a polymeric material in the film. Most of the mass units can be represented by fragments from a partially chlorinated hydrocarbon polymer and their Li adducts such as LiCHClCHCl (103), Li-PC (109), LiCH₂CHClCH₂Cl (118), CH₃CH₂CHClCH₂Cl (127), CH₃CH₂CHClCH₂CLi (134), and CH₃CH₂CHClCHClCH₂Li (147).

Surface layers on electrochemically deposited Li have also been studied by *in situ* x-ray diffraction. Data for galvanostatic deposition on a Ni substrate are shown in Fig. 7. The experimental procedure and the cell design used have been discussed elsewhere (22). A broad peak at low 2θ angle (14°-24°) which is characteristic of polymeric compounds has been observed, as was a narrow peak at 32° (2θ) characteristic of Li₂CO₃. In the presence of residual water, diffraction lines characteristic of the oxide have been observed (20).

Fig. 6. As Fig. 5, but with high mass range

The morphology of electrochemically deposited Li on metallic substrates has been studied using SEM. Li deposited on a Ni substrate from PC, 1.5M LiClO₄ is shown in Fig. 8. The electrode was washed with PC and transferred to the SEM chamber by use of a He-filled transfer rod. Special care was taken not to expose the specimen to air by inserting it into the Ar-filled SEM air lock sur-

Fig. 7. *In situ* x-ray diffraction of the surface layer on electrochemically deposited Li on a Ni substrate. Li₂CO₃ and polymeric compounds are identified.

Fig. 8. SEM showing the micromorphology of Li deposited on a Cu substrate from PC, 1M LiClO₄.

rounded by an Ar-purged plastic bag. A porous structure of the deposit was observed in most cases. This porous deposit may be responsible for rapid film formation and poor rechargeability of the Li electrodes. In this structure, one can well imagine the formation of isolated regions of lithium by localized corrosion, as postulated in the literature (17).

Conclusions

In situ and *ex situ* studies of surface layers on Li electrodes in PC-based electrolytes demonstrate that PC reacts with Li under formation of several products, primarily what appears to be a chlorine containing polymer product and Li₂CO₃. When water is present, Li₂O is also formed. LiClO₄ decomposes during potential cycling of Li electrode between -2 and +2V. Surface layers are of complex composition and structure. Depth profiling of the surface layers indicates an inhomogeneous structure with concentration gradients of different components across the film. Electrodeposited Li shows a highly porous micromorphology. The use of advanced *in situ* techniques, such as x-ray diffraction with a position-sensitive detector, with its high sensitivity and short time response, promises to provide new insight into the initial step of film formation.

Effect of Residual Water in Propylene Carbonate on Films Formed on Lithium

Gholamabbas Nazri* and Rolf H. Muller*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT

Low concentrations of water in propylene carbonate solutions result in the formation of protective surface layers on lithium electrodes. Increasing concentrations of water have been found by infrared spectroscopy and x-ray diffraction to result in increasing lithium oxide and decreasing carbonate and polymer content in the layers. The oxide layers are protective and greatly reduce the rate of corrosion reactions of the metal with the electrolyte. They represent the principal resistance to current passage and can be removed by breakdown at high potential. Water-free solvent interacts differently with lithium resulting in the continuous formation of lithium carbonate and polymeric materials. Use of a thin layer cell with 10 μm electrode separation has been shown to eliminate the effect of low concentrations of water.

The structure and composition of surface layers are a major controlling factor in the dissolution and deposition of Li in ambient-temperature nonaqueous electrolytes (1-4). Peled (5) proposed migration of Li^+ in a solid electrolyte interphase as a controlling factor in the electrochemistry of lithium. The surface layers formed on Li in 1M LiClO_4 and LiAsF_6 in propylene carbonate (PC) have been investigated using potential pulse techniques and electrochemistry (6-8). Semiconductor properties of the surface layer on Li due to defects in the crystal lattice have also been reported (9). However, despite the use of various techniques, structure and composition of the surface layer formed on a Li electrode exposed to propylene carbonate (PC) containing residual water are still not definitely known. Decomposition of the PC in contact with lithium and formation of Li_2CO_3 as a surface layer has been postulated by several authors (10, 11). However, such a composition cannot fully explain the behavior and properties of the layers, and is not in agreement with optical observations (7, 8). The effect of electrolyte impurities on the performances of Li batteries, although extensively investigated, is not well understood (11, 12). Some

trace impurities such as H_2O , O_2 , and N_2 have been found to favorably affect the cycle life of lithium anodes (11, 12).

One of the major problems in electrochemical studies of Li is the purification of the electrolytes. Distillation of solvents does not remove traces of water. More than 10 ppm of residual water is often detected. Several procedures for purification of electrolytes have been established (10, 13, 14). These procedures include the pre-electrolysis of salts, recrystallization of salts and drying under vacuum, storage of solvents on molecular sieves, and distillation of solvent along with the treatments with Li amalgam or Na/K (50/50) alloy. Distillation of solvent after treatment with amalgam or NaK alloy is desirable to remove decomposition products of the solvents which may form during treatment. Purification of nonaqueous electrolytes is a tedious and time consuming process. Since most of the procedures being used today are open to questions, an effective way to minimize the effect of impurities is to use a small amount of electrolyte (less than a drop) after reasonable purification. A thin layer cell has been used for that purpose. Another difficulty in electrochemical studies of Li is the existence of an initial film on the Li electrode. Even in an inert atmosphere box with less than 1 ppm O_2 , H_2O , and N_2 , a film will form on the

*Electrochemical Society Active Member.

surface in less than 1s. Some research groups produced clean electrode surfaces *in situ* by mechanical removal of the surface layer, electrochemical pulse cleaning, or deposition of Li on metallic substrates (15-19).

The objective of this work is to understand the structure and composition of the surface layer formed on Li in PC, 1M LiClO₄ containing residual water. The effect of impurities has been minimized by use of a thin layer cell. The composition and structure of the surface layers has been analyzed using *ex situ* and *in situ* x-ray diffraction and transmission IR spectroscopy. The role of the residual water was also studied using potential cyclic voltammetry and potential pulse measurements.

Experimental Procedure

LiClO₄ has been recrystallized from water and dried under vacuum at 150°C. The dehydration of LiClO₄ has been studied by thermogravimetry. All physically and chemically adsorbed water is released below 150°C at 10⁻³ torr. After treatment with Li amalgam, the concentration of water in PC was below the detection level of the GC (1 ppm).

A cylindrical cell and a thin layer cell have been used in this work. The cylindrical cell (7, 8) contains two parallel disk electrodes of 1.9 cm diam, 3 cm apart from each other. One of these disks served as working electrode, the other as counterelectrode. The reference electrode was a Li wire with diameter of 3 mm forced into the polypropylene in such a way that only its cross section was exposed to the electrolyte. The distance between reference and working electrode was about 2 mm. The two optical win-

dows on this cell have been used in previous ellipsometric studies.

A thin layer cell has also been used. Its design is shown in Fig. 1. A pellet of lithium (Foot Mineral Company, 1.22 cm diam and 0.6 cm height) is held between two stainless steel current collectors contained in polypropylene rods. This lithium is cut in half by use of a stainless steel wire of 0.5 mm diam with the two halves serving as working and counterelectrodes. A drop of electrolyte was placed between the two electrodes and the gap between them was adjusted to 10 μm using a micrometer, which carried one of the electrodes on its nonrotating tip. Although the thin layer cell was operated inside the inert atmosphere box (Vacuum Atmospheres Company), with concentration of O₂, H₂O, and N₂ of less than 1 ppm, a polyethylene bag was placed around the cell for further isolation. This bag could be collapsed by evacuation and refilled with ultrapure He from a separate supply. This system also enabled us to expose the electrodes to any gas without contaminating the dry box atmosphere. An application of the capability will be reported separately.

The formation of surface layers on Li has been studied potentiostatically and galvanostatically using a PAR potentiostat, programmer, and coulometer. During potentiostatic pulse measurements, the results were monitored by a storage oscilloscope, then recorded by an X-Y recorder (H-P 7044B). Copper was mostly used as a substrate because of its optical properties, although alloy formation occurred with Li, as was the case for Ag, Au, and Pt and, to a lesser degree, with Ni and stainless steel. The Cu substrates were successively polished with 600 emery paper, 1 μm, and 0.25 μm diamond paste. They were then cleaned in ethanol, dried in pure He, and washed with dry PC in the glove box. Electrode potentials have been corrected for IR drop in the solution, determined at the beginning of an experiment by conventional current interruption techniques.

The composition of surface layers formed on Li in PC, 1M LiClO₄ with different water concentrations has been analyzed by transmission IR spectroscopy. The Li electrode was washed with dry PC and then evacuated for

evaporating the solvent. The surface layer on the electrode was collected from the dried electrode by a glass rod and ground with KBr in the dry box. A pellet of the mixed powder was made for transmission IR spectroscopy. During the measurement, the sample chamber of the IR machine was purged with pure Ar gas. The decomposition products of the PC on Li amalgam have also been analyzed using the IR spectrometer. The IR spectrum of the surface layer was compared to the spectra of PC, Li_2CO_3 , and Li_2O . The Li electrode was potentiostatically cycled 20 times by sweeping the potential ($\pm 2\text{V}$ vs. Li) at a rate of 20 mV/s. The electrode was removed from the electrochemical cell, washed with dry PC, and isolated inside a polypropylene transfer cell with a Mylar window for the collection of x-ray diffraction data from the electrode surface. The design of the transfer cell for x-ray diffraction analysis is shown in Fig. 2.

In situ x-ray diffraction of surface layers formed on Li electrodes during anodic and cathodic polarization has been presented separately (20).

Results and Discussion

The effect of residual water in PC, 1M LiClO_4 on Li electrodes has been studied using sampled current voltammetry (21). The experiments have been performed with dry and wet PC in both the cylindrical and the thin layer cells. A potential step has been imposed on the working electrode, and the current response as a function of time has been measured for each potential step. The current observed 1s after application of the potential step is shown in Fig. 3 as a function of the potential. In these measurements, the double-layer charging does not affect the measured current. The advantage of this technique is that at the beginning of each potential step the concentration of electrolyte at the interface is the same because the bulk concentration is allowed to be reestablished before the next pulse is applied. As shown in Fig. 3, the current density observed with dry electrolyte is much higher than that in the presence of water. This result may be due to the presence of an oxide film on the electrode surface

Fig. 3. Effect of water content and volume of the electrolyte on sampled-current voltammetry of Li electrodes in dry PC, 1M LiClO_4 , 20 cm^3 cylindrical cell (curve A), same solution containing 300 ppm water, 20 cm^3 cylindrical cell (curve B), same solution containing 500 ppm water, thin layer cell (curve C). Potentials for curves A and B corrected for IR drop in solution; curve C represents cell voltage.

Fig. 4. Cyclic voltammetry of Li electrodes in PC, 1M LiClO_4 containing 300 ppm water using thin layer cell (solid line), and cylindrical cell containing 20 cm^3 electrolyte (broken line). The electrode surface areas were the same in both cells. IR-free electrode potential shown for cylindrical cell, cell voltage for thin layer cell.

which forms by reaction of Li with H_2O before application of the potential step. The film appears to begin to break down at higher potentials as evidenced by the change of slope at applied potentials $> 4\text{V}$. The resulting current density depends on the concentration of water in the electrolyte and the time for which the electrode has been exposed to it before the measurements are taken. The formation of an oxide layer on the electrode surface by trace amounts of water has been credited for the higher cycling efficiency of Li anodes in the presence of residual water (10).

The ability of the thin layer cell to discriminate against the effect of residual water in the electrolyte is illustrated in Fig. 4. Cyclic voltammetry of Li in PC, 1M LiClO_4 containing 300 ppm water, using thin layer cell and cylindrical cell, are compared. Higher current densities are obtained in the thin layer than in the cylindrical cell. In addition, the anodic dissolution of Li in the thin layer cell does not show the passivation seen with the cylindrical cell. Similarly, experimental results from the thin layer cell for electrolyte with 500 ppm water have been found to be almost the same as those with dry solution (< 1 ppm water) obtained in the cylindrical cell which contains 20 cm^3 of solution.

Delay-time phenomena in the passivation and activation are illustrated in Fig. 5. Four successive potential pulses of 40s duration have been applied to the Li working electrode in the cylindrical cell containing 20 ml of dry PC, 1M LiClO_4 . The current response to each subsequent potential pulse at different potential varies as

$$i_1 < i_2 < i_3 < i_4 \quad \text{for } 0.2 < E < 1.6\text{V vs. Li}$$

and

$$i_1 > i_2 > i_3 > i_4 \quad \text{for } 1.6 < E < 3.0\text{V vs. Li}$$

where i_1 , i_2 , i_3 , and i_4 are currents corresponding to the first, second, third, and fourth pulses, respectively. Up to a pulse height of 1.6V, the current increases with time and the response to the first pulse is smaller and builds up more slowly than the response to subsequent pulses. This behavior indicates that film removal (or breakdown) takes place during the first pulse and continues to a lesser degree during the succeeding pulses. These results are in agreement with a diffusion-limited migration of Li ions through the interface. For potential steps higher than 1.6V, the current decreases with time and the initial current response to the first pulse is lower than the initial response to subsequent pulses, indicative of a film-removal process, as in the low potential regime. However, after a few seconds, the current for the first pulse remains

Fig. 5. Potential pulse measurements (I vs. t). Response to first pulse (—), second pulse (---), third pulse (-·-·-·-·-), and fourth pulse (-·-·-·-·-). Height of anodic pulse listed in volts; potentials corrected for IR drop in solution (dry PC < 1 ppm H_2O , 1M $LiClO_4$); pulse duration 40s; current response shown only for first 20s.

higher and declines less rapidly than that of subsequent pulses. This behavior indicates a limitation of the dissolution rate by mass transfer or film formation at high current densities. Below 0.2V, the current densities are the same for the four pulses, showing that the film remains intact and Li ions migrate through it. Removal of the film from the electrode surface by successive anodic pulses can be used for cleaning the Li surface *in situ*.

Lithium was galvanostatically deposited on a Cu substrate from PC, 1M $LiClO_4$ at 30 mA/cm² with a Li counterelectrode for a thickness of 1000Å based on Li bulk density. The formation of Li deposits on Cu with 60-70% current efficiency was determined by immersion in water and measurement of H_2 evolved. Higher current efficiencies had been found with stainless substrates. *In situ* x-ray diffraction also showed the presence of Li metal. The open-circuit potential of the Li electrode, vs. Li reference, has been monitored with electrolytes of different water content (Fig. 6). Immediately after deposition, the cell voltages were almost independent of water content. The potential of the electrodeposited Li is different from that of bulk Li (used as reference) probably because it represents a mixed potential of alloy, corrosion

Fig. 6. Effect of water content in the electrolyte on the potential of electrochemically deposited Li (1000Å) on a Cu substrate at open circuit vs. Li reference electrode. PC, 1M $LiClO_4$ with different H_2O content.

Fig. 7. IR spectra of the surface layers on a Li electrode formed after 20 cycles $\pm 2V$ vs. Li in PC, 1M $LiClO_4$ containing less than 1 ppm (curve A), 500 ppm (curve B), and 1% water (curve C). Curve D represents spectrum of the Li_2O .

products, UPD, and substrate. We have observed similar anomalous potentials for Li deposits on Cu in 2 Me-THF, $LiClO_4$. At later times, a potential characteristic of the substrate is reached much faster when no water is present. This observation shows that no protective film is formed on the electrode surface in the absence of water, allowing Li to continue to react with the electrolyte. The resistivity of the Li electrode is much higher with higher concentrations of water in the electrolyte, in agreement with the formation of a thicker, more resistive and protective oxide film. The oxide film does not fully protect the Li electrode, but greatly reduces the rate of reaction with the electrolyte.

The surface layers formed on Li in PC, 1M $LiClO_4$ containing different concentrations of water have been analyzed by transmission IR spectroscopy. Comparison to the spectra of Li_2O and Li_2CO_3 , obtained by the same procedures, shows that increasing concentrations of water result in increased Li_2O (3560 cm^{-1}), and decreased Li_2CO_3 ($860, 1430, 1500\text{ cm}^{-1}$) and C-Cl (620 cm^{-1}) content (Fig. 7). This result is consistent with the view that a partially protective oxide layer reduced the rate of lithium corrosion and solvent decomposition. Cyclic voltammetry with a Cu electrode in PC, $LiClO_4$ showed that PC decomposes anodically above 3.5V vs. Li (Fig. 8). Similar results have been obtained with Ni, Ag, and SS electrodes; with Pt, decomposition occurs at a lower anodic potential.

A Li electrode that had been cycled anodically and cathodically in PC, 1M $LiClO_4$ 20 times between $\pm 2V$ vs.

Fig. 8. Cyclic voltammetry of Cu electrode in PC, 1M $LiClO_4$ showing decomposition of PC above 3.5V vs. Li.

Fig. 9. X-ray diffraction of the surface layer formed on a Li electrode electrochemically cycled in PC, 1M LiClO₄ containing 700 ppm water, showing presence of Li₂CO₃, Li₂O, and a polymeric compound.

Li at a sweep rate 20 mV/s was subjected to analysis by x-ray diffraction. For this purpose, the electrode was removed from the cell, washed with dry PC, and inserted in the transfer cell with a Mylar window for placement in the diffractometer. A diffraction pattern of this electrode, shown in Fig. 9, confirms the presence of Li₂O, and Li₂CO₃ apart from Li. A noncrystalline (probably polymeric) material, which appears to result from reactions of the solvent, is indicated by a broad peak at low 2θ . The same film materials have been identified by *in situ* x-ray diffraction (20, 22). The formation of a polymeric membrane has been reported by Epelboin *et al.* (23).

Conclusions

Composition and properties of surface layers on lithium electrodes in propylene carbonate solutions, which are mainly responsible for the performance of this electrode, have been analyzed. The layers are strongly affected by small amounts of water in the solutions. The formation of an oxide in an earlier-postulated (8) inner layer in the presence of water has been confirmed. This layer greatly reduces the rate of Li corrosion, which occurs in its absence under formation of carbonate and polymer products. At low current density migration of Li ion through this film appears to control the rate of dissolution and deposition of Li. The effect of low to moderate concentrations of water (and other electrolyte impurities) on the lithium electrodes can be avoided by use of a small electrolyte volume in a thin layer cell.

AC Impedance of the Carbon Monofluoride Electrode

Mary R. Suchanski*

Eastman Kodak Company, Research Laboratories, Rochester, New York 14650

ABSTRACT

The ac impedance of carbon monofluoride (CF) half-cells and Li/CF batteries that contain 1M LiBF₄/4-butyrolactone electrolyte was measured as a function of state of charge. The nonfaradaic components of the CF half-cell impedance were resolved with the aid of a one-dimensional macroscopic treatment of a porous electrode. The values of the nonfaradaic components and their variation with charge withdrawn provide information concerning the nature of cathode discharge products, the degree of tortuosity in the cathode and separator matrices, and the cathode failure mechanism. The CF electrode capacitance, as measured by the low frequency quadrature impedance, can serve as a semiquantitative measure of battery state of charge under certain conditions.

The electrochemical technique of ac impedance can be used, under appropriate conditions, to evaluate several important parameters of a porous electrode. The interfacial area between the electrode and the electrolyte can be obtained from the quadrature component of the impedance, provided that the double-layer capacitance of the pure electroactive component is known (1-3). Both faradaic components of the electrode impedance (charge transfer and diffusion resistances) and nonfaradaic impedance components (internal electrolyte resistance and interelectrode resistances) can be quantitatively identified from complex-plane plots (3, 4). Analysis of porous-electrode impedance data in terms of a semi-infinite cylindrical-pore model (5, 6) or, as has been done more recently, in terms of finite cylindrical pores (7), leads to values of pore radius, pore length, and pore number. Such analyses have been attempted for sintered-plate cadmium electrodes (8), gold powder and Raney gold electrodes (2), sintered nickel (2, 7), Raney nickel (4), and zinc powder (9). With Raney nickel, the impedance technique was used to obtain the pore radius, length, and number of micropores inside the catalyst grain (4).

Problems remain in characterizing the structure of porous electrodes, particularly technologically important ones, via the impedance method. Although the impedance data of simple structures, such as loosely packed metal powders, can be adequately interpreted in terms of an equivalent cylindrical-pore model (2, 9), for more complex structures, such as Raney catalysts and sintered metals, tortuosity must be introduced in the internal pore network (2, 8). Furthermore, for electrodes made of two or more materials with different particle shapes and sizes (for example, Teflon-bonded electrodes), a single pore radius cannot account for the distribution of pore sizes. Regarding pore shape, the impedance of an individual pore will reflect pore shape (7), but the impedance of an assembly of shaped pores will resemble that of cylindrical-pore electrode (2). Hence, pore shapes are better elucidated by electron microscopy. Nonetheless, the ac impedance technique can provide useful information concerning structure and mechanism in porous electrodes.

We report here the ac impedance of carbon monofluoride (CF) half-cells in 1M LiBF₄/4-butyrolactone electrolyte at different states of charge. Cognizant of the difficulties in treating the complex impedance of porous electrodes with a cylindrical-pore model, we used a macroscopic approach with two parameters, the internal electrolyte resistance and the electrode capacitance, to interpret the data. Tortuosity in the internal pore network of the electrode is related to the volume fraction solids of the electrode through an equation originally derived for ion movement in an ion-exchange membrane (10). The impedance technique can be used to resolve other nonfaradaic components of CF half-cells, including the interface resistance between the current collector and the electrode patch, the separator resistance, and the electrode capacitance. Finally, the low frequency quadrature

impedance data of both CF half-cells and commercial Li/CF batteries can be related to state of charge of the CF cathode.

Experimental

Materials.—The CF electrodes were composed of (by weight) 80% CF_{1.03} (Ozark Mahoning), 10% carbon (Vulcan XC-72, Cabot Corporation), and 10% Teflon (Teflon 30). Standard Teflon-bonded electrode fabrication techniques were used (11). The cathode current collector was Ti foil (0.013 cm thick) that has been etched in boiling 20% HCl. The lithium electrodes were made from 0.013 cm lithium foil. The electrolyte was 1M LiBF₄ (Foote Mineral Company, 97.5%) dissolved in 4-butyrolactone (Aldrich Gold Label) that had been vacuum distilled once over activated type-5A molecular sieves at 50°-55°C (1.5-2 mm Hg). The electrolyte was filtered once to remove LiF and stored in a Vacuum Atmospheres dry box in a flask containing activated type-5A molecular sieves.

The Li/CF batteries were standard 2/3A size (4300C rated capacity at 60Ω load) with a jelly-roll configuration and were manufactured by Matsushita Electric of Japan. The electrolyte in these batteries was 1M LiBF₄ in 4-butyrolactone.

Impedance vs. charge withdrawn.—Pairs of CF cathodes with various amounts of charge removed from them (0, 50, 100, 200, and 300C) were prepared by continuous discharge at a constant current density of 5 mA/cm². The cathodes were Ti foil with electrode dispersion applied to one side of the foil. The electroactive cathode patches were 2 × 2 × 0.032 cm, and the average coulombic content of the patches was 390C. One week after discharge, new cells were prepared from each pair of cathodes in which the electrode patches were positioned facing one another with one layer of nonwoven polypropylene fabric sandwiched between the two electrodes to prevent electronic contact (*cf.* Fig. 1). Fresh electrolyte was added to the cells, and the impedance of the cells was measured the next day. The cells were restrained during discharge and measurement taking to provide a minimum and uniform electrode-electrode gap.

Fig. 1. Configuration of impedance cell

* Electrochemical Society Active Member.

The ac response of the CF electrodes and batteries was measured in the admittance domain by a cross-correlation technique described by Bentz *et al.* (12). A 2 mV peak-to-peak sine-wave excitation voltage with fixed frequencies in the range 0.00563-1780 Hz was generated by a Hewlett-Packard Model 203A function generator and was applied to the electrochemical cell via a PAR Model 173 potentiostat. The PAR potentiostat was used to null any voltage across the cell terminal (*i.e.*, cell held at open circuit for measurement taking) as well as to monitor the cell current via a current-to-voltage converter plug-in unit (PAR Model 176). The ac cell current was amplified 220 times and then cross correlated with an in-phase and quadrature square wave provided by the function generator. The cross-correlator output signals with frequencies > 1 Hz were integrated by a Butterworth filter, and the output signals of < 1 Hz were integrated via a gating technique. A 10Ω resistor was used to calibrate the impedance apparatus before each data collecting session. All measurements were made at room temperature.

Theory

We treated the impedance of a porous electrode by an approach similar to that of Keiser *et al.* (7) for the impedance of a cylindrical pore of finite length. Since it was unlikely that we could characterize a Teflon-bonded electrode made of three materials with different particle shapes and sizes by a single pore radius and pore length, we chose a macroscopic approach in which the geometric detail of the pore is ignored (13). The electrode with thickness l is divided (*cf.* Fig. 2) into N segments along an axis perpendicular to the plane of the electrode, and each segment is characterized by two impedance elements—a resistance R_k ($k = 0$ to N) due to the electrolyte and a corresponding capacitance, C_k , due to the electrochemical double layer. The electronic resistance of the cathode patch has been ignored in this treatment for two reasons: (i) dc resistance measurements of CF cathode patches with no coulombs withdrawn showed that the electronic patch resistance was 8-22% of the total resistance as evaluated by the ac impedance technique, and (ii) carbon is formed during CF electroreduction, which is likely to cause a decrease in patch resistance as more coulombs are withdrawn. The derivation also assumes that under the conditions of the measurements (open circuit) the contributions from any faradaic impedances are minor in comparison to the double-layer capacitance.

The network shown in Fig. 2 can be solved for using cascaded network theory in which each pair of impedance elements (R_k and C_k) is considered a two-port network (14). For a series of N such cascaded networks, calculation of the impedance becomes quite cumbersome, as it involves the multiplication of N matrices. For this circuit, it is much simpler to use the standard circuit-analysis technique of successive reduction of parallel and series impedances (15). Starting at the far right of the circuit and moving toward the left leads to the following it-

Fig. 2. Equivalent circuit of a porous electrode with thickness l . R_k is the average resistance of the electrolyte in the k th segment, and C_k is the average double-layer capacitance in the k th segment.

Fig. 3. Complex-plane diagram of the porous electrode impedance according to Eq. [1], with $R_k = 1\Omega$, $C_k = 0.1F$, and $N = 30$.

erative equation in which the circuit impedance from segments k to N is related to the circuit impedance from segments $(k + 1)$ to N

$$Z_k = R_k + 1/(j\omega C_k + 1/Z_{k+1}) \quad [1]$$

It is assumed that at $x = l$ the electrode is at open circuit; hence the impedance of the N th segment Z_N is infinite. By successive substitution of values of R_k and C_k into Eq. [1], the total electrode impedance Z_0 is calculated.

Figure 3 shows the Argand diagram of the complex impedance of a porous electrode according to Eq. [1], with $R_k = 1\Omega$, $C_k = 0.1F$, and $N = 30$. The Argand diagram plots the real or resistive part of the complex impedance *vs.* the imaginary or capacitive component of the electronic impedance. At higher frequencies where the current does not completely penetrate through the electrode, the phase angle between the real and the quadrature components of the impedance is 45° . At lower frequencies where the current has a chance to penetrate through the electrode, the real component approaches a constant value of $R_{sol}/3$, where R_{sol} is the total electrolyte resistance within the pores of the electrode (in this case $R_{sol} = 30\Omega$), and the quadrature component is inversely proportional to the total electrode capacitance C_T . The result shown in Fig. 3 is also obtained from the following equation derived by de Levie (6) for shallow, pores of depth l

$$Z_a = \sqrt{ZR} \cotanh lR/\sqrt{ZR} \quad [2]$$

In Eq. [2], Z_a is the impedance of a single pore of length l , Z is the pore-wall impedance per unit length ($1/j\omega C$ in our case), and R is the electrolyte resistance per unit length of pore. For an electrode consisting of n pores in parallel electrically, the relationship between the pore impedance Z_a and the electrode impedance Z_0 is as follows

$$Z_0 = Z_a/n \quad [3]$$

We used two equations to compute solution phase resistance for comparing calculated values with those obtained from impedance data via the technique outlined above. The first equation corresponds to a porous matrix in which the ions are free to travel in an unobstructed tunnel whose axis is perpendicular to the electrode face. For this case, in which ion mobility in the solution phase is assumed to be the same as in the pure solution, the resistance will be given by the equation

$$R_{sol} = l[A(1 - v_2)\kappa_0] \quad [4]$$

where l is the electrode thickness, A is the electrode face area, v_2 is the volume fraction solids of the porous matrix,

and κ_0 is the conductivity of the pure solution phase. The second equation introduces tortuosity in the diffusion pathway and was originally derived for ion diffusion through water-swollen cation-exchange resins (10). Here a cubic-lattice model was used in which each lattice site is occupied by a portion of the solid phase, an ion, or pure solvent. The increase in the length of the diffusion path over pure liquid is

$$\theta = (1 + v_2)/(1 - v_2) \quad [5]$$

According to Mackie and Meares (10), the ion mobility in a porous matrix will be reduced by the square of θ ; hence, in this case the solution phase resistance is

$$R_{\text{sol}} = l/(A\kappa_0/\theta^2) \quad [6]$$

Note that Eq. [4]-[6] can be applied to other porous phases of an electrochemical cell, for example, the nonwoven polypropylene separator.

Fig. 4. Complex-plane impedance data of CF half-cells in 1M LiBF₄/4-butyrolactone electrolyte as a function of the amount of charge withdrawn.

Fig. 5. Equivalent circuit of CF half-cell

Results and Discussion

Half-cell data.—Figure 4 shows the Argand diagrams of CF half-cells that have had 0, 100, 200, and 300C withdrawn per electrode patch (average is 400C stored per patch). The inset in the top diagram (0 C withdrawn) is an expansion of the high frequency portion of the Argand diagram. The high frequency portions of the Argand plots for the other CF half-cells are similar to the one in the top diagram and therefore have not been expanded. The complex-plane plots in Fig. 4 have the following features: (i) a series resistance component of $\sim 2\Omega$, (ii) a 45° angle between the impedance Z and the real axis at high frequencies, and (iii) a steeply rising quadrature impedance at low frequencies. Hence, aside from the series resistance component, which was not included in Eq. [1], there is excellent agreement between the form of the high frequency CF half-cell impedance plots and that predicted by Eq. [1]. In general, the form of the complex-plane plots at the low frequency is similar to that in Fig. 3, but in certain instances deviations occur at $f \leq 0.01$ Hz, possibly due to contributions from faradaic reactions or from diffusion. On the basis of the general good agreement between the experimental complex-plane plots and the theoretical plot in Fig. 3, we feel that analysis of the experimental data in accordance with Eq. [1] is justified.

Table I lists the impedance parameters of the CF half-cells as a function of the charge withdrawn. The series resistance is the value of Z_R at 1780 Hz (the highest frequency in the measurement) and is accurate to 0.1 Ω . The value of R_{sol} is three times the difference between Z_R at a frequency where the quadrature impedance Z_Q begins to rise steeply (0.316-0.0136 Hz) and the series resistance. The total cell capacitance is the average calculated from Z_Q at 0.01, 0.0178, and 0.0316 Hz and has a maximum deviation from the mean of ± 0.02 F. The following paragraphs treat each of these three impedance parameters separately.

Series resistance.—Initially, we thought that the series resistance was composed of the ionic resistance of the separator and the electronic resistance of the titanium current collector. Calculations of the separator resistance using Eq. [4] and [6] showed that the series resistance was too large to be composed of just these two components; therefore, to account for the series resistance, the equivalent circuit shown in Fig. 5 was used. In this equivalent circuit representation, R_{Ti} is the electronic resistance of the titanium current collector, R_I is the interface resistance between the Ti and the cathode patch, R_{sep} is the separator resistance, and Z_E is the cathode patch impedance. In this analysis, $Z_E = Z_0/2$, where Z_0 is the impedance of the two cathode patches in series. At high frequency, the series resistance is equal to $2R_{\text{Ti}} + 2R_I + R_{\text{sep}}$. R_{Ti} was determined from ac resistance measurements of bare Ti foil. Hence, this equation has two unknowns, and another equation is needed to solve for R_I and R_{sep} . For this, we built a cell with two layers of the separator, in which case the series resistance was equal to $2R_{\text{Ti}} + 2R_I + 2R_{\text{sep}}$.

Table I. Impedance parameters of CF half-cells as a function of charge withdrawn

R_{T_1}	0.05

^a 0 C withdrawn.

Table II shows the values of the series resistance of the components of the CF half-cell in 1M LiBF₄/4-butyrolactone. The separator resistance (1.41 Ω) is in exact agreement with that calculated from Eq. [6] for a tortuous-pore network. Equation [4] predicts a value of 0.46 Ω for the separator, which is a third of that measured. Measurements of this type were also made in an electrolyte that is almost twice as conductive as the 1M LiBF₄/4-butyrolactone, and the result was the same; the separator resistance was within 10% of that calculated from Eq. [6]. Since the ion mobility in the nonwoven polypropylene separator is quantitatively linked to its volume fraction polymer per Eq. [6], it is concluded that the pore network of the separator is tortuous.

R_{sol} .—Figure 6 compares the cathode resistance R_{sol} measured via the impedance technique with those calculated via Eq. [4] and [6]. The input parameters for the calculations, *i.e.*, the electrode thickness l and the volume fraction solids v_2 , are shown in Table III. The volume fraction solid v_2 was calculated from the measured electrode dimensions and the known densities of the electrode constituents (CF, Teflon, carbon, LiF). Note that the electrode thickness approximately doubles over the course of the discharge, whereas the volume fraction solids decrease by a factor of 2.5. The measured cathode resistances do not closely match the calculated values for either the straight-pore model or the tortuous-pore model, but rather fall somewhere between the two sets of calculated data. For cathodes with 0 C withdrawn or $\geq 50\%$ of the stored coulombs withdrawn, the electrode behaves more like a tortuous network, whereas at 12.5–25% of the coulombs withdrawn the electrode behaves more like a straight-pore network. From the above comparisons, we find evidence for tortuosity in the internal pore network of Teflon-bonded CF electrodes, particularly for cathodes with 0 C or $\geq 50\%$ of the coulombs withdrawn.

Another feature of the cathode resistance data that deserves comment is the fact that as charge is withdrawn, the cathode resistance values do not increase above the original value. This result correlates with the flat discharge curve of Li/CF cells (16). If it is assumed that the impedance values reflect mainly the interparticle pore network, then it can be concluded that clogging of the

Table III. Input parameters to electrode resistance calculations

Charge withdrawn (C)	Electrode thickness (cm)	v_2
0	0.062	0.50
50	0.087	0.37
100	0.103	0.30
200	0.115	0.24
300	0.143	0.20

interparticle pore network with discharge products (*i.e.*, LiF) is an unlikely cathode failure mechanism. More likely, cathode failure mechanisms include concentration polarization or passivation of the CF particle with LiF.

Electrode capacitance.—The data in Table IV show that the CF electrode capacitance, as calculated from the low frequency impedance data, increases between 0 and 300C withdrawn. The increasing capacitance is due to the formation of carbon from the electroreduction of CF. This carbon has a high electrochemical surface area (92 F/g), which correlates with increases in the electrode's physical surface area with charge withdrawn as measured by Hg intrusion porosimetry (17). It will be shown in the following section that the CF electrode capacitance can provide limited state-of-charge information about commercial Li/CF batteries.

Battery data.—Figure 7 shows the complex-plane impedance plots for commercial Li/CF batteries with 0, 500, 1000, and 3000C removed. These measurements were arbitrarily made three months after the batteries were discharged. The high frequency arc is due to the activation resistance of the Li anode, and its variation with state of charge and time after discharge has been published elsewhere (18). It was concluded that R_{act} of Li could not be used as a measure of state of charge in commercial batteries. The low frequency battery impedance data (< 1 Hz) are assigned to the CF cathode on the basis that its capacitive component increases with charge withdrawn in a manner similar to that of the CF half-cell impedance. Table V shows that there is a semiquantitative relationship between Z_q values at 0.00563 Hz and state of charge for batteries with < 1000C withdrawn (< 25% of total stored charge) and that the low frequency Z_q values are reasonably constant from three months to four years after discharge. In a separate set of experiments in which the battery impedance was measured periodically for one year after discharge, Z_q values stabilized after two months. Thus, low frequency battery impedance data can

Table IV. Capacitance of CF half-cells as a function of charge withdrawn

Charge withdrawn (C)	Capacitance, C_T (F)	Carbon formed ^a (F/g)
0	0.25	—
50	0.54	93
100	0.87	100

provide semiquantitative state-of-charge information for stored batteries, but would not be useful for determining the state of charge of batteries actively in service.

