

A Statistical Study of Sources of Variation in Primary Battery Testing

K. Y. Cheung,* W. S. Lindsay, and D. J. Friedland*

Allied Corporation, Buffalo Research Laboratory, Buffalo, New York 14210

ABSTRACT

An analysis of variance (mixed model) experimental design was employed to quantify sources of variation in primary battery testing procedures for lithium/fluorinated carbon (CF_x) systems. Factors investigated were mix repeatability, mix uniformity, electrode fabrication method, and cell assembly and testing. Parameters measured were percent utilization and closed-circuit voltage (CCV) at various depths of discharge (DOD). The standard deviations (for a random cell from a random blend on a random day) for percent utilization and CCV at 50% DOD were 4.2 percentage points (0.49 relative standard deviation) and 16 mV (0.006 relative standard deviation), respectively, indicating that the test method was adequate for evaluation of the performance of different CF_x samples. No significant difference due to electrode fabrication method in any of the measured parameters was observed. The CCV at 50% DOD was identified as the representative quantity of the performance of a CF_x sample. Improvements have been made in the areas of variability identified by this study, leading to more consistent test results.

Extensive study of nonaqueous lithium batteries incorporating fluorinated carbon (CF_x) as a cathode has resulted in commercialization of lithium/carbon monofluoride battery (1-6). The system offers a very stable high discharge voltage (about 2.6V on 1 k Ω load) during 85% of its discharge life, excellent shelf life, and a wide range of operating temperatures. It is used as a backup power supply for volatile computer memory and is a primary power supply in the disk camera, digital watches, and other electronic devices where a portable energy source is required.

We have found large variations in the performance of CF_x samples from different manufacturers and batches. Because no physical or chemical property can reliably predict electrical performance, a battery testing procedure has been developed to evaluate the performance of CF_x prepared from different carbon starting materials under various process conditions.

Any test procedure will be subject to a number of variations other than the intrinsic characteristics of the material of interest. It is very important to separate these variables from the intrinsic properties, so that differences of materials can be investigated. To differentiate a good sample from a bad one, it is necessary to know the precision (standard deviation) of the test method; this allows one to assess the difference that the method is able to detect. We have applied components of variance analysis to our test procedure in order to determine the precision of the test and the contribution of each factor to the overall variation. We also intend to determine in this study a representative quantity of the battery performance of CF_x samples for comparison purposes. In this paper, the results of the statistical study are presented.

Statistical Background

In many scientific test procedures, it is often desirable not only to know the major sources of variation in the experimental data, but to quantify the effect of each factor. The components-of-variance method allows a quantitative analysis. Having identified the major sources of variation, one can improve the test by reducing the contribu-

tions of these major sources. This section explains briefly how the experimental design was set up and discusses some of the terms used in analysis of variance studies.

Proper planning is very important for a meaningful analysis of variance design. Practical experience of the researcher is very helpful in determining what factors should be investigated. Four factors were selected for the analysis of variance design in our study: preparation of the cathode mixture (blend), electrode fabrication methods (method), between-run repeatability (day), and within-run repeatability (cell). The interactions between method and blend, and between method and day, were also investigated. Six cathode mixtures were prepared using one single batch of CF_x , and each mixture was used on two separate days for a total of 12 days. The experimental procedures for a given mixture on a given day consisted of preparing two electrodes for each of the electrode fabrication methods and discharging these electrodes in laboratory test cells with a constant load. A schematic diagram of the design is given in Fig. 1. In the model below, the cell effect, or within-run repeatability, is referred to as either the random experimental error or the noise effect. Although it is true that experimental error is always present in an experiment, it is considered a selected factor here because we made the choice to run a statistical design in which this experimental error could be separated from the other effects by making repeat runs.

Once the factors (potential sources of variation) were identified, the following mathematical model was postulated

$$X_{ijk} = \bar{X}' + M'_i + B'_j + (MB)'_{ij} + D'_{k(j)} + (MD)'_{1k(j)} + E'_{eijk}$$

where

- X_{ijk} = an observation on method i , blend j , day k
- \bar{X}' = average effect
- M'_i = method effect $i = 1, 2$ (fixed effect)
- B'_j = blend effect $j = 1, 2, 3, 4, 5, 6$ (random effect)
- $(MB)'_{ij}$ = method-blend interaction effect (assumed to be a random effect)
- $D'_{k(j)}$ = day effect $k = 1, 2$ (random effect)

* Electrochemical Society Active Member.

Factor in the Design

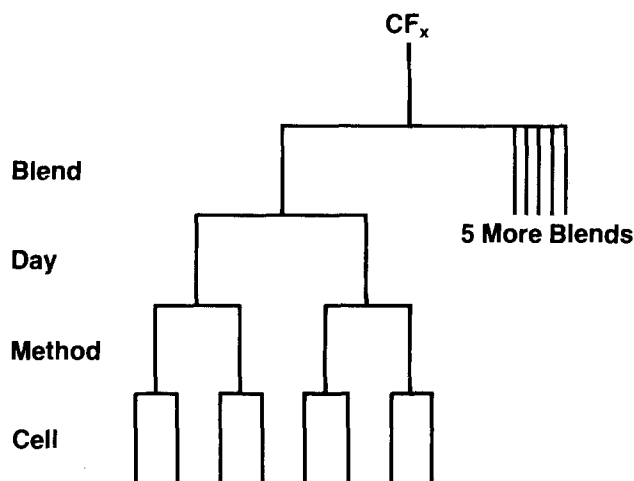

Fig. 1. The statistical design

$(MD)'_{(ikj)}$ = method-day interaction effect (assumed to be a random effect)

$E'_{e(ijk)}$ = random error, cell effect, noise, repeat effect, $e = 1, 2$ (random effect)

This model, in analysis of variance terminology, is a mixed model due to the inclusion of random and fixed effects.

After the model was expressed and the levels of all the factors had been decided, an important mathematical expression known as the expected mean square (EMS) was derived for each factor (Table I). The EMS is the mean square to be expected if the model is correct. Each factor's variance component was determined from the appropriate EMS expression, using a computer program. The EMS expressions were also used to determine which mean squares should be compared in order to test for the statistical significance of effects. For example, in order to determine if the variance component due to "blend" is significantly different from zero, it must be compared to the variance component due to "days." This comparison of ratios is known as the F-test. The resulting F-ratio is compared with published values in statistical F-tables using the proper degrees of freedom associated with the numerator and denominator for each F-ratio. If the observed F-ratio exceeds the tabulated value at some predetermined confidence level, then statistical significance is concluded at that level of confidence. A derivation of an EMS expression is involved, and a simple algorithm (7) has been developed to formulate the EMS expression for each factor in an analysis of variance design. The algorithm makes use of the specified model, whether the factors are fixed or random, and of the levels of each factor. The EMS expressions can be formulated manually, or analysis of variance programs (such as BMDP8V) from the BMDP statistical software package (8) can be used.

There are inseparable subsources of variation contained in the factors selected for this study. The results of this study will reveal the collective contribution of these subfactors to the overall variance. The "blend" factor con-

tains the uniformity of CF_x , the variation of composition in other components, and the repeatability of the mixing method. When a cathode mix is divided into two portions, each run on separate days, the uniformity of the mix is the primary source of variation in the "day" factor. Two electrode fabrication methods are studied: forming a large pellet using all the cathode mix and cutting out electrode pieces for tests (method A); and sampling material from the cathode mix to form electrodes and use as formed (method B). The subfactors included in "method," therefore, are the difference in sampling from both the large pellet and the mix, the pressures of forming the pellets, and the geometric areas. The "cell" factor is similar to the repeatability of a test, consisting of the variation in cell assembly, the environmental factors such as temperature, and the inherent error of the test method. Table II lists the summary of these components in the investigated factors. Results will be discussed in terms of the components which are believed to be the most important (underlined in Table II).

The situation of the interacting factors is more complicated because the numbers of subfactors and interactions are increased. The two interactions (method \times blend and method \times day) considered in this study contain primarily the compounding effects of different fabrication methods and the uniformity of cathode mix. For example, different pelletizing pressures may have enhanced the difference in composition of electrodes, leading to different morphologies in the resultant electrode species. Due to their random nature in contributing to the test results, and in order to evaluate the individual effect of method and uniformity of the mix, we have considered these interactions as a part of the "cell" factor in the discussion of results.

Experimental Section

Preparation of cathode blends.—Six blends containing, by weight, 1 part CF_x (Ozark Mahoning, Lot RT-11-4A), 0.2 parts carbon (Electrodag[®] 230, obtained from Acheson Colloids), and 0.2 parts PTFE (Fluon[®] AD1, obtained from ICI Americas) were prepared in the same way. Electrodag (1.05g) was added to about 20 ml of isopropyl alcohol in a 150 ml beaker and was dispersed by placing the beaker in an ultrasonic bath for about 3 min. CF_x (1.2g) was then added and dispersed in the same way. The pH of the dispersion was adjusted to 10 by dropwise addition of 7.4N NH_4OH , and 0.29 ml of the PTFE dispersion was added with stirring. Once again, the beaker was placed in the ultrasonic bath to assure homogeneity. Finally, solvent was removed by heating on a hot plate, causing coagulation of the dispersion.

Fabrication of electrodes.—Half of each mixture was used to form two 9.5 mm diam pellets at 6.2×10^7 Pa and one 28.6 mm diam pellet at 4.8×10^7 Pa. The three pellets were then heat-treated at 250°C under vacuum for 3h. Two 7×7 mm² electrode pieces were cut from the 28.6 mm pellet. The two 9.5 mm pellets (geometric area 71.3 mm²) and the two cut pieces (geometric area 49 mm²) were tested for battery performance.

Test cell assembly.—The electrolyte used in our tests was 1M $LiBF_4$ in an equal volume mixture of propylene carbonate (PC) and 1,2-dimethoxyethane (DME). The lith-

ium salt was obtained from Ozark-Mahoning and dried at 100°C under vacuum. The solvents, purchased from Burdick and Jackson, and Aldrich, respectively, were dried by refluxing with CaH_2 , followed by distillation under reduced pressure for PC and under argon atmosphere for DME. The dried components were transferred into a Vacuum-Atmosphere dry box, and the salt was dissolved in the mixed solvent. The electrolyte was further purified by electrolysis at 2.5V between two lithium electrodes, filtered, and stored over 3A molecular sieves in the dry box.

Test cells, employing a 12.7 mm diam drilled-through PTFE Swagelok® union (Fig. 2), were assembled entirely in the dry box. The CF_x cathode and the lithium anode were separated by a nonwoven polypropylene absorber (Permion® A-1260 supplied by RAI Research Corporation) soaked with the electrolyte. The sandwich was placed between two 304 stainless steel pistons, through which the electrical contact was made.

Data acquisition and analysis.—The assembled test cell was removed from the dry box and discharged across a 10 k Ω resistor. The discharge voltage was recorded every 2h using a HP-3497 multiplexor/voltmeter (measurement precision = 0.3 mV) controlled by a HP-85 computer. The typical discharge curves for this CF_x material are shown in Fig. 3. Because of the sloping nature of these curves, it is not apparent which closed-circuit voltage (CCV) is most representative of the discharge characteristics of the material. Three of the quantities used in this study as measures of battery performance are noted on this figure: discharge voltage at 50% DOD (V_1), 66.7% DOD (V_2), and at 2/3 of the time to the cutoff voltage (V_3). The MINITAB (9) subsystem installed on a Hewlett-Packard Model 3000 computer was used to extract these values from the discharge data. The time to a 2V cutoff was determined by applying the linear regression capabilities of the MINITAB package to the last five ex-

Fig. 3. Typical discharge performance of CF_x electrodes. (—) fabricated using method A; (---) fabricated using method B.

perimental data points, including the first one below 2V. The discharge voltages at 50 and 66.7% DOD were determined by applying the linear regression method to the five data points closest to the desired depth of discharge. The time needed to reach the CCV values differs from cell to cell due to the different weight of electrodes. The average discharge time of 6 typical cells to V_1 , V_2 , V_3 , and cut off voltage is 68, 92, 80, and 119h, respectively.

The fourth measure of battery performance, percent utilization of CF_x , is calculated from the theoretical energy and the energy actually delivered to a 2V cutoff. The theoretical energy is calculated from the weight and fluorine content of the CF_x in the cathode. The delivered energy is determined by integration of the discharge curve prior to the 2V cutoff, using the trapezoid method. Graphical analysis (10) of the data was performed (Fig. 4-7) to identify any outliers which would unduly influence the analysis. An example of an outlier is seen in Fig. 4 for blend 3, method A, day 2. Also, the cell prepared from blend 2 using method B and tested on day 1 is an obvious outlier, as shown in Fig. 5-7. In Fig. 6, the result for blend 4, method B, day 1 also appears to be an outlier. These suspected outliers were verified using statistical methods (Nair's statistic) (11). For every outlier, a value equal to the average of the other values from the mix was assigned before the variance components were calculated. By doing so, the requirement of the analysis of variance program for an equal number of observations per blend was met. Also, the statistical significance of the analysis was not changed any more than that introduced

by discarding the outliers. The total variance in the measured parameters was separated into the components due to the sources investigated using an analysis of variance program (BMDP8V) from the BMDP statistical software package (8). The computational aspects of analysis of variance will not be discussed here, but many textbooks (12) and journal articles (13) are available which provide the necessary details.

Results and Discussion

The results of the statistical analysis are given in Table III. The standard deviation, as determined by the square root of the total variance of the significant random effects, of percent utilization is 4.2 percentage points (0.49 relative standard deviation). In other words, the precision of the percent utilization determined by our test method is ≈ 4.2 . For the CCV at 50% DOD (V_1) and at 2/3 the time to the cutoff voltage (V_3), the precision is ≈ 16 mV (0.006 relative standard deviation). For the CCV at 66.7% DOD (V_2), the precision is ≈ 38 mV (0.015 relative standard deviation). The CCV precisions are very meaningful quantities when compared to an instrument precision of 0.3 mV. These figures are very close to the acceptable range generally employed in the battery manufacturing industry. This signifies that our test method is adequate for evaluating the battery performance of the fluorinated carbon material.