Summary

The following nonfaradaic components of CF half-cell impedance were resolved on the basis of a one-dimensional macroscopic treatment of a porous electrode: resistance due to electrolyte in the cathode pores, interfa-

cial resistance between current collector and cathode patch, separator resistance, and cathode capacitance. The major contributor to the ohmic resistance was the electrolyte resistance within the cathode patch. Furthermore, the impedance data provided evidence for tortuosity in the internal pore network of the nonwoven polypropylene separator and in the cathode matrix at certain states of charge (0 and $\geq 50\%$ of the coulombs withdrawn).

The mechanistic implications of the CF half-cell impedance data are as follows: (i) it is unlikely that CF cathode failure is caused by clogging of the interparticle pore network with LiF. Cathode failure may be caused by passivation of CF with LiF or by concentration polarization. (ii) Carbon with a high electrochemical surface area (92 F/g) is formed as an end product of CF electroreduction.

Finally, low frequency quadrature impedance data can serve as a semiquantitative measure of Li/CF battery state of charge, provided that the batteries have been stored for at least two months after being under load.

Chemisorption and Catalysis in Polythionic/Thiosulfate Stress Corrosion Cracking

Hugh H. Horowitz*

Exxon Research and Engineering Company, Florham Park, New Jersey 07932

ABSTRACT

The stress corrosion cracking of sensitized stainless steels due to thiosulfate and tetrathionate has been associated with an increased rate of anodic dissolution in the active-passive region of voltammetric scans, via the mutual sensitivity of both phenomena to a series of anionic inhibitors. The increased anodic dissolution is caused by the adsorption of the sulfur compound and its catalysis of metal oxidation. The inhibitors function, not by competitively desorbing the corrodent, but by aiding the passivation process.

The problem of "polythionic acid stress corrosion cracking" has plagued the petroleum industry for more than forty years, and related problems have recently turned up in the nuclear industry as well. Intergranular cracks form in "sensitized" austenitic stainless steels, under stress, in the presence of air, water, and a sulfide scale on the interior walls of the vessel or pipe. "Sensitization" refers to a heat-treatment of the steel to the range of 400°-800°C, causing chromium-rich metal carbides to precipitate at the grain boundaries and depleting chromium content there to the point where corrosion resistance is lost (<12% Cr). Sensitization was first noted in the heat-affected zones around welds, but has also been caused by the process conditions themselves, as well as by fabrication heat-treatments.

The problem was first reported in a fluidized bed catalytic cracker during World War II (1). In 1956-1957, it was first ascribed to polythionic acids ($H_2S_{3-6}O_6$) by Dravnieks and Samans (2). The problem has been observed in various types of hydrodesulfurization units, in sulfur plants, catalytic crackers, cokers, and residuum-treatment units of various types. More recently, related problems have cropped up in the nuclear industry. In the Girdler process for the production of deuterium oxide, multiple fractional distillations of water are carried out in the presence of H_2S . When the equipment is opened to the atmosphere, conditions similar to those in petroleum refineries exist (3). In pressurized water reactors, solutions of sodium thiosulfate, included in auxiliary lines as quenching agents for radioactive iodine, were found in separate studies (4, 5) to be extremely potent crack promoters, acting very similarly to the closely related tetrathionate, $S_4O_6^{2-}$, which is a member of the polythionate family. A recent review summarizes both the science and the technology (6).

Dravnieks and Samans devised a method for simulating polythionic acid stress corrosion cracking in the laboratory using Wackenroder's liquid, an acidic mixture of sulfur compounds formed by the reaction of H_2S and SO_2 saturated water. Recently, workers at the University of Roorkee (7) have found that, of all the polythionic acids in this mixture, only the tetrathionate was active in promoting stress corrosion cracking. In addition, the nuclear industry work cited above showed that the strong acidity of Wackenroder's liquid (due to the strong polythionic acids as well as to free sulfuric acid) is not necessary. Cracking occurred at pH 5, where the strong acids exist exclusively as doubly charged anions $S_2O_3^{2-}$ and $S_4O_6^{2-}$.

In a previous publication (8), we reported that the above active anions did not act as sulfide did to promote hydrogen entry into a ferritic steel. They both gave rise to a pronounced anodic peak in voltammetric scans. These observations suggested that these two anions function by promotion of anodic dissolution processes within the crack rather than by promotion of hydrogen embrittlement. As to the similarity of action of the two, we noted

that the theoretical potential for the reduction of $S_4O_6^{2-}$ to $S_2O_3^{2-}$ is above the corrosion potential of steel in the absence of air and that the reduction could actually be carried out on a steel electrode. Therefore, the true corrodent at the crack tip could be $S_2O_3^{2-}$ in all cases. Thiosulfate is known to be a complexing agent for metal ions including ferric and probably ferrous ions.

The aim of this paper is to shed light on the nature of the effects of $S_2O_3^{2-}$ (and $S_4O_6^{2-}$) on the cracking process and on crack electrochemistry through stress corrosion cracking tests under electrochemical control, through adsorption studies, and through studies of the effects of added anions.

Experimental

Slow strain rate tests.—Slow strain rate tests were modeled after the work of Humphries and Parkins (9). The device used was a Model P-2000 constant extension rate tensile machine purchased from the WT Specialty Company (Orient, Ohio). It was equipped with a BLH load cell of 2000 lb capacity using a Daytronics Model 3170 signal conditioner which fed its output to a Norland 2001 digital processing oscilloscope.

The samples were 0.635 cm (1/4 in.) diam rods of stainless steel Type 304, 22.9 or 25.4 cm long, having the following compositions

Sample	Cr	Ni	Si	Mn	Mo	S	P	N	C
22.9 cm	18.0	9.5	0.67	1.89	0.36	0.003	0.010	0.021	0.056
25.4 cm	18.0	8.9	0.54	1.70	0.30	0.002	0.011	0.019	0.043

They were sensitized by holding at 1040°C under argon for 4h, cooling slowly under argon to 600°C, holding at 600°C under nitrogen for 100h, and cooling to room temperature. The 100h heat-treatment time/600°C combination lies at the center of Piehl's (10) time-temperature diagram for the sensitization of Type 304 stainless steel.

After heat-treatment, the rods were machined so as to provide a gauge length of 1.27 cm and a 0.25 cm diam (± 0.0013 cm) at the center with smooth transition regions at each end (0.38 cm long, 0.476 cm radius of curvature). The ends of the rods were threaded for attachment to the heads of the tensile device. The rods were degreased before use. For electrochemical tests, the unwaisted area was masked off with an electrically insulating paint.

The aqueous environment was maintained in a cylindrical Teflon container of 1 liter capacity which fitted on and around the sample rod via a watertight seal. This container had a closed lid with which one could maintain a nitrogen atmosphere, include a reference electrode to follow the potential of the specimen, or include a circular platinum counterelectrode to control the potential of the specimen via a potentiostat. A BC 1200 potentiostat from Stonehart Associates was used with the test piece as grounded working electrode. When the potentiostat was not used, air was sparged through the cell electrolyte to hold the potential around 0 V/SCE. A nitrogen atmosphere was maintained during potentiostat controlled

* Electrochemical Society Active Member.

runs. All experiments were conducted at room temperature.

The results of the tests were plotted in terms of percentage of elongation based on the 1.27 cm gauge length, and tensile stress based on the cross-sectional area of the gauge length. The most commonly used extension rates were 1 or 3×10^{-6} /s.

Voltammetric scans and polarization curves.—Voltammetric scans were run on end faces of 1/4 in. rods of Type 1018 carbon steel or a Type A329 steel nominally containing 7% Cr-0.5% Mo. The actual composition was

C	Mn	P	S	Si	Ni	Cr	Mo
0.10	0.41	0.021	0.025	0.58	0.33	7.9	0.6

The sides of the rod were masked either with a hardened epoxy or with Teflon tape. The electrode surface was polished on a belt sander to a 600 grit finish. Preliminary tests were also run on a 0.2 cm² disk of 4130 carbon steel mounted in a rotating disk electrode. The electrode face was immersed downward in 50 cm³ of electrolyte in a glass apparatus with a facing Pt counterelectrode and a Luggin capillary mounted to one side. The potential was controlled by a Princeton Applied Research Model 173 potentiostat with a Model 179 plug-in, for current read-out and resistance compensation, and a Model 175 programmer for ramp or pulse generation.

For pseudosteady-state polarization curve measurements, the potentiostat was controlled by a Hewlett-Packard 9836 desktop computer interfacing through a HP 3497 A data acquisition and control unit. The open-circuit potential was allowed to stabilize under nitrogen. 8 mV steps were then applied to the potential, cathodic first, and the response was measured at intervals of 0.25s for about 40 points, until a pseudosteady state was reached. Only in the voltage range where passivation occurred was a constant value not reached within this time period. The last eight current density values at each voltage were averaged and plotted on a semilogarithmic graph vs. the voltage corrected for uncompensated resistance using a HP 7470A graphics plotter. The resistance values used for ohmic drop compensation were determined early in the experiment by applying 10 mV voltage pulses around the open-circuit potential at 1000 cycle/s and determining the initial current response.

Corrosion currents were estimated by extrapolating either the anodic or cathodic Tafel slope, or both, back to the open-circuit potential. Confirmatory values were obtained from linear plots of the voltage-current density relation around the corrosion potential. The average of all these data was taken.

Adsorption experiments.—Adsorption was measured by transferring a test electrode between two electrochemical setups, each equipped with Luggin capillary, saturated calomel reference electrode, and a platinum counterelectrode. Typically a freshly polished electrode was inserted in base electrolyte solution, 0.9M sodium acetate plus 0.1 M acetic acid, and a base case scan was run. The electrode was then removed from the cell and rinsed in distilled deionized water, both with a jet of flowing liquid and with bulk water in a beaker. It was then transferred to the second solution, base electrolyte containing 0.001M sodium thiosulfate or tetrathionate, and a second scan was run, showing enhancement of the passivation peak due to the sulfur compound. After the electrode had returned to the open-circuit potential, it was removed from the cell, passed through the rinsing process, and replaced in the first cell containing the base solution, and rescanned, generally showing most of the peak enhancement due to the thiosulfate. A relatively rapid scan rate, 500 mV/s, was used during this procedure to avoid destroying the adsorbate. Several variations of the sequence, such as omitting one or both of the intermediate scans, or including inhibiting anions in the rinse water, were made as described in the text to obtain further mechanistic information.

The electrodes used were, in many cases, the same ones that were used in the voltage scan studies, including masking of the cylindrical face. However, because of the possibility of entrapment of liquid in possible crevices between the masking material and the metal, many adsorption tests were run using unmasked electrodes. Here, an exact definition of the surface area was sacrificed to unequivocally demonstrate the adsorption phenomenon.

Results and Discussion

Evidence for anodic current during the cracking process.—In the slow strain rate test on sensitized 304 stainless steel, failure occurred ductilely after 80-100% elongation in air or in acetate buffer without added corrosives. Stress-elongation curves showed a long region of plastic flow (Fig. 1). When a small amount of thiosulfate (0.01M) was added, brittle failure occurred after less than 10% elongation (Fig. 2) and the fracture surface showed the separated crystalline look typical of intergranular cracking (Fig. 3).

In a number of tests, a reference electrode was inserted in the cell and the potential of the stainless steel tensile specimen was followed as the sample was strained. Before failure occurred, the potential rested in the neighborhood of 0 vs. SCE, held at this relatively noble value by the presence of the air. Samples failing ductilely exhibited a sharp decrease in potential at the point of fracture (Fig. 1). This was undoubtedly due to the current required to restore the passive oxide layer on the freshly created surface.

When intergranular stress cracking occurred close to the point where the stress began to fall below the ductile failure levels, the potential began to decrease rapidly. It continued low until just after failure occurred (Fig. 2). This means that an active anodic center developed within the crack, causing the total electrode to take on a mixed potential wherein the anodic current issuing from the crack was equal to the cathodic current of oxygen reduction on the surface of the steel.

The anodic current was measured using a counterelectrode and a potentiostat, holding the stainless steel surface at a potential of 0 vs. SCE. Again, when cracking began and the stress fell below the expected relation, a small current was observed, rising to a peak of 250 μ A and falling to values close to zero as the cracking process was completed (Fig. 4). Similar potential and voltage excursions during stress corrosion cracking have been reported in Ref. (5), (6), and (13).

A rough integration of the current-time trace indicates that a total of about 4 μ m of metal was removed from the

Fig. 1. Potential decrease during a ductile failure. Sensitized stainless steel, Type 304, in 0.01M Na₂S₂O₃ + 0.02M each Na₂HPO₄-NaH₂PO₄, pH 6.8; air saturated; 25°C; extension rate 3×10^{-6} /s. 1 KSI = 6.89 MPa.

Fig. 2. Potential decrease during stress corrosion cracking. Sensitized stainless steel, Type 304, in 0.01 $\text{Na}_2\text{S}_2\text{O}_3$ in 0.02M each Na acetate-acetic acid, pH 4.8; air saturated; 25°C; extension rate 10^{-6} /s. 1 KSI = 6.89 MPa.

cross section of the waisted area. Since there are multiple cracks and many dead-end crack branches, it would appear that a large fraction of the sensitized metal in the crack area is removed.

Effect of added anions on cracking process.—A number of sodium or potassium salts were added to 0.01M $\text{Na}_2\text{S}_2\text{O}_3$ to determine if their anions would inhibit the cracking process. The results were that chloride, sulfate, nitrate, and acetate did not inhibit cracking, whereas cracking was inhibited by nitrite, various forms of phosphate at different pH's, carbonate, borate, and, to a lesser extent, hydroxide. In the presence of the first group of ions, the percentage of elongation at failure remained mostly at 20% or below, while in the presence of the second group, predominantly ductile failure occurred at 66-100% elongation (Table I).

The ability of certain anions to eliminate the action of the sulfur anions provided a variable parameter for the correlation of electrochemical phenomena with the cracking process. Also, it should be noted that the effect of the anions is not merely to make the solution basic, although the inhibitors do that in some cases. The nitrite ion leaves the solution neutral, while the phosphate was active in three different pH regions. The trisodium phosphate is strongly alkaline, while the mixed sodium monohydrogen and dihydrogen phosphate are around pH 6.5 and the dihydrogen phosphate alone is fairly acidic (pH 4.3).

Fig. 3. Scanning electron micrograph of stress cracked surface. Sensitized stainless steel Type 304 cracked at 4.5% elongation in 0.01M $\text{Na}_2\text{S}_2\text{O}_3$ + 0.04M NaCl; air saturated; 25°C; extension rate 3×10^{-6} /s.

Fig. 4. Anodic current accompanying crack growth. Sensitized stainless steel, Type 304, in 0.025M $\text{Na}_2\text{S}_2\text{O}_3$ in 0.05M each Na acetate-acetic acid; N_2 saturated; 25°C; potentiostated at 0.0V vs. SCE; extension rate 3×10^{-5} /s. 1 KSI = 6.89 MPa.

Effect of thiosulfate on voltammetric scans.— Voltammetric scans were run on steel samples in thiosulfate or tetrathionate solutions to verify the enhancement of anodic activity at the crack tip as hypothesized from the cracking experiments and the previously reported hydrogen permeation studies (8). The steels used contained 0 or 7% chromium to simulate the Cr-depleted metal in the grain boundaries of the sensitized stainless. A Type 4130 steel, was used initially, followed by a 1018 carbon steel, followed by a 7% Cr, 0.5% Mo steel, and finally by a special 9% Ni-7% Cr steel. All gave similar enhancements of the anodic peak in voltammetric scans due to the addition of small concentrations of sodium thiosulfate or tetrathionate (usually 0.001M). The peak size differed from steel to steel, but the relative difference between the base case and the thiosulfate-doped solutions remained about constant. A typical case is given in Fig. 5, where it will be seen that a peak passivating current of about 1 mA/cm² in acetate buffer was increased to about 24 mA/cm² by the addition of 0.001M thiosulfate. At higher concentrations, e.g., 0.1M, corrosion was so severe that the electrode surface was not stable—corrosion products began falling rapidly from the electrode surface and clogging the space between the electrode and the Luggin capillary.

Table I. Effect of added anions on stress corrosion cracking promoted by thiosulfate^a

Concentration	Percentage elongation at failure	Concentration	Percentage elongation at failure
None	3, 13, 15, 23	0.04M NaNO_3	101

0.02M Na acetate	5, 8, 7, 20, 48	0.02M Na_2CO_3	74
+ 0.02M acetic acid		0.02M NaHCO_3	99
		+ 0.02M Na_2CO_3	
		0.02M NaOH	46
		0.01M $\text{Na}_2\text{B}_4\text{O}_7$	66

^a Conditions: 0.01M sodium thiosulfate in deionized water at room temperature. Air saturated. Stainless steel 304 sensitized at 600°C for 100h. Waisted area 0.1 in. diam, 0.5 in. long pulled at an extension rate of 3×10^{-6} /s.

^b Chloride without thiosulfate caused no cracking; ductile failure occurred at 98% elongation.

^c Some brittle failure observed in SEM. Without thiosulfate, NaOH caused ductile failure at 94% elongation.

Fig. 5. Promotion of anodic dissolution by thiosulfate. 7% Cr-0.5% Mo steel in 0.9M Na acetate-0.1M acetic acid; pH 5.6; N₂ atmosphere; 25°C; scan rate 5 mV/s.

As to the effect of scan speed, it was found that the peak heights in all cases increased with scan speed, but that the greatest relative difference between the base case and the thiosulfate case was observed at low scan speeds. The data of Fig. 5, for example, were taken at a low scan speed, 5 mV/s. In the base case, the peak height increased approximately linearly with the square root of the scan speed, suggesting a diffusion-limited anodic process. This could be, for example, the formation of a partially soluble iron salt, which eventually reaches the saturation concentration and precipitates on the electrode surface to begin the passivation process. In many of the thiosulfate-promoted cases, the peak height increased less than linearly with the square root of the scan speed. Our best guess at present for the scan speed effect with thiosulfate is that the coverage with passivation oxide grows slowly with time at a given voltage, while the metal dissolution rate on the unpassivated fraction of the surface rises rapidly as the voltage is increased. Thus the faster the scan rate, the more opportunity for dissolving metal rapidly before further passivation can occur. Prior rotating disk studies (8) showing rotation speed dependence in the base case but not in the thiosulfate case support this explanation. However, no attempt to analyze the scan rate effect quantitatively was made in this work. The scan rate appropriate to the cracking process would depend on the crack velocity, but would probably be on the high side of the range studied here.

Catalytic action of thiosulfate.—While the peak height increased with the scan speed, it was possible to observe steady-state currents at various voltages around the current peak over relatively long periods of time. These were almost as high as the currents observed in the voltammetric scans at low scan rates. In one run on 1018 carbon steel, the total number of coulombs passed at constant voltage corresponded to more than all of the thiosulfate present in the solution. Yet solution analysis showed only a minor depletion of the thiosulfate. In a series of runs, the ratio of metal atoms dissolved to thiosulfate ions consumed corresponded to 100 to 400 to 1. Analysis of the solution after one of the runs showed that the amount of dissolved iron corresponded closely to that calculated from the number of coulombs of electricity passed (Table II).

In other words, the effect of the thiosulfate was catalytic. A small amount of thiosulfate catalyzed the dissolution of a large amount of iron. This may explain the results of Ref. (4) where 0.1 ppm of thiosulfate (10⁻⁶M) was sufficient to induce stress corrosion cracking. In that case, the amount of iron involved in the cracking reaction must have been much greater than the total amount of thiosulfate in the liquid in the crack or in the external liquid zone surrounding the crack.

^b Calculated Fe concentration from charge passed: 0.0248M; measured polarographically: 0.0247M.

Effect of added anions on voltammetric scans.—It was found that the addition of certain soluble salts to solutions of thiosulfate eliminated the peak enhancement normally produced by the thiosulfate. Other salts had no effect. Figures 6 and 7 show the results obtained with both thiosulfate and tetrathionate on the 7% Cr-0.5% Mo steel. The peak heights increased with the scan speed in all cases; but nitrate, chloride, and sulfate additions did not affect the results obtained with the untreated thiosulfate, while nitrite, phosphate, borate, and carbonate reduced and peak height down to the base case levels or below. Figure 8 shows similar results in 1018 carbon steel with thiosulfate, although the NO₂⁻ is not as effective here.

The point is that the ions which decreased the anodic peak due to thiosulfate are the same ones which inhibited intergranular stress corrosion cracking in sensitized stainless steel, while the ions which did not affect the corrosion promotion affect of S₂O₃²⁻, also did not inhibit stress corrosion cracking. For both the stress cracking of the sensitized stainless steel and the stimulation of the anodic corrosion of nonstainless steels, the inhibitors were phosphate, borate, nitrite, and carbonate; noninhibitors were acetate, chloride, sulfate and nitrate.

Fig. 6. Effect of inhibitors on anodic peak in voltammetric scans; 7% Cr-0.5% Mo steel in 0.001M Na₂S₂O₃; 25°C; N₂ atmosphere. ●: 0.9M Na acetate-0.1M acetic acid, pH 5.6 (= A). +: A plus 0.05M Na₂SO₄. ◇: A plus 0.05M KNO₃. X: A plus 0.05M NaCl. □: A plus 0.05M NaNO₂. ▽: A plus 0.05M Na₂S. ○: A without Na₂S₂O₃. △: 0.025M Na₂HPO₄ + 0.025M NaH₂PO₄. ◆: both 0.5M NaHCO₃ + 0.05M Na₂CO₃ and 0.1M Na₂B₄O₇.

Fig. 7. Effect of inhibitors on anodic peak in voltammetric scans; 7% Cr-0.5% Mo steel in 0.001M $\text{Na}_2\text{S}_2\text{O}_3$; 25°C; N_2 atmosphere. \odot : 0.9M Na acetate/0.1M acetic acid, pH 5.6 (= A). $+$: A plus 0.05M Na_2SO_4 . \diamond : A plus 0.05M KNO_3 . \circ : A without tetrathionate. \triangle : A plus 0.025M Na_2HPO_4 -0.025M NaH_2PO_4 . \square : A plus 0.05M KNO_3 .

This is a very strong indication that the two phenomena are closely related, and led to the conclusion that enhanced anodic dissolution at or near the crack tip is the cause of the cracking.

The presence of thiosulfate also affected the anodic and cathodic branches of the polarization curve, but not nearly so dramatically as it raised the passivation current. On the 7% Cr-0.5% Mo steel, the thiosulfate increased the anodic iron dissolution current and decreased the cathodic hydrogen evolution current, thereby decreasing the corrosion potential by about 80 mV, but had a relatively small effect on the overall corrosion current (Fig. 9). The effects of thiosulfate and inhibiting and noninhibiting anions on passivation peak currents and on corrosion currents are summarized in Table III. On the 1010 carbon steel, the effect of $\text{S}_2\text{O}_3^{2-}$ on the corrosion current was very small relative to the passivation peak effect of Fig. 8 (see Fig. 10).

An interesting point is that sulfide ion acted as an inhibitor for the action of thiosulfate (Fig. 6 and Table III), again pointing to the fact that thiosulfate is not acting simply as a progenitor of an iron sulfide film. The two ions act antithetically.

Preliminary information has been obtained on the nature of the adsorbate using x-ray photoelectron spectroscopy (XPS) and Auger spectroscopy. In both analysis, the adsorbate formed on a 7% Cr-0.5% Mo steel and on a 9% Ni-7% Cr steel showed sulfur peaks corresponding to a mixture of sulfate, or SO_x , and sulfide, S^{2-} . No peaks corresponding to elemental sulfur were observed. Thiosulfate itself exhibits both an SO_x and a sulfide in XPS so that it is not possible to tell at present whether the thiosulfate has remained intact or cracked upon adsorption. Further details of this work will be given in future publications.

Demonstration of the adsorption of $\text{S}_2\text{O}_3^{2-}$ and $\text{S}_4\text{O}_6^{2-}$.—Chemisorption of thiosulfate and tetrathionate was demonstrated by means of the electrode transfer experiments described in the Experimental section. After a voltammetric scan in a thiosulfate solution, which produced considerable enhancement of the passivation peak as compared to the $\text{S}_2\text{O}_3^{2-}$ -free buffer, rinsing the electrode and transferring it back to the base solution generated a passivation peak much larger than the original base case and almost as large as the peak directly in the thiosulfate solution. This is illustrated in Fig. 11 with thiosulfate and Fig. 12 with tetrathionate.

A number of variations were made of this procedure. It was found unnecessary to run a scan in the $\text{S}_2\text{O}_3^{2-}$ solution; a simple dip would suffice. However, it was not

Table III. Effect of added ions on corrosion current and passivation peak current on 7% Cr, 0.5% Mo Steel

possible to demonstrate adsorption after immersion of a freshly ground surface into thiosulfate solution without scanning at all. A scan in the base case solution or in the thiosulfate solution was necessary. Such a scan either removes impurities or generates a hydrous oxide layer with which the $\text{S}_2\text{O}_3^{2-}$ reacts.

As to desorption of the adsorbed species, it was found that repeated scans in thio-ion-free electrolyte produced a gradually declining peak (Fig. 11). Holding the electrode at a potential near the passivation peak also produced a declining current, followed by a decreased anodic peak current in a subsequent scan. Both of these indicate loss of adsorbed thiosulfate at oxidizing potentials. It was for this reason that the scan rate used for the detection of adsorption was kept high, at 500 mV/s, so as to minimize the time spent at potentials where loss of adsorbate could occur. This loss could occur through the oxidation and removal of the underlying layer of steel upon which the adsorbate rests, or there could be an anodic reaction of the adsorbate-metal complex. We know from the catalytic studies that there is some loss of $\text{S}_2\text{O}_3^{2-}$, albeit small, during corrosion of the steel, which is not seen in nonreacting, stored solutions of thiosulfate in buffer electrolyte, lending credence to the reaction hypothesis.

Chemical interactions of thiosulfate and iron ions.—In an attempt to explain the effect of thiosulfate on the passivation process, its interaction with iron ions was investigated. Page reported in 1954 (11) on the existence of a soluble ferric ion-thiosulfate complex $\text{Fe}(\text{S}_2\text{O}_3)^+$ with a fairly low dissociation constant, 0.02 at 0.5 ionic strength. He also obtained indirect evidence for a weaker ferrous ion complex, FeS_2O_3 with a dissociation constant of 0.12.

We have now verified the existence of the weak ferrous-thiosulfate complex by measuring the increase in the solubility of ferrous oxalate due to the addition of sodium thiosulfate at 25°C. The pH was held at 4.0 with acetate buffer. This reduced the free oxalate concentration by a factor of 2.64, via the formation of HC_2O_4^- , but

gave more reproducible results than at pH 7 where precipitates were observed to form. There was a definite increase in dissolved iron concentration with thiosulfate concentration.

Combination of the equilibria

and

generates the relation

$$[\text{total Fe}^{2+} \text{ dissolved}]^2 = 2.64 \times K_{sp}(1 + [\text{S}_2\text{O}_3^{2-}]/K_d)$$

From the slope of the relationship between the total dissolved iron and the thiosulfate concentration (Fig. 13), a value of K_d of 0.11 was obtained, an essential confirmation of Page's value. This high a value of the dissociation constant does not indicate strong complexation. At 0.01M of both ferrous and thiosulfate, for example, only 8% of the Fe^{2+} ions would be complexed. Only if the thiosulfate concentrations reached 1M, say at a crack tip, would 70% of the ferrous ions be complexed.

While the above soluble ferrous ion complex does not look mechanistically impressive, precipitates formed in neutral solutions were possibly more promising in explaining the crack promotion and voltage scan data. It was found that titration of a solution containing a ferrous salt (the sulfate) plus sodium thiosulfate with aqueous alkali (NaOH) produced a black precipitate. This was not simply iron hydroxide, which is green, or iron sulfide. Treatment with HCl released a mixture of elemental sulfur, SO_2 , soluble thiosulfate, and iron ions, but no H_2S . Similarly, dissolution into dilute acetic acid released thiosulfate into solution. The precipitates contained only traces of sodium as determined by inductively coupled plasma emission spectroscopy, indicating that the source of the thiosulfate released was not simply occluded sodium thiosulfate solution. It appears that

Fig. 11. Adsorption of thiosulfate on 7% Cr-0.5% Mo steel. 0.9M Na acetate/0.1M acetic acid buffer at pH 5.6; scan rate 500 mV/s; Na_2 atmosphere; 25°C.

Fig. 12. Adsorption of tetrathionate on 7% Cr-0.5% Mo steel. 0.9M Na acetate/0.1M acetic acid buffer at pH 5.6; scan rate 500 mV/s; Na_2 atmosphere; 25°C.

Fig. 13. Effect of added thiosulfate on ferrous oxalate solubility. Fe^{2+} ion concentration determined by atomic absorption.

ferrous ion, hydroxide, and thiosulfate form a solid complex in neutral solutions. Unfortunately, we have succeeded in obtaining neither consistent stoichiometry of this complex nor consistent x-ray diffraction spectra. The material appears to have a highly variable composition depending upon exact preparation conditions and would appear to require careful study to elucidate its structure-composition relationship. However, the existence of such a substance strongly suggests that the thiosulfate ion is able to enter into the passivating film on steel and change its composition and structure. This is probably one of the ways it may alter the passivation process, in an addition to mechanistic effects on the anodic and cathodic electrode reactions.

The role of inhibiting anions.—Experiments were run to determine whether the anions which inhibit the action of thiosulfate do so by competitively desorbing the thiosulfate. The adsorption procedure was modified to include inhibiting anions in the water used to rinse the electrode after the adsorption step. In the subsequent voltammetric scan in base electrolyte, no reduction in the $\text{S}_2\text{O}_3^{2-}$ -promoted passivation peak was observed; the inhibitor did not desorb the $\text{S}_2\text{O}_3^{2-}$ even after a 5 min soak. In contrast, when the inhibitor was included in the final test solution, then inhibition did occur, as shown by a sharp reduction in the passivation peak current (Table IV).

Thus the inhibitor does not cause the desorption of thiosulfate; it must be in solution in the presence of adsorbed thiosulfate to work. The four ions in question are known to promote the passivation of steel (12). This was observed in the present studies where carbonate and borate were observed to reduce drastically the passivation currents, relative to acetate, in the absence of thiosulfate (Table III).

Further tests were run to show that the inhibitors do not adsorb on the surface of the steel. A series of scans were run in which the 7% Cr-0.5% Mo steel was dipped alternately in buffer containing 0.001M thiosulfate and 0.001M thiosulfate plus 0.01-0.05M of the various inhibitors. In every case, the peak height was high in the thiosulfate solution and low in the thiosulfate inhibitor solution; i.e., the inhibitor effect did not carry over into the uninhibited solution. There was no evidence for adsorption of the inhibitor, as the thiosulfate was adsorbed.

The inference then is that thiosulfate or tetrathionate enters into the anodic film so as to render it less protective. Anodic dissolution is thus able to occur readily through the imperfect film. The inhibiting ions must be helping to bolster or repair the imperfect film, probably by the formation of insoluble salts or mixed oxides or hydroxides.

Summary and Conclusions

There are a number of significant findings in this work and deductions that can be made therefrom.

1. The promotion of intergranular stress corrosion cracking in sensitized stainless steel by thiosulfate and tetrathionate is accompanied by anodic current emanating from the crack. Cracking can be inhibited by the addition of certain ions to the solution, whereas other ions do not affect it.

2. Thiosulfate and tetrathionate also produce sharp increases in the passivation currents on nonstainless steels related to those which would be found on the walls of an intergranular crack in sensitized stainless steels. This has been observed with four different steels. The effect appears to be of sufficient generality that it is a virtual certainty that it will be the same in the sensitized grain boundary areas, whatever their exact composition.

3. Supporting the contention that the anodic process on the nonstainless steels is related to the intergranular cracking process is the observation that the same ions which inhibit the cracking also eliminate the high passivation currents caused by the sulfur oxyanions, while the ions which did not inhibit cracking did not reduce the high passivation currents.

4. The thiosulfate and tetrathionate promote the increased anodic currents by adsorbing on the surface of the steel and catalyzing the dissolution of iron. The adsorption step explains how extremely small concentrations of $\text{S}_2\text{O}_3^{2-}$ can promote cracking.

5. The inhibiting ions which prevent stress corrosion cracking and eliminate the anodic stimulation due to $\text{S}_2\text{O}_3^{2-}$ and $\text{S}_4\text{O}_6^{2-}$ do not desorb the adsorbed sulfur compounds from the surface, but must be present in solution to inhibit. Presumably, they function by reinforcing passive film formation by generating insoluble iron salts. Conversely, this implies that the adsorbed sulfur compounds render the surface film nonprotective either by changing the granularity or porosity of the film or by promoting ferrous ion transport.

We now come to the question of how increased anodic dissolution promotes intergranular stress corrosion cracking. One might expect anodic dissolution to promote crack blunting. The simplest explanation seems to be that this is a case of active path dissolution or "stress-assisted intergranular corrosion." The corrodents, by delaying repassivation, keep the anodic process going within the grain boundary region until the zone of very high stress arrives at the next weak point. This could be a defect, dislocation, precipitate, or strain-induced phase transformation, etc. Metal cracking then occurs, generating fresh metal surface which reinvigorates the anodic dissolution reaction, continuing the process. This follows the observations of the Brookhaven workers (13) giving evidence for intermittent crack growth, sometimes at rates higher than can be accommodated by anodic dissolution only. Because the sides of the crack walls around the growing crack tip participate in the anodic process due to the action of the corrodent, the actual current densities are lower than that required by Faraday's law for crack tip advancement.

Calculation of the Electrical Resistance of a Compact Tension Specimen for Crack-Propagation Measurements

Mark E. Orazem*

Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia 22901

ABSTRACT

The electrical resistance of a notched compact specimen for determination of plane-strain fracture toughness was calculated using numerical methods coupled with the Schwarz-Christoffel transformation. Experimental measurement of this resistance is commonly used to obtain the crack length in notched specimens subjected to stress corrosion and hydrogen embrittlement tests. The results presented here predict the shape of the calibration curve for this experiment and facilitate optimal design of notched specimens for sensitivity of the resistance measurements to crack length. The electrical resistance is shown to be most sensitive to crack length for specimens containing a small starter notch. Placement of the current input leads also influences the sensitivity of the specimen resistance to the crack length. An analytic interpolation formula is presented for the primary resistance as a function of cell dimensions that reproduces the calculated results to within 5%.

The plane-strain fracture toughness of metals can be determined through tensile loading of notched specimens that have been precracked in fatigue. Common methods for this test are described in the annual book of ASTM standards (1). Measurement of crack length is an important step in the test procedure. Electrical resistance measurements have been used to monitor crack lengths in the course of hydrogen embrittlement (2), fracture toughness (3), sustained load (4), fatigue crack growth (5, 6), and stress corrosion cracking experiments (7, 8). This method has the advantages that the crack length can be monitored continuously and that the specimen is not subjected to intermittent loading and unloading of tensile stress.

The objective of this work is the calculation of the electrical resistance of a compact tension fracture specimen as a function of crack length. This calculation can be used as an aid in the selection of specimen dimensions for optimal sensitivity of electrical resistance to crack length. The results presented here can also be applied to other electrical or electrochemical systems of similar shape for which primary current and potential distributions apply.

Primary current and potential distributions apply to systems for which the surface overpotential can be neglected and the phase adjacent to the electrode has a uniform potential. These assumptions are strictly valid for

solid conductors in which the current is electronic. Calculation of the primary current and potential distributions involves solution of Laplace's equation, $\nabla^2\Phi = 0$, which is not trivial, even for simple geometries. The method of images (9), separation of variables (10), and superposition (11, 12) have been used to solve Laplace's equation for a number of systems. A review of analytic solutions has been presented by Fleck (13).