If a single CCV value had to be chosen as representative of the discharge characteristics of a CF_x sample, V_1 would be a suitable choice. It can be determined precisely, as the standard deviation suggests. Examination of the dis-

Table III. Distribution of variance by sources

	% Utilization	CCV at 50% U (V_1)	CCV at 66.7% U (V_2)	CCV at 2/3 the time to cutoff (V_3)
Standard deviation	4.2	0.016	0.038	0.016
Source	% of total variance			
Mix repeatability	NS	16	3	33
Mix uniformity	44	8	2	NS

Cell assembly and testing	56	76	95	67

NS = not significant.

charge curve (Fig. 3) shows that V_1 is situated at the flat region of the curve and is therefore less susceptible to the variations in the test. V_2 is located nearest the vicinity where the discharge voltage begins to drop. The value of V_2 is therefore sensitive to small variations in battery testings. The choice of V_3 as one of the measured CCV values is rather arbitrary, and it is measured at different DOD for different cells. It is located in the region just before the CCV starts to drop and is therefore a more precise value than V_2 .

Examining the contribution of variance by source, no significant difference due to electrode fabrication method was observed in any of the measured parameters. This indicates that the different pressures used in forming the pellets and the different sampling procedures did not contribute any significant variation to the quantities measured in this study. It also indicates that the different geometric areas of the two types of electrodes in the test did not have any significant effect on the battery performance. The nominal discharge current density (2.6V on 10 k Ω) is 5.31×10^{-1} mA/cm 2 for 49 mm 2 electrodes and is 3.65×10^{-1} mA/cm 2 for 71.3 mm 2 electrodes. We did observe a detrimental effect on battery performances when the geometric area of the electrode was reduced to 36 mm 2 in tests outside of this statistical study. These data suggest that the electrodes formulated and fabricated in the way described can sustain the discharge current densities in the range of our study; when a higher current density is drawn from the cell, the battery performance could be more susceptible to small variations in the electrode formulation, leading to premature failure.

The variance in percent utilization is due to the "mix uniformity" and the "cell assembly and testing," the latter being the more important factor. "Cell assembly and testing" is the major component of variance in CCV values. Mix repeatability is also significant, particularly for V_3 . "Mix uniformity" for CCV values is insignificant compared with the effect it has on percent utilization.

The sample size required to detect a difference in performance between two cells depends on several criteria. The size of the difference to be detected, as well as the desired significance level, must be determined. As shown in Table III, the estimated standard deviation in V_1 for one random cell from a random blend on a random day is 16 mV. Two standard deviations is 32 mV. Therefore, the 95% confidence interval for V_1 would be $V_1 \pm 32$ mV. The largest variance component for V_1 is cell assembly and testing. Thus, the estimated standard deviation of V_1 is decreased by running additional cells. If four cells are tested for a given blend on a given day, the estimated standard deviation of V_1 is reduced to 10 mV, and the 95% confidence interval for V_1 is $V_1 \pm 20$ mV.

Conclusions

The test method described here is adequate for evaluating CF_x samples for nonaqueous lithium battery applications. The CCV at 50% DOD (V_1) is recommended as a representative quantity to measure the performance of a CF_x sample, due to the high precision of this quan-

tity. Fabrication and sampling methods have no significant effect on any of the performance parameters measured. The geometric area of an electrode also shows a null effect. However, if the area is excessively reduced, a detrimental effect will result. Based on our results, mix repeatability, mix uniformity, and cell assembly are the areas in which improvements can be made for more consistent test results. Factors like uniformities of CF_x , cathode mix and electrode in both composition and morphology, good electrical contact in the cell, and thorough wetting of the electrode would likely yield a significant improvement. Indeed, we have made progress along these lines and have now been able to reduce the standard deviation of V_1 to below 10 mV.

A General Energy Balance for Battery Systems

D. Bernardi,** E. Pawlikowski,* and J. Newman*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A general energy balance for battery systems has been developed. This equation is useful for estimating cell thermal characteristics. Reliable predictions of cell temperature and heat-generation rate are required for the design and thermal management of battery systems. The temperature of a cell changes as a result of electrochemical reactions, phase changes, mixing effects, and joule heating. The equation developed incorporates these effects in a complete and general manner. Simplifications and special cases are discussed. The results of applying the energy balance to a mathematical model of the LiAl/FeS cell discharged through two different reaction mechanisms are given as examples. The examples illustrate how the energy equation may be applied to a specific system to examine the relative contributions corresponding to the terms in the equation. The examples show that the processes involved in cell heat generation may be complex and that the application of a sufficiently general energy equation is advantageous.

Energy balance calculations are required for the design and thermal management of battery systems. A proper cell energy balance will give reliable predictions of thermal characteristics such as heat generation and temperature-time profiles. In this work, we present a general energy-balance equation for battery systems. This equation includes energy contributions from mixing, phase changes, and simultaneous electrochemical reactions with composition-dependent open-circuit potentials. Such a thorough treatment has not appeared in the literature.

The problem of determining heat effects with simultaneous electrochemical reactions was first addressed by Sherfey and Brenner in 1958 (1). They presented an equation for the rate of thermal energy generation in terms of the current fraction, the entropy change, and the overpotential for each reaction. Later, Gross (2) presented essentially the same equation, but introduced a quantity called the enthalpy voltage for each reaction. The enthalpy voltage is the enthalpy of reaction per coulomb of charge, and it may be derived from the overpotential and the entropy change terms in Sherfey and Brenner's equation. These treatments are restricted in their application to cell reactions in which every reactant is present in a single, pure phase. Gibbard (3) discussed the calculation of thermodynamic properties of battery systems when some of the reactants are dissolved in solution; however, his treatment of the energy balance considers the case of a single reaction without mixing effects.

Numerous researchers (1, 2, 4-8) have adopted experimental approaches and used calorimetry to determine heat output directly. Dibrov and Bykov (5) used calorimetric data and enthalpy voltages to determine current fractions of the reactions of cadmium-silver-oxide and zinc-silver-oxide cells.

The formulation of a general energy balance is useful in developing a fundamental understanding of the processes involved in cell heat generation. However, in its most rigorous form, the energy balance presented is difficult to apply without a detailed mathematical model because instantaneous composition profiles and current fractions are required. For example, Tiedemann and Newman (9) have developed such a model for the lead-acid cell. A model for the lithium-aluminum iron-sulfide battery was presented by Pollard and Newman. (10, 11) These models do provide the necessary information needed to calculate the thermal characteristics from an energy balance such as the one presented in this work; however, these works utilize a relatively simple energy equation in which mixing effects are ignored and a single cell reaction occurs. Pollard's model calculates current fractions of the two simultaneously occurring reactions, but the fractions are not utilized in the energy balance. In practice, it is difficult to obtain concentration profiles and to predict the partitioning of current among possible reactions. However, applying an energy equation that includes the effects of simultaneous reactions to experimental measurements will allow the calculation of the current fractions. In this work, simplifications and special cases of the general energy equation are discussed. The results of

applying the energy balance to a mathematical model of the LiAl/LiCl-KCl/FeS cell are given as examples. The relative contributions corresponding to the terms in the equation are examined.

The Energy Balance

In this section, the general energy balance for a battery system will be derived. The temperature of the battery is assumed to be uniform throughout and changes with time to be determined by the following processes

- (1) reactions
- (2) changes in the heat capacity of the system
- (3) phase changes
- (4) mixing
- (5) electrical work
- (6) heat transfer with the surroundings

A battery may be thought of as a composite of many discrete phases that are changing in energy content. It is assumed that these phases are interacting by way of electrochemical reactions, phase changes, and mixing processes. The first law of thermodynamics may be written as

$$\frac{dH_{\text{tot}}}{dt} = q - IV \quad [1]$$

where H_{tot} is the sum of the enthalpies of the phases expressed as

$$H_{\text{tot}} = \sum_i \int_{v_j} \left[\sum_i c_{i,j} \bar{H}_{i,j} \right] dv_j \quad [2]$$

and i and j denote the individual species and phase, respectively. The term q represents the rate of heat transfer with the surroundings, and IV is the electrical work. It is convenient to define an average composition for each of these phases and write dH_{tot}/dt as

$$\frac{dH_{\text{tot}}}{dt} = \frac{d}{dt} \sum_j \sum_i \left[n_{i,j} \bar{H}_{i,j}^{\text{avg}} + \int_{v_j} c_{i,j} (\bar{H}_{i,j} - \bar{H}_{i,j}^{\text{avg}}) dv_j \right] \quad [3]$$

The first term on the right side of Eq. [3] represents the rate of change of the enthalpy of the cell when all species are present at their average composition. The second term is a correction accounting for composition variations. In the development that follows, the first term in Eq. [3] will be split into three separate terms. Applying the product rule for differentiation and recalling that

$$\left(\frac{\partial \bar{H}_{i,j}^{\text{avg}}}{\partial T} \right)_p = \bar{C}_{p,i,j}^{\text{avg}} \quad [4]$$

we obtain

$$\sum_j \sum_i \frac{d}{dt} (n_{i,j} \bar{H}_{i,j}^{\text{avg}}) = \sum_j \sum_i \left[n_{i,j} \bar{C}_{p,i,j}^{\text{avg}} \frac{dT}{dt} + \bar{H}_{i,j}^{\text{avg}} \frac{dn_{i,j}}{dt} \right] \quad [5]$$

for the first term in Eq. [3].

It is assumed that there are several simultaneous electrode reactions of the form

$$\sum_i s_{i,l} M_i^{z_i} = n_l e^- \quad [6]$$

occurring within the battery. The reactions are written so that species i is always in phase m , having a certain secondary reference state. For example, in a LiCl-KCl molten salt cell, all the electrode reactions are written so that the ionic lithium species is always present in the molten electrolyte phase and so that any precipitation of LiCl is accounted for separately.

A species balance may be written as

$$\frac{dn_{i,m}}{dt} = \sum_i \frac{s_{i,l} I_l}{n_i F} - \sum_{j,j \neq m} \frac{dn_{i,j}}{dt} \quad [7]$$

The first term on the right side of Eq. [7] represents the amount of i that is produced or consumed by electrode reactions. The partial current, I_l , is positive for a cathodic

reaction and negative for an anodic reaction. The second term accounts for phase changes such as the LiCl precipitation mentioned above. Integration of Eq. [7] yields

$$n_{i,m} = n_{i,m}^0 - \sum_{j,j \neq m} (n_{i,j} - n_{i,j}^0) + \sum_l \frac{s_{i,l}}{n_i F} \int_0^t I_l dt \quad [8]$$

We may express partial molar enthalpies in the form

$$\bar{H}_{i,m}^{\text{avg}} = H_{i,m}^0 - RT^2 \frac{d}{dT} \ln (a_{i,m}^{\text{avg}}) \quad [9]$$

The theoretical open-circuit potential for reaction l at the average composition, relative to a reference electrode of a given kind, is given by

$$U_{i,\text{avg}} = U_l^0 - U_{\text{RE}}^0 + \frac{RT}{n_{\text{RE}} F} \sum_i s_{i,\text{RE}} \ln (a_{i,\text{RE}}) - \frac{RT}{n_l F} \sum_i s_{i,l} \ln (a_{i,m}^{\text{avg}}) \quad [10]$$

By utilizing the Gibbs-Helmholtz relation for each reaction, we may write the standard reaction enthalpy in terms of the standard cell potential

$$\sum_i \frac{s_{i,l}}{n_l F} H_{i,m}^0 = T^2 \frac{d}{dT} \left(\frac{U_l^0}{T} \right) \quad [11]$$

Looking at Eq. [5] and [7], we can see that the contribution to the rate of enthalpy change associated with the electrode reactions may be written as

$$\sum_m \sum_i \bar{H}_{i,m}^{\text{avg}} \sum_l \frac{s_{i,l} I_l}{n_l F} = \sum_m \sum_l \frac{I_l}{n_l F} \sum_i \bar{H}_{i,m}^{\text{avg}} s_{i,l} \quad [12]$$

Using Eq. [9] and [11], we may write this contribution in terms of the electrode reaction potentials

$$\sum_m \sum_l \frac{I_l}{n_l F} \sum_i \bar{H}_{i,m}^{\text{avg}} s_{i,l} = \sum_l I_l \left[T^2 \frac{d}{dT} \left(\frac{U_l^0}{T} \right) - \frac{RT^2}{n_l F} \sum_i \frac{d}{dT} \ln (a_{i,m}^{\text{avg}})^{s_{i,l}} \right] \quad [13]$$

Using Eq. [10], we may write Eq. [13] in terms of the theoretical open-circuit potentials relative to a reference electrode of a given kind as

$$\sum_l I_l \sum_m \sum_i \frac{\bar{H}_{i,m}^{\text{avg}} s_{i,l}}{n_l F} = \sum_l I_l \left[T^2 \frac{d}{dT} \left(\frac{U_{l,\text{avg}}}{T} \right) \right] \quad [14]$$

The quantity multiplying I_l on the right and left sides of Eq. [14] is sometimes termed the enthalpy voltage of reaction l .