The Schwarz-Christoffel transformation (14-16) is a powerful tool for the solution of Laplace's equation in systems with planar boundaries. This method was used by Moulton (17) to derive the current and potential distribution for two electrodes placed arbitrarily on the boundaries of a rectangle. Hine *et al.* (18) used this method to describe the primary current and potential distribution for two plane electrodes of infinite length and finite width confined between two infinite insulating planes, perpendicular to but not touching the electrodes. Wagner (19) presented the primary and secondary current distribution for a two-dimensional slot in a planar electrode. Newman (20) has presented the primary current distribution for two plane electrodes opposite each other in the walls of a flow channel. These solutions made use of the Schwarz-Christoffel transformation.

Theoretical calibration curves for fracture specimens have also been obtained through application of conformal

*Electrochemical Society Active Member.

mapping for a number of simple specimen geometries, such as center- and edge-cracked plates with various starter notch or crack configurations (21-23). These are reviewed by Halliday and Beevers (24). Aronson and Ritchie (25) and Ritchie and Bathe (26) have obtained numerical solutions of Laplace's equation for the compact tension specimen considered here through application of finite element analysis. Some discrepancy was found between experimental and calculated crack lengths at long crack lengths. This discrepancy was attributed to the size of the finite-element mesh. Accurate use of finite-element solutions of Laplace's equation for this system requires a large number of nodes due to the singularities observed at the electrode edges. This difficulty is alleviated by use of the Schwarz-Christoffel transformation.

Application of the Schwarz-Christoffel transformation is generally limited, however, by the difficulty of generating solutions to the resulting integrals. Analytic solutions allow calculation of the primary current and potential distributions throughout the cell, but are possible for a limited number of system geometries. Numerical evaluation of these integrals allows calculation of both the primary current distribution along the electrodes and the cell resistance. Orazem and Newman (27) have coupled application of the Schwarz-Christoffel transformation with numerical integration to calculate the primary resistance and current distribution for a cell containing a slotted electrode. A similar approach is taken here.

Cell Geometry

The geometry of a compact tension specimen for measurement of plane-strain fracture toughness is presented in Fig. 1. The ASTM standards for specimen design are included within the figure. These standards are modified for the study of crack growth in response to fatigue. The envelope of the starter notch is typically small; Hackett *et al.* (8) used a larger notch envelope to accommodate a reference electrode. Use of a large notch may require other adjustment of the cell dimensions, e.g., use of smaller loading pinholes or wider specimens. Under the ASTM standards, the test block must be sufficiently

Fig. 1. Notched specimen for determination of plane-strain fracture toughness.

thick that edge effects do not influence the propagation of the crack as a plane. This requirement is consistent with analysis of the primary resistance of this system as being that of a two-dimensional specimen of the shape presented in Fig. 1 and of thickness W .

Under the assumption that electrodes for resistance measurement are placed directly opposite each other, the specimen may be bisected by a plane of symmetry represented by AC in Fig. 1. Thus the specimen will have twice the electrical resistance of the system presented in Fig. 2a, where constant potential surfaces are designated by RS and PQ and all other boundaries are considered to be insulating. The pinholes (see Fig. 1) were assumed to be filled by a close fitting pin with the conductivity of the test specimen. The specimen is placed in a complex coordinate system such that the line OA lies on the real- z axis. The coordinate system of Fig. 2a is transformed through an intermediate half-plane t (see Fig. 2b) to a coordinate system (Fig. 2c) in which Laplace's equation can be solved easily.

Theoretical Development

The primary current distribution along the electrodes and the cell resistance can be calculated through application of the Schwarz-Christoffel transformation. Complex coordinate systems are used, thus

$$z = z_r + jz_i$$

The z coordinate system is related to the t coordinate system of Fig. 2b by

$$z = \int_0^t \frac{(e-t)^{\beta/\pi}}{t^{1/2}(a-t)^{1/2}(b-t)^{1/2}(c-t)^{1/2}(d-t)^{\beta/\pi}} dt \quad [1]$$

where a , b , c , d , and e are the values of t corresponding to z values of A, B, C, D, and E, respectively. The outside angle at D is represented by β such that $\beta/\pi = 1/2$ for a right-angle corner. The electrodes PQ and CS correspond to p q and c s in the t plane.

The variable χ (see Fig. 2c) is related to the t variables by the Schwarz-Christoffel transformation

$$\chi = \int_0^t \frac{1}{(t-p)^{1/2}(q-t)^{1/2}(c-t)^{1/2}(s-t)^{1/2}} dt \quad [2]$$

Solution of Laplace's equation for the χ system yields the potential as a linear function of χ

$$\Phi = \frac{\chi_i}{\chi_{i,\max}} V \quad [3]$$

where $\chi_{i,\max}$ is the separation between electrodes cs and pq in the χ system, and V is the potential difference between the electrodes. The potential drop in the original cell of Fig. 1 is $2V$. The current density is related to the potential derivative at the electrodes. The relationships among the potential derivatives at the electrodes in the χ , t , and z coordinate systems are developed in Appendix A. These relationships are the basis for a system of nonlinear integral equations that can be solved to obtain the current density along either electrode in the z coordinate system.

Fig. 2. Schematic diagram of the sectioned cell with coordinates. a: $z = z_r + jz_i$. b: $t = t_r + jt_i$. c: $\chi = \chi_r + j\chi_i$.

The dimensionless primary resistance, $W\kappa R$, is obtained through integration of the current density. The numerical method used in this calculation is presented in Appendix B. The primary current distribution and the dimensionless resistance are functions only of geometric ratios.

Results

The methods outlined in Appendix B were used to calculate the primary current distribution and the primary resistance of the crack-propagation test block. The calculation of the primary current distribution was used primarily to check the calculations. The quantity of greatest interest for test block design is the primary resistance, presented in the Primary resistance section.

Current distribution.—The current distribution close to the edge of an electrode adjoining an insulator with an angle α is

$$\frac{i(z_i)}{i_{avg}} = \text{const.} \frac{\pi}{2\alpha} (Q - z_i)^{\pi/2\alpha - 1} \quad [4]$$

where Q is the point of intersection of the electrode and the insulator. The calculated current distribution shows the expected asymptotic behavior, being proportional to $(Q - z_i)^{-1/2}$ at P , Q , and S , and approaching a finite value at C .

Primary resistance.—The primary resistance of the cell can be expressed as the dimensionless group $W\kappa R$. The dimensionless primary resistance is a function of the angle β , three geometric ratios associated with cell shape (e.g., z_l/z_h , z_m/z_h , and z_u/z_h), and three geometric ratios associated with electrode placement (e.g., z_1/z_h , z_2/z_h , and z_3/z_h). In the limit of the starter envelope area approaching zero, the primary resistance approaches that of a rectangle with appropriately placed electrodes. The solution for this problem has been presented by Moulton (17) in terms of tabulated elliptic functions (29) as

$$W\kappa R_m = K(1 - m_\lambda)/K(m_\lambda) \quad [5]$$

where $K(m_\lambda)$ is the complete elliptic integral of the first kind with parameter m_λ . The parameter is obtained from the geometry of the rectangle by

$$m_\lambda = \frac{\text{sn}^2(z_2|m) - \text{sn}^2(z_1|m)}{\text{sn}^2(z_3|m) - \text{sn}^2(z_1|m)} \quad [6]$$

where m is the parameter defined by $K(1 - m)/K(m) = L/h$, z_1 is the location of point Q , z_2 is the location of point P , and z_3 is the location of point S . Equation (16.23.1) in Ref. (29) was used to calculate values for the elliptic function sn .

The primary resistance of a rectangle is presented in Fig. 3 as a function of the dimensionless length of the electrode cs [$\xi = (z_h - z_u - z_c)/z_h$]. This value represents a first approximation to the primary resistance of the notched specimen and includes the influence of electrode placement and crack length. The variable ξ approaches zero as the crack grows to bisect the block, and the primary resistance approaches infinity according to

$$W\kappa R \rightarrow -2/\pi \ln(\xi) \quad [7]$$

The greatest sensitivity of primary cell resistance to crack length is shown to be for values of ξ less than 0.5. Under the ASTM standards, the maximum value for ξ is 0.4. The range of values for ξ that are of greatest interest for crack-propagation experiments extends from 0.1 to 0.4. Under the restriction of the ASTM standards for the length of the starter crack envelope, this corresponds to values of dimensionless crack length z_c/z_h of 0 to 0.3. Placement of electrodes in a manner that increases the mean path for current flow ($z_k/z_h \rightarrow \infty$) also increases the sensitivity of resistance to crack length in the region of primary importance to crack-length measurements; this advantage is offset by the disadvantage that the resistance in this region can no longer be represented by Eq. [7].

Primary resistance curves are presented in Fig. 4 for test blocks with finite crack envelope areas. The sensitiv-

Fig. 3. Moulton's solution for the primary resistance of a rectangular conductor with $z_u/z_h = 0.4$. The resistance of the specimen shown in Fig. 1 is obtained by multiplying the resistance given above by two.

ity of resistance measurements to crack length in the region $0.1 < \xi < 0.4$ decreases with increasing envelope area. A large notch is associated with a reduced area available for conduction of electrical current. Thus, Moulton's solution for a rectangular conductor with no notch area represents a lower limit to the primary resistance of the notched specimen. The influence of the notch is greatest for z_c/z_h equal to zero ($\xi = 0.4$) and is a strong function of crack length in this region. The notch has a smaller influence on the resistance as the crack length increases and is associated with a uniform contribution to the primary resistance in the limit of $\xi \rightarrow 0$.

The primary resistance can therefore be represented by the sum of Moulton's solution and an additional resistance associated with the notch area. The additional resistance associated with notch area is presented in Fig. 5 as a function of crack length. This term is a function of notch area and electrode placement, but is relatively independent of block length. An interpolation formula for this term can be developed such that the primary resistance of the block is written

$$W\kappa R = W\kappa R_m + \Gamma + (1.4\xi + 4.24\Gamma - 0.056) e^{-(\xi_0 - \xi)/\xi} + \frac{m}{L} \left[0.5 \left(\frac{\mu}{1 - \mu} \right)^{1.5} - 0.10 \right] + \Delta_2 \quad [8]$$

Fig. 4. Primary resistance of a sectioned cell with dimensions $z_u/z_h = 0.4$, $z_k/z_h = 0.16$, $z_u/z_h = 0.6$, and $\beta = 0.25$. Moulton's solution for a rectangular conductor is given by dashed lines. The resistance of the specimen shown in Fig. 1 is obtained by multiplying the resistance given above by two.

Fig. 5. Contribution to the primary resistance associated with a finite starter notch envelope. Cell dimensions are given in Fig. 4.

where $W\kappa R_m$ is the solution obtained by Moulton, Γ is a function of the notch area given by

$$\Gamma = \left\{ \frac{z_m}{0.6z_h} \left(z_u - \frac{1}{2} z_m \tan [\pi(1/2 - \beta)] \right) \right\}^{1.523} \quad [9]$$

ξ_0 is $(z_h - z_u)/z_h$, μ is z_k/z_h , and Δ_2 is a difference variable plotted in Fig. 6 as a function of ξ . Neglect of Δ_2 results in an error of less than 5% for the primary resistance of a notched test specimen with dimension close to the ASTM standards.

These results suggest that Eq. [7] provides a suitable form for calibration curves for compact tension specimens with small notch areas. This work does not address the question of potential lead placement. Aronson and Ritchie (26) state that the top surface close to the notch is the preferred location for positioning leads for measurement of potential differences across the cracked region. This location minimizes errors associated with the uncertainty of probe location. The resistance obtained as a function of crack length with leads separated from the current inputs will differ from the resistance presented in

Fig. 6. Dimensionless correction to Eq. [8] for the primary resistance of a crack-propagation test specimen. Cell dimensions are given in Fig. 4.

Fig. 3 and 4 by a constant amount. The curves of Fig. 3 and 4 will be shifted in the downward direction. Electrical isolation of the pins from the test block (see Fig. 1) will result in an upward shift of these curves.

Conclusion

Application of electrical resistance methods for measurement of crack length in notched specimens is contingent upon the sensitivity of the resistance to crack length. This sensitivity is a strong function of specimen dimension and is specified by the calculations presented here. A large notch in the specimen reduces the sensitivity of the resistance method for crack length measurement; thus maximum sensitivity is found in the limit of a negligible notch area. Placement of electrodes in a manner that increases the mean path for current flow also increases the sensitivity of resistance to crack length in the region of primary importance to crack-length measurements; this advantage is offset by the disadvantage that the resistance in this region can no longer be represented by Eq. [7].

An expression is presented for the primary resistance of a notched test specimen. This expression is accurate to within 5%, and can be used to predict the resistance of such objects. This work should not be used, however, to calculate independent calibration curves for test blocks. The calculations presented here involve the assumption of a uniform specimen conductivity. A nonuniform conductivity is frequently the result of localized stress such as expected near the crack tip. This work, however, predicts the shape of the calibration curve and facilitates the optimal design of the test block for sensitivity of crack measurement.

APPENDIX A

Theoretical Development

The primary current distribution along the electrodes and the cell resistance can be calculated through application of the Schwarz-Christoffel transformation. Complex coordinate systems are used, thus

$$z = z_r + jz_i$$

The z coordinate system is related to the t coordinate system of Fig. 2b by

$$z = \int_0^t \frac{(e-t)^{\beta\pi}}{t^{1/2}(a-t)^{1/2}(b-t)^{1/2}(c-t)^{1/2}(d-t)^{\beta\pi}} dt \quad [A-1]$$

where a , b , c , d , and e are the values of t corresponding to z values of A , B , C , D , and E , respectively. The outside angle at D is represented by β such that $\beta/\pi = 1/2$ for a right-angle corner. The electrodes PQ and CS correspond to pq and cs in the t plane. Along the electrode PQ, Eq. [A-1] can be expressed by

$$\frac{dz_r}{dt_i} \Big|_{pq} = jf(t_r) \quad [A-2]$$

where

$$f(t_r) = \frac{(e-t)^{\beta\pi}}{t^{1/2}(t-a)^{1/2}(b-t)^{1/2}(c-t)^{1/2}(d-t)^{\beta\pi}} \quad [A-3]$$

These equations will be used to calculate the derivative of the potential at the electrode; z_r is the direction normal to the electrode in the z plane, and t_i is the direction normal to the electrode in the t plane. Along the cs electrode, the relationship can be expressed as

$$\frac{dz_r}{dt_i} \Big|_{cs} = -jf(t_r) \quad [A-4]$$

where $f(t_r)$ is given by Eq. [A-3].

The variable χ [see Fig. 2c] is related to the t variables by the Schwarz-Christoffel transformation

$$\chi = \int_0^t \frac{1}{(t-p)^{1/2}(q-t)^{1/2}(c-t)^{1/2}(s-t)^{1/2}} dt \quad [A-5]$$

Along the electrode pq , this equation can be expressed as

$$\left. \frac{dz_r}{dt_i} \right|_{pq} = jg(t_r) \quad [A-6]$$

and along electrodes cs by

$$\left. \frac{dz_r}{dt_i} \right|_{cs} = -jg(t_r) \quad [A-7]$$

where

$$g(t_r) = \frac{1}{(t-p)^{1/2}(q-t)^{1/2}(c-t)^{1/2}(s-t)^{1/2}} \quad [A-8]$$

The variable χ_i is normal to the electrode in χ space, and t_i is normal to the electrode in t space.

The potential in the χ system is a linear function of χ

$$\Phi = \frac{\chi_i}{\chi_{i,max}} V \quad [A-9]$$

where V is the potential difference between electrodes cs and pq . The potential drop in the original cell of Fig. 1 is $2V$. The separation between electrodes in the χ system is denoted by $\chi_{i,max}$. The current density is related to the potential derivative at the electrodes. In the χ system, this derivative is given by

$$\left. \frac{\partial \Phi}{\partial \chi_i} \right|_{pq} = \frac{V}{\chi_{i,max}} \quad [A-10]$$

The potential derivative at the electrode pq in the t system is

$$\left. \frac{\partial \Phi}{\partial t_i} \right|_{pq} = \left. \frac{\partial \Phi}{\partial \chi_i} \right|_{pq} \left. \frac{\partial \chi_i}{\partial t_i} \right|_{pq} \quad [A-11]$$

and the potential derivative in the z system is given by

$$\left. \frac{\partial \Phi}{\partial z_r} \right|_{pq} = \left. \frac{\partial \Phi}{\partial t_i} \right|_{pq} \left. \frac{\partial t_i}{\partial z_r} \right|_{pq} \quad [A-12]$$

From these relationships, the potential derivatives along the electrodes in the original z coordinate system are obtained as functions of t_r

$$\left. \frac{\partial \Phi}{\partial z_r} \right|_{pq} = \frac{g(t_r) V}{f(t_r) \chi_{i,max}} \quad [A-13]$$

and

$$\left. \frac{\partial \Phi}{\partial z_r} \right|_{cs} = \frac{g(t_r) V}{f(t_r) \chi_{i,max}} \quad [A-14]$$

respectively.

The current distribution along the electrode PQ is therefore given by

$$i_{avg} = \frac{g(t_r)}{f(t_r) \int_p^q g(t_r) dt_r} \quad [A-15]$$

A similar expression results for the electrode CS . The primary cell resistance is given by

$$W\kappa R = \frac{\chi_{i,max}}{\int_p^q g(t_r) dt_r} \quad [A-16]$$

The primary current distribution and the dimensionless cell resistance $W\kappa R$ are functions only of geometric ratios.

APPENDIX B
Numerical Method

The Schwarz-Christoffel transformation is coupled here with numerical integration of the transformation equations. The solution of these equations involves two steps:

determination of t variable parameters, and integration of Eq. [A-15] and [A-16] to get the primary current distribution and cell resistance.

Determination of the t variable parameters ($a, b, c, d, e, p, q,$ and s) associated with the locations of the corners and electrode edges in the z coordinate system involves the solution of eight coupled equations of the form

$$G_i(\mathbf{x}) = \text{Re}\{A\} - \int_0^a \frac{(e-t)^{\beta_i \pi}}{t^{1/2}(a-t)^{1/2}(b-t)^{1/2}(c-t)^{1/2}(d-t)^{\beta_i \pi}} dt \quad [B-1]$$

where $G_i(\mathbf{x}) = 0$, and \mathbf{x} is a vector denoting the unknown values a through s . Through use of a Taylor series expansion about a trial solution denoted by the superscript o , the series of equations can be written in the form

$$\underline{G}^o = \underline{B}^o \Delta \mathbf{x} \quad [B-2]$$

where \underline{B}^o is related to the Jacobian of the function \underline{G}^o , i.e.

$$B_{ik}^o = -\frac{\partial G_i^o}{\partial x_k} \quad [B-3]$$

and $\Delta \mathbf{x} = \mathbf{x}^o - \mathbf{x}$. The Jacobian is a strong function of \mathbf{x} and is evaluated numerically. The inverse of the Jacobian is evaluated, and a converged solution is obtained through Newton-Raphson iteration. The amount of time associated with this computation is strongly dependent upon the value of \mathbf{x}^o . In order to reduce computation times, the inverse of the Jacobian was used to calculate a parameter sensitivity coefficient [see, e.g., Ref. (28)]

$$d_k = \underline{B}^{-1} s_k \quad [B-4]$$

where s_k is the vector $(\partial G / \partial p_k)_r$, and p_k represents a given parameter, e.g., dimensionless crack length. Thus, from the converged solution for parameters \underline{p}^o a first approximation for $\mathbf{x}(\underline{p} + d\underline{p})$ is obtained as

$$\mathbf{x}(\underline{p} + d\underline{p}) = \mathbf{x}^o + \sum_{k=1}^M d_k dp_k + O(d\underline{p}^2)$$

The predicted value for \mathbf{x} is further refined by Newton-Raphson iteration.

Once the values of $a, b, c, d, e, p, q,$ and s are obtained, the current distribution can be obtained through numerical integration of Eq. [A-15], $\chi_{i,max}$ can be obtained through integration of Eq. [A-5] from p to q , and the primary resistance can be obtained from evaluation of Eq. [A-16].

ABSTRACT

An automated ellipsometer is used to study the galvanostatic electrodeposition of lead dioxide films onto a platinum substrate from an electrolyte containing lead acetate. The films exhibit regular optical properties over the thickness range from 0 to 600 nm. At a wavelength of 632.8 nm, the refractive index and extinction coefficient are 2.03 and 0.045, respectively. If the deposition process is assumed to require the transfer of two electrons per molecule deposited, the density of the deposited film is calculated to be 7.13 g/cm³. When the lead dioxide films are subjected to alternate anodic and cathodic galvanostatic cycles in neutral borate electrolyte, the optical data exhibit a complex but reproducible structure with inflections at points where the potential-time curve is featureless. A limited quantitative analysis of the optical cycling data can be carried out by requiring consistency between results at widely different film thicknesses. It is possible that the complex optical cycling behavior is due to the presence of two different types of sites for hydrogen within the film.

The experiments whose results are reported in this paper form part of our continuing study of electrochemical conversion in thin film systems. We have found ellipsometry to be a very effective technique for studying such processes both in electrochromic systems, where optical properties are of direct interest, and in battery systems, where they are only of indirect interest. Systems which are suitable for study by ellipsometry must remain stratified during the conversion process, *i.e.*, composition may vary with depth into the film but not with lateral displacement. We have observed homogeneous conversion in the anodic oxide of tungsten (1) and the hydroxides of nickel (2, 3) and iridium (4), and heterogeneous conversion with a sharp phase boundary between component layers in the anodic oxides of molybdenum (5) and vanadium (6). In all of these systems, the mobile ion is thought to be hydrogen, and the transport process is thought to dictate whether conversion is a homogeneous or heterogeneous process.

Although there is an extensive literature on the electrochemical conversion of lead dioxide films, ellipsometric studies are usually referenced (7, 8) as unpublished work or work to be published. One exception is the paper by Naegele and Plieth (9), who used an automated ellipsometer to study the galvanostatic deposition of PbO₂ on platinum. They present 1000 data points recorded at 0.25s intervals, but use an analysis technique which they state is not valid for thicknesses beyond 65 nm, and analyze only their first 70 points. Their analysis indicates that the refractive index varies by 20% and the extinction coefficient by a factor of 5 over the range of thickness spanned by their 70 data points, and they conclude only that the optical properties show irregular behavior below 50 nm.

The work we report in this paper has two specific objectives: (i) to study the optical properties of the deposited film to see whether they are as irregular as has been reported, and (ii) to study the optical changes associated with electrochemical conversion of the film to see what ellipsometry can add to our understanding of the processes involved. Our objectives here are similar to those in our recent study of MnO₂ films (10). *A priori*, we expect electrochemical conversion to be a more complicated process in PbO₂ than in MnO₂, but the ease with

which PbO_2 can be cycled should make it possible to get better optical data than can be obtained on MnO_2 films.

Experimental

Films were deposited onto a platinum single-crystal electrode from a buffered lead acetate solution (1M in lead acetate, sodium acetate, acetic acid) of refractive index 1.3752 under conditions which have been reported to favor the deposition of alpha lead dioxide (7, 8, 11). Electrochemical conversion of the films was studied in a neutral borate buffer of refractive index 1.3333, an electrolyte which we have used extensively in anodic oxidation studies and which Peter (8) used to study the reduction of lead dioxide. The optical cell consists of a hollow equilateral glass prism with standard-taper joints for the working-electrode holder, a platinum counterelectrode, a gas dispersion tube, and the mercury-mercurous sulfate electrode, to which all potentials quoted in this paper are referenced. The electrolyte was maintained at room temperature (22°C), and was not deaerated in these experiments since the samples are exposed to the air during transfer from the deposition cell to the cycling cell. The working electrode is in the form of a cylinder with a flat on one side for optical measurements, and when it is clamped between Teflon washers in its holder and mounted in the cell it exposes a vertical surface 1.44 cm² in the area to the electrolyte.

The self-nulling ellipsometer uses quadrature Faraday modulation decoded by a two-phase lock-in amplifier and fed back to ministeping drives through voltage-to-frequency converters. Under typical operating conditions, the instrument has a response time of a few tenths of a second and a resolution of a few thousandths of a degree. The angle of incidence is set at 60° to accommodate the equilateral cell, and refractive index values quoted here are for a wavelength of 632.8 nm, the wavelength of the helium-neon laser source.

A process-control computer operates the circuitry used with the cell and records current and potential along with polarizer and analyzer settings at specified time intervals. Potentials are digitized by a 16 bit analog-to-digital converter with a 25 μs conversion time. The operation of the ellipsometer is monitored on a four-trace oscilloscope, and progress of the experiment is followed on two storage displays and an X-Y plotter, which are updated by the computer.

Results and Discussion

Figure 1 shows the optical results from a deposition experiment carried out at a current density of 694 $\mu\text{A}/\text{cm}^2$. A polarizer *vs.* analyzer (P-A) plot of the ellipsometer null settings is shown in the upper portion of the figure, and the corresponding thickness values are plotted *vs.* accumulated charge in the lower portion. At point A, the substrate is free of film, and the null settings determine the refractive index N and extinction coefficient K for platinum. As deposition proceeds, the null settings spiral outwards in a clockwise direction on the P-A plot. P-A curves of this type are characteristic of the growth of a film which absorbs a small amount of the light passing through it. An ellipsometer measures the change in polarization resulting from interference between light reflected at the electrolyte-film and film-substrate interfaces, and the growth of a transparent film produces a "loop" on a P-A plot which closes when the product of the film thickness and the cosine of the angle of refraction is equal to half the wavelength of light in the film. If the film is slightly absorbing, the P-A locus spirals outward at a pitch which is a measure of the extinction coefficient.

The optical data trace out an essentially continuous curve, and the circles identify every third point from the set of 51 points at equal charge increments used in the optical analysis. The analysis technique, although straightforward, merits some discussion since it leads to conclusions which are quite different from those reached by Naegele and Plieth (9). Optical models assume that films

Fig. 1. Galvanostatic deposition of PbO_2 onto a platinum substrate at 694 $\mu\text{A}/\text{cm}^2$. The circles identify every third point from the set used in the optical analysis, and the calculated thicknesses are for a film with N equal to 2.03 and a mean K of 0.045.

are homogeneous in composition and uniform in thickness, but real films rarely exhibit these ideal characteristics. Anodic oxide films on valve metals owe their uniformity in thickness to the high field growth process, but electrodeposited films are bound to be somewhat nonuniform in thickness even under the best deposition conditions, and an analysis technique which is highly sensitive to film nonuniformity is not likely to give meaningful results. Naegele and Plieth use an instrument which measures an additional optical parameter, the mean reflectivity, and their analysis technique enables them to determine a unique value for N , K , and the film thickness D from a measurement at a single film thickness in an ideal system. This technique is useful when measurements cannot be performed at more than one thickness, but the conclusion that N varies by 20% and K by a factor of 5 over a relatively narrow thickness range is more likely a consequence of the limitations of the mean reflectivity analysis technique than of irregularity in the optical properties of the films themselves.

In the analysis technique used here, a set of points at equal charge increments is selected from the data, and sets of K and D values are calculated from the data for various values of N . The value of N which we judge to fit the data best is one for which both the standard deviation in K and the deviation from a linear dependence of D on Q are as small as possible. We could equally well fix the value of K and express goodness of fit in terms of the standard deviation in N , but the most meaningful measure of the standard deviation in both N and K is obtained by comparison with the values which provide the best fit to other deposition runs.

Analysis of the optical data in Fig. 1 shows the best fit is obtained when N is equal to 2.03. At this value, the mean of the fitted K values is 0.045 with a standard deviation of 0.01, and the standard deviation in the D *vs.* Q slope is 0.1%. Other deposition runs at the same current density give N values between 2.03 and 2.05, K values between 0.045 and 0.053, and D *vs.* Q slopes which differ by as much as 1.5%. The variation in K is consistent with a standard deviation of 0.01, and the run-to-run D *vs.* Q slope variation is not surprising since it is sensitive to variations in roughness factor. In the lower portion of Fig. 1, D is plotted *vs.* Q , and it can be seen that the analysis spans the thickness range from 0 to over 600 nm. If we fit only over the thickness range from 0 to 80 nm, the fit gets better, not worse (the standard deviation in K is halved),

and hence our films do not show the irregular optical properties below 50 nm which have been reported elsewhere (9).

The slope of the D vs. Q plot enables us to calculate the density of the film if we assume that the efficiency and roughness factors are unity, and that the film is entirely PbO_2 deposited by a two electron per molecule process. Under these assumptions, we get a value of 7.13 g/cm^3 for the density of the deposited film, a value which is about 75% of the value we would expect for a compact crystalline film. Peter (7) obtained a value of 6.85 g/cm^3 from interferometric data by assuming a refractive index equal to the bulk value of 2.23 at 600 nm, but this assumption is not consistent with a density which is substantially lower than the bulk value. Our measured value for the refractive index, 2.03, appears consistent with a density which is 75% of the bulk value, but there are other factors to be considered. Neutron diffraction (12-14) and inelastic scattering (15) studies indicate that electrochemically deposited films, whether alpha, beta, or amorphous in structure, undoubtedly contain some hydrogen. Further, the Pb:O ratio appears to be very close to 0.5, and if hydrogen is incorporated in crystalline material as lattice water or hydroxyl ions, the oxygens occupy normal lattice sites. The presence of hydrogen in the film, although insignificant in terms of its effect on formula weight, may lower the average number of electrons transferred per molecule deposited below the value of 2 which we assumed in the density calculation. If it does, then our calculated value of 7.13 g/cm^3 will be an underestimate of the density of the deposited film. We will return to this point when we discuss the results of the cycling experiments.

The cycling experiments are all carried out at a current density of $173 \mu\text{A/cm}^2$ in the borate buffer electrolyte. Film deposition from acetate electrolyte (at $694 \mu\text{A/cm}^2$) is followed optically, and when the desired film thickness is reached the circuit is opened. When no further optical changes are noted, a cell containing borate buffer is mounted on the ellipsometer table, the sample is transferred to this cell, and the ellipsometer is prepared to follow the optical changes associated with the galvanostatic conversion cycles. The anodic cycles extend all the way to the oxygen evolution potential, but the cathodic cycles have to be restricted to avoid damage to the sample. (The choice of the cathodic turning point is dealt with below in the discussion of Fig. 8.)

Figure 2 shows the potential-time plot from a cycling experiment on an 80 nm thick film. The as-deposited film has an anodic current applied to it at A to drive it to the anodic end point at B, then two complete cathodic-anodic cycles, B-C-D and D-E-F, are applied followed by two cycles with restricted cathodic end point, F-G-H and H-I-J. The film is then cycled to the cathodic end points so that a cycle with a restricted anodic end point, K-L-M,

Fig. 2. Galvanostatic cycling of an 80 nm film of PbO_2 at $173 \mu\text{A/cm}^2$ in borate buffer electrolyte.

Fig. 3. Optical data on the deposition of an 80 nm film of PbO_2 (A-B) and its subsequent cycling in borate buffer (C-D-E). C-D-E indicates the same cycle in Fig. 3 as it does in Fig. 2.

can be applied. Although quantitative analysis of multiple-cycle experiments of this kind is complicated by a progressive irreversible change in the film, qualitative features change fairly slowly from cycle to cycle, and the advantages of having a complete set of measurements on the same sample outweigh the disadvantages.

Figure 3 shows the optical data obtained during deposition of the film which was subsequently subjected to the cycles shown in Fig. 2. The optical data from the first full anodic-cathodic cycle in Fig. 2, C-D-E, are also shown in the figure, and, although the change in refractive index between the deposition and cycling electrolytes introduces a small offset between the two sets of data, the magnitudes of the optical changes associated with the film growth and film conversion processes can be compared directly. The conversion curve has a complex structure with well-defined inflection points, and the irreversible optical changes which offset the final point E from the initial point C are clearly much smaller than the reversible optical changes which occur during the cycle.

Optical results from a similar experiment on a 274 nm film are shown in Fig. 4 on the same scales as used in Fig. 3. The deposition follows the curve in Fig. 1, and the conversion curve exhibits the same amount of structure as the curve in Fig. 3, and again the irreversible optical changes are small, but the detailed shape of the conversion curve reflects the fact that the film is more than three times as thick as in Fig. 3. Corresponding inflection points can easily be identified in Fig. 3 and Fig. 4, and, since the thickness ratio is known, unique N and K values

Fig. 4. Optical data on the deposition of a 274 nm film of PbO_2 (A-B) and its subsequent cycling in borate buffer (C-D-E). The cycle has the same end points as the 80 nm film cycle in Fig. 3.

can be calculated if it is assumed that the film is a single homogeneous layer at these points.

The detailed shape of the optical cycle in Fig. 3 and its correlation with the potential-time plot in Fig. 2 are shown in Fig. 5. Point X, at which the deposition was terminated (corrected for the difference in electrolyte index), and point Y, at which the cycling began, are included in the plot of the optical data in the upper portion of the figure. When the circuit is opened to terminate the deposition, optical changes continue in the X-Y direction at a decreasing rate. Although this is the direction of continued film growth, comparison with experiments at other film thicknesses shows that the magnitude of the shift is proportional to the film thickness, and hence the change in the optical properties must be due to a relaxation process of some kind involving the entire film. The curve is similar in slope and curvature to segment G-H of the cycling data in this region, and hence the processes producing the optical change in these regions may be related.

Point A, the initial point of the cycle plotted in Fig. 5, is the point which was identified as C in Fig. 2 and Fig. 3. The potential-time plot exhibits an initial overshoot between A and B when the current is made anodic, then rises progressively toward point C just past the midpoint of the cycle. Beyond C, the potential decreases slightly before rising steadily through D then increasing rapidly to the oxygen evolution potential at E. The cathodic segment of the cycle shows somewhat less structure: the potential falls rapidly at first, then at a steady rate through F and G to a plateau between G and H. The P-A locus in the upper portion of the figure is a complex curve with several sharp inflection points. The time dependence of the optical data is not plotted explicitly, but estimates can be made using the time intervals between corresponding points on the voltage-time plot. (The most notable feature of time dependence is the very rapid shift from E toward F when the current is reversed.)

Optical cycling data are expected to exhibit cusps or sharp inflections at the points where the current is reversed, but cusps at points such as F and G where the voltage-time plot is featureless are quite unexpected. These cusps add a vertex in the X-Y-F-G region to the vertices at A and E to give the P-A plot a triangular structure. The first half of the anodic cycle and the second half of the cathodic cycle both exhibit the optical behavior characteristic of film conversion by a single electrochemical process. One might expect the initial anodic and final cathodic processes to be converses of each other,

but the optical data show that this is not the case here. The second half of the anodic P-A locus traces out a tight loop with no cusp, behavior which we think is characteristic electrochemical processes operating in parallel rather than in sequence, but which we make no attempt to model here. The cusps at F and G divide the cathodic cycle into three segments, but this does not necessarily mean that three different processes are involved. The voltage-time data appear more consistent with two overlapping cathodic processes, one operating between E and G and the other between F and H. In a two-process model, X becomes the vertex toward which the first process is directed, and the locus followed between F and G is the result of superposition. (If the vertex at X can only be reached under deposition conditions, it is not surprising that the film relaxes in the direction of Y when the circuit is opened.)

We can carry out a quantitative optical analysis of the data in Fig. 5 if we make use of the data in Fig. 4 and assume that corresponding points all have the same thickness ratio. If the cusps at F and G result from the overlap of two cathodic processes, the only points likely to be identified with homogeneous films of corresponding compositions are the vertices X, E, and H (or A). The analysis of the deposition data indicates that $N = 2.03$, $K = 0.061$, and $D = 80.68$ nm at X, and analysis of corresponding points gives $N = 2.157$, $K = 0.103$, and $D = 81.97$ nm at E, and $N = 2.051$, $K = 0.033$, and $D = 85.88$ nm at H. Since only two data sets are involved in the analysis, it is difficult to assign error limits to these values, and it is safest to conclude only that at E both N and K are higher, and at H K is lower and D is higher than the corresponding values for the as-deposited film.

Quantitative optical analysis also has something to say about the nature of the film-conversion processes. In regions B-C and G-H, conversion appears to be a homogeneous rather than heterogeneous process, and takes place uniformly throughout the film rather than by working inwards from the electrolyte interface. We have attempted no quantitative modeling between C and E, and between E and F it is more the rate of change than the shape of the locus which requires explanation.

Cycles with restricted anodic and cathodic end points provide information which helps us distinguish between the effects of the various processes. Figure 6 shows a cycle (identified as F-G-H in Fig. 2) in which the anodic current is reapplied at a point which is just past G on the cycle in Fig. 5. At this point, the first cathodic process

Fig. 5. Correlation of the optical cycling data from Fig. 3 with the corresponding potential-time plot from Fig. 2.

Fig. 6. A cycle with a restricted cathodic end point (cycle F-G-H from Fig. 2).

should be complete, and when the current is made anodic we see first a shift indicating partial reversal of the first cathodic process, then a hook in the optical locus as the second cathodic process begins to reverse, a cusp at D when reversal of the second cathodic process is complete, and finally a continuation of the initial shift when reversal of the first cathodic process is the only process operating. This behavior appears to indicate that the first cathodic process produces optical changes which are proportional to changes in overpotential or electric field and require very little charge transfer. The second cathodic process appears to be a more normal electrochemical process in which changes in the oxidation state of the film are proportional to the charge transferred.

A cycle with a restricted anodic end point is shown in Fig. 7. The cycle is the same one identified as K-L-M in Fig. 2. The displacement between the anodic and cathodic segments of the P-A locus provides a measure of the electrochemical irreversibility of the processes involved. The same quantitative optical analysis which indicated that A-B is characteristic of a homogeneous process shows that if a single process operates along B-C it must be an inhomogeneous process which proceeds inward in from the electrolyte interface.

The cycle in Fig. 7, the final cycle of the sequence plotted in Fig. 2, was followed by two additional cycles with restricted anodic end points, and the second of these, shown in Fig. 8, had its cathodic range extended to demonstrate the effects of film breakdown. Beyond C, the point at which cathodic cycles normally terminate, there is an additional reduction wave which reverses the curvature of the P-A locus, but beyond D the ellipsometer null signal deteriorates rapidly, and the film begins to break up at point E. C was chosen instead of D as the cathodic cycle end point in order to reduce the possibility of accidental damage to the film. The additional charge required to reach D can be estimated from Fig. 8, but it must be remembered that the cycle is the final one in an extended sequence, and the result may not be a very accurate estimate of the corresponding charge for the early cycles.

The oxidation state of lead dioxide films is usually expressed in terms of the value of x in PbO_x , but since the oxygen content of the film does not in fact vary appreciably, it might be better to define x as half of the average valence of the lead in the film. If we assume that the deposited film has $x = 2$, we find that $x = 1.17$ at point D in Fig. 8, and this is the lowest value we can reach without destroying the sample. We can lower the minimum x esti-

Fig. 7. A cycle with a restricted anodic end point (cycle K-L-M from Fig. 2).

Fig. 8. A cycle with a restricted anodic end point and a cathodic end point beyond the point at which the film begins to break up (point E).

mate to a bit below 1.17 if we compensate for effect of multiple cycling on the data in Fig. 8, but even without this correction we are close to the 1.15 value where Peter (8) attributes irreversible change to nucleation of a film of lead.

We do not think it likely that the as-deposited film actually has an x value of 2. If we estimate the charge required to reach the optical end point on the initial anodic cycle in Fig. 2, and assume $x = 2$ at this point, we conclude that the deposited film has $x = 1.892$, a value which could be achieved with a hydrogen content of 0.216 atoms per PbO_2 unit. This result is in close (though perhaps fortuitous) agreement with the 0.21 hydrogen atoms per PbO_2 unit detected in beta- PbO_2 by incoherent neutron scattering (12). If we assume that the hydrogen content is a measure of the amount of the film deposited by a one electron per molecule process, we calculate the density of the film to be 8.00 g/cm^3 , a value which is somewhat higher than the value we calculated above.

If we assume for the cycle in Fig. 5 that the x value is 2.00 at the anodic end point, then it is 1.35 at the initial point on the anodic cycle, 1.93 at the first cathodic cusp, and 1.83 at the second. The values at the cathodic cusps bracket the value for the deposited film as they must in a model with two overlapping cathodic processes. The presence of hydrogen in the deposited film may explain why the optical effects associated with the two cathodic processes are so very different. If the hydrogen incorporated in the film during deposition takes part in electrochemical oxidation and reduction but is not exchanged with the electrolyte, it may produce relatively large optical effects at low concentrations, and may account for the very rapid optical changes observed during the first cathodic process. The hydrogen which enters the film during the second cathodic process must occupy a different type of site in the structure and migrate back to the electrolyte on the subsequent anodic cycle.

The discussion in the previous paragraph is both speculative and rather far removed from the ellipsometric measurements on which it is based. We are on much firmer ground when we conclude that ellipsometry provides a clear picture of the electrodeposition process and offers promise as a technique for studying the electrochemical conversion of lead dioxide films.

ABSTRACT

Vacuum-evaporated palladium was used as catalyst for electroless Ni-P deposition on polyimide and alumina substrates. The effect that varying amounts of Pd had on the early stages of electroless plating was investigated by means of Rutherford backscattering spectrometry and transmission electron microscopy. No significant diffusion of the catalyst into the Ni-P film was observed; in some cases, a small amount of Pd tended to diffuse into the deposited Ni-P film, particularly on polyimide substrates. The deposition rate of the Ni-P film on polyimide was always less than that on alumina. An increased amount of catalyst decreased the deposition rate significantly without altering the stoichiometry of the plated film. When less than 10^{16} Pd at./cm² were evaporated onto the substrate, the catalyst formed clusters of palladium particles on the surface, whereas larger amounts of Pd (e.g., 2×10^{16} at./cm²) settled as a continuous film at the substrate.

The catalyst determines to a great extent the quality of the finished product of electroless plating, owing to both its influence on the adhesion of the plated layer to the substrate, and the way it controls the appearance of the film (*i.e.*, pinhole abundance, film thickness, and crystallite size). Palladium is also an expensive metal, and therefore the consumption of catalyst will be significant for the cost effectiveness of the electroless plating as a whole. The most extensively investigated catalytic systems for electroless plating have been the two-step method with a tin sensitizer and a palladium activator, and the mixed catalyst where Pd and Sn are in the same solution (1-11). The discussion about the catalyst mechanism (1, 2), improvement in sensitizer (3), and the properties of active site (4) has been done by some workers. The combination of UV ray irradiation with the catalyst (5, 6) has also been studied. There have been a few published results on the evaporated Pd catalyst (12) despite its increasing commercial importance. Recently, we have reported some new findings (13, 14) on the behavior of a commercial Pd catalyst evaporated on a polyimide substrate when used with a nickel alloy plating bath. The present communication discusses the results of our continued investigation of the evaporated Pd catalyst on polyimide and alumina.

Experimental

Preparation of catalytic substrates.—Palladium was evaporated by an electron-beam evaporator onto two types of substrates: 96% alpha-alumina ceramics from NGK Spark Plug Company Limited, and 75 μ m thick polyimide from Torey Company Limited. The conditions

were as follows: substrate temperature 25°C, pressure less than 10^{-4} torr, and target 99.99% Pd. The amount of Pd on the substrate was controlled by varying the evaporation time from 20 to 90s. For the TEM studies, evaporation times of 10 and 180s were added. For reference, substrates were prepared by the repeated two-step technique where the sample is first in a Sn sensitizer solution, then in a Pd activator solution, and repeating both dips (13).

Plating.—The prepared catalytic substrates were plated with the same ammoniacal citrate bath as the one called Ni-P(b) in Ref. (13). The bath consists of 0.027 mol/liter NiSO₄, 0.068 mol/liter (NH₄)₂SO₄, and 0.066 mol/liter NaH₂PO₂, at pH 9.0 by NaOH, and plates at 90°C. For each type of catalytic substrate, as listed in Table I, deposition periods of 10, 20, 40, and 100s were adopted. The deposition time of Ni-P film is the real time for deposition and excludes the 1 ~ 2s induction time before plating starts, *i.e.*, when the first hydrogen bubble appears.

RBS analysis.—A very brief introduction to Rutherford backscattering spectroscopic (RBS) analysis is given in Ref. (13). The RBS results were obtained by irradiating each sample with 2.0 MeV ⁴He⁺ ions to a preset beam dose

Table I. Catalysts and substrates investigated by RBS

Catalyst	Pd evaporation time (s)	Substrate used
20Pd	20	Alumina and polyimide
50Pd	50	Alumina and polyimide
90Pd	90	Alumina and polyimide
Sn/Pd	Repeated two step	Polyimide only

*Electrochemical Society Active Member.

All samples have been plated 40s with electroless Ni-P prior to investigation. a: Alumina substrate; solid line 20Pd, dotted line 90Pd. b: Polyimide substrate; solid line 20Pd, dotted line 90Pd. c: Polyimide substrate with Sn/Pd catalyst.

and detecting the backscattered alpha particles, using a surface-barrier detector situated at an angle of 161° relative to the incoming beam. The pressure was kept below 5×10^{-7} torr.

TEM observation.—Acetylcellulose, whose surface conditions are very similar to those of polyimide, was used as substrate for the Pd-catalysts investigated by transmission electron microscopy (TEM). After having deposited Pd on acetylcellulose, carbon was evaporated on top at less than 10^{-7} torr. The substrate was then mounted on a TEM mesh after the acetylcellulose removed in a methylacetate solution.

Results and Discussion

Amount and behavior of Pd catalyst.—Figure 1 shows typical RBS spectra of the Pd catalyst on alumina and polyimide. For all the spectra shown, the integral beam dose was $20 \mu\text{C}$, but the maximum yield varies noticeably (different units on the ordinates). All the substrates shown in the figure have been plated for 40s in the Ni-P bath. Without the metal layer on top of the catalyst, the peaks would have been located opposite the respective arrows on the abscissa. In Fig. 1c, the lower energy part of the double peaks stems from Pd and the higher from Sn. In this case, the Pd shoulder would occur where the arrow indicates, and the Sn shoulder would occur at an even higher energy. The following conclusions can immediately be drawn.

1. The peaks from the same evaporating time on alumina and polyimide are always larger and narrower on polyimide (compare the yields in Fig. 1a and 1b).

2. The maxima in Fig. 1a are located at the same energy, but in Fig. 1b the maximum of the smaller peak is situated at lower energy. This finding shows that the Ni-P layers deposited on top of the catalyst both have the same thickness in Fig. 1a, but in Fig. 1b the lesser amount of Pd has a thicker Ni-P layer on top.

Table II. Amount of catalyst on various substrates

Catalyst	Substrate used	Amount of Pd or Pd + Sn measured with RBS ($\times 10^{15}$ at./cm 2)	Converted thickness (\AA)
20Pd	Polyimide	11.1 ± 0.7	16.3 ± 1.0
20Pd	Alumina	6.9 ± 0.6	10.2 ± 0.9
50Pd	Polyimide	21.2 ± 1.3	31.2 ± 2.0
50Pd	Alumina	15.4 ± 1.8	22.7 ± 2.6
90Pd	Polyimide	34.3 ± 2.2	50.4 ± 3.2
90Pd	Alumina	30.3 ± 2.0	44.5 ± 2.9
Sn/Pd	Polyimide	2.6 ± 0.3^a	
Sn/Pd	Alumina	2.6 ± 0.4^a	
Sn/Pd	Carbon	$30.0 \pm 2.2^{a,b}$	
Torey	Polyimide	2.5 ± 0.3^b	

^a Includes both the Sn and Pd signals.

^b Previous data from Ref. (13).

3. In all three cases Fig. 1a, 1b, and 1c, there is a small fraction of the catalyst giving a signal stemming from the surface, especially when using alumina as substrate. In general, the Pd peak is wider and tails off more slowly on the low energy side when originating from alumina substrates.

The results concerning the catalysts are quantified in Table II together with previous data from Ref. (13). In RBS, the thickness of a layer is measured in atoms per square centimeter as in column 2. This, however, can be converted into a more "common" linear thickness by assuming a density for the layer. In obtaining column 3, a tabulated density for Pd was used. The table only states one thickness for each combination of substrate and catalyst because it remains the same within the experimental error, irrespective of the plating period. By comparing the numbers in column 2 one finds the following.

First, within the experimental error the differences in the integral signals on polyimide and alumina are the same when comparing samples that have been evaporated for the same period of time (20, 50, and 90s), with the amount on alumina always being the lower. A highly probable explanation of this is that the rugged surface of the sintered alumina causes a certain proportion of the catalyst to be hidden from detection.

Second, the amount of catalyst is the same on both types of substrate when using the chemical route to place catalyst on polyimide and in alumina. This similarity also holds for the ratio of Sn to Pd.

Third, the amount evaporated or sputtered by Torey onto their polyimide substrates is less than one-fourth of that which we found necessary to render polyimide catalytic (20s evaporating time). Also, the behavior of the commercial Torey catalyst, as described in Ref. (13), can only be described by dissolution of Pd into the Ni-P layer. A similar statement cannot be justified on the basis of the small surface signals found in this investigation, as they might well relate to imperfections in the Ni-P layer.

Effect of evaporated Pd catalyst on deposited Ni-P film.—Two typical RBS spectra are shown in Fig. 2. The top one, 2a, relates to a polyimide substrate, and the bottom one, 2b, to alumina; both spectra are obtained with an integral beam dose of $20 \mu\text{C}$. In both cases, the evaporating time for the Pd catalyst was 20s and the precipitation time for the Ni-P layer 10s. When using alumina substrates, all the peaks (P, Ni, and Pd) are oblique towards lower energies, which suggests plating in the pores of the surface, whereas plating on polyimide forms a flat surface layer. The stoichiometry is readily obtained from such spectra. The results of the present investigation are listed in Table III together with two results from Ref. (14); there is good agreement between the stoichiometries

Fig. 2. Complete RBS spectra of 20Pd on alumina (a) and 20Pd on polyimide (b). Both plated 10s with electroless Ni-P prior to investigation.

Table III. Stoichiometry of Ni-P films

Catalyst	Substrate	Ni (a/o)	P (a/o)
20Pd	Polyimide	81.4 ± 1.0	18.6 ± 3.8
50Pd	Polyimide	77.9 ± 3.8	22.0 ± 3.8
90Pd	Polyimide	81.2 ± 1.1	18.8 ± 1.1
Sn/Pd	Polyimide	79.3 ± 0.5	20.7 ± 0.5
Torey	Polyimide	83.7 ± 1.1	16.3 ± 1.1 ^a
20Pd	Alumina	81.5 ± 4.6	18.5 ± 4.6
50Pd	Alumina	77.7 ± 1.9	22.3 ± 1.9
90Pd	Alumina	78.7 ± 1.6	21.3 ± 1.6
Sn/Pd	Alumina	80.1 ± 1.7	19.9 ± 1.7 ^a

Table IV. Deposition rate measured by RBS on the Ni signal

Catalyst	Substrate	Deposition rate (Å/s)
20Pd	Polyimide	12.7
20Pd	Alumina	18.5
50Pd	Polyimide	8.2
50Pd	Alumina	16.3
90Pd	Polyimide	8.3
90Pd	Alumina	17.2
Sn/Pd	Polyimide	12.1
Torey	Polyimide	11.1 ^a

^a Previous data from Ref. (14).

from the two investigations, although the P content seems to be slightly higher in the present one. The same enhancement of the P content observed for the very early stages in Ref. (14) has also been registered in the present investigation. The results in Table III demonstrate finally that the stoichiometry is not affected by the amount of catalyst present.

Behavior of the deposition rate.—Nickel-phosphorus films are found to deposit faster on alumina than on polyimide, in agreement with previous results (14). Table IV summarizes the findings on deposition rate. These show nearly 50% higher deposition rate on alumina than on polyimide for the 20Pd catalyst, and approximately 100% enhancement for 50Pd and 90Pd. The deposition rate on alumina stays almost the same irrespective of the amount of Pd, but on polyimide there is a drastic change, as can be seen in Fig. 3. The results from the Pd/Sn catalytic system are also included and follow about the same slope as does the 20Pd evaporated catalyst; hence, a large amount of evaporated Pd decreases the deposition rate on polyimide.

Fig. 3. The relation between type of catalyst and the initial deposition rate of Ni-P on polyimide substrates.

Fig. 4. TEM micrographs of 20Pd and 90Pd on acetylcellulose.

TEM observations of Pd catalyst on acetylcellulose.—A range of acetylcellulose samples with Pd evaporated onto them for 10, 20, 50, 90, and 180s were investigated under TEM. Figure 4 shows typical transmission electron micrographs of 20Pd and 90Pd samples. The surface conditions of acetylcellulose, which is adopted because it dissolves more easily than polyimide, are assumed to be almost identical for the two polymers. The 10Pd and 20Pd samples display nearly the same surface structure of clusters of particles, with a cluster size of 0.1-0.2 μm across. The remaining samples 50Pd, 90Pd, and 180Pd all appear with a continuous Pd layer. This implies that evaporating less than ca. 10¹⁶ at./cm² (from Table II) onto a polymer gives discontinuous islands of particles, but large amounts of evaporated palladium (> 2 × 10¹⁶ at./cm²) form layers of continuous film. The deposition rate of Ni-P film on polyimide correlates with the TEM results, so the Pd catalyst in the form of clusters of particles promotes the deposition rate of electroless Ni-P plating and might also have a tendency to move into the Ni-P film. For the continuous Pd catalyst, both are less pronounced.

Conclusion

The results obtained by combining RBS and TEM techniques show a clear correlation between the catalytic activity of evaporated Pd and its conditions on the surface; a particulate layer of evaporated Pd causes faster electroless plating in the early stages, as does a solid layer. Because of the rugged surface of sintered alumina, a solid layer of Pd will not form as readily on this surface as on a smooth polyimide surface; hence, one must expect the plating rate to remain approximately the same on alumina. This is indeed the case. When the evaporated Pd catalyst is in its particulate state, it is as efficient a catalyst as the Ni-P layer and the dissolution of Pd catalyst

into the bath is not affected by the state of the catalyst, but the results might suggest that a particulate Pd catalyst diffuses more easily into the Ni-P film, especially if one takes the results in Ref. (13) into account.

Kinetic Investigations of the Primary Step of Electrochemical Coal Oxidation

Gerhard Kreysa* and Wolfgang Kochanek

Dechema-Institute, D-6000, Frankfurt am Main 90, Germany

ABSTRACT

Electrochemical coal oxidation in sulfuric acid has been investigated by a controlled potential coulometric technique. Both kinetic and analytical results indicate that the primary step of electrochemical coal oxidation may be considered as an indirect one in which hydroquinone groups are oxidized to quinone groups by Fe^{3+} , which is present under the experimental conditions because of the dissolution of the pyrite content of the coal.

In recent years, there has been a genuine interest in the development of new processes for coal conversion. Several studies from other authors have shown that, in addition to conventional chemical methods, electrochemistry is also of interest in this regard. Presently, three main routes are discussed in the literature: (i) electrochemical coal gasification with formation of hydrogen and carbon dioxide (1-6); (ii) modification of coal structure and its composition by electrochemical oxidation (7-11) or reduction (12-24); and (iii) anodic degradation of the highly condensed coal structure under formation of lower molecular substances, which are able to undergo cathodic hydrogenation (25).

Earlier reports have stated that a coal slurry can be oxidized in the anodic compartment of an electrochemical cell under formation of CO_2 , CO, and humic acids in various yields depending on the electrolyte, electrolysis time, temperature, and electrode material (3, 4, 10, 11).

Figure 1 shows anodic polarization curves obtained with a coal slurry in sulfuric acid (curve 1). If the coal is detached from such a slurry before electrolysis, the pure electrolyte shows the polarization curve 2. Curve 3 is obtained again with an acid coal slurry; however, for this experiment, a coal was used which was carefully washed free of pyrite as long as no iron could be detected in the electrolyte by atomic absorption. A comparison between these curves indicates that the electroactive species is not the coal but the dissolved Fe^{2+} . The same conclusion was drawn by Okada *et al.* (26) and Baldwin *et al.* (27), who carried out similar polarization experiments. However, Baldwin *et al.* found a residual current density ten times higher than that of curve 3 in Fig. 1. This may be due to a small remaining iron content of the coal after the washing procedure. The general role of Fe^{2+} during anodic coal oxidation has also been shown by Coughlin and co-workers (28).

A potentiostatic current time transient with addition of Fe^{3+} obtained by a slurry electrolysis of the native coal is shown in Fig. 2. The amount of 18,500C charge which was consumed during this experiment is much higher than the 680C which would be expected if only all dissolved

iron of the coal would be oxidized. This requires the conclusion that the coal is oxidized in an indirect mechanism with $\text{Fe}^{3+}/\text{Fe}^{2+}$ as a redox mediator. According to this result, anodic coal oxidation in acid media can be described by the following reaction scheme

In this communication, we shall report on our investigations of the kinetics of this reaction. The results published here have been originally presented at CHEMA 1982 (25). However, somewhat later, but independently of our work, Dhooze *et al.* (29, 30) published their investigations about the same topic. They did employ a quite similar experimental technique and also found an indirect electrochemical mechanism of coal slurry oxidation.

Fundamentals of the Experimental Method

Considering a reaction like reaction [1], the conventional kinetic examination would be done by adding coal

Fig. 1. Anodic polarization curves of coal slurries at a rotating glassy carbon electrode, 500 rpm. Curve 1: 20g native coal in 200 cm^3 1M H_2SO_4 at 20°C. Curve 2: detached electrolyte. Curve 3: 20g coal which was washed free of iron.

Fig. 2. Potentiostatic current time transient for anodic coal oxidation with addition of Fe^{3+} , 30g native coal and 0.3 mol Fe^{3+} in 300 cm^3 1M H_2SO_4 (β_{CO_2} was found to be less than 3%). Working electrode: expanded metal Ti/Pt with a geometric area of 256 cm^2 , 80°C, $E_{\text{SCE}} = +1250$ mV.

to a solution of Fe^{3+} and registration of the Fe^{3+} concentration with time. If a possible consecutive reaction after the primary step cannot be excluded, such a procedure has the disadvantage that in an early state the observed kinetics will be influenced by the consecutive reaction. This effect may be diminished by starting the reaction with a very small concentration of Fe^{3+} . In the controlled potential coulometry described by Bard *et al.* (31, 32) and also applied by Dhooge (29), the system is started without Fe^{3+} but with a certain amount of Fe^{2+} , which is electrochemically converted to Fe^{3+} with a current density corresponding to the actual concentration of Fe^{2+} .

The theoretical fundamentals of the method are briefly summarized in the following, since there are some modifications and generalizations compared with Bard (31, 32).

This kinetic method, which does not need any conventional analytical determination of concentrations, makes use of the circumstances that for a diffusion-controlled electrochemical reaction the current density contains simultaneously information about the actual concentration and its time derivative too. This may be expressed by the following equations

$$i = kFz_c c \quad [3]$$

$$i = \frac{VzF}{A} \frac{dc}{dt} \quad [4]$$

Considering a stirred tank reactor with a homogeneous concentration, the combination of these equations yields the well-known electrochemical batch reactor differential equation (33)

$$\frac{dc}{dt} = -A_s k c \quad [5]$$

Integration of Eq. [5] with the boundary condition $i_{t=0} = i_0$ results in the expression [4]

$$i = i_0 \exp(-A_s k t) \quad [6]$$

According to Eq. [6], the current time transient for a diffusion-controlled reaction, *e.g.*, a one-electron oxidation of S

can be described by an exponential function as illustrated in Fig. 3 by curve 1.

Let us now consider a more complex system with a chemical side reaction of S or S^+ with an electron acceptor or donor, respectively

In this system the reaction rate of S is given by

Fig. 3. Principal shapes of the $I(t)$ curves in a system with a parallel chemical side reaction of the electrochemical active species.

$$\left(\frac{dc_s}{dt}\right)_t = \left(\frac{dc_s}{dt}\right)_c + \left(\frac{dc_s}{dt}\right)_e \quad [10]$$

Contrary to Bard's treatment of the controlled potential coulometry, we do not assume $c_A \gg c_{\text{S}^{2+}}$. This seems to be more realistic and means that no steady-state current results. Therefore, the chemical rate constants cannot be derived from steady-state current and another method for evaluation of data is required.

By combining Eq. [3] and [5], the electrochemical term may be written as

$$\left(\frac{dc_s}{dt}\right)_e = -\frac{A_s}{z_s F} i(t) \quad [11]$$

whereas the total change of concentration is given by the time derivative of Eq. [3]

$$\left(\frac{dc_s}{dt}\right)_t = \frac{1}{kFz_s} \cdot \frac{di}{dt} \quad [12]$$

Inserting Eq. [11] and [12] into Eq. [10] and rearranging yields

$$\left(\frac{dc_s}{dt}\right)_c = \frac{1}{kFz_s} \frac{di}{dt} + \frac{A_s}{Fz_s} i(t) \quad [13]$$

This equation allows the determination of the reaction rate of the chemical step by the measurement of the potentiostatic current time transient in a batch reactor. Thereby it is presumed that the only electroactive species is S, and no direct electrochemical conversion of A and A^- occurs. Figure 3 illustrates the three principal shapes of the $i(t)$ curves as they may be obtained with the described system.

In general, for a reaction system consisting of n species, the complete kinetics can be described by n differential equations. This means that the concentration of m species has to be measured if $n - m$ independent balance equations are available. In the case of electrochemical or redox reactions for each elementary species which may occur in different oxidation states, one balance equation can be stated. Additionally, if electrochemical reactions are involved, a further charge balance equation is given; *e.g.*, for the reaction system [8]-[9] the following equations result

for S/S^+ mass balance

$$c_{\text{S}^0} + c_{\text{S}^+0} = c_{\text{S}}(t) + c_{\text{S}^+}(t) \quad [14]$$

for A/A^- mass balance

$$c_{\text{A}^0} + c_{\text{A}^-0} = c_{\text{A}}(t) + c_{\text{A}^-}(t) \quad [15]$$

for charge balance

$$Q(t) = z_s F V (c_{\text{S}^0} - c_{\text{S}}(t)) + z_A F V (c_{\text{A}^0} - c_{\text{A}}(t)) \quad [16]$$

Because four species are present in the reaction system [8]-[9], only the concentration of one species has to be

measured. If S is selected for this purpose, this can be done by recording the current density, which is in accordance to Eq. [3] proportional to the concentration of S.

Experimental

The electrochemical cell shown in Fig. 4 was employed for current time transient measurement under potentiostatic conditions. The anodic potential was kept within the diffusion-limited current density range of the Fe^{2+} -oxidation ($E_{\text{SCE}} = 1250 \text{ mV}$). The anode compartment (190 cm^3) contained a rotating platinum disk electrode (2000 rpm) with an area of 1 cm^2 . The anode compartment was separated from the cathode compartment (15 cm^3) by a ceramic diaphragm to avoid contact between the anolyte and the formed hydrogen.

The cathode was made of a 7 cm long platinum wire 0.25 mm in diameter, and the cell was thermostated by a heating jacket. In order to prevent Fe^{2+} from being oxidized by oxygen, the anode compartment was flushed with nitrogen. A suspension of coal (Westerholt Kohle, Germany; < 500 mesh) in 1M sulfuric acid containing 0.05M FeSO_4 was used as anolyte. The coal was washed free of iron by boiling under reflux in 0.1M sulfuric acid for a fortnight with daily change of the acid until no further iron could be analyzed by atomic absorption. The electrolysis was carried out using a Wenking Model POS 73 potentiostat.

Results and Discussion

Some time transients of the current density, as obtained by this method, from coal slurries and FeSO_4 at various temperatures and coal concentrations are shown in Fig. 5 and 6. The change in the initial current density with variation of the coal concentration can be only caused by a direct electrochemical reaction of the coal particles or by an enhancement of the mass-transfer coefficient of Fe^{2+} oxidation due to the presence of the particles. However, according to the polarization curves shown in Fig. 1, a direct electrochemical reaction of the coal particles can be excluded. The mass-transfer enhancement by the presence of inert particles in the electrolyte is well known (34).

Attempts were made to fit various kinetic models to the experimental data and it was found that the current-time transients can be well described by a reversible second-order reaction as the rate-determining step

Independent of the rate-determining step, in the overall reaction the primary oxidation of coal may be a z electron step. According to Eq. [17], the reaction rate of Fe^{2+} is

Fig. 4. Scheme of the applied electrochemical cell. REF: Reference electrode. WE: Working electrode. CE: Counterelectrode.

Fig. 5. Current density time curves as obtained by the transient method. a: 10g coal. b: 5g coal. c: No coal. $T = 70^\circ\text{C}$. Crosses, asterisks and dots recorded. Curves: calculated.

given by

$$\frac{dc_{\text{Fe}^{2+}}}{dt} = k_1 c_{\text{Fe}^{3+}} c_C - k_2 c_{\text{Fe}^{2+}} c_P \quad [18]$$

where c_C represents the concentration of the reactive centers at the coal, and c_P those of the oxidized product. The unknown concentrations, c_C and c_P , can be eliminated by making use of Eq. [16]. For the iron system, $z_S = 1$ is valid, whereas z_A is noted as z in the following

$$c_P = -\int_0^t \frac{i(t)A_E}{zVF} dt + (c_{\text{Fe}^{2+}}^0 - c_{\text{Fe}^{2+}}) \frac{1}{z} + c_P^0 \quad [19a]$$

$$c_C = -\int_0^t \frac{i(t)A_E}{zVF} dt + \frac{1}{kF} (i_0 - i(t)) \frac{1}{z} + c_C^0 \quad [19b]$$

With the substitution

$$-\int_0^t \frac{i(t)A_E}{zVF} dt + \frac{1}{kF} (i_0 - i(t)) = U(t) \quad [20]$$

Eq. [19] may be written as

$$c_P = \frac{U(t)}{z} + c_P^0 \quad [21]$$

Rearranging of Eq. [15] and introducing Eq. [21] results in

$$c_C = c_C^0 - \frac{U(t)}{z} \quad [22]$$

Fig. 6. Current density time curve as obtained by the transient method. 10g coal; 20°C . Crosses: recorded. Curve: calculated.

Table I. Experimentally obtained kinetic parameters of coal oxidation by Fe³⁺

Experimental conditions amount of coal (g)	T (°C)	Concentration of reactive centers at the coal (mmol/liter)	k ₁ [liter(s-mol) ⁻¹]	k ₂ [liter(s-mol) ⁻¹]
5	70	14.8	2.15 × 10 ⁻³	9.57 × 10 ⁻³
10	70	33.7	2.25 × 10 ⁻³	9.52 × 10 ⁻³
10	20	30.0 ^a	2.32 × 10 ⁻⁵	1.74 × 10 ⁻³

^a Fixed value.

In accordance with Eq. [3] and [14], $c_{Fe^{3+}}$ may be substituted by

$$c_{Fe^{3+}} = \frac{1}{kF} (i_0 - i(t)) \quad [23]$$

Introduction of Eq. [21], [22], and [23] into the kinetic rate Eq. [18] and substitution of $c_{Fe^{2+}}$ using Eq. [3] results in

$$\frac{dc_{Fe^{2+}}}{dt} = k_1 c_c^0 \left(\frac{i_0 - i(t)}{kF} \right) - k_1 \left(\frac{i_0 - i(t)}{kF} \right) \frac{U(t)}{z} - k_2 \frac{i(t)U(t)}{kFz} - k_2 c_p^0 \frac{i(t)}{kF} \quad [24]$$

Using Eq. [13] and [24] yields

$$\begin{aligned} \frac{1}{kF} \frac{di}{dt} + \frac{A_s}{F} i(t) &= k_1 c_c^0 \left(\frac{i_0 - i(t)}{kF} \right) - k_1 \left(\frac{i_0 - i(t)}{kF} \right) \frac{U(t)}{z} \\ &\quad - k_2 \frac{i(t)U(t)}{kFz} - k_2 c_p^0 \frac{i(t)}{kF} \end{aligned} \quad [25]$$

The coefficients $k_1 c_c^0$, k_1 , k_2 , and $k_2 c_p^0$ may be determined by a linear regression analysis of the experimental $i(t)$ data as given in Fig. 5 and 6, whereas $U(t)$ is defined by Eq. [20]. The charge number z of the overall oxidation of coal was set to 2 according to the mechanism suggested below. The resulting kinetic parameter values of k_1 , k_2 , and c_c^0 are summarized in Table I. At 20°C, c_c^0 was fixed at the same constant value of 30 mmol/liter as it was found for 70°C for a reasonable mathematical treatment of the experimental data. This was necessary to avoid physically unreasonable results of negative concentrations and rate constants by the fitting procedure and can be justified by the experimental conditions given in Table I. The concentration of the oxidized centers c_p^0 was found to be approximately zero.

In Fig. 7 and 8, experimental reaction rate transients as calculated by Eq. [13] are compared with the result of a

digital simulation of Eq. [18] using the kinetic parameters given in Table I.

A comparison of the simulated and experimental current density time curves in Fig. 5 and 6 shows a satisfying agreement. With the experimental rate constants of Table I, the activation energy of the reactions can be estimated by Arrhenius' law as

$$E_{Ak_1} = 18.1 \text{ kcal/mol}$$

$$E_{Ak_2} = 6.8 \text{ kcal/mol}$$

From the obtained c_c^0 values and the applied coal concentration, the molecular weight per one reactive center at the coal is estimated to be about 1700 g/mol. This value is valid for the applied particle diameter of < 500 μm.

Another experiment assists the assumption of a reversible reaction between Fe³⁺ and coal. If after a certain reaction time a further quantity of Fe²⁺ is added to the reaction system, the observed current density time curve runs below the theoretical batch reactor curve (corresponding to curve 1 in Fig. 3), as shown in Fig. 9. The actual current transient (b) after addition of Fe²⁺ shows the same behavior as curve 3 in Fig. 3. This can be well explained by the mechanism described above. In the beginning, the concentration of the reducible species P is approximately zero. This increases during reaction time. After a renewed addition of Fe²⁺, the back reaction between P and Fe²⁺ will dominate and the current density time curve runs below the theoretical batch reactor curve.

In the coal structure models as proposed by many authors (35, 36), the only group which is able to undergo a reversible redox reaction in the potential range of the Fe³⁺/Fe²⁺ system is the quinone/hydroquinone system. A possible mechanism as suggested by Vetter (37) for this system is shown in Fig. 10. The experimentally observed increase of the corresponding C=O IR bend (≈ 1600 cm⁻¹; 1100-1400 cm⁻¹) and the parallel reduction of the OH IR bend (≈ 3400 cm⁻¹) after electrochemical coal oxidation (28) is in accordance with this mechanism. Furthermore, this mechanism requires a decrease of the H:C ratio during electrolytic oxidation. For an experiment running for a longer period, the elementary analyses of the coal before and after the oxidation by Fe³⁺ are summarized in Table II. Apart from an increase of the O:C ratio

Fig. 10. Possible mechanism for the primary step of anodic coal oxidation.

due to a higher oxidation a decrease of the H:C ratio is observed. The fact that the concentration of the reducible species (quinone) is found to be approximately zero at the beginning of the reaction might be due to the washing procedure. Thereby, pyrite is partially dissolved to Fe^{2+} which can reduce all quinone groups which may be present in the native coal. An increase of the H:C ratio of about 1.7% should be expected for this reaction, if the concentration of such groups is considered to be 1 mol per 1700g of coal (see above). The observed increase given in Table II is in agreement with this value within experimental accuracy. According to the experimental results, electrochemical coal oxidation in acid media follows an indirect mechanism of charge transfer via $\text{Fe}^{2+}/\text{Fe}^{3+}$. It seems that this reaction causes no significant modification of the coal structure. More than 90% of the charge which the coal has consumed during the experiment shown in Fig. 2 may be explained by the oxidation of hydroquinone groups. Of course, also higher and other oxidized products are possible, but only a very small amount of CO_2 is formed.

The indirect mechanism of electrochemical coal oxidation offers the possibility of using other redox systems as mediator in order to get higher oxidized products or a higher reaction rate. Therefore, further experiments have

Table II. Elementary analysis of the coal after anodic oxidation by Fe^{3+}

been carried out also with the $\text{Ce}^{3+}/\text{Ce}^{4+}$ system, which has been investigated also by others (29, 30). The corresponding current time curve is shown in Fig. 11. In contrast to the experiments with Fe^{3+} , a comparable large amount of CO_2 is formed during electrolysis and the extraction yield in a 1:1 mixture of ethanol:toluol is increased by a factor of 2 compared with the native coal.