Substitution of Eq. [7], [8], and [14] into Eq. [5] and placing this result into Eq. [3] results in the final form for dH_{tot}/dt . Equating this to $q - IV$ (Eq. [1]) gives the following form for the energy-balance equation

Table I. Model discharge mechanisms in the FeS electrode

Reaction	a_l^0 [V]	$b_l \times 10^3$ [V/K]
Mechanism 1 (X-phase intermediate)		
1) $2\text{FeS} + 2\text{Li} + 2e^- \rightarrow \text{Li}_2\text{FeS}_2 + \text{Fe}$ (X-phase)	1.367	-0.022
2) $\text{Li}_2\text{FeS}_2 + 2\text{Li}^+ + 2e^- \rightarrow 2\text{Li}_2\text{S} + \text{Fe}$	1.454	-0.178
Mechanism 2 (J-phase intermediate)		
3) $26\text{FeS} + \text{Li}^+ + \text{Cl}^- + 6\text{K}^+ + 6e^- \rightarrow \text{LiK}_6\text{Fe}_{26}\text{S}_{26}\text{Cl} + 2\text{Fe}$ (J-phase)	1.955	-0.680
4) $\text{J} + 51\text{Li}^+ + 46e^- \rightarrow 26\text{Li}_2\text{S} + 24\text{Fe} + 6\text{K}^+ + \text{Cl}^-$	1.440	-0.024

^a a_l and b_l were obtained from Ref. (13).

$$q - IV =$$

$$\begin{aligned} & \sum_I \left[I_1 T^2 \frac{d \frac{U_{1,avg}}{T}}{dT} \right] \text{enthalpy-of-reaction} \\ & - \sum_j \frac{d}{dt} \left[\int_{v_j} \sum_i c_{i,j} R T^2 \frac{\partial}{\partial T} \ln \left(\frac{\gamma_{i,j}}{\gamma_{i,j}^{avg}} \right) dv_j \right] \text{enthalpy-of-mixing} \\ & - \sum_{i,j \neq m} \sum_i \left[\left(\Delta H_{i,j \rightarrow m}^0 - R T^2 \frac{d}{dT} \ln \frac{\gamma_{i,m}^{avg}}{\gamma_{i,j}^{avg}} \right) \frac{dn_{i,j}}{dt} \right] \text{phase-change} \\ & + \frac{dT}{dt} \left[\sum_j \sum_i n_{i,j}^0 \bar{C}_{p,i,j}^{avg} + \sum_i \int_0^t \frac{I_1 dt}{n_i F} \Delta C_{p,i} \right] \text{heat-capacity} \\ & + \sum_{i,j \neq m} \sum_i \left(\bar{C}_{p,i,j}^{avg} - \bar{C}_{p,i,m}^{avg} \right) (n_{i,j} - n_{i,j}^0) \end{aligned} \quad [15]$$

where

$$\Delta C_{p,i} \equiv \sum_i s_{i,i} \bar{C}_{p,i,m}^{avg} \quad [16]$$

and

$$\Delta H_{i,j \rightarrow m}^0 \equiv H_{i,m}^0 - H_{i,j}^0 \quad [17]$$

It should be recognized that all the composition dependence of Eq. [15] may be expressed in terms of activity coefficients ($a_{i,j} = x_{i,j} \gamma_{i,j}$). This is a reflection of the fact that the composition dependence of any thermodynamic quantity is completely determined if the activity coefficient behavior of the species is known. This analysis does not include enthalpy changes associated with nonfaradaic reactions. However, reactions such as self-discharge or corrosion may be divided into anodic and cathodic components and included in the enthalpy-of-reaction term (other reactions must be accounted for and included as an additional term). Also, the heat capacities of the battery support materials should be understood to be included in Eq. [15]. Actually, in most practical applications, the heat capacity of a battery module does not change substantially during operation. In such cases, the heat-capacity term may be replaced by some average value. Also, the rate of heat transfer q between the battery and surroundings may be expressed as

$$q = -hA(T - T_A) \quad [18]$$

where the heat-transfer coefficient h is based on separator area and is estimated from the heat losses for a battery module.

As an example of how Eq. [15] may be used, let us apply it to the LiAl/LiCl-KCl/FeS battery. We shall assume that any number of reactions may be occurring and that all the reacting phases are pure except the electrolyte. The molten LiCl-KCl electrolyte phase is considered to be a solution of varying composition throughout the battery. The species present are the Li^+ , K^+ , and Cl^- in the electrolyte and those corresponding to the pure reacting phases. The open-circuit-potential data are considered to be given at the eutectic composition of the electrolyte as a reference condition and to be of the form $U_{1,eut} = a_1 + b_1 T$. All the electrode reaction potentials are given relative to the two-phase (α , β) LiAl-alloy reference electrode. It is convenient that this is also the negative electrode material. We may relate $U_{1,eut}$ to $U_{1,avg}$ by

$$U_{1,avg} = U_{1,eut} - \frac{RT}{F} \ln \left[\left[\frac{a_{\text{LiCl}}^{avg}}{a_{\text{LiCl}}^{eut}} \right]^{\frac{S_{\text{Li}^+, \text{Li}}}{n_1}} \left[\frac{a_{\text{LiCl}}^{avg}}{a_{\text{LiCl}}^{eut}} \right]^{-\frac{S_{\text{Li}^+, \text{RE}}}{n_{\text{RE}}}} \left[\frac{a_{\text{KCl}}^{avg}}{a_{\text{KCl}}^{eut}} \right]^{\frac{S_{\text{K}^+, \text{Li}}}{n_1}} \right] \quad [19]$$

The resulting equation will allow for precipitation of pure LiCl and pure KCl solid phases. With the above considerations, Eq. [15] becomes

$$\begin{aligned} MC_p^m \frac{dT}{dt} &= -hA(T - T_A) - IV \\ &+ \sum_I I_1 \left[a_1 + \frac{RT^2}{F} \frac{d}{dT} \ln \left[\left(\frac{\gamma_{\text{LiCl}}^{avg}}{\gamma_{\text{LiCl}}^{eut}} \right)^{\frac{S_{\text{Li}^+, \text{Li}}}{n_1}} \left(\frac{\gamma_{\text{LiCl}}^{avg}}{\gamma_{\text{LiCl}}^{eut}} \right)^{-\frac{S_{\text{Li}^+, \text{RE}}}{n_{\text{RE}}}} \left(\frac{\gamma_{\text{KCl}}^{avg}}{\gamma_{\text{KCl}}^{eut}} \right)^{\frac{S_{\text{K}^+, \text{Li}}}{n_1}} \right] \right] \\ &+ \frac{d}{dt} \int_v \epsilon R T^2 \left[c_{\text{LiCl}} \frac{\partial}{\partial T} \ln \left(\frac{\gamma_{\text{LiCl}}}{\gamma_{\text{LiCl}}^{avg}} \right) + c_{\text{KCl}} \frac{\partial}{\partial T} \ln \left(\frac{\gamma_{\text{KCl}}}{\gamma_{\text{KCl}}^{avg}} \right) \right] dv - \frac{dn_{\text{LiCl}_s}}{dt} \left[\Delta H_{\text{LiCl}_s}^0 + R T^2 \frac{d \ln \gamma_{\text{LiCl}}^{avg}}{dT} \right] - \frac{dn_{\text{KCl}_s}}{dt} \left[\Delta H_{\text{KCl}_s}^0 + R T^2 \frac{d \ln \gamma_{\text{KCl}}^{avg}}{dT} \right] \end{aligned} \quad [20]$$

where dn_{LiCl_s}/dt and dn_{KCl_s}/dt are the crystallization rates of solid LiCl and KCl phases, respectively. There is a considerable amount of simplification involved in going from Eq. [15] to Eq. [20]. For example, the ionic activity coefficients, ionic concentrations, and ionic partial molar enthalpies have been combined into neutral combinations that refer to undissociated LiCl and KCl. If the electrolytes were considered to be completely dissociated, then Eq. [15] could be rearranged to contain mean ionic activity coefficients (neutral combinations of individual ionic activity coefficients).

In the next section, each of the terms in Eq. [15] will be discussed. Afterwards, Eq. [20] will be applied more specifically to the LiAl/FeS cell.

Discussion of Terms

Enthalpy-of-reaction.—If we use an average heat capacity and do not consider enthalpy-of-mixing and phase-change terms, then Eq. [15] may be written as

$$q = IV + \sum_I I_1 \left[T^2 d \frac{U_{1,avg}}{dT} \right] + MC_p^m \frac{dT}{dt} \quad [21]$$

During discharge, the chemical energy of the cell is directly converted into work in the form of electricity. The work that the cell delivers is maximum when the cell op-

erates reversibly. This reversible work, expressed as a rate, can be written as

$$IV_{\text{rev}} = \sum_i I_i [U_{i,\text{avg}}] \quad [22]$$

and is tucked into the enthalpy-of-reaction term. The difference between V_{rev} and V is the cell overpotential. The overpotential is indicative of irreversibilities such as ohmic losses, charge-transfer overpotentials, and mass-transfer limitations. The overpotential multiplied by the current is termed the polarization heat and is composed of the joule heating within the battery, as well as the energy dissipated in electrode overpotentials.

Also housed in this enthalpy-of-reaction term is the entropic-heat

$$q_{\text{rev}} = - \sum_i I_i \left[T \frac{d(U_{i,\text{avg}})}{dT} \right] \quad [23]$$

Equations [22] and [23] represent the power and the heat generation that accompany reversible isothermal cell operation, respectively. The reversible work is related to the change in Gibbs function of the cell's contents. The entropic-heat is related to the entropy change. We may write Eq. [21] in terms of these contributions as

$$q = \left[IV - \sum_i I_i U_{i,\text{avg}} \right] + \sum_i I_i T d \frac{U_{i,\text{avg}}}{dT} + MC_p^m \frac{dT}{dt} \quad [24]$$

Equations [22] and [23] have allowed the enthalpy-of-reaction and electrical work terms in Eq. [21] to be combined and restated as irreversible and reversible heat effects. This form is most convenient when dealing with reversible conditions because the polarization heat, $IV - \sum_i I_i [U_{i,\text{avg}}]$ is zero in that case. Furthermore, Eq. [24] is the form of the energy balance that is most commonly encountered in the literature. The composition dependence of the open-circuit potential is contained in $U_{i,\text{avg}}$ (see Eq. [10]). The original form (Eq. [21]) has an advantage in that a strong composition dependence of the two terms separately may partially cancel in the enthalpy voltage. Also, if the open-circuit potentials $U_{i,\text{avg}}$ are independent of composition and linearly related to temperature, then the enthalpy-of-reaction term becomes

$$- \sum_i I_i a_i \quad [25]$$

Notice that the temperature coefficients, b_i , are not needed and that the enthalpy voltage of reaction l is $-a_l$.

Enthalpy-of-mixing.—The enthalpy-of-mixing term represents the heat effects associated with generation or relaxation of concentration profiles. For example, if we do not consider phase-change terms, then this term represents the rate of heat generation after current interruption of cell operation. First, the definition of the average composition will be discussed. Later, an estimate of the adiabatic temperature rise due to relaxation of concentration profiles in a lead-acid cell after full discharge will be made.

The enthalpy-of-mixing term is the only term in Eq. [15] that is dependent on the spatial variation of composition. This term may be thought of as a correction because the other terms depend only on the average composition. The term is difficult to treat because it involves integrations of concentration profiles. Consequently, it is instructive to discuss the conditions under which it may be neglected. The definition of the average composition of species i is arbitrary. Therefore, if mixing effects are to be neglected, then the average composition should be chosen such that the value of this neglected term is minimized. For a binary phase, with components 1 and 2, it

can be shown that the integral in the mixing term may be minimized if the average concentration is defined as

$$c_1^{\text{avg}} = \frac{\int_v c_1 dv}{\int_v dv} \text{ or } x_1^{\text{avg}} = \frac{\int_v c x_1 dv}{\int_v c dv} \quad [26]$$

where

$$c = c_1 + c_2$$

This will be shown as follows. For a binary system, the integral in the mixing term in Eq. [15] may be written as

$$\int_v c [H - (x_1 \bar{H}_1^{\text{avg}} + x_2 \bar{H}_2^{\text{avg}})] dv \quad [27]$$

where the molar enthalpy is defined as

$$H = x_1 \bar{H}_1 + x_2 \bar{H}_2$$

and \bar{H}_i^{avg} is the partial molar enthalpy of species i at the average composition. It should be recognized that in this development it is assumed that the spatial variation of composition is fixed and that Eq. [27] is only a function of x_1^{avg} . By writing the mixing integral in this form, we may obtain a clearer interpretation of the mixing term. The sum subtracted from H is the tangent line to the enthalpy-*vs.*-composition ($H - x_1$) plot at the average composition. The integral may be considered to be a measure of the ability to approximate the H curve with a tangent, in the range of composition variation throughout the cell. Therefore, if the enthalpy curve is linear in this range, then \bar{H}_1 and \bar{H}_2 are independent of composition, and the integral is zero regardless of the value of x_1^{avg} . Also, if the activity coefficients are independent of temperature (see Eq. [9]), then mixing effects can be ignored. Different choices of the tangent, corresponding to different values of the average composition may give better or worse approximations of the enthalpy curve. Equation [27] may be minimized with respect to the average composition by solving the following equation for x_1^{avg}

$$\frac{d}{dx_1^{\text{avg}}} \left[\int_v c(x_1 \bar{H}_1^{\text{avg}} + x_2 \bar{H}_2^{\text{avg}}) dv \right] = 0 \quad [28]$$

In formulating Eq. [28], it was recognized that the composition profiles and enthalpy curve are independent of the choice of x_1^{avg} . We may further simplify Eq. [28] and write

$$\int_v c_1 dv \frac{d\bar{H}_1^{\text{avg}}}{dx_1^{\text{avg}}} + \int_v c_2 dv \frac{d\bar{H}_2^{\text{avg}}}{dx_1^{\text{avg}}} = 0 \quad [29]$$

The Gibbs-Duhem equation

$$x_1^{\text{avg}} \frac{d\bar{H}_1^{\text{avg}}}{dx_1^{\text{avg}}} + x_2^{\text{avg}} \frac{d\bar{H}_2^{\text{avg}}}{dx_1^{\text{avg}}} = 0 \quad [30]$$

may be applied, and Eq. [29] may be solved for x_1^{avg} as given in Eq. [26]. The corresponding development for multicomponent mixtures is given in Appendix A. Equation [26] is guaranteed to be the choice of the average composition that will minimize Eq. [27] only if the integral has simple behavior. The behavior is said to be simple if the second derivative of the integral is nonzero for all possible values of x_1^{avg} (in range of concentration variation throughout the cell). For example, if the integral has a point of inflection such that its value may be either positive or negative depending upon x_1^{avg} , then x_1^{avg} may be chosen so that the integral is zero. In this case, the best choice of the x_1^{avg} is not necessarily defined by Eq. [26]. Regardless of the behavior of the integral, Eq. [26] is the most convenient definition of the average composition. It has physical significance, and it is usually a simple function of state-of-charge. It is the final uniform composition of a concentration profile that is allowed to relax, and the energy effect associated with this process, in this case, is

proportional to the value of the integral for the initial profile.