Conclusions

It has been shown that as the primary step of electrochemical coal oxidation the oxidation of hydroquinone groups can be considered. This reaction follows an indirect mechanism via Fe^{3+} . This result is supported by a kinetic analysis using a current transient method, results of IR spectroscopy, and elementary analysis. Due to the indirect mechanism, it is obvious that the electrochemical coal conversion is limited by the redox potential of the mediator system. On the other hand, this mechanism offers the possibility of applying other redox systems in order to change the reaction rate or of getting other products. Furthermore, the limitation in space-time yield, which is typical for any suspension electrolysis, may be overcome by a high concentration of the redox mediator system.

Mo₆Se₆: A New Solid-State Electrode for Secondary Lithium Batteries

J. M. Tarascon

Bell Communications Research, Murray Hill, New Jersey 07974

ABSTRACT

The practical utilization of nonaqueous secondary lithium cells has never been realized, mainly because of electrode problems such as the absence of suitable cathode materials or dendritic regrowth of the lithium on the anode short circuiting the cell. Over the last few years, the cathode problem has been overcome by the discovery of new materials such as TiS₂, NbSe₃, V₆O₁₃, etc. The crystallographic structural feature that makes these compounds attractive for batteries is that they can act as "hosts," incorporating lithium atoms between the layers (TiS₂), chains (NbSe₃), or into the channels (V₆O₁₃) without an irreversible change in crystal structure. However, in spite of intensive research, the anode problem still remains. We have undertaken research in this direction. Initial results of this early work are the subject of this paper. This study reports a new solid-state electrode material (Mo₆Se₆) which can be used both as cathode and anode in secondary lithium cells. Mo₆Se₆ can take up reversibly nine lithium atoms per Mo₆Se₆ without losing its linear chain structure, leading to a theoretical volume energy density of about 1.1 Wh/cm³, compared to 1.2 for TiS₂ cathodes. Another important promising possibility which arises from this work is the use of the lithiated compounds Li₉Mo₆Se₆ as the anode instead of lithium metal in secondary lithium cells.

Over the last decade, the continuous need for high energy storage devices prompted the study of several new types of secondary rechargeable batteries. This work led to the discovery of several promising battery systems based on lithium (1, 2). However, their practical utilization has never been realized, mainly because of electrode problems such as absence of suitable cathode materials or dendritic regrowth of lithium on the anode short circuiting the cell after several cycles.

In recent years, the cathode problem has been overcome by the discovery of new solid-state electrode materials. Among them are the class of early transition metal dichalcogenides such as TiS₂ or VS₂, which, due to their open layered crystal structure, can accommodate lithium reversibly (e.g., lithium can enter into the structure and be removed easily) (3). These intercalation reactions are not limited to layer compounds, but also can occur within three-dimensional structures having large open channels such as in V₆O₁₃ (4) or in the Chevrel phases Mo₆X₈ (5-7). Another class of materials capable of intercalating lithium are the trichalcogenides of Group IVB or VB transition elements such as TiS₃ or NbSe₃. Their structures (8) can be thought of consisting of parallel chains, each only a few

atoms thick and loosely bonded to the chains around it. On discharge, three lithium ions are absorbed between the chains, giving to NbSe₃ one of the highest theoretical volume energy densities (1.6 Wh/cm³) (9-10). However, none of these materials is being used commercially because of the short cycling life of the lithium anode as alluded to above. In spite of an intensive research currently focused on decreasing the reactivity of the lithium anode by alloying it with other metals, the anode problem still remains.

In a recent study (11), we reported the synthesis of a new metastable ternary molybdenum chalcogenide of formula Li₉Mo₆Se₆, whose structure can be thought of as composed of (Mo₃Se₃)₂ chains separated by two rows of lithium atoms. The similarity of this structure to that of NbSe₃ led us to embark on a study of the chemical and electrochemical insertion of lithium into Mo₆Se₆. We found that Mo₆Se₆ is a good cathode material, and we showed that the fully lithiated compound Li₉Mo₆Se₆ can be used as an anode, replacing lithium metal.

Mo₆Se₆ was synthesized at a temperature of 420°C by oxidation of In₂Mo₆Se₆ (prepared by direct reaction of In, Mo, and Se powder in an evacuated silica tube at 1100°C)

under an HCl flow (12). The indium chloride formed during this reaction condensed at the colder part of the tube, leaving behind pure Mo_6Se_6 . The course of the reaction was followed by the weight change. The reaction was complete after 24h. This was confirmed by x-ray fluorescence analysis, which showed no trace of indium in the Mo_6Se_6 after such treatment. Prior to its use in electrochemical cells, the Mo_6Se_6 was baked at 400°C under vacuum to ensure the absence of gas molecules trapped between particles. The Mo_6Se_6 powder is composed of thin needle-like crystals which tend either to aggregate at one point more like a fan or to entangle much like a wool ball as illustrated in Fig. 1.

Fig. 1. Scanning electron micrographs of $53\ \mu\text{m}$ sieved Mo_6Se_6 powder prior to being used as the cathode material. a: Fanlike aggregates of Mo_6Se_6 crystals. b and c: Wool ball aggregate of Mo_6Se_6 crystals.

$\text{Li}/\text{Mo}_6\text{Se}_6$ electrochemical swagelock test cells (13) were assembled in a helium atmosphere using a lithium metal disk anode separated from the cathode (Mo_6Se_6) by porous glass paper soaked in $1\text{M LiAsF}_6/2\text{Me THF}$ electrolyte. Propylene carbonate commonly used as solvent in all secondary lithium cells was not used in this work because we previously reported (14) its ability to solvate the lithiated materials $\text{Li}_x\text{Mo}_6\text{Se}_6$.

The cells described above were cycled with a current density of $1.0\ \text{mA}/\text{cm}^2$ and with known amounts of pure Mo_6Se_6 . The preliminary cycling data summarized in Fig. 2 reveal interesting features. The discharge curves (Fig. 2a, 2c, 2d, and 2e) indicate that approximately 2.3, 3.2, 5, and 7 lithium atoms per formula unit are used on discharge to 1, 0.6, 0.49, and 0.4V, respectively. These cells are reversible and retain their capacity over many cycles. A loss of approximately 10% in capacity is observed after the first cycle, then the cells could be recharged to 100% of capacity for several cycles (15, 10, and 2 are the maximum that we have tried down to 1, 0.6, and 0.49V, respectively). Such loss in capacity after the first cycle, frequently observed in secondary lithium cells, is generally due to a small amount of intercalated lithium trapped by defects which still remain in the structure after recharging the battery. The voltage composition curves do not exhibit plateaus, but do exhibit several slopes suggesting the existence of a single phase region over the entire range of composition $0 < x < 7$. However, some caution should be exercised in so interpreting the data since the small change in potential observed in the range $0 < x < 1$ or $2.4 < x < 3.2$ may also be the result of kinetic effects (e.g., too high current densities). Another interesting feature of Fig. 2 is the rapid drop in voltage over a narrow range of composition beyond $x = 1.5$. In some cases, the voltage of a lithium insertion cell is mainly determined by the electronic energy of the charge transferred electrons (e.g., the electronic structure of the host material). A rapid decrease in voltage may then indicate the presence of an energy gap. It is important to note that the position of the voltage drop around $x = 2 \pm 0.3\ \text{Li}^+$ (e.g., 2 ± 0.3 electrons) is strongly correlated to the band structure of these materials established by Hoffman *et al.* (15). Indeed, the authors predict that Mo_6Se_6 with two extra electrons should have a closed-shell electronic structure (e.g., a semiconducting behavior). This point will be discussed in more detail elsewhere. One can also remark that the smooth voltage drop around $x = 3.2$ present in all discharge curves vanishes when the cell is recharged. The origin of such behavior remains a puzzle. Another point is the slight bending in the voltage composition curve, present in the first discharge, which vanishes on subsequent cycles. We found that the amplitude of this anomaly, which changes from sample to sample, is strongly dependent on the preparation temperature of the first $\text{In}_2\text{Mo}_6\text{Se}_6$ and the Mo_6Se_6 prepared from it.

To further probe the reversibility of the $\text{Li}/\text{Mo}_6\text{Se}_6$ system at low potential as suggested above, a cell, after being cycled ten times from 2.7 to 0.6V was discharged to 0.25V and then cycled several times. Figure 3 shows that the cell, recharged from 0.3 to 0.8V (cycle a) discharged without losing its capacity. However, over subsequent cycles between 0.25 and 0.80V one notes a loss in capacity. This behavior may result from side reactions (electrolyte decomposition or reactions with cell containers) which occur quite frequently at these low potentials as previously reported (16).

Based on the electrochemical stoichiometry, the volume energy density of the $\text{Li}/\text{Mo}_6\text{Se}_6$ cell is $1.1\ \text{Wh}/\text{cm}^3$, compared to $1.2\ \text{Wh}/\text{cm}^3$ for the Li/TiS_2 system. This makes Mo_6Se_6 a good candidate for use as a cathode material in secondary lithium cells. Furthermore, the reversibility of these cells down to 0.3V suggests the possibility of using the fully lithiated phase as the anode material instead of lithium metal. The following describes preliminary data obtained with $\text{Li}_x\text{Mo}_6\text{Se}_6/\text{Mo}_6\text{Se}_6$ cells.

Two anode materials $\text{Li}_6\text{Mo}_6\text{Se}_6$ and $\text{Li}_3\text{Mo}_6\text{Se}_6$ prepared chemically and electrochemically, respectively, were in-

vestigated. Figure 4 shows the cycling results collected for the Li₆Mo₆Se₆/Mo₆Se₆ cell, in which twice the amount of cathode than anode material was used. The cell was cycled with a current density 1 mA/cm² between 1.9 and 0.2V. One may note again the reversibility of the intercala-

Fig. 2. Cycling data for a Li/Mo₆Se₆ cell at a current density of 1 mA/cm². 66 mg of cathode material was used. a, b, c, d, and e represent the behavior of the cell when cycled down to 1, 1, 0.6, 0.5, and 0.4V, respectively.

Fig. 3. The ability of an Li/Mo₆Se₆ cell to cycle over a wide range of composition and voltage is illustrated. (The cell contained 32 mg of Mo₆Se₆, and it was charged and discharged at a rate of 1.5 mA/cm².) The cell was cycled ten, one, and three times from 2.7 to 0.6, 0.8, to 0.3, and 0.8 to 0.25V, respectively.

Fig. 4. The electrochemical behavior of a Li₆Mo₆Se₆/Mo₆Se₆ cell. The cell contained 41 mg of Mo₆Se₆ and 20 mg of Li₆Mo₆Se₆, and it was cycled with a current density of 1 mA/cm².

tion reaction in this system as well as the small loss in capacity after several cycles (10% after 10 cycles). However, the capacity is quite low, since with this narrow range of potential (potential limited by the potential of the anode Li_xMo₆Se₆ taken as zero), Mo₆Se₆ can take up only 1.2 lithium.

A larger potential for discharge requires a lithiated phase with a greater lithium content. Li₉Mo₆Se₆ was obtained by discharging a Li/Mo₆Se₆ cell to 0.25V. Then the cell was opened in the dry box and the lithium was replaced by fresh Mo₆Se₆. The resulting Li₉Mo₆Se₆/Mo₆Se₆ cell, containing equal amounts of cathode and anode material after charging and recharging, behaves as reported in Fig. 5. Its capacity is greater than that of the previous cell, since Mo₆Se₆ can now take up reversibly two lithiums on discharge. The reversibility of the above two cells without significant loss in capacity on cycling is quite promising and seems to confirm the possible use of Li_xMo₆Se₆ instead of lithium as anode in secondary lithium cells based on Mo₆Se₆. The loss in capacity alluded to above is less than that measured after ten cycles on identical test cells based on TiS₂ as cathode materials.

Finally, reactions of Mo₆Se₆ with n-BuLi (1.6M in hexane) and lithium in liquid ammonia were used to mimic the discharge curves, and the final material was characterized by x-ray diffraction and atomic absorption analysis to determine the lithium content in the resulting prod-

Fig. 5. Typical cycling behavior of a $\text{Li}_x\text{Mo}_6\text{Se}_6/\text{Mo}_6\text{Se}_6$ cell. Current density was 1 mA/cm^2 . 22 mg of $\text{Li}_9\text{Mo}_6\text{Se}_6$ and Mo_6Se_6 was used. The ninth (solid curve) and tenth (dashed curve) cycles are shown.

uct. We found that the lithium content does not deviate too much ($\pm 4\%$) for the nominal composition. Even with a large excess of $n\text{-BuLi}$, Mo_6Se_6 incorporates only 2.5 lithium atoms per Mo_6Se_6 . Based on the electrochemical data, using $n\text{-BuLi}$ as the reducing agent with a reduction potential of 1V , one might expect to intercalate at least 2.3 lithiums. The chemical and electrochemical results agree quite well. The lowest value obtained electrochemically is not unusual and is generally attributed to the fact that during the battery discharge some of the cathode particles are electrically isolated. Then the experimental capacity for lithium insertion is less than that expected from the total mass of the electrode and the known maximum possible lithium content. By using lithium in liquid ammonia, we lower the reduction potential and therefore insert more lithium atoms. So far, we have inserted up to six lithium atoms by this method. Further experiments in progress should confirm a greater intercalation as suggested electrochemically.

The electrochemical data suggest that stoichiometries as high as $9 \text{ Li}/\text{Mo}_6\text{Se}_6$ can be taken up reversibly without any structural change. X-ray powder diffraction patterns of the lithiated compounds were collected at room temperature using $\text{Cu K}\alpha_1$ radiation, in the hope of shedding some light on the intercalation process. Since these compounds are extremely moisture sensitive, they were always handled in a helium atmosphere, and an x-ray holder which can be evacuated was used for obtaining the x-ray data. Figure 6 shows some of these diffraction patterns. The lithiated phases exhibit very weak diffraction peaks as used as few lines. Poor quality x-ray powder patterns are not surprising since they are commonly found in solids formed near ambient temperature even if the compound is crystalline. For Mo_6Se_6 , we believe that the weak diffuse x-ray diffraction pattern results from a high degree of disorder in the structure. In the absence of the ternary element, the $(\text{Mo}_6\text{Se}_6)_x$ chains are loosely bonded (van der Waals-type forces), and, conceivably, they can move with respect to each other. Such disorder would lead to weak diffraction peaks as observed experimentally. On the basis of the hexagonal unit cell, the two stronger lines present in all patterns and situated in the range of $2\theta = 12^\circ$ and $2\theta = 40^\circ$ are the (100) and (002) reflections, respectively. They reflect directly the variation of both hexagonal a_h and c_h lattice parameters. One can note that a_h decreases when In is removed from the structure, from 8.85 to 8.37\AA , then increases when lithium is absorbed between the chains to reach values of 8.82 and 9.90\AA when $x = 2.5$ and 6 , respectively. Simultaneously, the c_h axis decreases from 4.49 to 4.45\AA , and then increases again to 4.47\AA at $x = 6$. The large interchain increase observed between $x = 2.5$ and 6 may suggest that some ammonia molecules remain trapped between the chains after the liquid ammonia reaction. Further work is

Fig. 6. X-ray powder patterns of $\text{In}_2\text{Mo}_6\text{Se}_6$ (a), Mo_6Se_6 (b), and of the lithiated phases $\text{Li}_x\text{Mo}_6\text{Se}_6$ (c-e), with x approximately equal to 1.5, 2.5, and 6, respectively. The 2θ angles are given at the bottom; d-spacings at the top.

presently directed to check this possibility. It is interesting to note that the x-ray diffraction pattern of the cathode of a Li/Mo₆Se₆ cell after being discharged to 0.3V and recharged to 2.7V is identical to that of the starting material Mo₆Se₆. Based on the above findings, although very weak, the x-ray diffraction patterns clearly indicate that Mo₆Se₆ reacts reversibly with lithium without any major structural change (e.g., the basic chain structure is maintained on lithiation). The great ability of linear chain compounds to undergo topochemical reactions with lithium, as previously shown for NbSe₃ (10) and more recently for transition metal pentachalcogenides of formula MX₅ (17), is again confirmed with Mo₆Se₆. Preliminary electrochemical experiments with Mo₆Te₆ indicate a behavior very similar to that of Mo₆Se₆.

In summary, this study reports a new solid-state electrode material (Mo₆Se₆) which can be used both as cathode and anode in secondary lithium cells. Mo₆Se₆ can take up reversibly nine lithium atoms, without losing its linear chain structure, leading to a theoretical volume energy density of about 1.1 Wh/cm³ compared to 1.2 for TiS₂ cathodes. This research also indicates another important promising possibility, namely, the use of the lithiated compounds Li₉Mo₆Se₆ as anodes instead of lithium metal in secondary lithium cells.

Acknowledgment

I would like to thank many of my colleagues for fruitful collaborations and more specially D. W. Murphy for valuable discussions and for the use of his cell cycling setup.

Kinetics of Electrochemical Doping and Undoping of Polyacetylene

Fritz G. Will*

General Electric Company, Corporate Research and Development, Schenectady, New York, 12301

ABSTRACT

The kinetics of anodic doping and cathodic undoping of p-type doped polyacetylene electrodes is studied in organic solutions of LiBF₄ in sulfolane. The galvanostatic pulse technique is employed to obtain potential-time transients at various currents, from which the double layer capacitance and the kinetic parameters are determined. The observed capacitance shows that only the exterior surface of the microporous polyacetylene films is wetted with electrolyte. Polyacetylene is found to have rather slow kinetics, with the solid-state diffusion of the p-dopant, BF₄⁻, into and out of the polyacetylene structure controlling the rate. The rate of dopant transfer across the electrode-electrolyte interface is comparable to that of one-electron redox reactions on metals in aqueous solutions. The transfer coefficient shows considerable asymmetry of the energy barrier to charge transfer at the interface, favoring the anodic doping while impeding the cathodic undoping.

Polyacetylene is the simplest linear conjugated polymer. The first synthesis was mentioned as early as 1958 (1), but the preparation of well-characterized films was only reported in 1974 (2). Much of the intense interest in polyacetylene was stimulated by the finding that the polymer can be doped with electron donors and acceptors (3) with a concurrent rise in the room temperature conductivity of up to 12 orders of magnitude (4-6). It has been demonstrated that doping can be achieved electrochemically and reversibly (7). This opens the interesting possibility of employing polyacetylene as electrodes in rechargeable batteries (8).

Charge and discharge curves of various types of cells with at least one polyacetylene electrode (8-10) and cyclic voltammograms of polyacetylene electrodes (11) have been published. Other studies have been concerned with determining the diffusion coefficients of the p-dopants I (12-15), ClO₄⁻ (16), and BF₄⁻ (17), as well as that of the n-dopant Li (16, 18, 19) in polyacetylene. However, values reported by different authors vary by more than nine or-

ders of magnitude. Such large discrepancies appear to result from the fact that the degree of wetting of the microporous fibrillar structure of polyacetylene and, hence, the surface area active for diffusion, was unknown (17). Regarding the kinetics of the charge transfer process at the interface polyacetylene/electrolyte, this issue has apparently not been addressed in the past. Yet, a knowledge of the electrode kinetics is necessary to evaluate the inherent rate capability of polyacetylene and to provide guidance in improving the physical properties of polyacetylene electrodes with respect to improved performance in electrochemical cells and batteries.

The following study determines the rate of the charge transfer reaction at the polymer electrode/organic electrolyte interface and the diffusion coefficient of the p-dopant BF₄⁻ in polyacetylene. The wetted surface area is determined from the measured double layer capacitance; problems arising from the diffusion of dopant in the micropores between fibers (interfibrillar diffusion) are avoided by essentially eliminating electrolyte penetration of the polyacetylene interior.

Experimental

Polyacetylene film had been prepared by the Rohm and Haas Company using the standard Shirakawa technique (2) at -78°C . Details regarding the synthesis conditions have been published elsewhere (20). Elemental analysis yielded 90.54% C, 7.35% H, and 1.69% O. The film had a thickness of 8.9×10^{-3} cm or 89 μm , a surface area of 40 m^2/g , and an apparent density of 0.56 g/cm^3 , as calculated from the weight and dimensions of the film. This constitutes 48% of the theoretical density of polyacetylene, as determined by x-ray diffraction measurements on *cis* polyacetylene films (21). The discrepancy is due to the known fibrillar morphology (2, 22) of polyacetylene, which results in micropores of several hundred angstroms dimensions between individual fibers. Fiber diameters are in the range from 200 to 400 \AA . Film characterization by infrared spectroscopy (20) showed the films to consist initially overwhelmingly of the *cis* isomer.

Electrodes were prepared from circular films of 1.6 cm diam (2 cm^2 area) by sputtering of an Au film of 1000 \AA thickness on the back side. Electrode contact was made by pressing a coiled Au wire against the Au film.

As air exposure at room temperature for even short periods of time has been shown to lead to oxidative degradation of polyacetylene (23-26), air exposure during polymer synthesis and subsequent handling was minimized. Samples, once prepared, were stored in dry Ar or under vacuum. Transfer into the sputtering apparatus required air exposure for a few minutes. Cell assembly and all subsequent measurements were carried out in a high quality Ar-filled dry box.

Measurements were performed at room temperature ($\sim 20^{\circ}\text{C}$) in a rectangular Teflon[®] polymer cell employing a Li counter- and a Li reference electrode. The latter was spaced from the polyacetylene electrode at a distance of approximately 3 mm. A schematic diagram of the cell is shown in Fig. 1. The electrolyte was a 30% by weight solution of LiBF_4 in sulfolane. This electrolyte has very high viscosity. Solute and solvent had been carefully purified by recrystallization and double distillation.

The galvanostatic pulse technique was employed to determine the electrode kinetics. Constant current pulses were generated with a Princeton Applied Research (PAR) Model 175 universal programmer and applied to the cell with a PAR Model 173 galvanostat/potentiostat. The pulses had a risetime of 1 μs . Potential-time transients were recorded and stored on a Nicolet Model 206 oscilloscope and, with suitable expansion of the time and voltage scales, reproduced on a Hewlett-Packard Model 7046A X-Y recorder. Pulse widths were varied from 100 μs to 100s and currents from 0.1 to 5 mA. Before applying cathodic (discharge) pulses, the electrode was doped

Fig. 1. Cell schematic with reaction scheme

anodically with 7 mole percent (m/o) BF_4 . Redoping was performed occasionally between discharge pulses to maintain the doping level at approximately 7 m/o. The doping level was maintained between 4 and 6 m/o during anodic (charge) pulse measurements.

Results

The overall reaction occurring during the electrochemical doping (anodic oxidation or charging) and undoping (cathodic reduction or discharging) of polyacetylene with an electron acceptor, such as BF_4 , is shown in Fig. 1.

Cathodic potential-time transients, resulting from the application of cathodic current pulses of 100 ms width and -0.1 to -3 mA amplitude, are presented in Fig. 2. The horizontal time axis is expanded by a factor of 32; and only the first 6 ms of the transients are displayed. The potentials on the ordinate are the deviations of the electrode potential E , under current flow, from its open-circuit value E_0 (both measured against the Li reference electrode) and include the ohmic voltage drop in the electrolyte between test and Li reference electrodes; E_0 for 7 m/o doping with BF_4 is approximately 3.8V. The transients exhibit a very fast initial rise followed by a gradual increase in cathodic potential with time. Application of pulses with widths of only 100 μs showed the initial rise to be of the order of microseconds and to be controlled by the risetime of the oscilloscope.

In order to evaluate the kinetics of slower steps in the electrode reaction, cathodic current pulses of 100s width were applied. Figure 3 shows the resulting cathodic potential transients over the entire pulse duration of 100s. To accommodate the transients from -0.1 to -4 mA on a single graph, the potential scale was changed from 20 mV/cm for the lower currents to 160 mV/cm for the highest currents. After the initial instantaneous potential rise, the transients exhibit steadily increasing potential over the entire time span of 100s. In fact, in longer-term experiments it was found that the potentials do not stabilize even in the course of many hours. With increasing cathodic current, the rate of potential change increases. With the exception of the -4 mA curve, all transients have concave curvature throughout the 100s observation time.

Anodic current pulses of 100 ms duration or shorter lead to anodic potential transients which are a mirror image of the cathodic transients shown in Fig. 2. Anodic transients for 100s pulse width and amplitudes from 0.1 to 5 mA are presented in Fig. 4a and 4b. While the character of cathodic and anodic transients is generally the same, closer examination reveals that the anodic transients result in smaller potential changes $E - E_0$ for identical currents. This is particularly evident for currents of 3 mA and larger. It is also noted that the anodic transients at 4 and 5 mA do not exhibit a change in curvature. In agreement with the observations made with cathodic polariza-

Fig. 2. Potential-time transients following cathodic current pulses (undoping) of 100 ms duration; dopant level 7 m/o.

Fig. 3. Potential-time transients following cathodic current pulses (undoping) of 100s duration; dopant level 6-7 m/o.

tion, the anodic potentials continued to rise indefinitely after applying a current pulse.

Discussion

Mathematical analysis.—The potential-time transients observed in this study have the typical shape shown schematically in Fig. 5. Such transients are observed in cases of electrode reactions involving an initial ohmic voltage drop followed by charging of the double layer capacitance and simultaneous slow rate of charge transfer and diffusion.

The mathematical equations describing this case were solved by Berzins and Delahay (27) for a reaction

Fig. 5. Schematic of potential-time transients, showing predominant influence of ohmic voltage drop, double layer capacitance C_D , exchange current density i_0 , and diffusion coefficient D_0 .

involving a single rate-determining electron exchange of the type

The doping and undoping of polyacetylene involving the oxidation and reduction of the monovalent anions BF_4^- , AsF_6^- , and ClO_4^- are of that type. The assumptions applicable to that mathematical analysis are (i) electron transfer at the polymer/electrolyte interface across an energy barrier and (ii) the use of planar electrodes with homogeneous bulk properties in unstirred solution with diffusion as the sole mode of mass transfer. Hence, the analysis pertains to the case of semi-infinite linear diffusion. These assumptions are tantamount to nonwetting of the interfibrillar micropores with electrolyte. It will be shown that this assumption applies well to the present case of a very high viscosity electrolyte.

Only the boundary conditions and the final mathematical solution of the analysis will be presented here; for more detail, the reader is referred to the original paper (27).

At any given time, the total current density (i_t) is the sum of the faradaic (i_f) and the capacitive component (i_c)

$$i_t = i_f + i_c \quad [2]$$

Fig. 4. Potential-time transients following anodic current pulses (doping with BF_4) of 100s duration; dopant level 4-6 m/o

The faradaic current density is given by

$$i_F = i_0 \left[\frac{c_0}{{}_0c_0} \exp(\alpha n F \eta / RT) - \frac{c_R}{{}_0c_R} \exp(-(1 - \alpha) n F \eta / RT) \right] \quad [3]$$

and the capacitive current density by

$$i_c = (C_D/A) d\eta/dt \quad [4]$$

In these equations, c_0 and ${}_0c_0$ are the concentrations of the oxidized species (BF_4 in the polymer) at the electrode surface and in the bulk polymer respectively, c_R and ${}_0c_R$ are the corresponding concentrations of the reduced species (BF_4^- in the electrolyte), α is the transfer coefficient, n the number of electrons exchanged, F the Faraday constant, η the overvoltage ($E - E_0$, with ohmic electrolyte loss subtracted out), R the gas constant, T the absolute temperature, and i_0 the exchange current density. The latter is given by

$$i_0 = n F k_0 c_0^\alpha c_R^{(1-\alpha)} \quad [5]$$

where k is the concentration-independent rate constant. The time dependence of the concentrations is given by Fick's law of diffusion

$$\delta c_0 / \delta t = -D_0 \delta^2 c_0 / \delta x^2 \quad [6a]$$

$$\delta c_R / \delta t = -D_R \delta^2 c_R / \delta x^2 \quad [6b]$$

Here x is the distance perpendicular to the electrode surface ($x = 0$) into the polymer ($x > 0$) and into the electrolyte ($x < 0$), respectively, t is the time counted from pulse initiation, and D_0 and D_R are the diffusion coefficients of the oxidized species in the polymer and of the reduced species in the electrolyte solution, respectively.

The pertinent initial and boundary conditions are

$$c_0 = {}_0c_0 \text{ for } x \geq 0 \text{ and } t = 0 \quad [7a]$$

$$c_R = {}_0c_R \text{ for } x \leq 0 \text{ and } t = 0 \quad [7b]$$

$$c_0 = {}_0c_0 \text{ for } x \rightarrow \infty \text{ and all } t \quad [8a]$$

$$c_R = {}_0c_R \text{ for } x \rightarrow -\infty \text{ and all } t \quad [8b]$$

$$i_F = n F D_0 (\delta c_0 / \delta x)_{x=0} = -n F D_R (\delta c_R / \delta x)_{x=0} \quad [9]$$

Solution of Eq. [2], [3], [4], and [6] with the initial and boundary conditions [7], [8], and [9] in closed form is not possible. For small overvoltages $\eta \ll RT/nF$, not too short times (27), and for a certain range of values of i_0 , as compared to the values of D and c (27), the following closed-form solution for the overvoltage as a function of time has been derived (27)

$$\eta(t) = \frac{(RT/nF)i_t}{\left[\frac{(2/nF\sqrt{\pi})(1/{}_0c_0\sqrt{D_0} + 1/{}_0c_R\sqrt{D_R})\sqrt{t}}{(RT/n^2F^2)(1/{}_0c_0\sqrt{D_0} + 1/{}_0c_R\sqrt{D_R})^2 C_D/A} + 1/i_0 \right]} \quad [10]$$

Determination of kinetic parameters.—An evaluation of overvoltage-time transients according to Eq. [10] allows the determination of the diffusion coefficient of the dopant BF_4 in polyacetylene and the rate constant of the discharge reaction of BF_4^- at the polymer/electrolyte interface. The dopant concentration in the polymer (${}_0c_0$), the solute concentration in the electrolyte, ${}_0c_R$, and its diffusion coefficient, D_R , must be known. The ohmic voltage drop and the double layer capacity can be determined from the transient curves at times near zero without using Eq. [10].

Ohmic voltage drop.—The trivial ohmic voltage drop in the electrolyte that results in the steep rise of the potential-time transient at time $t = 0$ (see Fig. 5) is not included in Eq. [10]. An evaluation of the initial potential rise (at $50 \mu\text{s}$) as a function of the applied current density in the short-duration transients of Fig. 2 should yield a straight line with a slope proportional to the electrolyte

Fig. 6. Ohmic voltage drop vs. current density $50 \mu\text{s}$ after applying current pulse.

resistivity

$$\rho = d(E - E_0)/di/L \quad [11]$$

The plot in Fig. 6 shows that a straight line is obtained, and from the slope of $824 \Omega\text{-cm}^2$ and the distance $L = 0.3 \text{ cm}$ between reference and test electrode, a resistivity of $2750 \Omega\text{-cm}$ is calculated, in close agreement with conductivity cell measurements.

Double layer capacitance.—If rate of diffusion and charge transfer were infinitely fast, the initial step rise in potential would be followed by a linear rise with time, as represented by the dashed line in Fig. 5. The slope of the straight line is inversely proportional to the double layer capacitance. For finite rates of charge transfer and diffusion, the potential rises more slowly, and the double layer capacitance may be determined from the slope of the curves at $t = 0$, obtained at various current densities. According to Eq. [4], a straight line should result in a plot of $d\eta/dt$ against $i_c \cong i_t$, whose slope is inversely proportional to C_D/A . The value of $C_D/A = 11 \mu\text{F}/\text{cm}^2$ is derived from the slope of the straight line in Fig. 7, where A is the projected electrode area. This value falls within the range of

Fig. 7. Initial slope of cathodic or anodic potential-time transients at $50 \mu\text{s}$ vs. current density to determine C_D .

10-40 $\mu\text{F}/\text{cm}^2$, which are the capacitance values for the ionic double layer observed on various metal surfaces in aqueous electrolytes (28). Similar values are observed for metals in organic electrolytes. The finding of 11 $\mu\text{F}/\text{cm}^2$ of projected polyacetylene area is important evidence that in fact only the exterior surface of the microporous fibrillar polyacetylene electrode facing the electrolyte is wetted by electrolyte. Considering the high viscosity of a 30% solution of LiBF_4 in sulfolane and the very small pore size (several hundred angstroms) of the electrode, this finding is not surprising. To which extent the wetted area deviates from the projected area is uncertain. The "roughness factor," *i.e.*, wetted/projected area, is determined by the accessible surface area of the polyacetylene fibers at the exterior face of the electrode.

If the internal surface area of the microporous polyacetylene fiber structure were wetted with electrolyte, one would derive a value of only 0.0055 $\mu\text{F}/\text{cm}^2$ of true surface area. This value follows from the BET surface area of 40 m^2/g and the polyacetylene electrode weight of 0.005g, from which one determines a ratio of total true area to projected area of 2000. A value of 0.0055 $\mu\text{F}/\text{cm}^2$ is unreasonably small. It can be associated neither with the ionic double layer nor with the polyacetylene.

The capacitance associated with a charge depletion or accumulation layer in the polyacetylene is expected to have a value in excess of 10 $\mu\text{F}/\text{cm}^2$. This estimate follows from the high dopant density of $3 \times 10^{-3} \text{ mol}/\text{cm}^3$ or 1.8×10^{21} dopant molecule/per cm^3 for any dielectric constant larger than 9 and any flatband potential smaller than 1V (29). For larger dielectric constants and smaller flatband potentials, the capacitance attains values larger than 10 $\mu\text{F}/\text{cm}^2$. Such values are clearly incompatible with a value of 0.0055 $\mu\text{F}/\text{cm}^2$ resulting from complete wetting of the microporous electrode interior.

Diffusion coefficient of dopant in polyacetylene.—According to Eq. [10], straight lines should result in a plot of

Fig. 8. Polarization (undoping) vs. \sqrt{t} for cathodic current pulses of 100s duration. Plot according to Eq. [10] to determine D_0 and i_0 . Electrode area 2 cm^2 .

the overvoltage against \sqrt{t} for not too large values of η . The slopes should be proportional to the diffusion coefficient and the applied current density. Figure 8 shows the cathodic voltage transients of Fig. 3 as a function of \sqrt{t} . Straight lines result from which a diffusion coefficient of BF_4^- in the polymer, $D_0 = 5.7 \times 10^{-12} \text{ cm}^2/\text{s}$ is determined. The following values for the other parameters were used: dopant concentration $c_0 = 3.1 \text{ mol}/\text{liter}$ or 7.1 m/o ; electrolyte concentration of BF_4^- , $c_R = 4.6 \text{ mol}/\text{liter}$; diffusion coefficient of BF_4^- in the electrolyte, $D_R = 1.2 \times 10^{-8} \text{ cm}^2/\text{s}$. The latter value was calculated from the measured conductivity, using the Nernst-Einstein relationship.

Similarly, Fig. 9 shows the anodic voltage transients of Fig. 4a in a plot of η against \sqrt{t} . The resulting straight lines yield the same value for the diffusion coefficient with the known dopant concentration of 1.8-2.7 mol/liter , corresponding to between 4.1 and 6.2 m/o .

Figure 9 shows a deviation from straight line behavior at larger values of η . This is expected since Eq. [10] is an approximation valid only for $\eta \ll RT/F$.

The good agreement between calculated and experimental curves, evidenced by Fig. 8 and 9, demonstrates the validity of a simple linear diffusion model with simultaneous charge transfer hindrance. There is no need to invoke a field-enhanced diffusion model as it has been postulated recently (16). In fact, the application of such a model to polyacetylene doped sufficiently high to be in the metallically conducting regime is questionable, as the Debye length (electronic screening length) is much smaller than the polymer fiber radius. The doping levels

Fig. 9. Polarization (doping) vs. \sqrt{t} for anodic current pulses of 100s duration. Electrode area 2 cm^2 .

applied in the present study, namely, 7 m/o, place polyacetylene well into the metallic regime.

The value of 5.7×10^{-12} cm²/s for the diffusion coefficient follows from the η vs. \sqrt{t} transients if only the exterior surface of the electrode is wetted with electrolyte. Identical transients would have been observed if the interior were also wetted and the diffusion coefficient were correspondingly smaller, as determined by $A\sqrt{D_0} = \text{const}$. As the interior surface is 2000 times larger than the projected area, the diffusion coefficient would then have a value of only 1.4×10^{-18} cm²/s. Based upon the capacitance measurements, we regard this case as inapplicable.

The dominant influence which different degrees of wetting of the large interior surface of polyacetylene obviously have on the magnitude of the diffusion coefficients, as determined from transient measurements, make it mandatory to establish the degree of wetting independently. The fact that this has not been done in previous studies may explain the large discrepancies in the values of diffusion coefficients reported by different authors.

Several groups (12-16) have studied the diffusion of the p-dopants I and ClO₄ in polyacetylene. By measuring the I₂ absorption and desorption from very dilute solutions of I₂ in pentane, "macroscopic" diffusion coefficients in the range from 2.1×10^{-10} to 2.8×10^{-8} cm²/s were determined (12), as related to the projected polyacetylene film area. These values do not reflect the inherent diffusion coefficient of I in polyacetylene as they contain the effects of the fast diffusion (10^{-5} cm²/s) of I₂ through the solution that has penetrated between the fibers (interfibrillar diffusion) (13). In good agreement with the present study, a value of 3×10^{-12} cm²/s was later reported by the same group (15) on the basis of microwave measurements of the electrical conductivity of I-doped polyacetylene. This study pointed out the need of avoiding fast I₂ transport through the interfibrillar void space. The large value of 1.5×10^9 cm²/s reported for I diffusion in polyacetylene on the basis of short-circuit current decay measurements on a solid electrolyte cell (14) may have been affected by fast interfibrillar I₂ transport, possibly in the gas phase, as no liquid electrolyte was being used.

Kaufman *et al.* (16) estimated diffusion coefficients in the order of 4×10^{-18} cm²/s for both ClO₄ and Li, based upon open-circuit voltage decay measurements following charging in LiClO₄-propylene carbonate electrolyte. Complete wetting of the interior surface had been assumed to arrive at such low numbers. If one assumes wetting of the exterior surface only (17), then the data yield a value of 10^{-12} cm²/s, in good agreement with the value of 3×10^{-12} cm²/s determined in this paper.

Other studies of Li diffusion in polyacetylene give values of 10^{13} cm²/s at 83°C (18) and 2×10^{-17} cm²/s (19). The former value was determined from the open-circuit potential recovery of Li-doped polyacetylene after charging of a solid polymer electrolyte battery (18). ESR results of Li absorption from solutions of Li benzophenone in THF are interpreted in terms of an interfibrillar diffusion coefficient of 10^{-9} cm²/s and an intrinsic intrafibrillar diffusion coefficient of 2×10^{-17} cm²/s (19).

Kinetics of interface reaction.—Doping and undoping require the transfer of BF₄⁻ ions from the organic solution phase to the solid polyacetylene phase and vice versa. It is likely that the transfer of an electron from the ion to the polymer chain occurs at the interface. This expectation derives from the high electronic conductivity of polyacetylene when doped with dopant levels exceeding the insulator-metal transition threshold (4-6). The dopant concentrations employed in this study are well into the semimetal conduction state. The rate of the charge transfer reaction, as expressed by the exchange current density, i_0 , can be determined from the η vs. \sqrt{t} transients shown in Fig. 8 and 9. Based on Eq. [10], the intercept of the extrapolated straight lines with the axis $\sqrt{t} = 0$ is proportional to i/i_0 , so that for any applied i the exchange

current density i_0 can be determined. We find an average value of $i_0 = 8 \times 10^{-4}$ A/cm² from both cathodic and anodic transients for a BF₄⁻ concentration of 4.6×10^3 mol/cm³ and a BF₄ dopant concentration of 3.1×10^{-3} mol/cm³. The value of i_0 is referred to the projected area of the polyacetylene electrode, consistent with the double layer capacitance and the diffusion coefficient.

The observed exchange current density of the reaction $(\text{CH})_x + \text{BF}_4^- = (\text{CH})_x\text{BF}_4 + e^-$ on polyacetylene is comparable to values of i_0 for simple one-electron redox reactions on inert metal electrodes. Thus, values for the reactions $\text{Ti}^{3+} = \text{Ti}^{4+} + e^-$, $\text{Ce}^{3+} = \text{Ce}^{4+} + e^-$, and $\text{Mn}^{2+} = \text{Mn}^{3+} + e^-$ are 3×10^{-4} (30), 2×10^{-4} (31), and 2×10^{-5} A/cm² (32), respectively, for concentrations of the redox species of the order of 10^{-5} - 10^{-3} mol/cm³. Similar features between redox reactions and doping-undoping reactions of polyacetylene pertain to the diffusion of oxidized and reduced species, both present in a large possible concentration range. It is recognized, however, that the transfer of species from a liquid electrolyte into a solid polymer of crystalline nature constitutes a major difference from a true redox reaction.

The anodic transfer coefficient α of the reaction cannot be determined from the η - \sqrt{t} transients in Fig. 8 and 9 since α does not occur in Eq. [10] owing to the linearization of the exponential terms in Eq. [3]. However, α can be determined from an appropriate solution of the equations valid for large values of η ; the solution in this case (33) is

$$\eta = \frac{RT}{\alpha F} [\ln(i/i_0) + \ln(1 + \sqrt{t/\tau})] \quad [12]$$

where

$$\tau = (\pi/4)D_0F^2c^2/i_2 \quad [13]$$

The anodic transfer coefficient is determined from a plot of η vs. $\log(1 + \sqrt{t/\tau})$ which should yield a straight line with slope proportional to $1/\alpha$. Figure 10 shows that a straight line is indeed obtained, and a value of $\alpha = 0.19$ is determined from the slope. The data in Fig. 10 are the same as those in Fig. 9 for $i = 0.5$ mA/cm². In the latter figure, the data deviate from straight line behavior for large η since application of Eq. [10] is inappropriate for large η .

The anodic transfer coefficient is quite small, meaning that the energy barrier for charge transfer is quite asymmetrical, favoring the anodic doping reaction while impeding the cathodic undoping. Asymmetry of the energy barrier to the extent found here is not unusual, however. Values for $(1 - \alpha)$ of 0.25 and 0.28 have been observed in the reactions $\text{Ce}^{3+} = \text{Ce}^{4+} + e^-$ and $\text{Mn}^{2+} = \text{Mn}^{3+} + e^-$, respectively (31, 32).

The concentration-independent rate constant k can be determined from the exchange current density i_0 with a knowledge of α and of the concentrations ${}_0c_0$ and ${}_0c_R$. The value computed from Eq. [5] is 2.5×10^{-6} cm/s.

Fig. 10. Polarization (doping) vs. $\log(1 + \sqrt{t/\tau})$ for anodic current pulse of 1 mA amplitude and 100s width. Plot according to Eq. [12] for large η to determine α .

Conclusions

Application of an electrode kinetic analysis involving semi-infinite linear diffusion, double layer capacitance charging, and charge transfer at the polyacetylene/electrolyte interface has led to quantitative agreement with experimental results on the doping and undoping of polyacetylene with BF_4 using controlled current pulses. The observed double layer capacitance, $11 \mu\text{F}/\text{cm}^2$ of projected area, is a measure for the wetted surface area of the microporous fibrillar polyacetylene and shows that only the exterior surface is wetted with electrolyte. This justifies application of a semi-infinite linear diffusion model to determine the diffusion coefficient of the dopant BF_4 in polyacetylene as $5.7 \times 10^{-12} \text{ cm}^2/\text{s}$. Using studies which do not independently establish the wetted, electrochemically active surface area, one cannot arrive at a valid diffusion coefficient. Thus, if the erroneous assumption of complete wetting of the interior surface were made, the diffusion coefficient would have the exceedingly small value of $1.4 \times 10^{-18} \text{ cm}^2/\text{s}$.

Even with the observed value of $5.7 \times 10^{-12} \text{ cm}^2/\text{s}$, solid-state dopant diffusion is the rate-determining step in the charge and discharge of polyacetylene electrodes and explains the known sluggishness of polyacetylene in attaining steady-state potentials during charge, discharge, and open circuit. The rate of dopant transfer across the polyacetylene-electrolyte interface is determined as $8 \times 10^{-4} \text{ A}/\text{cm}^2$, equivalent to a rate constant of $2.5 \times 10^{-6} \text{ cm}^2/\text{s}$. Such values are comparable to those found for a variety of one-electron redox reactions on metals in aqueous solutions. The anodic transfer coefficient is 0.19, corresponding to a quite asymmetrical energy barrier that favors p-doping or charging while impeding undoping or discharging.

ABSTRACT

The present report summarizes the performances of the solid-state batteries using a superionic conductor as solid electrolyte and polyacetylene as electrode material. Two types of cells have been tested. A first class uses the mixed ionic solid RbAg_4I_5 together with a silver anode. The second one uses $\beta''\text{-Al}_2\text{O}_3$, $x\text{Na}_2\text{O}$ together with sodium-doped $(\text{CH})_x$. Both fulfill the objective of being able to discharge at room temperature. In addition to the usual performances such as voltage, current, capacity, weight, shape, etc., we give the results over 4 yr of investigations on the discharge life and storage life. Many practical problems have been encountered, especially in the case of the sodium-polyacetylene battery. They are also reported, as well as some improvements made during that period such as encapsulation, diffusion inhibitors, and separation of the components until the first charge. The conclusion is that polyacetylene is proved to be a useful electrode material in solid-state batteries at the laboratory level. The possible further development to reach the industrial stage is discussed in terms of lifetime energy, density, and cost.

The conducting organic polymers like polyacetylene (1) or polyparaphenylene (2) are attracting more and more interest from the battery, energy conversion, and energy storage industries. Such applications have been pioneered by MacDiarmid and his group with the discovery that doped polyacetylene could be used as electrode material together with an organic solvent to form an electrochemical battery (3). This followed the prior discovery by the same group (4) that $(\text{CH})_x$ presents a high electrical conductivity after suitable doping (5) by a number of possible foreign molecules (I_2 , AsF_5 , Na , K , ...). Also, after this discovery, we took interest in the doping mechanisms of polyacetylene by iodine using radioactive techniques (6) as well as proposed that the conducting organic polymers can be used also in solid-state batteries (7) working at room temperature. At the same time, Chiang (8) reported an all-polymeric solid-state battery using both polyacetylene and polyethylene-oxide which can operate above 60°C .

The doping process is essential in all those applications. In most cases, doping is even achieved during the charge of the battery. A piece of polyacetylene alone can easily be doped from a vapor source when the dopant is volatile like iodine (9) or inside a liquid solution like iodine in pentane or sodium-naphthalide in THF (10). However, electrochemical doping developed by Nigrey *et al.* (11) is more convenient for electrochemical applications as it gives a better control of the concentration. Moreover, electrochemical doping can serve as the charge itself (12, 13). This is the case in the solid-state batteries we have developed (7) and that we are describing in the present paper after 4 yr of investigation.

Basic Principles

A superionic conductor used as solid electrolyte is combined with a conducting polymer used as the cathode and/or the anode material. The polymer is doped by suitable impurities which enable the polymer to conduct electricity and which will, at the same time, be the active material(s) of the electrochemical reaction. Until now, the choice has been limited to polyacetylene as for the electrode material. Because of its fibrillar morphology, it can absorb considerable amounts of active material. As for the solid electrolyte, we have set the objective that our cells should operate around the room temperature. This requirement restricts the choice of the solid electrolytes exhibiting a high ionic conductivity with practically no electronic conductivity at room temperature to (i) RbAg_4I_5 (which can be used even somewhat below the phase transition at 27°C). The conductivity is due to the Ag^+ ions, or (ii) beta-alumina such as $\beta''\text{-Al}_2\text{O}_3$, $x\text{Na}_2\text{O}$. The carrier here is Na^+ . Both are used in the two types of cells which are considered in the present paper.

The obvious advantage of a solid-state battery is to provide a waterproof component. We found it necessary to encapsulate our cells inside a resin coating. This precaution is particularly important in the case of the sodium-

doped $(\text{CH})_x$ anode in order to prevent oxidation of sodium. Another crucial feature of our cells is possible storage in the uncharged state. The polymer remains undoped for any period of time, over years, if required. During that period, obviously, no degradation due to chemical interaction between the polyacetylene and the dopant can occur. It is the first charge which by electrolysis decomposes a part of the electrolyte into the products which dope by diffusion the conducting polymer. After this stage, the product(s) having doped the polymer form the active material of the battery, which is then ready to discharge. The storage life of the battery is greatly increased.

Materials Preparation

Polyacetylene.—We have used polyacetylene samples synthesized either by the group of Schué at the University of Montpellier (France) or in our laboratory, in both cases following Shirakawa's method.

In the case of the sodium battery, the polyacetylene film has to be synthesized upon the surface of the alumina itself. For that purpose, the alumina disks of the battery are introduced in the reactor. The catalyst $\text{AlEt}_2/\text{Ti}(\text{O}Bu)_4$ is sprayed upon one or two of the main surfaces so that a $(\text{CH})_x$ film grows on the solid electrolyte. The thickness is then a little less than $10\ \mu\text{m}$.

The $(\text{CH})_x$ cathode used in the silver or sodium battery is prepared separately. Though prepared at -70°C and therefore in the *cis* form, the further use at room temperature as well as the doping process induce the *cis-trans* isomerization (14, 15). We have tested all sorts of films of density varying from $0.1\ \text{g}\cdot\text{cm}^{-3}$ up to the almost nominal density with correspondingly largely variable thicknesses in the range $10\text{--}1000\ \mu\text{m}$. One or more films are introduced in a Pascal press and compressed to a maximum pressure of $5 \times 10^8\ \text{Pa}$.

β -Alumina.—We use the β'' -alumina doped with Na_2O synthesized at Marcoussis (France) by the Compagnie Générale d'Electricité for the experimental sodium-sulfur battery. The high ionic conductivity in this material is due to the fast motion of the Na^+ ions. In a separate study (16), the mobility and the flux of sodium ions through the alumina samples were measured by using radioactive Na-22 as a tracer and a sectioning technique. This confirmed directly the expected fast mobility of sodium which was measured. Even at room temperature, the resistance of the solid electrolyte is only $100\ \Omega$. Disks (slightly bent) of a thickness of $1\ \text{mm}$ and of $13\ \text{mm}$ diam are shaped from large β -alumina tubes.

RbAg_4I_5 .—The silver conducting electrolyte is prepared by mixing stoichiometric amounts of AgI and RbI together with a small proportion of silver powder in water. When a thick paste is obtained, the water is evaporated by heating at 120°C for 20h. The dry paste is then ground. The resulting powder is introduced in a glass tube, sealed under vacuum, heated at 350°C for 20 min and slowly

cooled down to room temperature. The electrolyte is then ground again and kept at 160°C under vacuum for 24h. After that preparation, the material is stored at 70°C under vacuum before use. The x-ray powder diffraction diagram is in excellent agreement with the data reported by Geller (17). The present mode of preparation of α -RbAg₄I₅ is intended to prevent moisture and thermal decomposition. Silver atoms are added in order to act as a getter for the iodine molecules, which tend to diffuse from the cathode to the anode through the electrolyte.

Silver anode.—Thin powder of silver is mixed with some graphite powder and pressed together as a disk of 13 mm diam at a pressure of 2×10^8 Pa. The graphite is used to improve the electrical contacts.

Silver Battery

Cell assembly.—The polyacetylene-silver battery is schematically shown in Fig. 1. It has a cylindrical form of 13 mm diam and 2 mm thickness. It is prepared in a pressure chamber of that diameter in which are successively pressed the silver powder with a little graphite (anode), the electrolyte α -RbAg₄I₅ containing silver, the polyacetylene, and finally the graphite. The electrical contacts are taken by metallic wires embedded inside the graphite. The whole element is thereafter encapsulated inside an epoxide resin coating.

Piles of, generally, three elements are prepared in the same way by successive pressing. A lead sheet separates adjacent elements to prevent iodine from diffusing from one to the next element. They deliver a voltage of 2V.

Though it is possible to start with a polyacetylene cathode already doped with iodine, the battery is generally assembled with pure polyacetylene. The polymer is later doped electrochemically *in situ* by forcing a charge of electricity which creates a partial electrolysis of RbAg₄I₅ (18) according to the reaction

and the subsequent doping of (CH)_x

The charge is proceeded at a constant current of, typically, 10⁻⁴A. The electrolysis is adjusted to reach a doping level such that $y = 0.2$. For a typical mass of 20 mg of (CH)_x, a charge of 28 Cb is needed, i.e., 8.2×10^{-3} Ah, which is reached after 82h in the experimental cells. Higher currents can be used to reduce the time of the charge. The cell becomes Ag/RbAg₄I₅/((CHI)_y)_x ready to supply electricity.

Internal resistance.—A battery is allowed to discharge on loads varying from 1 to 10⁶Ω. The current I and potential U are measured immediately before any polarization occurs. A characteristic U vs. I curve is shown in Fig. 2. The internal resistance r is derived from Pouillet's equation: $U = E - rI$, where E is the electromotive force, that is from the slope of the straight line of Fig. 2. This parameter changes from cell to cell in the range 10-40Ω. The best cells are those where r is minimum. The summation of the separate resistances of the individual components gives a much lower value: the electrolyte disk whose area

Fig. 1. Prototype of the polyacetylene-silver battery. 1: Leads. 2: Silver point. 3: Graphite. 4: Silver. 5: RbAg₄I₅. 6: CH_x. 7: Resin coating.

Fig. 2. Galvanostatic measurement of the voltage of a polyacetylene-silver battery. $R = 30\Omega$, $E_{oc} = 0.625\text{V}$, $I_{cc} = 21 \text{ mA}$.

and thickness are 1.3 cm² and 0.1 cm, respectively, contributes for less than 1Ω. The internal resistance of the doped (CH)_x has been measured in the same conditions, namely, inside its coating of resin. This was made possible by a microwave technique which avoids using any electrode (19). Again, this contributes for less than 1Ω. Last, when both RbAg₄I₅ and (CH)_x are removed from the battery the overall resistance of all the leads and contacts is found to be about 1Ω. To conclude, the cell resistance is mainly due to the interfacial resistance, which depends on the pressing conditions. Nevertheless, it is quite acceptable when compared to the dry batteries.

EMF at constant temperature.—The electromotive force depends on the temperature and on the iodine activity. The influence of this later parameter at the constant temperature of 30°C is shown in Fig. 3. The EMF E is measured as a function of the concentration of iodine inside (CH)_x and reported as E vs. y , y being the iodine content corresponding to the formula (CHI)_y, i.e., close to the mole fraction. E has been measured in three distinct ways: (i) in separate cells using chemically doped (CHI)_y cathodes, (ii) in separate cells using electrochemically doped (CHI)_y cathodes, and (iii) in the same cell with an original $y = 0.07$, allowed to partially discharge and measured after 24h to reach the equilibrium value.

The good agreement between the results is to be noticed, as it gives clear evidence that iodine formed by decomposition of RbAg₄I₅ smoothly diffuses into (CH)_x though it is pressed.

The experimental results on Fig. 3 also show that the EMF is $E = 0.660\text{V}$ for $y = 0.30$ at 30°C. This is quite simi-

Fig. 3. Influence of the iodine content y of the (CHI)_y cathode on the electromotive force at 30°C. The data points correspond to chemically doped (CHI)_y cathodes (open circles), electrochemically doped cathodes (filled circles), and same cell after partial discharges (stars).

Fig. 4. Temperature dependence of the electromotive force of a polyacetylene-silver cell with $y = 0.07$.

lar to the value observed in the Owens battery (20), which used a charge transfer complex instead of the present conducting polymer. This value compares well with the EMF associated with the reaction $\text{Ag} + 1/2 \text{I}_2 \rightarrow \text{AgI}$ which would have given from Nernst equation and the standard free energy of formation of AgI: $E^0 = 0.687\text{V}$. The electrolyte would serve solely as an inert electrolyte (21). This would also mean that the effective reactant is iodine, either physically adsorbed at the surface of the fibrils of $(\text{CH})_x$ (and weakly bonded) or even as iodine gas present in the pores of the interfibrillar space and in equilibrium with the iodine of the fibrils.

However, one may consider a complete charge transfer between I_2 and $(\text{CH})_x$, which should be then written as $[(\text{CH})^{y+} (\text{I}^-)_y]_x$ or $[(\text{CH})^{y+} (\text{I}_3^-)_y]_x$. The cathodic reaction would then be the reduction $(\text{CH})_x^+ + e^- \rightarrow (\text{CH})_x$; the iodide (or polyiodide) ion would play at the same time the role of a counterion. But, taking the reduction potential of $(\text{CH})_x$ as measured by Shacklette *et al.* (22) would give a much higher EMF. It might also be supposed that, in that case, the electrolyte would be decomposed and that one would then observe the decomposition potential of RbAg_4I_5 , according to reaction [I], which is very close to the decomposition potential of AgI at 27°C.

Influence of temperature.—The influence of temperature has been carefully measured in order to determine as accurately as possible the thermodynamic parameters enthalpy, entropy, and free energy of the electrochemical reaction. As E depends both on temperature θ and iodine content y , the open-circuit voltage was measured as a function of temperature in seven cells for various y ranging from $y = 0.053$ to $y = 0.21$ in the temperature range $-30^\circ \leq \theta \leq +30^\circ\text{C}$. The data E vs. θ (Fig. 4) show the expected straight line. The enthalpy and entropy are derived from the equations

$$\Delta H = -F[E - T(\partial E/\partial T)]$$

$$\Delta S = F(\partial E/\partial T)$$

The values for ΔH and ΔS reported in Table I indicate a continuous decrease of ΔH and ΔS as y increases. They are to be compared with the parameters of the reaction

Table I. Entropy and enthalpy change in the electrochemical reaction of the polyacetylene-silver battery

y ($\times 100$)	5.3	5.7	7.09	7.78	7.85	8.02	21
ΔS ($\text{cal}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$)	5.22	4.85	3.88	3.60	2.88	2.79	1.57
ΔH ($\text{kcal}\cdot\text{mol}^{-1}$)	-12.32	-12.51	-13.07	-13.26	-13.49	-13.55	-14.44

which at 30°C are $\Delta H = -14.91 \text{ kcal}\cdot\text{mol}^{-1}$, $\Delta S = 3.14 \text{ cal}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$, $\Delta G = -15.86 \text{ kcal}\cdot\text{mol}^{-1}$, giving $E = -\Delta G/F = 0.687\text{V}$. As a matter of fact, the AgI_2 battery using pure solid iodine (in equilibrium with its vapor) at the cathode without $(\text{CH})_x$ or any other charge transfer complex does give $E = 0.687\text{V}$ (23). Making the assumption of Owens (21) that the electrolyte RbAg_4I_5 plays no electrochemical role in the discharge which should thus be written as

the difference between the reactions [III] and [IV] is the reaction of fixation of iodine on the fibrils (namely, reaction [II]). This allows estimation of the thermodynamic parameters of the absorption process. For $y = 0.07$ and $\theta = 25^\circ\text{C}$, one obtains $\Delta S = 0.74 \text{ cal}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$ and $\Delta H = -1.84 \text{ kcal}\cdot\text{mol}^{-1}$ (i.e., 0.08 eV). One would conclude that the doping by iodine is an exoenergetic process, as it might have been expected, but only slightly. In other words, the interaction seems to be quite weak.

Influence of the iodine content.—The influence of the iodine content y on E (Fig. 3) is difficult to interpret. There are no real successive steps as one would have expected from the structure studies of Baughman *et al.* (24), who assume a number of successive intercalated layers for given values of $y = 0.056$ -0.079-0.13-0.20-0.39 (first, second, and third stages with full and half-filled planes). A possible explanation would involve the experimental conditions and the fact that equilibrium is not reached so that the intercalated compound was not given enough time to be formed. To avoid this, the measurements are separated by at least two days. Such a long time was also found necessary for doping by ClO_4^- (25). This period would correspond to the time necessary for the dopant to reach the center of the fibril. Any estimation of this time requires knowledge of the diffusion coefficient. There is some discussion in the literature depending on the method of measurement. The overall diffusion coefficient assuming $(\text{CH})_x$ as a bulk material is obviously orders of magnitude larger (see *e.g.*, results shown in Fig. 18) than the microscopic diffusion coefficient. Taking a cylindrical fibril of radius $r = 100\text{\AA}$ and the microscopic diffusion coefficient $D \sim 5 \times 10^{-18} \text{ cm}^2\cdot\text{s}^{-1}$ measured with tracers (6), the diffusion time would be

$$\tau = r^2/5.78D \sim 10\text{h}$$

One can consider those fibrils homogeneously doped after approximately 5τ , which corresponds well to the time interval of 2 days between the measurements.

The experimental dependence E vs. y follows a logarithmic form shown in Fig. 5. In fact two ranges are observed. For $y < 0.08$, the results are described by the empirical equation

$$E = 0.515 \times 0.12 \log y$$

This recalls the Nernst equation $E = E^0 + 0.06 \log C$ though the coefficient is far from the theoretical value of 0.060 at 30°C. The same empirical dependence was observed for doping by ClO_4^- by Kaneto *et al.* (25) with an even higher coefficient: $E = 3.43 + 0.32 \log y$. Shacklette *et al.* (22) also observe a departure from Nernst equation (for lithium and sodium) with a plateau in the range $y = 0.01$ -0.05.

Discharge at constant current.—Cells kept in a thermostat are let to discharge with a galvanostat, while the voltage is recorded with a high impedance setup. A complete discharge at $I = 66 \times 10^{-6}\text{A}$ is shown in Fig. 6. One notices the good stability until the final drop which

Fig. 5. Semilogarithmic representation of E vs. $\log y$

quantitatively corresponds to the full consumption of iodine. In other words, the Faraday efficiency for relatively low currents approaches unity. It seriously diminishes over $100 \mu\text{A}$. Figure 7 shows the voltage as a function of capacity in milliampere-hours. The cell is charged at the constant current $I = 0.25 \times 10^{-3}\text{A}$ (the corresponding voltage being also shown) and then let to full discharge. Results for $I = 0.4$ and $0.6 \times 10^{-3}\text{A}$ are shown. The Faraday efficiency subsequently drops down to 80 and 54%, respectively.

The energy efficiency is also calculated as the ratio W_d/W_c , with

$$W_c = I_c \int U_c dt$$

and

$$W_d = I_d \int U_d dt$$

with U_c and U_d being the voltages during the charge and discharge. The respective energy efficiencies are 60 and 43% and continuously decrease with increasing current.

Charge-discharge cycles.—We have investigated the reversibility of the cell to determine to which extent it could be considered as a rechargeable or secondary battery. Two sets of tests have been performed.

Partial discharge.—A cell having a capacity of 5 mAh was submitted to sequences of partial charges and discharges of 6 min each. This was done at the constant temperature

Fig. 6. Full discharge as a function of time of a polyacetylene-silver cell at $I = 66 \times 10^{-4}\text{A}$ and 30°C .

Fig. 7. Full discharges as a function of capacity of a polyacetylene-silver cell at higher currents: $4 \times 10^{-4}\text{A}$ (a) and $6 \times 10^{-4}\text{A}$ (b). The charge (dotted line) is made at $I = 2.5 \times 10^{-4}\text{A}$.

$\theta = 30^\circ\text{C}$ and for various values of the current kept constant with a galvanostat. This corresponds approximately to 2% of the capacity (full charge). This is shown on Fig. 8 for several currents (0.5, 0.76, and 1.52 mA) and two complete cycles. One observes the good behavior of the cell: reproducibility in the cycles, almost uniform voltage, and small polarization. However, for higher current, $> 3 \text{ mA}$ (Fig. 9), the voltage dramatically drops down and the cycles are no longer reproducible. We have therefore used 1 mA for the systematic tests; then, the good reproducibility is obtained over only 100 cycles. It is believed that the partial electrolysis of RbAg_4I_5 , during the charge gives Rb_2AgI_3 , which is a very poor conductor (26) and, in addition, is not fully decomposed to regenerate the electrolyte during the charge.

Full discharge.—The reversibility was also tested for complete discharge cycles using smaller currents, typically 0.1 mA. A perfect reproducibility is observed for the first cycles with an excellent efficiency. Unfortunately, this is not the case after a score of cycles. The cells contain 1g of electrolyte, and each full charge corresponds to the electrolysis of about 5% of RbAg_4I_5 . Therefore, after 20 cycles the complete amount of electrolyte would have suffered decomposition. The fact that the cell does not operate afterwards proves that the decomposition is not reversible.

To conclude these tests, the polyacetylene-iodine cathode seems to provide an efficient reversible electrode. However the duration of the cell is limited by the lifetime of the electrolyte $\text{RbAg}_4\text{I}_5 \rightarrow \text{Rb}_2\text{AgI}_3$, which prevents its use as a real secondary battery. Some other electrolytes could be better in that respect, possibly silver orthophosphate, Ag_3PO_4 or $\text{Ag}_7\text{PO}_4\text{I}_4$ (27).

Kinetics.—The kinetical study of the discharge was also performed on the same cells containing approximately 10 mg of CH_x doped by a first charge for various values of y . In fact, the kinetics depend on the doping level. The cell is thereafter let to discharge on a resistance (1Ω) much smaller than the internal resistance so that the dis-

Fig. 8. Partial charge-discharge cycles of a polyacetylene-silver cell for $I = 0.5, 0.76,$ and 1.52 mA .

Fig. 9. Partial charge-discharge cycles for $I = 3 \text{ mA}$

charge is practically a short circuit. The current can then be recorded as a function of time (Fig. 10). The analytical form of $I = f(t)$ depends on y . For $y < 0.08$, the current varies as $1/\sqrt{t}$, as shown in Fig. 11. This behavior follows Cottrell's equation

$$I = ZFSC_0 \sqrt{d/\pi t} \quad [1]$$

where F is the Faraday, S the area of the interface, C_0 the constant concentration of iodine throughout the electrode, and D the diffusion coefficient. This indicates that the limiting process of the discharge is the diffusion of the active species (iodine) from the $(\text{CH})_x$ cathode towards the electrode/electrolyte interface, where it reacts. However, when $y > 0.08$, the current remains high for the first minute (Fig. 12) and the time variation departs from $t^{-1/2}$ (Fig. 13). Such a change for the critical value of $y = 0.08$ is to be connected with the two different regimes observed for E vs. y (Fig. 3 and 5) below and above this critical value. It favors the assumption of an intercalated compound for $y \sim 0.08$. The kinetics of the phase transformation would thus be added to the overall kinetics, accounting for the relative slowness of the kinetics observed above $y = 0.08$.

In order to derive the diffusion coefficient D from Eq. [1], we have chosen its domain of applicability, namely, $y < 0.08$. Cottrell's equation contains the initial condition that $C = C_0$ for $t = 0$ and the boundary conditions $C = C_0$ far from the interface and $C = 0$ at the interface $x = 0$. This condition can be checked by measuring the current I immediately after a preset voltage U with a potentiostat. The results I vs. U are shown on Fig. 14. Whereas for $U > 0.3\text{V}$, the current depends on the voltage, I is almost constant for $U < 0.3\text{V}$. This corresponds to a concentration of iodine $C \sim 0$ at $x = 0$. The kinetics were determined by

Fig. 10. Short-circuit discharge of a polyacetylene-silver cell with initial $y = 0.08$.

Fig. 11. Time dependence of the short-circuit current I vs. $t^{-1/2}$ with initial $y = 0.08$.

Fig. 12. Short-circuit discharge of a polyacetylene-silver cell with initial $y = 0.12$.

Fig. 13. Time dependence of the short-circuit current I vs. $t^{-1/2}$ with initial $y = 0.12$.

following 35 short discharges on a resistor of 1Ω . The short-circuit current (typically around 10 mA for a cross section of 1 cm^2) was measured by recording the voltage drop between the ends of that resistance. This method gives practically the same results as the potentiostatic method since the voltage remains very much smaller than 0.3V and therefore the current does not depend on the voltage.

A long time (several days) is necessary between two successive discharges to get the new homogenization of iodine inside the polymer. When the iodine content C_0 was supposed uniform, the next discharge was recorded which made C_0 (or y) to decrease. This was repeated 35

Fig. 14. Potentiostatic measurement of the current of a polyacetylene-silver battery.

Fig. 15. Short-circuit current as a function of $t^{-1/2}$ at constant temperature (30°C) for the following iodine cathode contents: $\gamma = 0.058$ (circles), 0.047 (squares), 0.03 (filled triangles), and 0.014 (open triangles).

times until $C_0 \sim 0$. Some of the results are shown in Fig. 15. They all obey the time dependence of Eq. [1]. The slope of the straight lines should thus be equal to

$$\alpha = \frac{d(I)}{d(t^{-1/2})} = ZFSC_0 \sqrt{D/\pi} = FS \frac{y\rho}{M} \sqrt{D/\pi} \quad [2]$$

where ρ is the specific mass of pressed $(\text{CH})_x$ and M the mass of a CH unit (13g). The linear dependence of that slope α as a function of γ (Fig. 16) is in agreement with the theoretical equation. The diffusion coefficient derived from Eq. [2] is $D = 1.5 \times 10^{-9} \text{ cm}^2\text{-s}^{-1}$ for that constant temperature of 30°C .

This result compares well with the diffusion coefficient measured in the desorption of iodine out of $(\text{CHI}_y)_x$ with a radioactive technique (6). One must, however, emphasize that this coefficient is not the diffusion coefficient of I_2 into the crystalline part of $(\text{CH})_x$. It is the overall coefficient which integrates all the phenomena involved in the transfer of iodine from the polymer: intrafibrillar diffusion, diffusion in the interfibrillar spaces, desorption from the surface, etc. It is simply noteworthy that a tracer technique and an electrochemical method give independently the same result, also in agreement with the overall diffusion coefficient of profiles measured with the electron microprobe (28, 29).

Activation energy of diffusion.—The same potentiostatic measurements were performed as a function of temperature in the range -20° to $+40^{\circ}\text{C}$. A bigger cell with 33 mg of $(\text{CH})_x$ was initially charged at the level $\gamma = 0.06$. The discharge $I = f(t)$ was followed for 10s at several temperatures. Between two runs the temperature was raised at 30°C for 24h or more until equilibrium was reached again. The linear dependence of I vs. $t^{-1/2}$ is observed for all the

Fig. 16. Influence of the iodine cathode content on the short-circuit current (plotted as the slopes of the straight lines such as those of Fig. 15 vs. γ).

temperatures except 40°C (Fig. 17), which means that above 30°C , diffusion of iodine is no longer the only rate-controlling mechanism. The diffusion coefficient derived from Eq. [2] is plotted on Fig. 18 as $\ln D$ vs. the reciprocal temperature. It obeys the Arrhenius equation

$$D = 85 \exp(-0.607/kT) \text{ cm}^2\text{-s}^{-1}$$

The relatively large activation energy of 0.607 eV probably measures the energy of migration inside the fibrils, which would be the rate-controlling mechanism.

Self-discharge.—The main cause of self-discharge is the diffusion of molecular iodine throughout the solid electrolyte. As a matter of fact, RbAg_4I_5 is under the form of a sintered powder which allows iodine to diffuse through the pores (21, 30). We adopted the remedy proposed by Owens (20, 21), consisting in mixing a little silver powder with the electrolyte so that the escaping iodine would be trapped by the silver atoms encountered inside the electrolyte to give silver iodide. The theoretical equations of this diffusion mechanism have been established by Oldham and Owens (21). We have carried out the experimental investigation of the diffusion of iodine into RbAg_4I_5 using radioactive I-125 .

Pressed pellets of RbAg_4I_5 are prepared with the main surface of area equal to 0.75 cm^2 , accurately smoothed with a microtome. The diffusion of iodine is then let to occur at constant temperature. The iodine source is a mixture of natural and radioactive iodine in a precisely

Fig. 17. Short-circuit current as a function of $t^{-1/2}$ at constant iodine content ($\gamma = 0.06$) for the several temperatures indicated.

Fig. 18. Arrhenius plot of the overall diffusion coefficient of transfer of iodine in $(\text{CH})_x$.

known ratio. The concentration of iodine is thereafter readily derived from the measurement of the radioactivity. After diffusion, the sample is sectioned with a microtome in parallel sections of a thickness usually equal to 20 μm . The radioactivity due to the gamma-rays emitted by I-125 is measured in each section with an automatic counter. As an example, the diffusion profile at $\theta = -10^\circ\text{C}$ is shown in Fig. 19. The following conclusions are drawn.