It is useful to examine further the sign of the integral. The sign of Eq. [27] will indicate such things as whether mixing effects will tend to heat or cool a cell during operation. It is convenient now to look at Eq. [27] as a function of the mixing behavior and assume that the average composition in it is fixed. Equation [27] will be positive if

$$H > (x_1 \bar{H}_1^{\text{avg}} + x_2 \bar{H}_2^{\text{avg}}) \quad [31]$$

The right side of Eq. [31] is linear in x_1 . If Eq. [31] is differentiated twice with respect to x_1 , we obtain

$$\frac{d^2 H}{dx_1^2} > 0 \quad [32]$$

In other words, if in the range of concentration variation throughout the cell the enthalpy curve is always concave upward, then the integral will be positive. Conversely, the integral will be negative if the enthalpy curve is everywhere concave downward. For example, in the lead-acid cell, the sulfuric acid-water system has an enthalpy curve that is always concave upward. Consequently, the temperature of a well-insulated lead-acid cell will always increase after current interruption during operation due to relaxation of concentration profiles. To illustrate this, in Appendix A, Eq. [15] is used to estimate this temperature rise. The temperature rise, after full discharge, is approximately 1.6 K. It is also important to investigate the consequence of neglecting mixing effects in thermal calculations. For the lead-acid cell, the temperature during operation (generation of concentration profiles) is overestimated if calculations are made by neglecting the mixing term. The situation is reversed for a high-temperature cell employing LiCl-KCl electrolyte. In the range of concentration variation throughout this cell, the enthalpy curve is always concave downward and the cell temperature will decrease due to mixing effects after current interruption. Calculations that neglect mixing will give underestimations of temperature when concentration profiles are being generated (during cell operation). This will be investigated in greater detail later.

If the enthalpy curve, in the range of composition variation, may be concave upward or concave downward, then the sign of the integral depends on the choice of the average composition. Certain associated systems, such as ethanol and water, exhibit inflection points in their enthalpy curves.

Phase-change terms.—In the enthalpy-of-reaction term of Eq. [15], all the reactions have species i in the same phase m . For example, in Eq. [20], LiCl is always present as a molten LiCl-KCl solution phase in all reactions. However, one of the phases present in the cell during operation may be pure solid LiCl. The purpose of the phase-change terms is to account for the enthalpy change due to crystallization of this solid phase. For example, ice crystals form during low temperature operation of aqueous batteries, and an energy balance such as Eq. [23] would not correctly predict cell temperatures. If the m phase types in the enthalpy-of-reaction contribution (Eq. [15]) are the only phases present in the cell during operation, then the phase-change terms are zero.

Heat-capacity.—The quantities to the right of dT/dt in the heat-capacity term of Eq. [15] represent the heat capacity of the cell. This heat capacity changes with time because the composition of the cell changes due to electrochemical reactions and phase changes. The first part of this heat capacity represents the initial heat capacity of the cell's reactive material. The heat capacity of the cell's inert supporting material should be included in this part. The second and third parts account for changes in the initial heat capacity as a result of electrochemical reactions and phase changes, respectively.

As mentioned earlier, the total heat capacity of a typical cell (including supporting material) is approximately constant so that this term usually reduces to a simple expression.

Description of Examples

The results of applying Eq. [15] to the existing model of the LiAl/LiCl, KCl/FeS cell will be given. The purpose of these examples is to illustrate how the energy-balance equation may be applied to a specific system and to examine the relative contributions corresponding to the terms in this equation. The use of Eq. [15] is best illustrated by application to a mathematical model of a battery in which concentration profiles can be used to calculate energy contributions from mixing, and current fractions can be used to calculate energy contributions from simultaneous reactions. This model was originally developed by Pollard and Newman in 1981, and the details of the theoretical analysis are given in their publications (10, 11). The model gives the galvanostatic discharge behavior of a one-dimensional cell sandwich consisting of a porous LiAl negative electrode, porous FeS positive electrode, electrolyte reservoir, and separator. The model simulates the discharge processes in the positive by the two simultaneously occurring reactions given as mechanism 1 in Table I. Pawlikowski (12) in 1982 developed a model of the cell with mechanism 2 as the positive electrode discharge reactions. Mechanisms 1 and 2 yield the same overall reaction and differ mainly in the intermediate phase (X-phase or J-phase).

The electrochemistry of the FeS electrode is reasonably well understood. The actual discharge processes are complicated and are more like a mixture of the two proposed mechanisms along with simultaneously occurring chemical reactions. There is evidence, however, for the simple 2-reaction mechanisms under certain operating conditions (13). In practice, batteries are operated between 400° and 500°C. Higher operating temperatures and LiCl concentrations tend to favor mechanism 1. Lower temperatures and LiCl concentrations favor mechanism 2. Discharge through the X-phase intermediate is preferred because of the poor reversibility of the J-phase reactions. For purposes of comparison, the simulations of the two mechanisms will use the same initial temperature and electrolyte composition.

The model discharges are meant to simulate a well-insulated (but not adiabatic) battery operating in an ambient temperature environment with no external heating. The relevant input data and energy equation specific to each mechanism are given in Appendix B.

Results

Figure 1 gives the cell temperature as a function of utilization for both mechanisms. The dashed lines show the temperature profile for adiabatic and reversible discharge. Under these conditions the two mechanisms yield the same temperature at 100% depth of discharge because the overall reaction is the same. In both cases, the reactions are exothermic, so that the cell temperature increases throughout discharge. Though the adiabatic-reversible profile of mechanism 1 appears linear, there is actually a slight amount of curvature, due to the logarithmic dependence of the cell temperature. The composition dependencies associated with the J-phase reactions result in the more discernible curvature of each portion of the adiabatic-reversible profile of mechanism 2. The criterion of reversibility allows the stoichiometry of the reactions to yield the discontinuities in slope located at 50% and 12% for mechanism 1 and mechanism 2, respectively. For example, with mechanism 1 up to 50% utilization, only reaction 1 occurs, and after this point reaction 2 occurs. The dashed curve in Fig. 2 is the heat generation rate for reaction 1. It is approximately constant because the temperature is not changing substantially, and this is responsible for the apparent linearity in Fig. 1. With the J-phase reactions, the stoichiometry dictates that the transition from reaction 3 to reaction 4 occurs at 12% utilization.

It is interesting to compare these results to the results of the more realistic simulations. The solid lines in Fig. 1 are the results of the mathematical models. The relevant input data and energy equation specific to each mecha-

Fig. 1. Cell temperature as a function of utilization for mechanisms 1 and 2. The dashed lines are for adiabatic-reversible discharge. The solid lines are the results of the mathematical model simulations. Cutoff voltages of 1.2 and 1.0V were used for mechanisms 1 and 2, respectively.

nism are given in Appendix B. In these simulations, the irreversibilities associated with ohmic losses, migration effects, mass-transfer, and charge-transfer overpotentials cause electrode polarization. The onset of the second reaction of each mechanism may occur before the prediction based on reversibility, because of the resulting potential distribution in the porous, positive electrode. Compared to the values of 50% and 12% utilization, the second reaction begins at 30% and 11% utilization for mechanisms 1 and 2, respectively. At these operating conditions, the reaction potential difference $U_{3,avg} - U_{4,avg}$ for the J-phase mechanism is always about four times larger than the difference $U_{1,avg} - U_{2,avg}$ for the X-phase mechanism. We see that the onset of the second reaction occurs closer to the reversible prediction in the case of the J-phase mechanism because a larger positive electrode polarization is required to promote the onset of the second reaction as compared with the X-phase mechanism.

The solid lines in Fig. 2 are plots of the terms in Eq. [B-1] as functions of utilization for the X-phase mechanism up to 30% utilization. The dashed line in Fig. 2 is called the entropic-heat and has the value of $-i_1 b_1 T$. It would be the only term on the right side of Eq. [B-1] if the equation were written for the adiabatic-reversible case. The polarization heat, $i_1(U_{1,avg} - V)$, and the entropic heat add up to the enthalpy-of-reaction and electrical-work term. The heat-loss contribution does not change markedly because the cell is well insulated and the overall cell temperature does not change substantially. The profile for the X-phase mechanism in Fig. 1 follows the adiabatic-reversible profile up to about 5% utilization because the heat-loss contribution tends to cancel the polarization heat. The polarization heat is mainly responsible for the increasing departure of the cell temperature from the reversible case throughout discharge. With increasing utilization, the polarization heat increases because the open-circuit potential ($U_{1,avg}$) is approximately constant and the cell voltage drops.

These results can be contrasted to the results with the J-phase mechanism from 0% to 11% utilization. The average LiCl concentration increases, and the composition de-

Fig. 2. Terms comprising the energy balance for a LiAl/FeS cell [Eq. B-1] as a function of utilization.

pendent $U_{3,avg}$ decreases accordingly (Eq. [19]). Actually, $U_{3,avg}$ decreases at about the same rate as the cell voltage, so that the polarization heat remains relatively constant. Up to about 5% utilization, the heat-loss term approximately cancels the polarization heat, and the temperature profile follows the adiabatic-reversible case. The cell temperature increases enough from 5% to 11% utilization so that the heat-loss term dominates, and the temperature remains below the adiabatic-reversible case. After 12% utilization, the heat losses and $U_{4,avg}$ stay approximately constant, so that the polarization heat dominates; by the time of 36% utilization, the profile lies above the adiabatic-reversible case.

Although the mixing term offers a negligible contribution to the energy balance, it is interesting to investigate the processes that determine its behavior. As we mentioned earlier, for the molten LiCl-KCl system, the value of the integral in Eq. [B-1] is always negative. Therefore, if the heat losses are made negligible, the cell temperature will decrease after current interruption. Prior to the onset of precipitation, this is entirely a mixing effect. At 25% utilization in Fig. 2, this temperature decline is only about 0.2 K. Before precipitation, the concentration of LiCl steadily decreases in the positive electrode and increases in the negative electrode, and the average composition, $x_{LiCl}^{avg} = 0.58$ (defined by Eq. [26]), is constant. The mixing term (the time derivative of the integral) also increases, and the cell temperature would be slightly underestimated if mixing effects were ignored. The concentration throughout the separator and reservoir volumes remains close to the average composition, so that their contributions to the integral are two orders of magnitude smaller than the contributions from integration through the electrodes. Figure 2 shows that the integral increases in magnitude to the point where the mixing term is zero (26.5% utilization). After this point, the mixing term is slightly negative, corresponding to a decrease in the magnitude of the integral with time. The mixing term decreases when KCl precipitates because, in the region of precipitation, the electrolyte composition is approximately constant at its saturation value. Following the onset of precipitation, the adiabatic temperature decline after current interruption is determined by the more complex processes of simultaneous melting of KCl and electrolyte mixing. We present the breakdown of contributions only up to 30% utilization, because when the second reaction begins simultaneously, reaction heat effects and

precipitation effects cause oscillatory behavior. The description and discussion of this phenomenon will be treated in a subsequent publication.

Conclusions

The examples presented help to illustrate that the processes involved in cell heat generation may be complex and that the application of a sufficiently general energy equation is advantageous. Equation [23], written for a single cell reaction, is the energy equation most commonly used in battery applications. The use of this form of an energy balance is justified only if phase-change effects, mixing effects, and simultaneous reactions are not important. An energy equation including the effects mentioned above is, of course, most easily applied to modeling studies. However, applying an energy equation that includes the effects of simultaneous reactions to experimental measurements may help elucidate reaction mechanisms. For example, if heat generation rates and cell voltage measurements are made on LiAl/FeS cells under isothermal operating conditions, an energy equation may be fit to the experimental data to determine the current fractions of simultaneously occurring reactions. The experiments performed under truly isothermal conditions have the advantage that an estimate of the mean cell heat capacity is not required. However, if experimental cells are not kept isothermal, then heat capacity effects or the effects of nonuniform temperature may obscure the relationship of the experimental results to the energy balance.

The reversible-isothermal model is relatively easy to construct from knowledge of the stoichiometry of the probable cell reactions and the temperature dependence of their open-circuit potentials. The comparison of such a model with experimental results may also aid in the understanding of the system, just as the adiabatic-reversible model was used to aid in the interpretation of the simulation of the well-insulated cell in the examples. Regardless of the application, understanding the fundamental processes involved in cell heat generation will aid our ability to design and develop more efficient and reliable battery systems.

APPENDIX A

Choice of the Average Composition for a Multicomponent System

For a multicomponent phase, the integral in Eq. [15] may be written as

$$\int_{\nu} \sum_i c x_i (\bar{H}_i - \bar{H}_i^{avg}) dv \quad [A-1]$$

In this development, it will be assumed that Eq. [A-1] is only a function of the average composition and that the spatial variation of composition is fixed. If the molar enthalpy is defined as

$$H = \sum_i x_i \bar{H}_i \quad [A-2]$$

Eq. [A-1] may be written as

$$\int_{\nu} c [H - \sum_i x_i \bar{H}_i^{avg}] dv \quad [A-3]$$

In certain cases, Eq. [A-1] is minimized with respect to the average composition by equating the total differential

to zero. Recognizing that the enthalpy is independent of the choice of the average composition, we may write

$$\begin{aligned} d \left[\sum_i \int_{\nu} \bar{H}_i^{avg} c x_i dv \right] \\ = \sum_i \left(\int_{\nu} c x_i dv \right) d \bar{H}_i^{avg} = 0 \end{aligned} \quad [A-4]$$

If we multiply and divide each term in Eq. [A-4] by x_i^{avg}

$$\sum_i \left[\frac{\int_{\nu} c x_i dv}{x_i^{avg}} \right] x_i^{avg} d \bar{H}_i^{avg} = 0 \quad [A-5]$$

and compare this to the Gibbs-Duhem equation

$$\sum_i x_i^{avg} d \bar{H}_i^{avg} = 0 \quad [A-6]$$

we see that the bracketed quantity in Eq. [A-5] must be equal to a constant. This constant

$$K = \frac{\int_{\nu} c x_i dv}{x_i^{avg}} \quad [A-7]$$

must be independent of x_i^{avg} in order to satisfy the Gibbs-Duhem equation. If we apply a mole fraction balance

$$\sum_i x_{i,avg} = \frac{\sum_i \int_{\nu} c x_i dv}{K} = 1 \quad [A-8]$$

we may solve for this constant

$$K = \int_{\nu} c dv \quad [A-9]$$

Substituting this into Eq. [A-7], we obtain the final form for the average composition

$$x_i^{avg} = \frac{\int_{\nu} c x_i dv}{\int_{\nu} c dv} \quad [A-10]$$

Equation [A-10] is guaranteed to be the average composition that minimizes Eq. [A-1] only if its second total differential is positive for all possible values of x_i^{avg} .

Estimate of the Temperature Rise in a Lead-Acid Cell Following Current Interruption

Prior to discharge, the cell is assumed to have a uniform composition of 5 molal sulfuric acid. It is assumed that one-third of the electrolyte is contained in the cathode and anode spaces and that one-third is in the space between the electrodes. It is also assumed that during discharge the concentration of acid in the intermediate space remains unchanged and that the acid concentrations throughout the electrode compartments are uniform. Basing the discharge on two Faradays (1 mol PbO₂) and a transference number of 0.74 for hydrogen ion, we may calculate that the concentration in the cathode space and anode space drops to 1.04 and 2.79 molal, respectively (14). If we regard the cell as well-insulated, and if there are no phase changes (such as formation of ice crystals), Eq. [15] may be written as

$$\begin{aligned} 1.15 \frac{dT}{dt} (n_{\text{PbSO}_4} C_{\text{PbSO}_4} + n_1 \bar{C}_{p_1}^{avg} + n_2 \bar{C}_{p_2}^{avg}) = \\ - \frac{d}{dt} \int_{\nu} c [H - (x_1 \bar{H}_1^{avg} + x_2 \bar{H}_2^{avg})] dv \end{aligned} \quad [A-11]$$

In writing this equation, it is assumed that the heat capacity of the battery support material is 15% of the heat capacity of the reactive material. The integral on the right side is easy to evaluate in this case because the concentration is uniform and the volume is the same in each compartment. The average composition of acid, defined by Eq. [26], is 2.95 molal. As mentioned earlier, this is the

final uniform concentration after relaxation, and the temperature rise is proportional to the value of the integral when the current is interrupted (8630J or 6.5 J/g of electrolyte). Using the data available in Ref. (14) (for 298 K), we calculate the temperature rise to be about 1.6 K (if we allow 1.25 mol of PbO₂ for discharge, the concentrations in the cathode and anode space drop to 0.05 and 2.23 molal, respectively, and the temperature rise is 2.9 K). We recognize that the assumed concentration jumps at the interfaces are artificial and that, realistically, diffusion tends to equalize the concentrations. The estimated temperature rise would be slightly lower if the above effect were taken into account. We must also, however, recognize the effects of nonuniform reaction distribution in porous electrodes and that this will tend to make the concentration distribution nonuniform. Reference (9) gives spatial distributions of concentration and reaction for a one-dimensional model of a lead-acid cell.

APPENDIX B

Energy Equations for Model Studies

Mechanism 1 (the number subscripts refer to the reactions in Table I)

$$\frac{M}{A} C_p^m \frac{dT}{dt} = -h(T - T_A) \quad \text{heat-losses}$$

$$+ (i_1 a_1 + i_2 a_2) - V(i_1 + i_2) \quad \text{enthalpy-of-reaction and electrical-work}$$

$$+ \frac{d}{dt} \int_0^L \epsilon R \left[c_{\text{LiCl}} T \ln \left(\frac{\gamma_{\text{LiCl}}}{\gamma_{\text{LiCl}}^{\text{avg}}} \right) \right]$$

$$+ c_{\text{KCl}} T \ln \left(\frac{\gamma_{\text{KCl}}}{\gamma_{\text{KCl}}^{\text{avg}}} \right) dy \quad \text{mixing}$$

$$+ \frac{1}{A} \frac{dn_{\text{KCl}_3}}{dt} [\Delta H_{\text{KCl}_3}^{\circ} + RT \ln \gamma_{\text{KCl}}^{\text{avg}}] \quad \text{KCl-precipitation} \quad [\text{B-1}]$$

Mechanism 2

The energy equation for mechanism 2 differs only in the enthalpy-of-reaction and electrical-work term, which may be written as

$$+ (i_3 a_3 + i_4 a_4) - V(i_3 + i_4)$$

$$- i_3 \frac{RT}{F} \ln \left(\left(\frac{\gamma_{\text{LiCl}}^{\text{avg}}}{\gamma_{\text{LiCl}}^{\text{eut}}} \right)^{5/6} \left(\frac{\gamma_{\text{KCl}}^{\text{avg}}}{\gamma_{\text{KCl}}^{\text{eut}}} \right)^{-1} \right)$$

$$- i_4 \frac{RT}{F} \ln \left(\left(\frac{\gamma_{\text{LiCl}}^{\text{avg}}}{\gamma_{\text{LiCl}}^{\text{eut}}} \right)^{-5/46} \left(\frac{\gamma_{\text{KCl}}^{\text{avg}}}{\gamma_{\text{KCl}}^{\text{eut}}} \right)^{-3/23} \right) \quad [\text{B-2}]$$

Relevant Input Data

New Electrochemical Process for Making Ni/Ni Hydroxide Battery Electrodes

C. K. Dyer*,¹

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Ni positive electrodes with coulombic capacities suitable for battery electrode use have been made using ac and dilute aqueous solutions of KCl and KBr. The process is simpler and offers several potential cost and performance benefits compared with the conventional electrochemical impregnation process.

Reported methods to produce thin hydroxide or "active" films directly from Ni, by conversion rather than by electrodeposition are: (i) anodize at constant current in KOH or neutral borate solutions (1), (ii) periodically reverse the current through a Ni electrode immersed in an aqueous KOH solution (2). The mechanism of film growth by these techniques has not been widely investigated or reported. Growth is presumably a result of Ni dissolution then immediate precipitation from the high pH solution in both methods rather than by the high field ion transport mechanism of film growth on valve metals where surface films have, essentially, no electronic conductivity. The amount of active material generated in these procedures (1-100 mC/cm²) is obviously insufficient to yield a practical battery electrode. But for this serious limitation there could be considerable cost and performance advantages compared with existing methods of manufacture of Ni electrodes for batteries, which involve chemical or cathodic electrochemical deposition of nickel hydroxide from a solution of a Ni salt (e.g., nitrate) into a porous Ni sinter substrate or "plaque." The preferred but costly electrochemical method requires very careful control of concentrations, pH, and temperature of the deposition electrolyte to obtain a "loading" of Ni(OH)₂ with a controlled amount of voidage, while the product of the chemical impregnation method (precipitation of hydroxide by alternately dipping, first, into Ni nitrate and, then, into NaOH) suffers from overloading and subsequent plaque expansion during battery cycling.

It is well known that breakdown of passivity and dissolution of many metals is enhanced in the presence of so-called "aggressive" anions, such as chloride. So, addition of chloride to the KOH solution during anodic polarization of a bare Ni surface might be expected to increase the amount of Ni oxidation to hydroxide under the otherwise usual constant current or pulsed conditions. Indeed, it would not be necessary to operate in alkaline solutions at all if the current is reversed, since the dominant hydrogen evolution reaction (HER) might raise the surface pH enough (3) to precipitate local Ni cations in the form of hydroxide (minimum equilibrium solubility of Ni(OH)₂ is 10⁻⁸ mol/liter at pH 10.2). On subsequent cycles, the hydroxide should still be stable: in neutral solutions the solubility rises but to only ~10⁻³ mol/liter. However, these are equilibrium solubilities and the kinetics of dissolution of hydroxides could be very slow. Previous work on another metal, Al, has shown (3) that a thin stable surface hydroxide can form by application of an alternating current even in acid solutions despite the high solubility of Al hydroxides in acid. It is particularly interesting and relevant to note that in that work, incorporation of chloride in the hydroxide was absent, an important consideration in the capacitor industry where this process finds application and any corrosion would be catastrophic. So, the possibility of using ac to form a pure (chloride-free) hydroxide product on Ni in aqueous halide solutions was thought to be possible.

The concept was tested, and the results confirmed that indeed uniformly thick, halide-free layers of hydroxide can be produced rapidly on Ni in neutral KCl, KBr, and other solutions using ac. Considerable cost benefits in production as well as improved electrode quality are anticipated to result from this process.

Experimental

Two Ni substrates were used in this work: pure Ni sheet, masked with epoxy resin to expose ~1 cm², and Ni sinter supported on a wire mesh (made by Eagle Picher Industries, Incorporated) with an overall thickness of 0.030 in. and a projected area of 1 cm². A 1 mm Ni wire lead was spot-welded to a coined edge of the sinter, to allow immersion in the cell. The average porosity of the sinter was 77.5% with mean pore size 12.7 μm.

A Model 371 EG&G potentiostat was programmed to give various controlled-current waveforms. Most of the work to date has been with square wave shapes.

After cycling, the electrodes with their transparent film deposits were washed in distilled water and charged and then discharged in 30% KOH at 2 mA/cm² (foil electrodes) or 250 mA/cm² (sinter); capacities were calculated from discharges to ~0.0V(NHE). The reference electrode was a cathodically charged Pd/PdH_x wire or a standard calomel electrode. Counterelectrodes were either graphite or a large area of Ni foil.

Results and Interpretations

Foil.—Table I shows the results with Ni foil. In pure 1M KOH, positive or positive then negative current pulses produce small amounts of hydroxide, as indicated by the low discharge capacities (*D*) and as expected from previous work (1, 2). The effect of negative pulses only was unexpected and indicates that corrosion might have taken place during the zero-current half of each cycle. The last column of Table I indicates the coulombic efficiency (2*D*/*C*₊) of conversion of Ni to Ni(OH)₂. It is in all cases less than 0.5%. The low return on power consumed makes it a poor candidate for a manufacturing process!

Film growth in 1M KCl solution was, in several cases, an order of magnitude greater and was accompanied by a similar improvement in efficiency. In some experiments, intermediate capacities were measured for the same specimen and showed an increasing discharge capacity (roughly proportional to "film thickness") with number of cycles applied [indicated by (1), (2), (3), etc., in Table I] without decline in efficiency. The highest discharge capacities resulted from asymmetric current (*i*) cycling such that *i*₊ > *i*₋. There was also an effect of frequency (while maintaining similar charge (*q*) during each half cycle, i.e., *q*₊ = *q*₋). The discharge capacity decreased with increase in frequency from 0.5 to 10 Hz, as did the efficiency, and, unlike at lower frequencies (0.5 Hz), efficiency did not stay nearly constant with cycling, but decreased; this can be seen in Table I at 1, 2, and 20 Hz. Reduction in KCl concentration to 0.2M at 10 Hz, however, raised *D*. At lower pH (in 1M HCl) the capacity, as expected, was low.

The efficiency of conversion to useful hydroxide in KCl solutions, although much higher than in KOH alone,

* Electrochemical Society Active Member.

* In 30% KOH at 2.0 mA/cm².

was considered to be unattractive for a commercial process to make battery plates from Ni in the form of foil. The low efficiency was believed to be due to considerable loss of precipitated hydroxide to the electrolyte, since large accumulations were observed in the bottom of the cell during this work. A better substrate from this point of view was considered to be the porous sinter in which a higher $[\text{Ni}^{2+}]$ should be encountered internally with gradients in concentration of Ni^{2+} and OH^- from the Ni sur-

faces such that the solubility product would be exceeded closer to the Ni surface to cause more adhesion and less loss of hydroxide.

Sinter.—The results with sintered electrodes are shown in Table II and Fig. 1 and 2. As a reference point, 1 cm² of electrodes loaded by the conventional electrochemical impregnation or deposition process (4, 5) ("ED") gave discharge capacities of 62-78 C/cm², measured under the same conditions as electrodes in Table II.

* In 30% KOH at 250 mA/cm².