1. The concentration at the origin is about $0.2 \text{ g}\cdot\text{cm}^{-3}$, and this value is found constant in the temperature range -20° to $+20^\circ\text{C}$. This quite large concentration corresponds almost exactly to the complete filling of the pores between the grains of the pressed electrolyte. The theoretical density of RbAg_4I_5 is $5.38 \text{ g}\cdot\text{cm}^{-3}$. The measured density of our samples is $5.23 \text{ g}\cdot\text{cm}^{-3}$, which gives a porosity of 3%. The pores are therefore filled at the interface with condensed iodine which diffuses further into the crystal.

2. The initial condition being $C_{i,x=0} = C_0$, one would expect the diffusion profile to follow the complementary error function $C = C_0 [1 - \text{erf}(x/2\sqrt{Dt})]$. In fact, no profile could be fitted with this equation. It was then examined whether a reaction of fixation of iodine is also occurring during the diffusion. One might think either of a

Fig. 19. Diffusion profile of I_2 into a RbAg_4I_5 pressed pellet at -10°C .

reaction of chemisorption or alternatively of a true chemical reaction like

The diffusion profile would then be given by

$$C \sim C_0 \exp(-x\sqrt{k/D})$$

where D is the diffusion coefficient and k the rate constant assuming the kinetics of the first order. Unfortunately the fitting was not improved by a large extent. The diffusion mechanism remains to be clearly elucidated.

3. Because of the poor quality of the fitting, only a rough estimation of D can be made: $10^{-9} < D < 10^{-8} \text{ cm}^2\cdot\text{s}^{-1}$. The most interesting feature is that D hardly depends on temperature. This clearly confirms that the penetration of iodine is not a solid-state diffusion mechanism. Instead, one can conclude that diffusion is controlled by diffusion of gaseous iodine through the pores, followed by some diffusion into the grains.

The general conclusion of that study was the necessity of the procedure used to prevent self-discharge, consisting in filling the pores by silver thin particles which efficiently trap the iodine molecules.

Sodium Battery

The general conclusion about the polyacetylene-silver battery is that it is a good system, at least from the electrochemical point of view. However, when compared to the other primary cells — particularly that of Leclanché — its energy cost may seem too high. It obviously comes to mind that the substitution for silver by an alkali metal would drastically cut down this cost. As a matter of fact, silver is a very heavy and very expensive metal, which enters the composition of both the anode and the electrolyte. So, another prototype polyacetylene-sodium was simultaneously studied. Sodium was chosen because of the availability of the sodium ion conducting solid electrolyte, namely beta-alumina. Chiang (8) investigated the cell $(\text{CHNa}_y)_x/\text{PEO-NaI}/(\text{CHI}_y)_x$ above 60°C . The advantage of β -alumina is its possible use at room temperature (31). Lithium would give an even higher energy density, but until now there is no satisfactory solid electrolyte conducting by the lithium ions at room temperature. Sodium has already advantages over silver as the anode (1F for 23g instead of 130g) as well as the electrolyte (a membrane of 0.2g can be used instead of 1g of RbAg_4I_5). Last, higher voltages are expected also contributing to increasing the power density.

Cell $\text{Na}/\beta\text{-Al}_2\text{O}_3/(\text{CHI}_y)_x$.—This cell was formed by assembling the cathode shown on Fig. 20 with pure sodium inside the glove box in argon atmosphere. One finds $V_{OC} = 2.76\text{V}$ and $I_{SC} = 35 \times 10^{-6}\text{A}$ at 25°C .

From the tables of thermodynamic constants, one derives the Gibbs free energy of formation of NaI at 25°C of $\Delta G_{f,\text{NaI}}^\circ = -69.99 \text{ kcal}\cdot\text{mol}^{-1}$ and hence the standard po-

tential associated with the formation of NaI: $E^\circ = 2.95\text{V}$. The electromotive force of the cell would then be $E = 2.95 \times 0.059 \log a_i$, where a_i is the activity of iodine inside $(\text{CH})_x$. Taking $a_i = 0.07$ leads to $E = 2.88\text{V}$, so that the experimental $E = 2.76\text{V}$ is well accounted for. However, the cell cannot keep the charge for more than 1h because we could not prevent oxidation of sodium. This forced us to use $(\text{CH})_x$ on both sides, *i.e.*, at the negative as well as at the positive electrode.

Preparation of the polyacetylene-sodium anode.—We have found a simple and cheap method to dope $(\text{CH})_x$ with Na inside a resin coating so that oxidation of sodium by air is prevented. Sodium is allowed to dope the film of pure $(\text{CH})_x$ by an electrochemical method through the solid electrolyte like that in Fig. 20. Several sources of sodium were tried: aqueous solution of NaOH, aqueous solution of NaNO_3 in ethanol, and solution of NaI in N-methylacetamide. Electrolysis is performed at a constant voltage. The dependence of the current on time always follows the same trend: very small current during the first hours before a sudden abrupt rise. At first, it was assumed that the current is initially limited by the high electrical resistance of the undoped $(\text{CH})_x$. After a minimum amount of sodium, the conductivity increases drastically, which accelerates the doping. The voltage must exceed 3V, which is the decomposition potential of NaI. Cracks can be observed in the alumina membrane after some use of the battery. We now think that the initial stage corresponds to the time necessary for the cracks to form, propagate, and to be filled with metallic sodium, which would eventually short-circuit the membrane.

So, the final goal is reached: $(\text{CH})_x$ can be doped by a solid-state electrochemical method, inside a protecting coating of resin, which provides an efficient and cheap method of doping. Among the various electrolytic solutions, the organic solution of NaI in N-methylacetamide gives the best results. The aqueous solutions are to be avoided because they damage the Al_2O_3 electrolyte more quickly and also the subsequent grain boundary diffusion of water molecules must be forbidden.

Study of the $(\text{CHNa}_y)_x/\beta''\text{-Al}_2\text{O}_3/(\text{CHI}_y)_x$ battery.—One more problem arose when, after assembling the cell with a sodium-doped anode and an iodine-doped cathode, it was only possible to draw a very small current. As a matter of fact, the internal resistance was $> 10^6\Omega$ instead of the $10^2\Omega$ expected with this electrolyte at 25°C . The major part of the resistance was supposed to take place in the anode/electrolyte interface. The traces of oxygen or water molecules adsorbed on the fibrils would form a highly resistive film of sodium oxide. A great improvement was found when, instead of assembling the $(\text{CH})_x$ anode and the electrolyte as separate elements, the polymer was synthesized directly upon the surface of the beta-alumina membrane. Finally, the measured internal resistance is typically $10^3\Omega$, still a large value, but providing a more acceptable current of about 10^{-5}A . The maximum short-circuit current of $\sim 10^{-3}\text{A}$ was observed in a cell which presented cracks.

Two different types of discharge curves were observed. The first one is given in Fig. 21. The initial open-circuit voltage reaches 2.94V, corresponding exactly to formation of NaI. However, it rapidly decreases down to 0.8V in a few hours without any current having been drawn. The examination of such cells revealed cracks throughout the solid electrolyte. The cracks therefore allowed metallic sodium to be formed during the charge, but at the same time gave an obvious way for the active species to diffuse and react without producing electricity. This accounts both for the high initial open-circuit voltage and fast self-discharge. The second type of discharge is more interesting (Fig. 22): the open-circuit voltage of 1.3V is lower but practically stable over several days. The short-circuit current is limited by the internal resistance of the cell. Typical values of $20\ \mu\text{A}$ are found.

In the case of the electrochemical doping in an aqueous or organic solution, the dopants transfer their charges and

Fig. 21. Open-circuit voltage of a $\text{CHNa}_y/\beta''\text{-Al}_2\text{O}_3/\text{CHI}_y$ battery charged at high voltage.

remain in the polymer as simple counterions such as Na^+ or I_3^-

at the negative electrode, and

at the positive electrode.

The further electrochemical doping would thus be simply reduction of $(\text{CH})_x$ at the anode and oxidation of $(\text{CH})_x$ at the cathode. The free energy is the sum of the oxidation and reduction energies, which theoretically coincides with the energy gap which is 1.3V in $(\text{CH})_x$. The electromotive force should thus be equal to 1.3V (32), which is in good agreement with the present results observed when the thermodynamical equilibrium is reached. It is noteworthy that the liquid state $(\text{CH})_x$ batteries also give $E = 1.3\text{V}$ (32).

Energy density.—As an example, the battery of initial composition $(\text{CHNa}_{0.1})_x/\beta''\text{-Al}_2\text{O}_3, \text{Na}_2\text{O}/(\text{CHI}_{0.1})_x$ and a voltage of 1.3V has an energy density of 95 Wh/kg. The weight of the solid electrolyte as well as container, resin, and leads has obviously to be taken into account. All these factors make the energy density decrease down to 20 Wh/kg. This is only one-half the energy density of the lead battery. Some gain on the weight could be expected by decreasing the thickness of the electrolyte, increasing the doping level, substitution of sodium by lithium if a solid

Fig. 22. Open-circuit voltage of a $\text{CHNa}_y/\beta''\text{-Al}_2\text{O}_3/\text{CHI}_y$ battery charged at low voltage.

electrolyte conducting by the lithium ions was discovered. Substitution for iodine by a lighter acceptor impurity is also desired.

Conclusion

The present study has shown that polyacetylene can be used as the electrode material in solid-state batteries working at room temperature, at least in two prototypes at the laboratory level. The obvious question is will such polyacetylene solid-state batteries ever reach the industrial level? Some important steps have been made.

1. A battery with pure $(\text{CH})_x$ and a solid electrolyte can be stored for any period of time. A partial electrolysis of the solid electrolyte leads after solid-state electrochemical doping of the polymer to making the battery ready for use only when needed. The consequence is a very long lifetime.

2. It is vital to insure a good electrical contact between the polymeric electrodes and the solid electrolyte, for instance, by synthesizing the polymer directly on the solid electrolyte.

However, there remain many improvements to achieve before one could hope to reach the commercial stage:

1. The current density $\sim 10^{-4}$ A-cm $^{-2}$ restricts the possible market to the supply of the electronic devices and liquid crystal displays.

2. The energy cost has to be reduced: both the solid electrolytes used here are quite expensive, either because of the materials (Ag and Rb in RbAg_4I_3) or because of the high technology of Al_2O_3 , $x\text{Na}_2\text{O}$.

3. The energy density has to be increased.

The final conclusion is that we have shown that polyacetylene (or any other conducting polymer) solid-state batteries are promising. However, new solid electrolytes would be desired to improve the performances.

Heterojunction Photoelectrodes

II. Electrochemistry at Tin-Doped Indium Oxide/Aqueous Electrolyte Interfaces

Oliver M.-R. Chyan and Krishnan Rajeshwar*

Department of Chemistry, The University of Texas at Arlington, Arlington, Texas 76019

ABSTRACT

Redox electrochemistry at Pt- and tin-doped indium oxide (ITO) electrodes was studied in a comparative manner in aqueous electrolytes. This study was prompted by the applicability of ITO thin films as corrosion inhibiting agents in photoelectrochemical systems. Cyclic voltammetry and steady-state polarization measurements were used to probe the relative facility of charge transfer at the two electrode/electrolyte interfaces. The candidate redox systems were $\text{Fe}(\text{CN})_6^{4-/3-}$, I^-/I_3^- , and $\text{Fe}^{2+/3+}$, the latter in the presence and absence of Cl^- ion catalysts. The key finding of this study is that differences in kinetic facility between Pt and ITO manifest to varying degrees, which depend critically on the intrinsic kinetics of the particular redox couple.

A major obstacle confronting photoelectrochemical (PEC) methods of solar energy conversion is the proclivity of most narrow bandgap semiconductor electrodes to corrosion and passivation. Corrosion is a particularly severe problem in aqueous electrolytes. Of the approaches considered thus far for protection of semiconductor surfaces, the strategy of using some type of overlayer or coating has proved to be effective. The materials comprising such overlayers have been generally of three types: polymers, wide bandgap oxides, and metals (2). Early attempts to use oxides such as TiO_2 did not yield encouraging results because of the relatively high resistivity of these materials and the consequent need to use very thin layers (3). Such layers are prone to pinhole formation and electrolyte "undercutting" problems. Problems of similar nature occur with metal coatings, whose high optical absorptivities require the use of very thin layers.

Compounds such as heavily-doped SnO_2 and In_2O_3 in thin film form, however, are unique in that they combine good optical transparency to the visible spectrum with low electrical resistivity (4). The use of these materials as coatings for PEC electrodes, therefore, is not restricted to very thin layers and associated complications as with the materials discussed above. With this rationale in mind, electrode structures comprising Si and coated with Sn-doped In_2O_3 (ITO) thin films were fabricated in previous studies in this laboratory (1). These electrodes have shown excellent stability in aqueous media, even under testing conditions typical of a Cl_2 containing ambient (1, 5).

The juxtaposition of two interfaces, namely, semiconductor/surface layer and surface layer/redox electrolyte, in a heterojunction photoelectrode structure (cf. Fig. 1), alters the picture considerably from the classical semiconductor/electrolyte case. As with the metal-film electrode structures considered by previous authors (6), the photovoltaic junction is already "built in," for example, at the Si/ITO interface¹ and the electrolyte ideally should not influence this electrostatic barrier. However, electrochemical kinetics at the ITO/redox electrolyte interface should play a key role since the two interfaces are in series (cf. Fig. 1). This expectation is realized in terms of the vastly superior photoresponse of the p-Si/ITO heterojunction photoelectrode in contact with the $\text{Fe}(\text{CN})_6^{4-/3-}$ redox system, as compared to another redox couple with a virtually identical E° , namely, the I^-/I_3^- system. Relevant data are presented in Fig. 2; they were culled from

*Electrochemical Society Active Member.

¹Note that the Si/ITO junction characteristics are dependent on the method of its fabrication. For example, neutralized Ar⁺ ion beam sputtering of ITO yields a rectifying barrier on p-Si and an ohmic contact on n-type Si. Just the opposite is observed when the ITO thin film is prepared by spray pyrolysis. This behavior has been rationalized in terms of the formation of a damaged n-type Si layer just underneath the ITO during sputtering (i.e., a "buried" homojunction is induced) (7). In spite of this subtlety, the term "heterojunction photoelectrode" is retained here regardless of whether the substrate is n- or p-type. This is done merely for the sake of brevity.

previous studies in this laboratory (1). The redox kinetics of $\text{Fe}(\text{CN})_6^{4-/3-}$ on the ITO surface are obviously much better than in the case of the polyiodide couple, as also illustrated by steady-state (polarization) measurements on ITO electrodes (cf. Fig. 2). These aspects related to the electrochemistry at the ITO/redox electrolyte interface, are probed in more detail in this study, primarily via cyclic voltammetry (CV). Three model redox couples— $\text{Fe}(\text{CN})_6^{4-/3-}$, I^-/I_3^- , and $\text{Fe}^{2+/3+}$ —in suitable supporting electrolytes were chosen for this purpose. These new measurements were prompted by the sparsity of electrochemical data on conducting and transparent oxide surfaces in general, and on ITO in particular (see below).

Electrochemistry of Conducting and Transparent Oxide Thin Films

The majority of the literature data pertain to SnO_2 and, as such, are summarized here, since these data also should be fairly indicative of the behavior to be expected from ITO. Early researchers stressed the advantages over Pt or Au in the use of thin film electrodes such as Sb: SnO_2 in terms of high O_2 overpotential and lack of surface oxidation phenomena (8). These advantages were utilized in later studies for anodic electroanalytical chemistry (9). Particularly pertinent to the present work are studies from the same group (10) on the kinetics of model redox processes at Sb: SnO_2 thin film electrodes. Interestingly enough, Pt was used as the thin film substrate for these electrochemical studies. While highly doped ($N_D \sim 10^{20} \text{ cm}^{-3}$) SnO_2 specimens exhibited reversible behavior for $\text{Fe}(\text{CN})_6^{4-/3-}$ and $\text{Fe}(\text{o-phen})_3^{2+/3+}$ (o-phen: o-phenanthroline) redox couples, the cyclic voltammograms showed pronounced asymmetry for thin films of higher resistivity. This trend was interpreted in terms of the width of the space-charge region in Sb: SnO_2 and its dependence on doping level. At high doping, the barrier becomes transparent to the flow of electrons in either direction, whereas at a value of N_D equal to ca. 10^{19} cm^{-3} , the oxidation process becomes tunnel limited. Similar trends

Fig. 1. Schematic of the p-Si/ITO heterojunction photoelectrode structure

Fig. 2. Steady-state current-voltage characteristics under solar illumination for a p-Si/ITO electrode in contact with (a) 0.5M $\text{Fe}(\text{CN})_6^{4-3-}$ and (b) 1M $\text{KI}/0.05\text{M I}_2$ redox couples. The corresponding electrocatalytic activity towards the respective redox couples (curves c and d) of an ITO thin film is superimposed on the photocharacteristics [cf. Ref. (1)]. (Reprinted with permission from the Journal of American Chemical Society, 105, 324 (1983). Copyright (1983) American Chemical Society.)

are apparent for the $\text{Fe}^{2+/3+}$ redox process in a more recent study (11) on the photogalvanic applications of thin film SnO_2 electrodes.

Similar irreversibility (relative to Pt) has been observed on SnO_2 thin film electrodes in molten LiCl-KCl eutectic towards O^{2-} and Cl^- oxidation (12). In spite of this trend, however, the metal-like nature of these electrodes (in terms of their electrochemical behavior) toward a wide variety of redox reactions in molten salt electrolytes (13) was verified. The potential distribution across the SnO_2 /electrolyte interface has been analyzed via capacitance measurements both for nonaqueous (molten salt) (14) as well as for aqueous electrolyte cases (15, 16).

Other studies on the electrochemistry of conducting and transparent oxide thin films describe electrochemical platinization of SnO_2 surfaces (17a) and subsequent characterization by photoelectron spectroscopy (17). Photoelectron spectroscopy has also proved useful for probing changes in the surface composition of $\text{Sb}:\text{SnO}_2$ and ITO electrodes after electrochemistry (18). In the same study, the authors present the current-voltage (*i-E*) behavior of ITO thin film electrodes in 1N H_2SO_4 . To our knowledge, this is the only published report on the electrochemical behavior of ITO thin film electrodes.

Experimental

Instrumentation for CV and steady-state (Tafel) measurements has been described elsewhere (19). Additionally, an EG & G Model 264 electrochemistry system was also used in some cases. Standard three-electrode cell geometry with positive feedback *iR* compensation (80-90%) was employed for all measurements; these were performed at ambient temperature. The working electrode was either ITO or a Pt disk (IBM Instruments, Incorporated; geometric area: 0.20 cm^2). A Pt spiral was used as counterelectrode. Either a saturated calomel electrode or an Ag/AgCl electrode was used as reference. All potentials below, however, are quoted with respect to the latter reference. The cell contents were thoroughly purged with prepurified N_2 for ca. 10 min prior to an experiment to preclude interference from O_2 electrochemistry. All redox chemicals were reagent grade and were used as received. Triply distilled water was used for electrolyte preparation in all cases.

The ITO electrodes were fashioned out of wafers on glass slides. These thin films of ITO were deposited either by spray-pyrolysis or neutralized Ar^+ -ion beam sputtering, according to procedures described elsewhere (4, 20, 21). No differences in electrochemical behavior were observable between the films prepared by these two methods, such that further differentiation is not made for the data to be discussed below. The ITO films

utilized in this study had a nominal resistance of 7.5 Ω/\square and were ca. 0.5 μm thick. These films contained 9 mole percent (m/o) SnO_2 and had a nominal carrier concentration of ca. 10^{21} cm^{-3} . Conducting Ag epoxy (Epotek, Billerica, Massachusetts) was used for electrical connection to the ITO film surface. The requisite electrode area for voltammetric measurements (which was in the range 0.2-0.3 cm^2) was defined by careful application of insulating epoxy resin.

In electrochemical measurements employing solid electrodes, the nature of the electrode surface obviously is a key factor in controlling reproducible behavior for a given redox system (22). In preliminary survey experiments, wide variability in CV peak separation ΔE_p and values much higher than the theoretical value of 59 mV were observed for the $\text{Fe}(\text{CN})_6^{4-3-}$ system on Pt, confirming the findings of earlier authors on the extreme sensitivity of charge transfer kinetics of this redox couple to heterogeneous (surface) effects (24). A standard cleaning procedure, therefore, was established for subsequent experimentation on Pt as follows.

After the usual degreasing procedure (detergent followed by an organic solvent rinse), the Pt electrode was thoroughly washed with dichromate-sulfuric acid mixture. An electrochemical pretreatment followed in a 1M KNO_3 solution. The electrode was poised at -0.6V for ca. 10 min in this solution. Vigorous H_2 evolution at the electrode surface was noted. The potential was then moved slightly positive (ca. +0.1V) to oxidize any adsorbed hydrogen species on the electrode surface. Finally, the electrode was washed in deionized water several times.

The efficacy of the above treatment procedure was checked by monitoring ΔE_p for the particular electrode in $\text{Fe}(\text{CN})_6^{4-3-}$ redox medium. A value close to 60 mV was taken as a diagnostic criterion for the "cleanliness" of the Pt electrode surface.

For the ITO electrode, a washing sequence comprising deionized water-mild detergent-deionized water-methyl alcohol was employed followed by air-drying.

Results and Discussion

Behavior in supporting electrolyte.—Background voltammograms on ITO in neutral electrolytes (e.g., 1M KNO_3) are relatively featureless, as shown by a typical example in Fig. 3. The absence of "surface waves" at a variety of scan rates ranging from 0.001 to 0.20V/s is indicative of a relatively low degree of surface hydroxylation and oxidation of the electrode surface. High O_2 overpotentials are also typical on the ITO surface (cf. Fig. 3). (The behavior of a Pt electrode is included for comparison in the same figure). The absence of significant oxidative electrochemistry on ITO (a behavior which contrasts with that of an Au electrode, for example) is reminiscent of observations by previous authors on Sb-doped SnO_2 electrodes (8-10). The enhancement in the

Fig. 4. Steady-state voltammograms for ITO in 1M KNO_3 . Curve a is a scan between -0.4 and -1.0V . Curve b is a scan between the same limits after holding the electrode at -1.0V for ca. 30s.

available potential window (relative to Pt or Au) on SnO_2 and ITO also has been emphasized by previous authors (8-10, 18). A mechanism based on carrier depletion in the film at positive potential excursions [cf. Ref. (10-16)] would account for the relative sluggishness of anodic charge transfer at ITO and seems particularly appropriate to the Fe^{2+} oxidation case discussed in detail below. On the cathodic side, voltammograms are characterized by hydrogen adsorption prewaves, which become particularly noticeable at moderate to high scan rates ($> 0.10\text{ V/s}$) and on holding the electrode at a potential into the H_2 evolution regime. Representative behavior is shown in Fig. 4.

As discussed by previous authors (10a, 18) and confirmed by us, prolonged use of ITO electrodes at potentials beyond the limits shown in Fig. 3 is deleterious in terms of electrode stability. Specifically, irreversible loss of Sn and O species proceeds at extreme positive and negative potential excursions, respectively. In this respect, these electrodes behave similarly to the Sb: SnO_2 system (19). Interestingly enough, changes in carrier concentration and electrode resistance should ensue as a result of these corrosion processes. Work is under way to elucidate these effects.

Behavior in $\text{Fe}(\text{CN})_6^{4-3-}$ redox electrolyte.—Figure 5 shows cyclic voltammograms on Pt (Fig. 5a) and ITO (Fig. 5b) for $\text{Fe}(\text{CN})_6^{4-3-}$ redox electrochemistry.² Relevant parameters from these data are assembled in Table I. Pertinent here is the relative magnitude of ΔE_p on Pt and ITO.

²Note that, for the comparison in Fig. 5 (as well as for the cyclic voltammograms presented in Fig. 6 and Fig. 8-10), the geometric areas of the Pt and ITO electrodes that were exposed to the electrolyte were slightly different.

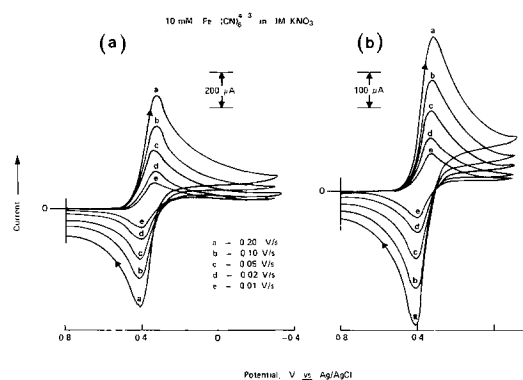

Fig. 5. Comparison of cyclic voltammograms for the $\text{Fe}(\text{CN})_6^{4-3-}$ redox couple in 1M KNO_3 at (a) Pt and (b) ITO electrodes.

In each case, ΔE_p increases with the potential scan rate, v —a trend consistent with the quasi-reversible behavior well established in the literature for the $\text{Fe}(\text{CN})_6^{4-3-}$ couple (23). But more importantly, ΔE_p is always higher for the ITO case. This difference is statistically significant in that electrode-to-electrode variations in ΔE_p on ITO ($\pm 2\text{ mV}$) is always much less than the observed difference between Pt and ITO. It should be pointed out, however, that the Pt surface exhibited wide variability in ΔE_p at a given v , unless the surface was “properly” preconditioned (cf. Experimental section). The value thus measured after optimization is very close to the theoretical value of 59 mV (at 25°C), particularly at low v . These observations with the $\text{Fe}(\text{CN})_6^{4-3-}$ couple on Pt confirm the findings of previous authors (23) on the extreme sensitivity of $\text{Fe}(\text{CN})_6^{4-3-}$ redox chemistry to surface effects.

The other CV parameters (e.g., peak current ratio) in Table I reveal fairly straightforward trends and no significant differences between Pt and ITO for the $\text{Fe}(\text{CN})_6^{4-3-}$ redox system.

Behavior in the polyiodide redox electrolyte.—Let us consider next the I^-/I_3^- redox system. Figures 6a and 6b are the counterparts of Fig. 5a and 5b for this redox system. Immediately obvious is the drastic differences in CV peak shapes in both cases relative to the $\text{Fe}(\text{CN})_6^{4-3-}$ redox system. Extensive literature (24-27) exists for adsorption effects on Pt for the I^-/I_3^- redox couple. An adsorption “spike” (the magnitude of which is dependent on v) is always present on the anodic wave on Pt and absent on ITO. The relative sharpness of the CV peaks on the latter, however, is typical of strong adsorption behavior. In both cases, the cathodic peak shapes are characteristic for reduction of strongly adsorbed species (I_2 in this case). The peak current ratios in Table II for various v values illustrate the nonideality of this redox couple in this regard. Nonzero intercepts in i_p vs. $v^{1/2}$ plots (cf. Fig. 7) are also characteristic of strong adsorption of iodine on Pt and ITO surfaces.

Notwithstanding the above similarities in I^-/I_3^- redox chemistry on Pt and ITO, important differences exist in the kinetics and symmetry of charge transfer in the two cases. The latter manifests again in the relative magnitude of ΔE_p values for the two electrodes (cf. Table II). For example, ΔE_p is as high as 1.20V (!) at $v = 0.20\text{ V/s}$ on ITO.

Behavior in the $\text{Fe}^{2+/3+}$ redox electrolyte.—Figure 8 illustrates cyclic voltammograms on Pt and ITO for the next

candidate system, namely Fe^{2+/3+}. Accompanying CV data may be found in Table III. Again, very high ΔE_p values on ITO (relative to Pt) demonstrate the inefficiency of charge transfer at this electrode surface for an intrinsically sluggish redox system (see below). The peak current ratios depart from unity at slow scan rates on ITO although the

ratio, $i_p/v^{1/2}$, is relatively constant, as in the Pt case (see also Fig. 7).

Kinetics in the Fe^{2+/3+} redox system are particularly amenable to improvement by "matrix" modification effects (28). Charge transfer becomes facile on adding Cl⁻ ions to the electrolyte, as illustrated in Fig. 9a and 10a for Pt. The improvement in kinetics is less dramatic on ITO, as exemplified by data in Fig. 9b, 10b, and 11. Note the systematic shift in peak potentials with v for ITO even at relatively high Cl⁻ concentrations and the "flatness" of the peak potential response on Pt (cf. Fig. 12).

The asymmetry in charge transfer at ITO, alluded to in a preceding paragraph, is particularly well typified by the cyclic voltammogram in Fig. 13, curve 1. Some degree of anodic current "recovery", however, is afforded by addition of H₂SO₄ to the electrolyte, curves 2-4, Fig. 13. Similar rectification in Fe^{2+/3+} redox chemistry has been noted by previous authors at SnO₂ electrodes in studies (11) related to photogalvanic applications.

Comparison of redox kinetics on Pt and ITO.—To couch the aforementioned differences in kinetic facility at Pt and ITO electrodes in more quantitative terms, the Nicholson method (29) was used. This method correlates the measured ΔE_p values in CV experiments with k_0 via the use of a parameter, ψ defined by Eq. [1]

$$\psi = \gamma^\alpha k_0 / \sqrt{\pi a D_0} \quad [1]$$

Here $\gamma = (D_0/D_R)^{1/2}$ and $\alpha = nFv/RT$. (Other symbols have their usual electrochemical identity.) Master plots were utilized to derive values for ψ from ΔE_p , and Eq. [1] was then used to compute k_0 . The assumption made herein, namely, that $\gamma = 1$, does not affect the results, at least in a

relative sense. The I^-/I_3^- redox system was excluded from these computations because of adsorption complications (see above).

The results of these calculations are assembled in Tables IV and V for $\text{Fe}(\text{CN})_6^{4-}/\text{Fe}(\text{CN})_6^{3-}$ and $\text{Fe}^{2+}/\text{Fe}^{3+}$ couples, respectively. The differences in ΔE_p values translate to an order-of-magnitude increase in k_0 values on Pt relative to ITO for the $\text{Fe}(\text{CN})_6^{4-}/\text{Fe}(\text{CN})_6^{3-}$ couple. The k_0 values on Pt accord well with those reported by previous authors for a rotating Pt disk electrode (30). For the case of $\text{Fe}^{2+}/\text{Fe}^{3+}$ in the absence of added Cl^- , computation of k_0 is precluded for ITO because the ΔE_p values lie outside the range of validity of the Nicholson method. [Note that this method applies only to a relatively restricted ΔE_p range ($65\text{--}160\text{mV}$) in the quasi-reversible charge transfer

Fig. 11. Variation of peak separation, ΔE_p , with scan rate and the influence of Cl^- concentration for (a) Pt and (b) ITO electrodes. Curve notation as in Fig. 9.

regime.] Even at high Cl^- concentrations (5M), k_0 values for Pt are four to five times higher than those on ITO. This has important consequences for photoelectrochemistry, as we shall attempt to show in the companion paper (31). Some overestimation is undoubtedly involved in the k_0 values corresponding to the Cl^- containing electrolytes, via the assumption that the D_0 value [$0.45 \times 10^{-5}\text{ cm}^2/\text{s}$, cf. Ref. (32)] is unchanged from the $1\text{M H}_2\text{SO}_4$ case. (The D_0 value is likely to be lower in the viscous LiCl ma-

^a Beyond the range of validity of the Nicholson method [cf. Ref. (29)].

trix). However, this difference is not of serious consequence, since we are interested here only in relative magnitudes on Pt and ITO electrodes. Again, the k_o values at Pt for the $\text{Fe}^{2+/3+}$ redox system in Table V fall within the range reported in previous studies (33).

The steady-state measurements yielded data which are consistent with the trends discussed above for CV. Thus, Tafel analyses reveal values for $j_{1,a}, j_{1,c}, j_o$, and α on ITO electrodes which were significantly lower than for Pt. Only the $\text{Fe}(\text{CN})_6^{4-/3-}$ and $\text{Fe}^{2+/3+}$ redox systems (the latter in the presence and absence of Cl^-) were included for these comparative experiments.

The aforementioned relative trends in redox electrochemistry on Pt and ITO cannot be rationalized simply in terms of difference in uncompensated resistances and other iR drop effects in the two cases. For example, analyses of CV data in terms of $(E_{p/2} - E_p)$ vs. i_p and $E_{0.8517i_p}$ vs. i_p plots, in the manner prescribed by previous authors (34), yield values for the overall resistance, R , (i.e., charge transfer plus uncompensated electrolyte resistance) which are different for $\text{Fe}(\text{CN})_6^{4-/3-}$ and $\text{Fe}^{2+/3+}$ redox systems. While values of R for a given ITO electrode agreed to within $\pm 10\Omega$ for the two types of analyses, order-of-magnitude differences (e.g. 60 vs. 920 Ω) are routinely observed for $\text{Fe}(\text{CN})_6^{4-/3-}$ and $\text{Fe}^{2+/3+}$ redox couples, respectively.

Figure 14 summarizes the important features of redox electrochemistry on Pt and ITO electrodes as revealed by CV experiments. The key finding here is that differences in kinetic facility between Pt and ITO electrodes are closely coupled with the intrinsic kinetics of the particular redox system involved (cf. Fig. 14). This finding underlies the importance of choosing a fast (preferably one-electron) redox couple in PEC regenerative systems

Fig. 13. Effect of acid concentration on the redox chemistry of the $\text{Fe}^{2+/3+}$ couple at ITO. In each case the redox concentration was 1 mM in 1M KNO_3 . Curves 1-4 denote H_2SO_4 of 0, 0.5, 1, and 2 mM, respectively.

based on the heterojunction photoelectrode concept. (Obviously, such a choice would be optimal for "conventional" PEC systems also, although the range of available redox candidates may be limited by electrode stability considerations in such cases). The relative trends in Fig. 14 and the data discussed in the preceding section also explain, in a quantitative manner, why the $\text{Fe}(\text{CN})_6^{4-/3-}$ redox couple was effective in the Si/ITO system while the polyiodide electrolyte was not [cf. Fig. 2 and Ref. (1)] Further detailed analyses of photoelectrochemical aspects as well as a critical examination of the heterojunction photoelectrode concept, are deferred to the companion paper (31).

Causal factors in kinetics differences between Pt and ITO and further comparisons with Sb:SnO₂ electrodes.—We now attempt to probe the causal factors for the observed differences in charge transfer kinetics at Pt and ITO electrodes (cf. Tables IV and V). It is pertinent to

Fig. 14. Dependence of CV peak separation, E_p , on scan rate, v for $\text{Fe}(\text{CN})_6^{4-/3-}$, $\text{Fe}^{2+/3+}$, and I^-/I_3^- redox couples on Pt and ITO electrodes. In each case, the concentration of active species was 10 mM and the supporting electrolyte was 1M KNO_3 .

point out here that, aside from this work, comparisons have been previously made for Pt and Sb:SnO₂ electrodes by other authors (10b). The findings of these authors essentially parallel ours: namely, that no correlation exists between E° and electrochemical reversibility on ITO and Sb:SnO₂ for the various redox couples that were tested in these two studies. Furthermore, Fe(CN)₆^{4-/-3-} is electrochemically reversible on both ITO as well as on Sb:SnO₂. The interpretation forwarded by previous authors for their observations on the latter system is that couples which show reversible behavior "have bulky ligands which may prevent a surface interference effect" (10b). We believe, however, that by and large (*i.e.*, unless adsorption effects are present), all one-electron outer-sphere redox couples, which are intrinsically fast at Pt, will show reversible behavior at these oxide electrode surface. also. Support for our assertion is provided by our recent studies on a variety of organic and organometallic one-electron redox couples at the ITO/nonaqueous electrolyte interfaces (35) and by the comparisons of the kinetics behavior at Pt and Sb:SnO₂ electrodes that have been presented by other authors for phenothiazine and benzoquinone redox systems in acetonitrile (36).

While the above interpretation is appealing from a phenomenological viewpoint, the mechanistic aspects of electron transfer at heavily doped metal oxide/electrolyte interfaces, and the behavior of these interfaces vis-a-vis the metal case, need to be further addressed. Arguments against a "semiconductor model" (based on depletion layer effects) have been advanced by previous authors (10b, 37) for heavily doped material ($N_D = 10^{18}$ - 10^{19} cm⁻³). Instead, the redox behavior of Fe^{2+/3+} and Ce^{3+/4+} at Sb or Ru:SnO₂ has been rationalized in terms of an electron hopping mechanism from the conduction band to surface states via deep lying donor states (37). It is plausible that a similar model can be applied to the ITO system considered here. The reversible behavior observed in acetonitrile for a series of redox couples spanning a significant portion of the ITO bandgap (35), however, necessitates invoking a uniformly high density of surface states right across the ITO bandgap at the interface. In any event, further speculation is clearly not warranted by the depth of information that is currently available on this aspect.