Initially, asymmetric waveforms were used since for foil this was more effective. However, for the sinter, symmetric shapes gave the highest discharge capacities (part 2 of Table II). Discharge capacities comparable or higher

than conventional ED electrodes were obtained. Also, efficiencies were much higher than with foil. The higher capacities were achieved at the lowest frequencies used in this work of 0.25 Hz and at low apparent current densi-

Fig. 1. Discharge capacities of 1 cm^2 (projected) Ni sinter after cycling at 0.5 Hz in 1M KCl with the following apparent current densities (mA/cm^2): ± 100 (Δ); ± 150 (\blacktriangle); ± 200 (\bullet); ± 250 (\square); and ± 500 at 1.0 Hz (\circ).

ties. The requirement for a combination of both positive and negative half-cycle currents contrasts with the process in KOH where either a succession of anodic or of cathodic current pulses were as effective as a combination. This indicates a different mechanism but similar to that proposed for Al dissolution during anodic then precipitation during cathodic half cycles (3). Overcycling results in a capacity plateau or a slight capacity loss as can be seen in Fig. 1 under several conditions at 0.5 Hz. At 0.25 Hz, where the highest discharge capacities were recorded, overcycling led to more dramatic drops (at ± 125 and $\pm 150 \text{ mA}/\text{cm}^2$) (Fig. 2).

Using 1M NiCl_2 , more cycling than 1M KCl was required to yield comparable discharge capacities, and so efficiencies were generally lower and some Ni plating may have occurred.

After cycling in 1M KBr, electrodes yielded similar capacities to those from 1M KCl solutions, but with slightly lower efficiencies under comparable conditions.

Optical micrographs of cross sections of epoxy-mounted electrodes were taken using a new technique to reveal the distribution of active material (6, 7) and are shown in Fig. 3 and 4 for a sintered Ni electrode which

Fig. 2. Discharge capacities of 1 cm^2 (projected) Ni sinter after cycling at 0.25 Hz in 1M KCl with the following apparent current densities (mA/cm^2): ± 75 (Δ); ± 125 (\blacktriangle); ± 150 (\bullet); and as above but in 1M KBr with $\pm 225 \text{ mA}/\text{cm}^2$ (\circ).

Fig. 3. Cross section of sintered Ni electrode made in 1M KCl at 0.5 Hz, $\pm 150 \text{ mA}/\text{cm}^2$, after 1600 cycles. Capacity: $64 \text{ C}/\text{cm}^2$. Ni: white. Ni hydroxide: dark gray (striated). Epoxy mount: light gray (from center). Magnification: 680X.

gave $64 \text{ C}/\text{cm}^2$ (0.5 Hz, $\pm 150 \text{ mA}/\text{cm}^2$, 1600 cycles in 1M KCl). The distribution of active material over Ni particles in the sinter (white) appears fairly uniform and from the surface to the center of the electrode, there were unblocked electrolyte channels in between prior to filling with epoxy. Such a structure should have an operational advantage over that produced by the ED process. Figure 5, taken at the same magnification, is a cross section of a conventional electrochemically impregnated electrode (4, 5) and shows a rather nonuniform distribution of active material, some only in poor contact (apparently) with Ni particles. Heavier loading of voids near the electrode surface and depletion of hydroxide in the electrode interior is a common and unwanted characteristic of some ED electrodes. Previous work (6, 7) showed that large particles of active material such as the one in the center of Fig. 5, oxidized (or charged) with difficulty when there were few or no electron sinks (Ni) within the particle [see Fig. 2 of Ref. (6)] and was more susceptible to electrical isolation on discharge [Fig. 3 of Ref. (6)]. Thus, a fraction of Ni hydroxide deposited in the ED process probably does not participate in charge storage and so leads to lower actual (or usable) electrode energy density in a battery. There may be other operational disadvantages associated with the heavier surface loadings of ED electrodes such as electrolyte blockage and outward migration of hydroxide.

Comparison of Fig. 3 and 4 with Fig. 5 shows that a considerable amount of Ni is converted by the ac process, and this must be at the expense of the mechanical sup-

Fig. 4. Same as Fig. 3

port function and so a stronger/thicker sinter will probably be required in making practical electrodes.

Examination by Auger electron spectroscopy did not reveal halides in the surface of ac deposited hydroxide that had been charged and discharged in KOH. After *in situ* ion milling for several thousand angstroms, no response from halide ions appeared above the detection limit of 0.1 atomic percent (a/o).

Discussion

The experimental work has demonstrated that the capacities of sintered Ni electrodes made by the very simple and easily controllable ac process are comparable with those of electrodes made by the conventional electrochemical-impregnation technique (4, 5) and that the uniformity of film thickness produced has operational advantages. In addition, the technique could be of general application where thick and uniform conversion layers of electrochemically active oxides or hydroxides of other metals are required, since anodic dissolution of many metals can be activated by the presence of "aggressive" halide ions and an increase in pH on current reversal can cause the solubility product of their hydroxides to be exceeded. Pourbaix (8) shows that a large number of metal hydroxides have minimum solubility even at low to neutral pH, while the metal can anodically dissolve at lower pH. Cycling the pH in this "window" at a suitable potential should, therefore, produce films of hydroxide in contact with substrate metal. The process could be generally accelerated by alternating anodic then cathodic potential excursions and by addition of suitable anions to break down passivating films. It is likely that anions other than chloride and bromide, for instance, iodide, oxyanions, etc., could promote conversion of metals to their hydroxides by ac. There are probably other waveshapes and frequencies and current densities which could be equally effective.

A detailed model of the unusual kinetics involved in ac deposition of Al hydroxide films on Al has been proposed (3) and with some modifications can also explain film growth by ac on Ni. In that work, scanning electron microscopy (SEM) supported by calculations of ion concentrations near the metal surface showed the formation of a thin cathodically deposited Al hydroxide film on application of ac to Al, in HCl. A cubic etch-pit formed during the anodic half cycle of applied ac, and then, on current reversal, the walls of the pit became covered and partially protected by a thin dense layer of Al hydroxide, as they became cathodic, and the local pH rose. Imperfections in this dense but thin layer then led to further local attack to form another cubic pit during the subsequent anodic half cycle, and so on. Eventually the Al developed a "cellular" structure with walls of Al covered by thin hy-

droxide deposits despite the low pH electrolyte, in which Al hydroxide solubility is normally high. In the case of Ni, the transparent hydroxide films formed are much thicker and less dense and the mechanism involves, during the anodic half cycle, probably more general dissolution activated by the halide ions, since the SEM microstructure does not show a metal/hydroxide cubic morphology similar to Al, but shows strands of Ni within low density hydroxide films (9).

During the cathodic half cycle immediately following an anodic half cycle on Ni, the generally high concentration of Ni²⁺, [Ni²⁺], within the pores of the Ni sinter would be lowered at the surfaces of Ni particles by precipitation if the pH was locally sufficiently high. The minimum solubility of Ni(OH)₂ occurs at pH 10.2 (8), although even at pH 8 its solubility is ~10⁻³ M/liter. So, near-neutral aqueous salt solutions are already close to these precipitation conditions. In addition to the high [Ni²⁺] present, steepening of the pH gradient near the metal surface is likely as the hydrogen evolution reaction (HER) occurs, this would cause precipitation close to and at the metal surface and so provide good contact between hydroxide and metal. While the limited internal electrolyte volume in pores may help increase [Ni²⁺], rapid diffusion of protons by mechanisms such as Grotthus hopping towards the surface may limit the pH rise (3). However, it is possible that, as in the Al case, protonic diffusion is slow under conditions prevailing in the pores and particularly slow near the surfaces of the Ni particles because of a high local [Ni²⁺] produced there by the end of the anodic half cycle, which might hinder rotation of water molecules. Measurements of the diffusion coefficient of H⁺ ions, D_{H⁺}, in aqueous chloride solutions measured polarographically (10) show that D_{H⁺} decreases with increase in salt concentration and depends upon the cation. It falls from 9 · 3 × 10⁻⁵ to 5 · 3 × 10⁻⁵ cm²/s from 0 to 2M Li⁺ solutions, while it only drops to 7 · 5 × 10⁻⁵ cm²/s for the equivalent concentration change in K⁺ solutions. It is likely that the dependence on the cation is related to its hydration number or the effective number of water molecules attached to the ion in its hydration sheath and partially "immobilized." The inability of these water molecules to orient in an electric field causes a decrement in the static dielectric constant of water containing metal ions which is larger for solutions of small, highly charged cations, where the interaction is greater. Hydration numbers can be calculated from the effect on the dielectric constant and show that, while K⁺ and Rb⁺ have hydration numbers ~1, for small ions, such as Li⁺, it is ~3, while for small but highly charged cations, such as Al³⁺, the hydration number is as high as 16 (11), which effectively immobilizes ~30% of the water molecules in 1M AlCl₃. For a divalent ion such as Ni²⁺, the hydration number is less, but only by about one-third, i.e., ~11, from several determinations (12, 13) which is sufficient to immobilize a larger number of water molecules, particularly near the metal surface, where the [Ni²⁺] gradient turns upward prior to the beginning of the cathodic half cycle. H⁺ ion transport would then be by conventional diffusion with D_{H⁺} ~ 2 × 10⁻⁵ cm²/s, comparable with D_{Ni²⁺}, so that a fairly steep upward gradient in [OH⁻] could prevail at the metal surface during HER and facilitate precipitation very close to the metal surface.

The physical and other properties of films will largely depend on the steepness of the pH gradient that can be developed at the metal/electrolyte interface, since this will affect the density of the deposit. The observed thick, low density Ni hydroxide films formed on Ni by ac (9) could be a consequence of a lower cathodic half-cycle pH gradient than at an Al/Al³⁺ interface, owing to less water immobilization. Factors other than the pH gradient might also affect the density and thickness of deposits. The pH dependence of Al hydroxide solubility is an order of magnitude greater than for Ni hydroxide (8), so that shorter pH excursions could result in precipitation. This, together with the lower pH for minimum solubility (by 5 pH units), could have contributed to-

wards the denser film precipitation on Al. However, equilibrium solubility data may not be appropriate in the discussion of a large ac perturbation! Indeed, it was the rate of surface pH adjustment that was calculated, in the case of Al hydroxide deposition, to be critical, and not the time needed for precipitation which was much faster.

The form of the deposit will also be affected by the frequency used. The much lower frequencies needed to build up thick Ni hydroxide films at high efficiency may be related not only to pH effects but to the need to build up a high $[\text{Ni}^{2+}]$ within electrolyte-filled voids in the Ni sinter, so that on current reversal, a precipitation front can move from the metal interface for some distance into the Ni^{2+} -rich electrolyte. The difference in conversion efficiency between foil and sinter could be explained in this way. This, together with the pH gradient at the Ni/Ni^{2+} interface, might explain the rather good adhesion between the hydroxide and Ni surface which is better than that produced by the ED process. SEM examination of ac-processed electrodes (9) did not reveal Ni particles of the sinter clearly separated from hydroxide in specimen fracture zones, as is commonly observed in ED electrode fractures. The frequency and shape of the cathodic half cycle is also important in determining the pH gradient and hence the film density.

The inefficiency of conversion presumably reflects coulombic losses to such processes as Ni hydroxide shedding, Ni plating, and possibly gaseous oxidation products, but conversion efficiencies as high as 60% for the sintered Ni electrodes makes the process highly competitive, in terms of power consumption, with conventional dc electrochemical impregnation. A fuller explanation of the general mechanism and understanding of the dependence on a low ac frequency as well as the requirement for symmetrical ac (in contrast to the foil experiments) requires further experimental investigation. However, it is already clear that, by whatever mechanism, a new commercial process for making Ni battery electrodes is feasible. Full commercialization might involve Co^{++} additive to the electrolyte if it is shown that increased utilization (14) and mechanical stabilization of the active material (15) are still required in the highly energy-efficient ac formed electrode. Also, a stronger sinter support-structure may be needed.

Several operational advantages in production are likely in addition to the low direct costs, anticipated, for this simpler process. It exhibits a high effective "throwing power" because the process involves local generation of Ni^{2+} followed by precipitation, so the latter is not limited by diffusion of Ni^{2+} from the bulk solution as in the ED process. Also, chloride ions are not consumed, but are, rather, recycled and hydroxyl ions are made available locally by the reaction: $\text{H}_2\text{O} + e^- \rightarrow 1/2 \text{H}_2 + \text{OH}^-$. This translates into uniform thickness of deposited layers throughout the Ni sinter. Uniformity in thickness of the electrochemically active hydroxide will reduce electrical isolation (6, 7) and so ensure high utilization, improve chargeability and dischargeability, and allow thicker Ni sinter to be uniformly "loaded." Each of these will increase the electrode energy-density. Also, sinter considered too poor for the ED process because of wide void size distribution can be used. So, the feature of high throwing power will provide an indirect cost advantage commercially.

Aspects of the process which lead directly to low anticipated commercial costs are as follows. There is no prepassivation necessary as in the electrochemical impregnation process. The electrolyte cost is low, as are

operating costs because of the room temperature operation, and there is no need for close pH control. Costs will also be reduced if the process is made contact-less which is easier for an ac process than for dc. Because of the high throwing power, sinters with a smaller mean pore size than usual for making electrochemically deposited electrodes can be used, which will allow higher energy density electrodes to be made and also help increase electrode strength. Finally, there is no "bath aging" phenomenon, which is characteristic of the ED process, where electrode loading decreases with time in a very complex manner (16), requiring eventually costly replacement of the ED solution.

Conclusions

Implementation of this ac method should offer the following advantages over the conventional dc electrochemical method: (i) cheap chemicals (NaCl , KCl , etc.); (ii) simpler control (wide operational "windows," for pH, temperature, etc.), (iii) a room temperature process, (iv) no prepassivation would be required, (v) more uniform distribution of active material, (vi) insensitivity to large void distribution in the sinter, (vii) the possibility of a contact-less process, (viii) thicker sinter of similar porosity could be deeply loaded, e.g., using higher current density or more ac cycles (than in Fig. 1 and 2) to raise electrode energy density, (ix) higher inherent energy density using less porous Ni sinter (because of conversion of Ni to hydroxide rather than addition of hydroxide to Ni), (x) better electrode performance (a more uniform distribution of active material will improve chargeability, reduce internal polarization, and reduce electrical isolation on discharge), (xi) high coulombic efficiency of conversion of Ni to $\text{Ni}(\text{OH})_2$, and (xii) no "bath aging" phenomenon.