ABSTRACT

We have developed photoelectrochemical cells with rectifying junctions between n-Si electrodes and thin film solvent free polymer solid electrolytes based on poly(ethylene oxide). We describe various surface modifications applied to the n-Si electrode which overcome a high activation energy barrier for efficient charge transfer to redox ions in the polymer solid electrolytes. We show that the efficiency of the present cells is limited by a high surface recombination velocity associated with surface states of the n-Si.

Solvent-free polymer solid electrolytes represent an important new class of ionically conducting materials (1). Their compatibility with thin film technology makes them potential candidates for a wide variety of technological applications.

We have developed a new type of photoelectrochemical cell (PEC) based on rectifying junctions between semiconductor electrodes and thin film polymer solid electrolytes. The absence of solvents in this system holds out the hope of being able to manufacture all thin film solid-state PEC's without the semiconductor surface corrosion problems associated with liquid electrolyte PEC's, thereby deriving the benefits both from the stability of solid-state systems and the ease of fabrication as well as the lack of susceptibility to grain barriers of electrochemical junctions. In addition, it allows for a conceptually easy construction of multispectral thin film cells based on more than one semiconductor in optical and electrical series (2).

Our present study has focused on surface modification techniques for improving the rates of charge transfer between semiconductor electrodes and redox ion couples in polymer solid electrolytes (3-5). Specifically, we have shown that surface modifications of n-Si electrodes with thin films of polypyrrole can dramatically reduce the large activation energy barrier against efficient charge transfer between bare semiconductor electrodes and polymer solid electrolytes.

Polymer Solid Electrolytes

Linear polyethers like poly(ethylene oxide) ($\text{CH}_2\text{-CH}_2\text{-O}$) (PEO) give conducting complexes with alkali metal salts (1). Such adducts are either crystalline materials or amorphous elastomers. The cations are solvated by a fraction of the ether oxygens, and a limited stoichiometry of four oxygen atoms per cation has been observed. Typically, both the cations and the anions move in the polymer matrix. The transference number of iodide, which is relevant to our study, has been measured to be in the range of 0.2-0.4 (6).

The conductivity of these electrolytes is relatively low at room temperature, typically in the 10^{-6} ($\Omega\text{-cm}$) $^{-1}$ range and increases to 10^{-4} ($\Omega\text{-cm}$) $^{-1}$ at 50°-80°C. Devices therefore require thin films.

Photoelectrochemical Cell Fabrication

The PEO electrolyte films used in the present study were solution cast from MeOH, in which were dissolved the PEO (Aldrich; molecular weight 600,000) and the complexing salt. The ion concentration, as given by the ratio of oxygen atoms in the polymer backbone to cations, was 8.

For the PEC's, we used thin films (ca. 0.5 μm) of PEO complexed with KI and I_2 to generate the iodide/triiodide redox couple. The thickness of the PEO films could be

varied by changing the viscosity of the solution and the rotation speed of the photoresist spinner. Fabrication of cells with films thinner than 0.5 μm became practically difficult. The films were spin coated onto a transparent conducting substrate, indium-tin oxide (ITO) on glass, and subsequently dried by heating under vacuum. The cell is completed by contacting the PEO with a 1 cm^2 n-Si chip by heating with light pressure under vacuum. It was found necessary to deposit 5-20Å of Pt on the ITO surface for greatly improved charge transfer between the ITO and the iodide/triiodide redox ions. Bare ITO is a highly irreversible electrode for iodide oxidation and reduction (4). Figure 1 shows a schematic cell configuration and an energy level diagram of the PEO based PEC.

Semiconductor Surface Modification

Our primary interest in this paper was to study various methods of interface modification between the semiconductor and the PEO electrolyte in order to reduce or eliminate the high activation energy barrier against efficient charge transfer of minority carriers from the n-Si to redox ions in the PEO electrolyte.

The effect of various types of Si surface modifications on the efficiency of charge transfer across the interface with the PEO electrolyte was studied by monitoring the photocurrent as a function of the surface modification under constant illumination.

The n-Si surface modifications we have studied include the following: (i) bare n-Si (etched in HF only), (ii) n-Si coated with 200-400Å polypyrrole $\cdot \text{BF}_4$, (iii) n-Si coated with 10-20Å electron beam-evaporated Pt, (iv) n-Si coated with 10-20Å Pt followed by deposition of polypyrrole $\cdot \text{BF}_4$, and (v) n-Si with 10-20Å Pt followed by deposition of polypyrrole \cdot iodide. The n-Si was always etched in HF before the surface modification. The polypyrrole films were grown on the n-Si surface with the technique of photoassisted electrochemical oxidation (7).

Figure 2 shows the effect of the surface preparations on the photocurrent density measured under constant illumination. A high activation energy barrier against charge transfer across the interface will result in a decreased photocurrent at a given light intensity.

As shown in Fig. 2, bare n-Si is a highly irreversible electrode for iodide oxidation in this medium. A similar high degree of electrochemical irreversibility has also been observed with bare semiconductor surfaces of II-VI and III-V compounds and polysulfide electrolytes (2, 8).

By polymerizing a thin coating (200-400Å) of polypyrrole $\cdot \text{BF}_4$ on the n-Si surface the charge transfer characteristics of the interface are improved by more than one order of magnitude. The addition of 10-20Å of Pt by electron beam gun evaporation onto the n-Si surface prior to the electrochemical growth of the polypyrrole $\cdot \text{BF}_4$ film

ELECTROCHEMICAL PHOTOVOLTAIC CELL
WITH SOLID POLYMER ELECTROLYTE

Fig. 1. a(left): Schematic cell configuration. b(right): Energy level diagram. Both of photoelectrochemical cell with polymer solid electrolyte and iodide/triiodide redox couple.

improves the electronic coupling between the n-Si and the polypyrrole, leading to more efficient scavenging of minority carriers from the n-Si. This has also been observed as improved junction characteristics measured in the solid state, as shown in the improvement in the quality factor of the junction from 2.2 to 1.4 (9).

As shown in Fig. 2, the most efficient interfaces incorporate iodide as the anion dopant in the polypyrrole. With the Pt-polypyrrole · iodide coating, the charge transfer characteristics relative to bare n-Si are improved by about

three orders of magnitude. The enhanced efficiency with iodide-doped polypyrrole could be due to specific iodide adsorption on the platinized Si surface. Since iodide is known to have a strong specific adsorption on Pt, this could result in efficient oxidation, or minority carrier scavenging.

Polypyrrole · iodide can be synthesized from acetonitrile solution containing tetraethylammonium iodide or KI complexed with PEO to improve solubility. Alternatively, to avoid the large parasitic currents associated with iodide oxidation, polypyrrole · iodide can be generated by ion exchange of polypyrrole · BF₄ with iodide. If iodide is the only anion in the electrolyte, it will be incorporated into the polypyrrole matrix for charge neutrality as the polypyrrole film grows in its oxidized state. The cyclic voltammogram in Fig. 3 clearly shows the signature of the iodide anion in the region where the polypyrrole is highly conductive. The iodide signal is superimposed on the capacitive charging current of the polypyrrole in its oxidized state, which is large due to the porosity and consequently large surface area of the polypyrrole film (10). The peak heights are linear with scan rate, characteristic of a surface bound species.

The cyclic voltammogram of polypyrrole · iodide is performed in an aqueous KCl electrolyte where iodide is soluble. After an initial reduction of about 40% during the first two scans, the peak heights are stable for multiple scans, indicating that besides a certain fraction of surface-bound iodide, most of the iodide is tightly bound to the polypyrrole matrix.

Current-Voltage Characteristics

The illuminated current-voltage characteristics of a PEC with PEO-iodide/triiodide electrolyte and n-Si/Pt/polypyrrole · iodide photoanode is shown in Fig. 4. The size of the Si chip was 1 cm² and the illumination was 100 mW/cm² unfiltered tungsten-halogen white light. Noticeably different I-V characteristics are observed when different size areas are illuminated. Decreasing the illuminated area by a factor of ten from 0.2 to 0.02 cm² increases both the short-circuit current density and the fill factor, defined as the fraction of the theoretical maximum efficiency with a given short-circuit current and open-circuit voltage. With an illuminated area of 0.02 cm², the fill factor was 0.5 and the energy conversion efficiency about 2%, or 3.6% corrected for absorption in the PEO/ITO.

Fig. 2. Short-circuit photocurrent of PEO-iodide photoelectrochemical cells with varying surface preparation of the n-Si photoelectrodes under constant illumination of 100 mW/cm² unfiltered tungsten halogen light.

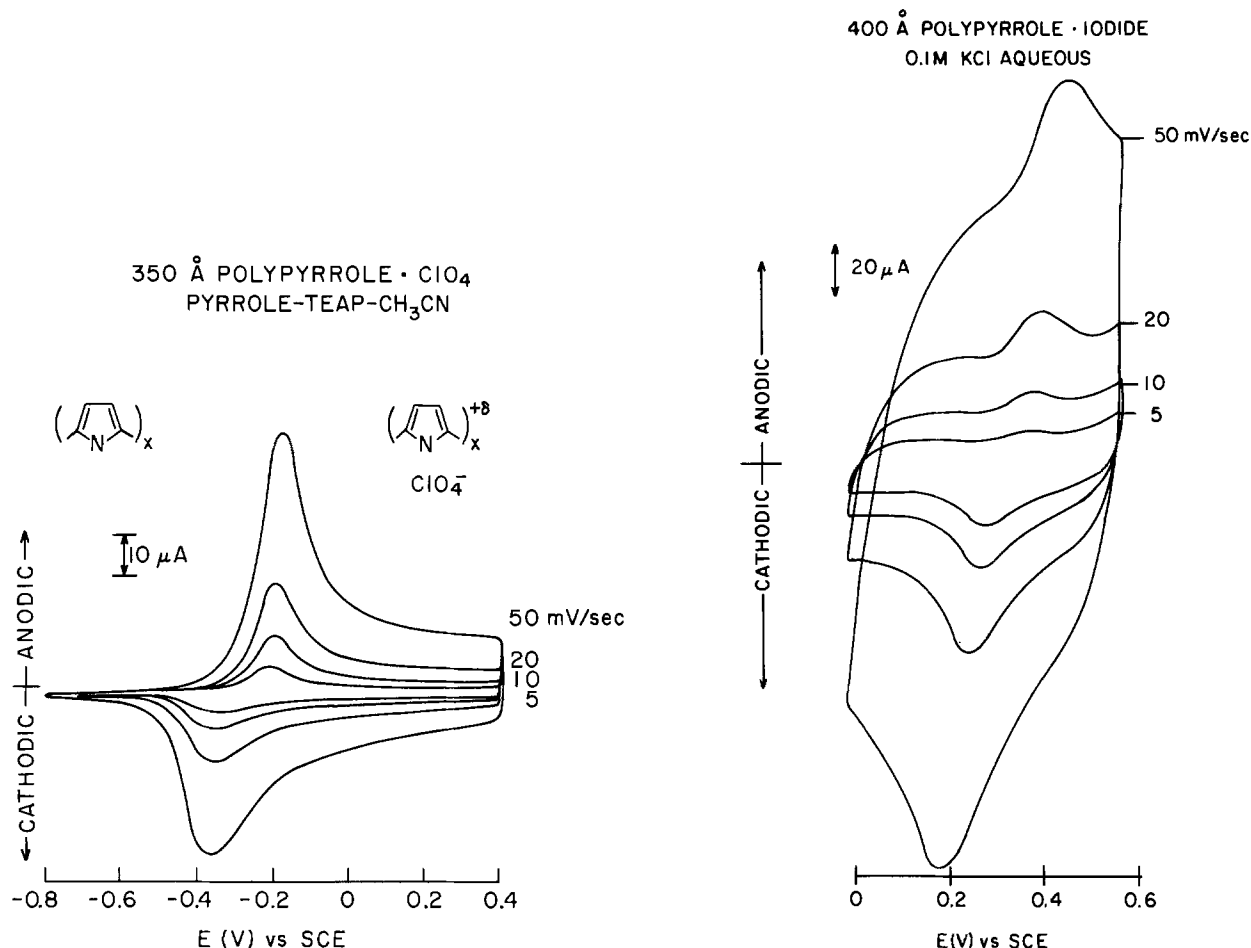

Fig. 3. Cyclic voltammogram of (a, left) polypyrrole · perchlorate in a MeCN-TEAP electrolyte containing pyrrole monomers, which are not electroactive in the region scanned, and (b, right) polypyrrole · iodide in aqueous KCl electrolyte.

The fill factor is strongly dependent on the series resistance of the cell. The forward I-V characteristics exhibit series resistance of the order of $100 \Omega/\text{cm}^2$. This is a contributing factor to the limit of the output efficiency, since photocurrents and fill factors are reduced for series resistances larger than a few ohms per square centimeter (11, 12).

The degraded response for larger illuminated areas are due to the inhomogeneities of the 1 cm^2 contact area between the Si and the PEO due to the thinness of the PEO film. Smaller illuminated areas ($< 1 \text{ mm}^2$) result in even

larger photocurrent densities, suggesting that technological optimization will lead to more efficient cells.

If the surface had been homogeneous, the fill factor would be expected to decrease upon illuminating a smaller surface area since the dark current stays the same

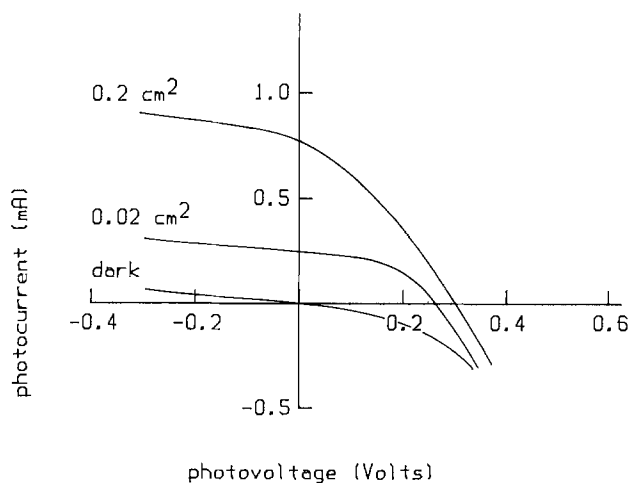

Fig. 4. Illuminated current voltage characteristics of a PEC with PEO · iodide/triiodide electrolyte and n-Si/Pt/polypyrrole · iodide photoanode. The Si chip was 1 cm^2 , and the sizes of the illuminated areas are indicated on the graph.

Fig. 5. Wavelength dependence of transmission of ITO/PEO · iodide and normalized spectral response of the short-circuit photocurrent of a cell with a n-Si/Pt/polypyrrole · iodide photoanode.

Fig. 6. Dependence on incident light intensity of the open-circuit voltage (a, left) and short-circuit photocurrent (b, right) for a cell with n-Si/Pt/polypyrrole-iodide photoanode. Maximum incident light intensity was 100 mW/cm² unfiltered tungsten halogen light, and reduced light intensity was achieved with neutral density filters.

but the photocurrent is reduced. The fact that the fill factor improves with smaller illuminated areas demonstrates that the interface is inhomogeneous.

As can also be seen from the figure, there are substantial reverse bias dark currents which are attributed to low shunting resistance due to edge effects of the Si chip. It is believed that better etching procedures will improve the shunt characteristics.

The effect of removing the PEO film is to reduce both the short-circuit current and the open-circuit voltage. The open-circuit voltages of n-Si/Pt/PP/ITO cells are consistently less than 0.2V, demonstrating the necessity of the n-Si/PEO electrochemical Schottky barrier junction for high efficiency cells.

Spectral Response

Figure 5 shows the wavelength dependence of the transmission of the PEO/ITO and the spectral response of the short-circuit photocurrent as determined by cutoff filters and normalized by the transmission of the individual filters.

The transmission of the PEO/ITO drops from about 50 to about 30% between 500 and 400 nm because of the iodide absorption in the PEO-iodide/triiodide electrolyte film. The drop in the photocurrent is much sharper than that of the transmission for wavelengths below 500 nm, or photon energies above 2.5 eV. We attribute the sharp drop in the photocurrent to high surface recombination velocities associated with a high density of surface states of the Si. Since the absorption constant of the Si increases with increasing photon energy, the higher energy photons are absorbed closer to the surface where the high recombination velocities decrease the carrier lifetimes, resulting in a decreased blue response (11).

Light Intensity Dependence of Photocurrent and Photovoltage

The dependence of the photocurrent and the photovoltage on the intensity of incident white light is shown in Fig. 6a and 6b, respectively. The open-circuit voltage increases logarithmically with light intensity over the almost two orders of magnitude studied using neutral density filters to reduce the incident light intensity from a maximum of 100 mW/cm². This is in accordance with the abrupt junction model (12). The open-circuit voltage increases by 90 mV for each decade increase in the light intensity, corresponding to a quality factor (ratio to $2.3kT/q$) of 1.5 for the barrier. A quality factor greater than 1.0 may

imply the existence of deleterious surface states acting as recombination centers (11, 12). This will reduce the open-circuit voltage by pinning the Fermi level to the surface states and limit the photocurrent by recombination of charge carriers.

The short circuit photocurrent is proportional to L^α where L is the light intensity and $\alpha = 1.07$ at low light intensities (up to 50 mW/cm²) and 0.70 at higher light intensities. The nonlinear behavior at higher light intensities indicates a decreasing quantum efficiency with increasing light intensity. The change in behavior at higher light intensities can be understood in a model where the quasi-Fermi level of the majority carriers reaches a higher density of interface states as it sweeps through the bandgap with increasing light intensity. As the Fermi level sweeps through the interface states, they are converted to recombination centers, thereby increasing the rate of recombination of charge carriers and lowering the quantum efficiency (13).

Summary

In summary, we have demonstrated techniques for derivatizing semiconductor surfaces which overcome the large activation energy barriers to efficient charge transfer between semiconductors and redox ions in PEO electrolytes. We believe these surface modification techniques represent an important advance in the control of charge transfer between semiconductor electrodes and polymer solid electrolytes.

The particular coupling of electronically and ionically conducting polymers to achieve efficient charge transfer which these techniques demonstrate is compatible with thin film technology and could, therefore, have important technological implications.

The energy conversion efficiency of the present-generation cells is limited by a high density of surface states on the n-Si electrode, and possibly by a high series resistance, and no longer by high activation energy barriers against efficient charge transfer from the semiconductor electrode to the redox ions in the PEO solid electrolyte. The continuation of this work will deal explicitly with the surface preparation of the n-Si in an attempt to eliminate the high density of surface states which degrade the behavior of the present photoelectrochemical cells.

ABSTRACT

The visible electroreflectance (ER) technique coupled to capacitive and voltammetric measurements has been used to characterize the redox properties of water-soluble porphyrins [the meso-tetrakis (4-N-methylpyridyl) porphine tetrachloride (TMPyP) and the meso-tetrakis (4-N-methylpyridyl) porphine cobalt (III) pentachloride (Co(III)TMPyP)] in the potential range where they are irreversibly adsorbed on Au electrodes. The spectral features are analyzed in terms of reflectivity difference between the oxidized and reduced species and compared with optical properties of the bulk species. The ER spectra give direct evidence for the location of a reversible electron transfer reaction and allow us to determine the redox potentials of the Co(III)/Co(II) and Co(II)/Co(I) systems in their adsorbed state. The Co(III)/Co(II) couple is detected in an acidic solution (0.1M HClO₄) at $E_1 = 0.45$ V/SCE, and the Co(II)/Co(I) system is determined in neutral solution (0.02M KClO₄) at $E_2 = -0.70$ V/SCE. These potentials do not differ from the values obtained for the unadsorbed metalloporphyrin. These results provide evidence for the ability of a gold electrode covered with adsorbed porphyrin to constitute a modified electrode with well-defined redox properties.

Modified electrodes are electrochemical tools for which many methods of preparation and investigation have been described during the last years (1). Relatively few applications in the field of electrochemical catalysis have been proposed. Developments in this field necessitate extensions of the fabrication procedures to other modified surfaces or research of new catalytic reactions with the well-known modified electrodes. For this purpose, *in situ* methods of investigation are very useful. The most investigated catalytic reaction is the oxygen reduction, for which many coordination compounds have been proposed as catalysts, among them, cobalt porphyrins (1b, 5) and phthalocyanines (4). Kuwana (3), Anson (2, 6), and Murray (1b, 5) have studied the electrochemical be-

havior of adsorbed or linked porphyrins and phthalocyanines. Some *in situ* methods of investigation have been proposed for such electrode-adsorbed (or -linked) compounds (1b, 7-10).

Water-soluble porphyrins of the tetramethylpyridyl or tetraphenylsulfonate type have not been so intensively investigated as other porphyrins. Some chemical and electrochemical properties have been described (11-12), and it was shown that electrochemistry of these compounds is not as well defined as those of water-insoluble compounds and need to be completed.

In the scope of new catalytic developments of these water-soluble porphyrins, we are interested in porphyrin-modified electrode and *in situ* methods of investigation of their electrochemical properties. Recent voltammetric study of Cytochrome C (22) and electroreflectance inves-

* Electrochemical Society Active Member.

Fig. 1. Capacity-potential curves for a polycrystalline gold electrode with the influence of the pH. a(left): pH = 1 in 0.1M HClO₄. b(right): pH = 6 in 0.02M KClO₄. Curve 1: with a clean gold surface. Curve 2: with adsorbed Co(III) TMPyP. Curve 3: with adsorbed TMPyP. Frequency $f = 15$ Hz. Modulation amplitude $\delta E = 5$ mV. Voltage sweep $V = 5$ mV·s⁻¹.

tigation on gold electrode (23) have shown the interest of coupled electrochemistry and spectrochemistry.

Therefore, in this paper we examine the electrochemical behavior of some water-soluble porphyrins adsorbed on a gold electrode by electroreflectance.

Experimental

The cobalt TMPyP and free-TMPyP were prepared by a modification (24) of the published method (25, 26).

The electrodes were polycrystalline gold disks with a surface of 0.65 cm². After mechanical polishing, the electrodes were rinsed first with concentrated H₂SO₄ and then with ultrapure water.

Before each experiment, an electrochemical cleaning procedure was performed in a supporting electrolyte (0.02M KClO₄) consisting of a set of slow voltage sweeps (20 mV·s⁻¹) between two potential limits of -0.8 and +1.2 V/SCE. This procedure allows for the formation of a monolayer of oxide and its subsequent reduction of each cycle. The voltage sweep was repeated until a satisfactory cleanliness of the interface was reached as revealed by the well-known voltammogram and capacitive characteristics (27). Then the electrode was wetted with a drop of porphyrin for about 10 min, followed by thorough washing to remove the excess of porphyrin before introducing it into the experimental cell containing the electrolyte (0.02M KClO₄ or 0.1M HClO₄). The extent of the potential excursion was limited so as to maintain the porphyrin adsorbed without its undergoing chemical degradation. The potential limits depend on the pH of the solution: it ranges between -1 and +0.5V at pH = 6 and between -0.5 and +0.7V at pH = 1. At the end of each experiment, the potential limit was extended to a more positive value, +1.2V, to oxidize the adsorbed layer and regenerate a clean gold surface.

Potentials were measured vs. a mercurous sulfate electrode in order to avoid contamination of the gold surface by Cl⁻ anions, but they are quoted with respect to SCE (by adding 0.41V).

Voltammograms were recorded at a variable voltage sweep in the range of 30-300 mV·s⁻¹. Capacity and

electroreflectance measurements were made with a 15 Hz modulation voltage superimposed on a slow sweep of 3 mV·s⁻¹. Optical measurements were carried out at normal incidence with plane polarized light, in the wavelength range 300-600 nm. The procedure and apparatus for obtaining the electrical capacity and optical signals (ER) have been described (27).

All the electrochemical studies were performed in 0.02M KClO₄ or 0.1M HClO₄ solutions. Curves were obtained with a three-electrode potentiostatic system.

A visible spectrum of porphyrin solutions (0.02M KClO₄ or 0.1M HClO₄) was made from a Unicam SP 1800 ultraviolet spectrophotometer. Reduction of the Co(III) TMPyP to Co(II) TMPyP was effected by addition of sodium borohydride (NaBH₄). All the experiments were performed at 25°C.

Results

Adsorption characterization.—The presence of Co(III) TMPyP molecules at the gold electrode surface is demon-

Fig. 2. Voltammogram for a modified gold electrode by adsorbed Co(III) TMPyP in aqueous solution of 0.1M HClO₄. The dashed curve indicates the behavior of a free gold surface (after desorption of porphyrin) $V = 300$ mV·s⁻¹.

strated by comparing the capacity of the gold interface after a cleaning treatment in the supporting electrolyte and after deposition of the porphyrin on the electrode surface. Capacity-potential curves in HClO_4 ($\text{pH} = 1$) and in 0.02M KClO_4 media ($\text{pH} = 6$) are presented in Fig. 1. In both media, the capacity is lowered in presence of porphyrin in a potential range larger than 1V , showing that it remains irreversibly adsorbed in this region without undergoing any chemical degradation.

Irreversible adsorption of the free-porphyrin (TMPyP) has been observed under the same conditions (Fig. 1).

In situ characterization of adsorbed Co(III) TMPyP.—0.1M HClO₄ medium.—The voltammetric curve of adsorbed Co(III) TMPyP is shown in Fig. 2. Waves that are not well defined are visible near $E = 0.45\text{ V/SCE}$ which corresponds to the peak in capacity-potential curve (see Fig. 1a).

The ER spectrum shown in Fig. 3 relative to Co(III) TMPyP is obtained in a narrow potential region near $E_p = 0.45\text{V}$ with a maximum amplitude at E_p . These structures completely disappear for any mean potential situated in more positive or negative region.

These typical spectra can be interpreted in terms of a valence change process occurring in the adsorbed layer. The ER structures displayed in the $400\text{-}500\text{ nm}$ range are relative to the simultaneous presence of both oxidized and reduced forms characterized by slightly different optical properties which are revealed by the modulation technique.

The adsorbance spectra of bulk Co TMPyP in the same acidic solution for both oxidized and reduced forms indi-

cate that the typical ER spectrum at $E_p = +0.45\text{ V/ECS}$ coincides with the differential spectrum obtained by subtracting the spectrum of oxidized, Co(III) TMPyP, from that of the reduced Co(II) TMPyP form in solution (Fig. 4). This demonstrates that the adsorbed species are probably maintained in a configuration similar to that in the solution.

The absence of any signal of adsorbed TMPyP (without metallic ion) in the same media, in the investigated potential range, indicates that the redox process concerns the cobalt ion. Thus, the capacitive, voltammetric, and electroreflectance signals are characteristics of the Co(III)/Co(II) system of the adsorbed porphyrin.

The cyclic voltammogram of the bulk Co TMPyP (Fig. 5) situates the apparent standard potential of the Co(III)/Co(II) couple at $+0.45\text{ V/ECS}$, in accordance with the value of Pasternak (19). Comparison between the electrochemical behavior of adsorbed and bulk Co TMPyP clearly shows that the redox couple Co(III)/Co(II) appears at the same potential in both adsorbed and bulk phases.

Neutral 0.02M KClO₄ medium.—Capacity and electroreflectance study of the adsorbed Co(III) TMPyP in 0.02M KClO_4 gives also one typical spectrum at a potential value of ca. -0.7 V/ECS (out of the potential range available in 0.1M HClO_4). Unexpectedly, no typical signal was observed at the redox Co(III)/Co(II) potential value previously identified in acidic solution.

The ER spectrum of Co(III) TMPyP shown in Fig. 6 was obtained in a narrow potential region near $E_p = -0.7\text{V}$. It exhibited double signed features which did not fit with the differential spectra obtained by subtracting

Fig. 3. a(left), curve a: Typical ER spectrum displayed at $E = +0.45\text{ V/SCE}$ for a modified gold electrode with adsorbed Co(III) TMPyP in 0.1M HClO_4 , $f = 15\text{ Hz}$, $\delta E = 100\text{ mV}$, r.m.s. Curve b: Calculated spectra obtained from the adsorption spectra of both oxidized and reduced species in the same HClO_4 solution. b(above), curve 1: Typical ER spectrum for a gold electrode surface near the potential of zero charge. Curve 2: Typical ER spectrum for the electrode covered with Co(III) TMPyP at a potential far from E_p , $E = -0.1\text{V}$.

Fig. 4. Absorption spectra of a $2.2 \times 10^{-5} \text{M-liter}^{-1}$ Co(III) TMPyP solution in 0.1M HClO_4 . Dot-dashed line: reduced form. Dotted line: oxidized form.

the spectrum of the oxidized species from that of the reduced species in solution (0.02M KClO_4).¹ This confirms that the typical ER spectrum obtained at $E_p = -0.7 \text{V}$ does not stem from the Co(III)/Co(II) redox process.

¹ Absorbance properties of Co TMPy porphine (oxidized and reduced species) in 0.02M KClO_4 solution are similar to those obtained in 0.1M HClO_4 .

Fig. 5. Cyclic voltammogram of $10^{-4} \text{M Co(III) TMPyP}$ on micro-gold electrode in 0.1M HClO_4 . $v = 200 \text{ mV-s}^{-1}$.

Fig. 6. Typical ER spectrum displayed at $E_p = -0.7 \text{V/SCE}$ for a modified gold electrode with adsorbed Co(III) TMPyP in neutral 0.02M KClO_4 .

Under the same conditions, the adsorbed free TMPyP does not give any signal in the capacity and electroreflectance spectra at the corresponding potential. Comparison of the results between Co TMPyP and free porphyrin indicates that the redox process at -0.7V is due to cobalt and probably to the Co(II)/Co(I) system.

Cyclic voltammograms of the Co(III) TMPyP in solution (0.02M KClO_4) present a poorly defined wave near $E = +0.45 \text{V}$ and a more well-defined one near $E = -0.7 \text{V}$ which can probably be attributed to the Co(III)/Co(II) and Co(II)/Co(I) redox systems.

Comparison of the electrochemical behavior of adsorbed Co TMPyP and that of bulk porphyrin clearly shows that a redox couple, which can be attributed to the Co(II)/Co(I) system, works at the same potential ($E_p = -0.7 \text{V}$) in both adsorbed and bulk phase. Unfortunately, ER spectra of adsorbed Co(III) TMPyP at -0.7V cannot be rigorously correlated to spectra in solution phase due to the lack of the UV-visible one of reduced (Co(I) TMPyP) form. Such a reduced form has never been described to our knowledge, probably because of the demetalation of this Co(I) porphyrin. We have observed that the characteristic voltammetric curves of Co(III) TMPyP solution were modified when the potential of the electrode was maintained at a value lower than -0.7V for a long time. The cobalt deposit confirms the demetalation process. Such a process seems to occur in the adsorbed state as observed by the disappearance of the typical ER spectra for a long negative polarization.

The absence of the ER spectra at $E_p = +0.45 \text{V}$ in neutral solution is not yet clearly understood. It should be explained by a drastic change in configuration of the Co(III) TMPyP from adsorbed form to bulk phase, or more probably by a shift of the redox potential [Co(III)/Co(II)] in a positive range out of the available do-

main. It can be noted that the positions of this couple have not been precisely characterized in solution and have never been described in this neutral media. The disappearance of a redox system in porphyrin-modified electrode has been observed by Murray (9) for a cobalt-metaleled (NH₄)₄ tetraphenylporphine attached to carbon or to platinum electrodes.

Conclusions

Co(III) TMPyP and TMPyP are strongly adsorbed on a gold electrode in a large potential range, in neutral and acidic media. A modified electrode can be easily prepared by this simple method.

Co(III) TMPyP behaves in the adsorbed form as in solution in acidic media. The Co(III)/Co(II) couple appears at +0.45V, in a potential range described by Pasternack (19) and confirmed by our experimental determinations. Thus, the catalytic applications of Co(III) TMPyP involving the Co(III)/Co(II) couple in such a medium should not be modified by linkage or adsorption on the electrode surface.

Concerning the neutral medium, our ER study gives evidence for the Co(II)/Co(I) system which has never been previously determined by bulk voltammetric studies. However, the proximity of potentials corresponding to water reduction and the possibility of demetalation reaction complicate the characterization of the bulk system.

Our results show that electroreflectance coupled with capacitance and voltammetric measurements appears to be a powerful technique in studying both spectroscopic and electrochemical properties of porphyrin derivative.

Electroreflection allows the investigation of electrode modified by adsorbed species and might be applied to other modified electrodes with good reflectance properties.

Electrochemical Activity in KOH Electrolyte of Carbon-Based Air Electrodes Containing Polymeric Iron Phthalocyanine by Direct Synthesis Methods

Toshiro Hirai and Jun-ichi Yamaki*

Nippon Telegraph and Telephone Corporation, Ibaraki Electrical Communication Laboratories, Tokai, Ibaraki-ken 319-11, Japan

ABSTRACT

Polymeric iron phthalocyanine (poly-FePc) was synthesized directly onto carbon supports, and carbon-based electrodes were fabricated using the carbon supports. Three synthesis methods, melt, liquid-phase, and gas-phase, were studied. Then activity on O₂ reduction in KOH solution was compared among three electrodes. The electrode obtained by melt synthesis showed the lowest polarization and maintained the most positive potential at a 10 mA/cm² discharge. The activity of poly-FePc was in the order: melt > liquid-phase > gas-phase synthesis methods. Comparing the activity of poly-FePc for the melt synthesis electrode with that for the electrode-impregnated poly-FePc from poly-FePc/conc. H₂SO₄ solution, the former showed a lower polarization and a smaller potential drop for a 10 mA/cm² discharge.

Polymeric iron phthalocyanine (poly-FePc) is reported to be a better catalyst for oxygen reduction than monomeric FePc (1). For this reason, poly-FePc as well as monomeric FePc has been examined by many authors (2-6). In these studies, poly-FePc was supported on carbon either by *in situ* gas phase methods or by an impregnation method.

Kreja and Plewka (7, 8) examined the catalytic activity of poly-FePc directly synthesized on carbon supports by a melt method. They synthesized a poly-FePc, which had few units lacking Fe central atoms, by increasing the ratio of FeCl₃/pyromellitic dianhydride (PA). They showed that the electrochemical activity of poly-FePc increased with an increase in this ratio. However, the activity and stability of poly-FePc using this method were almost the same as those of impregnated poly-FePc from poly-FePc/conc. H₂SO₄ solution (8).

In this paper, the excellent catalytic effect of poly-FePc on the carbon supports deposited by a direct synthesis method different from that adopted by Kreja and Plewka is reported. Although several methods have been previously given for the synthesis of polymeric metal phthalocyanines (9-11), in this case 1,2,4,5-tetracyanobenzene (TCB) was used as one of the reactants instead of PA in order to increase the poly-FePc yield. We then examined the influences of different synthesis methods, optimum synthesis condition, and optimum poly-FePc loadings by polarization and discharge measurements. Furthermore, it was shown that the direct synthesis method leads to a higher electrochemical activity and stability of poly-FePc than the impregnation method.

Experimental

Catalyst preparation methods.—Catalysts were supported in two different ways.

The first way was direct synthesis, for which the following three methods were adopted. (i) The melt method, where TCB, FeCl₃ (Tokyo Chemical Industry Company), urea (Kanto Chemical Company), and carbon supports were mixed and heated in an N₂ atmosphere. TCB was prepared from PA (Tokyo Chemical Industry Company), urea, and SOCl₂ (Kanto Chemical Company) according to the method reported by Epstein *et al.* (10), except using SOCl₂ instead of COCl₂. The synthesis was carried out under all combinations of temperature (300°, 350°, 400°, 450°, and 500°C) and reaction time (18, 40, 70, and 140h). The reaction was then continued at a temperature 50°C higher for an additional 2h. The product was finally extracted with pyridine and then with methanol until the washing solvent became colorless. (ii) The liquid-phase method, where the same materials as used in the melt method were mixed with 100 ml of ethylene glycol and heated at