Effect of Antimony on Lead-Acid Battery Negative

B. K. Mahato,* J. L. Strebe,* D. F. Wilkinson,* and K. R. Bullock*

Johnson Controls, Incorporated, Electrochemical Research, Milwaukee, Wisconsin 53201

ABSTRACT

The role of antimony on the lead-acid battery negative in terms of its effect on charge efficiency, its effect on gassing overpotential, its interactive influence with lignin expander in controlling the charge efficiency, and its retentive behavior or purging characteristics as SbH_3 in the overcharge gas stream was investigated. Linear potential sweep (LPS) cycling of Planté-type lead electrodes was used to determine the effect of antimony and/or lignin expander on charge efficiency. Pasted-type lead electrodes were used to determine the effect of antimony on gassing overpotential and to monitor its concentration either in the active material or the exit gas stream. Results showed a significant contribution of antimony in decreasing charge efficiency and an overwhelming role of lignin expander in suppressing the effect of antimony on charge efficiency. The critical lead-electrode potential for purging antimony from the electrode is close to -1275 mV (*vs.* $\text{Hg}/\text{Hg}_2\text{SO}_4$).

Antimony in a lead-acid battery negative electrode comes primarily from two sources: (i) oxide raw material prepared from battery scrap secondary lead, and (ii) the antimonial positive grid alloy. During normal battery operation, the antimonial positive grid corrodes and releases antimony as oxidized species. This antimony slowly migrates through the positive active material and the electrolyte and deposits at the lead electrode, initiating a performance degradation of the battery. Adverse effects include: (i) increased self-discharge, (ii) excessive water loss or increased maintenance, (iii) decreased charge efficiency, and (iv) formation of toxic stibine (SbH_3) environment around the battery.

The detrimental influence of antimony on the lead electrode performance is well known (1, 2). The use of expander, particularly the lignin constituent of expander, in the lead electrode in improving its overall performance has also been common in the state of the art (1-4). However, the information related to the effect of antimony on the lead electrode performance is still qualitative. There is no reference dealing with the possible interaction of expander and antimony that may influence the lead-acid battery negative electrode performance. The objectives of the present investigation have been (i) to estimate quantitatively the effect of antimony on the lead electrode charge efficiency, (ii) to evaluate the interaction of antimony and expander-lignin on the lead electrode charge efficiency, and (iii) to determine the antimony retention within or purging out the lead electrode during charging.

Experimental

Table I shows our experimental plan. For charge efficiency, we used linear potential sweep (LPS) cycling of Planté-type lead electrodes between 100 mV anodic and 200 mV cathodic to open-circuit potential. We calculated the charge efficiency as percent ratio of anodic to cathodic charge. For gassing behavior, we used the cathodic LPS of a pasted lead electrode from -980 mV to hydrogen evolution potential. To define the antimony purging behavior from or the retention within the plate, we used constant potential charging of pasted and Planté-type electrodes.

The LPS cycling equipment has previously been described (4). The test cell had a 2 cm long, 2 mm diam test electrode, an oversized counterelectrode, and a reference electrode, all immersed in sulfuric acid electrolyte. Both test and counterelectrodes were made out of 99.999% pure lead (Cominco). The reference electrode was $\text{Hg}/\text{Hg}_2\text{SO}_4/m\text{H}_2\text{SO}_4$, where m is the acid concentration in the reference electrode reservoir. The conversion of the electrode to a Planté-type, moderately high surface area electrode was carried out in two stages. In the first stage, the electrode capacity was developed by LPS cycling in 1.050 sp gr H_2SO_4 between -860 and -1160 mV (*vs.* reference) for 48h at 0.5 mV/s scan rate. The second stage was

the stabilization in 1.250 sp gr H_2SO_4 by identical cycling treatment for an additional 48h. The steady-state electrode charge efficiencies were monitored during development and stabilization cycles. This was followed by the determination of the effect of 20 ppm Sb, 20 ppm lignin-expander, and their combination in the cell electrolyte on the lead electrode charge efficiency. The antimony used in this series of experiments was the atomic absorption quality reference solution (1 $\mu\text{g}/\text{ml}$) obtained from Anderson Laboratory (Fort Worth, Texas). The lignin-expander was Maracell-XC obtained from American Can Company (Rothschild, Wisconsin).

The influence of antimony on the lead electrode gassing behavior was determined by the cathodic LPS between -980 mV (*vs.* reference) to free gassing potential at 0.5 mV/s scan rate. The electrode (type A) was commercially obtained $4.30 \times 5.00 \times 0.155$ cm dry charge negative with 10.5g active material. It was tested against two counter positive electrodes having the same dimensions in a three-plate-element cell with or without antimony in the electrolyte. The influence of constant potential overcharge on the antimony content in the lead electrode was carried out by testing a pasted lead electrode containing antimony. This electrode (type B) was $12.0 \times 14.0 \times 0.155$ cm with reagent-grade Sb_2O_3 fines (Fisher Scientific) in the paste. It was formed in a three-plate-element cell with two counter positives in 1.050 sp gr H_2SO_4 at -1125 mV (*vs.* reference) constant potential with total amount of charge equivalent to twice the theoretical amount needed to form the plate. The -1125 mV (*vs.* reference) charging potential was used to avoid the "antimony loss" from the plate during formation. The formed electrode was then tested for its antimony retention characteristics under potentiostatic overcharge with or without step input. The antimony retention in the plate was analyzed by neutron activation at the University of Wisconsin, Madison, facility. In one case, the testing was carried out in a sealed container in which the overcharged gas was continuously purged by 20 cm^3/min argon gas stream to two stibine gas absorbing solution columns in series. The solution used for stibine absorption was prepared according to Varma *et al.* (5). The antimony content in the absorbing solution was determined colorimetrically (5).

Results and Discussion

Effect of antimony and/or lignin expander on charge efficiency.—The steady-state capacity of Planté-type electrodes at the end of development and stabilization cycles are shown in Table II. Q_a , Q_c , and E are anodic charge, cathodic charge, and charge efficiency, respectively. The data show that the Planté-type electrodes prepared by LPS cycling have excellent reproducibility, charge efficiency in excess of 98% in 1.050 and 1.250 sp gr H_2SO_4 , and a greater anodic charge in 1.050 sp gr H_2SO_4 than in 1.250 sp gr. The four stabilized electrodes given in Table II were used to determine the effect of antimony, lignin-expander, and their combination on the charge ef-

Q_a = anodic charge; Q_c = cathodic charge; $E = Q_a/Q_c \times 100$.

iciency. Electrode 1, which was used as a control, underwent continued cycling in 1.250 s g H_2SO_4 ; electrode 2 was cycled in acid with 20 ppm lignin expander; electrode 3 was cycled in acid with 20 ppm antimony; and electrode 4 was cycled with 20 ppm lignin-expander plus 20 ppm antimony. All four electrodes were cycled for 290 cycles, i.e., for 4 days. Their steady-state charge/discharge characteristics were noted at the end of the test.

Table III summarizes the steady-state characteristics of the control and test electrodes LPS cycled with antimony and/or lignin-expander in the solution. The results indicate (i) that the charge efficiency of the control electrode was maintained close to 100%, (ii) that presence of expander did not affect the charge efficiency and helped to build up the steady-state capacity close to three times that of the control, (iii) that the antimony in the solution decreased the charge efficiency to 13.5% and capacity to about 75% of the control, and (iv) that inclusion of lignin-expander in antimony containing solution suppressed the adverse effect of antimony on charge efficiency and increased it to 80.6% level. Moreover the lignin-expander in antimony containing solution increased the test electrode anodic capacity to almost 3.5 times that of the control. These observations suggest the ability of lignin-expander in suppressing the effect of antimony on the lead electrode charge efficiency. These data also show a synergistic influence of lignin-expander and antimony on the lead electrode performance. The efficacy of the electrode in developing and maintaining its capacity during cycling was better in solution with lignin-expander and antimony than with lignin-expander alone.

The mechanistic understanding of the interaction of antimony and lignin-expander on the lead electrode performance is not clear from this series of experiments. However, the cyclic voltammograms (Fig. 1) and SEM micrographs (Fig. 2) of the electrodes taken at the end of the

Table III. Effect of lignin-expander and/or antimony on Planté lead electrode charge efficiency in 1.250 sp gr H_2SO_4

Electrolyte additive	Charge (C)		Efficiency (E)
	Q_a	Q_c	
No additive (control)	0.9587	0.9619	99.7
20 ppm lignin expander	2.9230	2.9380	99.5
20 ppm antimony	0.7200	5.3500	13.5
20 ppm lignin expander and 20 ppm antimony	3.388	4.206	80.6

Q_a = anodic charge; Q_c = cathodic charge; $E = Q_a/Q_c \times 100$.

test do help, at least qualitatively, to show the interaction of these two important components on the lead electrode behavior. The voltammogram in Fig. 1a is typical of the lead electrode in pure sulfuric acid solution (4). The low current acceptance at the end region of anodic and cathodic LPS indicates completion of the anodic ($Pb \rightarrow Pb^{2+} + 2e$) and cathodic ($Pb^{2+} + 2e \rightarrow Pb$) processes during cycling. Figures 1a-1d show that a change in the electrolyte composition does affect the cathodic portion of the electrode voltammograms more profoundly than their anodic counterparts. In presence of lignin-expander in the test solution (Fig. 1b), the cathodic voltammogram is characterized by a suppressed peak intensity and broadening of peak area, resulting in a significant increase in net cathodic charge. This increased cathodic charge is subsequently reflected in a greater anodic capacity. The decrease or suppressed cathodic peak intensity is due to restricted reaction surface or deposition sites caused by the surface adsorption of the lignin-expander. This observation agrees well with the previously reported findings (4). Figure 1c shows the dramatic influence of antimony in solution in changing the lead electrode cathodic voltammogram. It causes the onset of gassing at the electrode at 80 mV cathodic to open-circuit potential, a loss in anodic charge, and a significant decrease in charge efficiency. The decreased charge efficiency is primarily due to loss of its hydrogen overpotential, which, in turn, causes excessive gassing and possibly a deficiency in the $PbSO_4 \rightarrow Pb$ conversion process.

The cathodic voltammogram (Fig. 1d) shows the influence of lignin-expander in modifying the effect of antimony on the lead electrode cathodic process given in Fig. 1c. Figure 1d has two cathodic peaks and a noticeably high current acceptance at the end region of the cathodic LPS. We observed very little gassing on the electrode surface compared to what we observed with antimony in the solution (Fig. 1c) during the cycling. This partially explains the greater capacity development and maintenance of the lead electrode cycled in solution with antimony and lignin-expander (Table III). Out of two cathodic peaks observed in Fig. 1d, the first one is similar to the influence of lignin-expander on the lead electrode in absence of antimony in the test solution (Fig. 1b). The

Fig. 1. Steady-state lead electrode cyclic voltammograms between -1160 and -860 mV (vs. Hg/Hg_2SO_4) in 1.250 s g H_2SO_4 with (a) no additive, (b) 20 ppm lignin expander, (c) 20 ppm antimony, and (d) 20 ppm antimony plus 20 ppm lignin expander.

Fig. 2. Planté-type lead electrode surface morphology at the end of the test in 1.250 sp gr H₂SO₄ with (a) no additives, (b) 20 ppm antimony, (c) 20 ppm lignin expander, and (d) 20 ppm lignin expander plus 20 ppm antimony.

comparison of the cathodic voltammogram in Fig. 1b, 1c, and 1d suggests that the second cathodic peak in Fig. 1d must relate the interaction between the antimony and lignin expander on the lead electrode cathodic process. This change in the cathodic process may have resulted from the opposing effect of antimony and lignin-expander on the lead electrode hydrogen overpotential, preferential adsorption of lignin on freshly deposited antimony, and possibly the occurrence of a complexation reaction between Sb³⁺ and liginosulfonate anion at the reaction interface. More work is definitely needed to explain the interactive influence of antimony and lignin expander on the lead electrode charging process.

Another indication of the interactive influence of lignin and antimony on the lead electrode is apparent from the comparison of anodic capacities of lead electrodes developed in expander containing electrolyte with and without antimony. The anodic capacity of the lead electrode in the test solution with expander and antimony is about 16% greater than in the test solution with expander only (Table III). This suggests that trace antimony in the sys-

Fig. 3. Cathodic LPS behavior of pasted-type lead electrode as function of antimony content in the electrolyte.

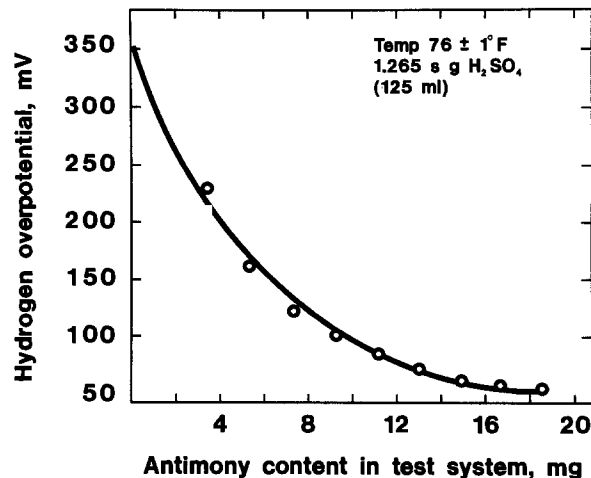

Fig. 4. Replotted data from Fig. 3 showing the hydrogen overpotential behavior of the test electrode as function of antimony content in the test system.

tem in the presence of expander may favor the formation of high surface area negative active material. The effect of expander and/or antimony on the lead electrode morphology is shown in Fig. 2. The low surface area of the lead electrode with or without antimony in the test solution (Fig. 2a and 2b) is apparent. Greater depth of the porous matrix, seen in Fig. 2b, may have resulted from the role of antimony in inducing the self-discharge or the lead oxidation process. A significant fineness in surface texture is evident for the electrode in the presence of expander (Fig. 2c). The very fine structure with interspersed lead sulfate is noticeable for the electrode with expander and antimony in the test system. This extrafine structure at least qualitatively explains the greater anodic capacity of this electrode compared to the electrode cycled in expander containing solution.

Effect of antimony on hydrogen evolution potential.—The effect of antimony on the hydrogen evolution overpotential of a pasted-type lead electrode (type A) was carried out in a three-plate element test cell with 125 ml 1.265 sp gr H₂SO₄ solution at 76° ± 1°F. The three-plate-element had one test electrode and two counter positives of identical dimension with microporous polypropylene separator in between. The fully charged test electrode was subjected to linear potential sweep at 0.5 mV/s from -980 mV (vs. Hg/Hg₂SO₄) to a cathodic potential of profuse hydrogen evolution. The experiment was repeated with continued addition of antimony to the electrolyte. The maximum concentration of antimony used in this study was

Fig. 5. Replotted data from Fig. 3 showing the isopotential cathodic current behavior of the test electrode as function of antimony content in the test system.

Fig. 6. Antimony purging behavior of pasted-type lead electrodes with antimony in the formed active material under constant potential charging.

close to 0.18%, based on the weight of negative active mass used in the test electrode.

The cathodic LPS data of the type A electrodes are shown in Fig. 3. The figure shows a continuous decrease in lead electrode gassing potential with increasing antimony content in the system. This study suggests that continuing accumulation of antimony at the lead electrode could decrease the lead electrode charging potential to less than -1100 mV *vs.* $\text{Hg}/\text{Hg}_2\text{SO}_4$, and could lead to a situation in which, under constant potential charging, excessive gassing, incomplete charging of negative, and rampant positive grid corrosion may occur.

Figures 4 and 5 are replotted from the data given in Fig. 3 to show the dependence of the lead electrode hydrogen overpotential and current acceptance on the antimony concentration in the test system. The hydrogen evolution

potential of the lead electrode is arbitrarily defined as the intersection of the base current of the lead electrode at -980 mV *vs.* $\text{Hg}/\text{Hg}_2\text{SO}_4$, and the tangent of the LPS curve at 0.5 A current acceptance. The lead electrode hydrogen overpotential is obtained by subtracting the hydrogen evolution potential from the open-circuit potential of the test lead electrode. Figure 4 shows the asymptotic decrease of hydrogen overpotential with increasing antimony content in the test system. The isopotential current acceptance characteristics of the lead electrode as function of antimony concentration are shown in Fig. 5. These isopotential lines show the approximate critical concentration of antimony for an electrode with 10.5 g lead active material and the possibility that antimony can be purged from the lead electrode at potentials close to -1260 mV *vs.* $\text{Hg}/\text{Hg}_2\text{SO}_4$.

Critical potential to purge antimony from the lead electrode.—Figure 6 shows the antimony retention behavior of type B electrode with 0.5% Sb in the formed active material during constant potential charging at 1175 , 1225 and 1275 mV *vs.* reference for a 10 day duration. We note that the steady-state antimony content in the lead matrix is overcharge potential dependent; no release of antimony at -1175 mV *vs.* reference) overcharge and steady-state "Sb" concentration of 0.340 and 0.182 weight percent (w/o) in lead matrix for overcharge potentials of -1225 and -1275 mV *vs.* reference), respectively. Overcharging the test electrode at potentials more cathodic than -1275 mV *vs.* reference) was not possible because of a 10 A current limitation in our potentiostat.

Figure 7 shows the antimony retention characteristics of antimony containing type B plates during constant potential step charging from -1175 to 1375 mV *vs.* reference) at 50 mV step using two approaches. In the first approach 1, we analyzed the conventionally washed and dried plate samples for antimony content after each step of overcharge. In the second approach, we analyzed the stibine absorbing solution after each step of overcharge.

Fig. 7. Antimony purging behavior of the pasted-type electrode under increasing constant potential step charging.

Fig. 8. Cathodic LPS of 2 mm diam and 2 cm long lead electrode in 100 ppm antimony containing 1.250 sp gr H_2SO_4 as function of -1270 mV vs. Hg/Hg_2SO_4 constant potential charge duration. Lead electrode cathodic LPS in 1.250 sp gr is included for comparison.

The residual antimony in the plate in the second approach was determined by difference. We used test plates with two levels of initial antimony content, one with 0.5% and the other with 0.53%, in these two experiments, as evident from Fig. 7. The amount of overcharge at each potential step was 4.63 Ah/(gram negative paste), equivalent to 20.5 times the theoretical capacity. The data for antimony retention in the plate using these two approaches are very consistent (Fig. 7). The slightly low value of antimony content obtained from the plate matrix analysis could be considered due to some material loss during washing and drying of plate samples. The data presented in Fig. 6 and 7 suggest that a significant amount of antimony, when present in the negative, may come out of the plate at potentials close to -1275 mV (*vs.* reference) and the complete removal of antimony from the lead electrode by constant potential charging may not be possible. These results further show that antimony, once it has migrated to the lead electrode, may become electrochemically inseparable. This is substantiated by a side experiment in which the lead electrode cathodic LPS was monitored as a function of constant potential overcharge at -1270 mV (*vs.* reference) in presence of 100 ppm antimony in the test solution. The results are shown in Fig. 8. It shows a dramatic decrease in lead electrode hydrogen overpotential after addition of antimony in the test solu-

tion. Upon continuous charging at -1270 mV *vs.* Hg/Hg_2SO_4 , the gas evolution potential shifted cathodically and recovered about 150 mV after 17h charge. However, even after extensive charging to the extent of an additional 175h, no further cathodic shift in gassing potential was observed. This, again, indicates that the lead electrode experiences an irreversible change in the presence of antimony.

Conclusions

1. The lead-acid battery negative electrode has a charge efficiency in excess of 98% and remains unaffected by the presence of lignin-expander.
2. Antimony in the negative electrode reduces its charge efficiency and hydrogen overpotential.
3. Lignin-expander suppresses the adverse effect of antimony on lead electrode charge efficiency.
4. The critical antimony purging potential for the negative electrode is close to -1275 mV (*vs.* reference).
5. Antimony causes an irreversible anodic shift in the lead electrode hydrogen overpotential.

An Optical Study of the Iron Electrode in Alkaline Electrolyte

Z. Q. Huang¹ and J. L. Ord*

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

Ellipsometric measurements made as an iron electrode is cycled galvanostatically in unstirred 0.05M NaOH show that a low density outer layer builds up progressively over an inner compact oxide layer. The inner layer reaches a maximum thickness of approximately 38Å at oxygen evolution and is removed by cathodic reduction, whereas the outer layer thickens by over 100Å on each cycle. The outer layer is made up of partially dissolved reaction products which are alternately oxidized and reduced on each cycle, but there is no evidence that the inner layer (of Fe₃O₄) undergoes solid-phase oxidation or reduction under galvanostatic cycling. Under anodic conditions, the inner layer acts as a barrier layer for field-limited ionic transport, and when it is reduced on a cathodic cycle it provides the iron which enables the outer layer to grow on the subsequent anodic cycle.

Much of the recent work on the anodic oxidation of iron, particularly work involving ellipsometric measurements, has been carried out in the deaerated neutral borate electrolyte initially selected by Cohen and co-workers (1) for cathodic reduction studies. This electrolyte has features which make it ideal for studies of the passivity of iron, but boron is involved in the electrochemical processes, and quite different results are obtained in other electrolytes of the same pH. The feature convenient for ellipsometric work is the ability to reduce the surface back to its initial optical state without significant surface roughening or buildup of a layer of reaction products. In our initial optical study of the passivity of iron (2), we used both neutral borate and sulfuric acid electrolytes, but we found that a reaction-product layer built up rapidly in acid electrolyte and made it difficult to study the underlying passive layer optically.

A variety of models for the passive film on iron can be found in the literature. These range from single-phase films of FeOOH or Fe₂O₃ to two-phase films of FeOOH on top of Fe₂O₃ or Fe₃O₄ on top of Fe₃O₄. Although work on the system continues unabated, in our opinion (3, 4), it is unlikely that a consensus will emerge as long as workers in the field hold widely differing views of the fundamental processes involved. Our work on the system (5, 6) culminated in a model in which high field ionic transport controls the growth of a two-phase film composed of a layer of Fe₂O₃ adjacent to the electrolyte and a layer of Fe₃O₄ adjacent to the iron substrate. This model differs from the model proposed earlier by Sato and Cohen (7, 8) in the kinetics of film growth, but not in the structure of the two-phase film. In our model, the field in the inner Fe₃O₄ layer limits film growth, and passivity is conferred by the outer Fe₂O₃ layer.

Nonequilibrium transport-limited models have long been used to describe the growth kinetics in valve-metal systems where the potentials are too high to have thermodynamic significance, but it is not surprising that such models encounter considerable resistance when they are applied to the iron system, where potential clearly has thermodynamic significance in the two-wave cathodic reduction process. Our model of the anodic oxidation of iron is definitely a nonequilibrium model; the Fe₃O₄ film continues to grow in the passive region at potentials where Fe₂O₃ is thermodynamically favored. This feature of the model is in accord with our experimental findings; we find no evidence of solid-phase oxidation or reduction processes converting films of Fe₃O₄ to or from films of Fe₂O₃ in deaerated neutral borate electrolyte.

In this paper, we report the results of an ellipsometric study of the oxidation and reduction processes which occur when an iron electrode is cycled galvanostatically in air-saturated alkaline electrolyte. The objectives of this study are (i) to look for evidence of solid-phase oxidation or reduction processes involving films of Fe₂O₃ or Fe₃O₄,

(ii) to see whether ellipsometry can identify processes involving dissolved intermediates, and (iii) to see whether ellipsometry is better able to deal with the buildup of by-product layers in alkaline electrolyte than it is in acid electrolyte. One recent study (9) details a complex series of sequential and parallel oxidation and reduction processes many of which involve dissolved phase intermediates. This study describes Fe₃O₄ as a second-stage oxidation product which is subsequently further oxidized, whereas others claim that the subsequent reaction is the production of Fe₂O₃ by direct oxidation of metallic iron (10). Still others regard Fe₃O₄ as a byproduct layer produced after 3-5 reduction cycles in lithiated electrolyte (11), or by aging of Fe₂O₃ · H₂O (12). Recently Dunnwald *et al.* (13) studied iron in alkaline electrolyte using Raman spectroscopy and concluded that a primary passivating layer of Fe₃O₄ is covered by a nearly nonadhesive low density outer layer of alpha-FeOOH.

Experimental

Our preliminary measurements in alkaline electrolyte were carried out in 1M NaOH, but the results reported here were all obtained in air-saturated 0.05M NaOH at 22°C. The cell holds 60 ml of electrolyte, which is free of reaction products at the beginning of an experiment. The iron electrode is a cylindrical single crystal with a flat on one side for optical measurements. It is clamped between Teflon washers in a glass electrode holder which exposes a vertical area of 1.145 cm² to the electrolyte when mounted in the cell. The cell also contained a mercury/mercurous sulfate electrode, to which all potential measurements are referenced, and a platinum counterelectrode, but no gas-dispersion tube, and the electrolyte was not stirred.

The self-nulling ellipsometer uses quadrature Faraday modulation decoded by a two-phase lock-in amplifier and fed back to ministepping drives through voltage-to-frequency converters. Under typical operating conditions, the instrument has a response time of a few tenths of a second and a resolution of a few thousandths of a degree. The angle of incidence is set at 60°C to accommodate the equilateral prism used as a cell, and refractive index values quoted here are for a wavelength of 6328Å, the wavelength of the helium-neon laser used as a light source.

A process-control computer operates the circuitry used with the cell and records current and potential along with the polarizer and analyzer settings at specified time intervals. Potentials are digitized by a 16-bit analog-to-digital converter with a 25-μs conversion time. The operation of the ellipsometer is monitored on a four-trace oscilloscope, and progress of the experiment is followed on two storage displays and an X-Y plotter which are updated by the computer.

Results

In situ measurements with a null ellipsometer are best performed under galvanostatic conditions, where the re-

*Electrochemical Society Active Member.

quired null-tracking rate can be controlled. Rotating analyzer instruments operate in a somewhat different manner, but they also require time to achieve accuracy, and perform best when the rate of the process being studied is controlled directly. Linear potential sweeps are also useful for ellipsometric studies, but processes which involve significant charge transfer over a narrow potential range require slow sweep rates if the tracking speed of the ellipsometer is not to be exceeded. Linear sweeps are popular because peaks on the current-potential plot identify most of the electrochemical processes involved, but care must be taken not to ignore processes such as field-limited film growth which only shift the base line.

We use galvanostatic cycles for all of the measurements we report here. Using our recorded data we can compute values of dQ/dV to plot *vs.* potential if we wish to generate a plot analogous to a linear potential sweep *i-V* plot. (In a linear sweep, V is proportional to t , and, hence, the current, dQ/dt , is proportional to dQ/dV .) A variety of techniques can be used to carry out the numerical differentiation, but there is no very satisfactory way of dealing with the overshoot which can occur under galvanostatic conditions.

The first series of figures shows the results of an experiment in which an iron electrode is cycled repetitively at $87 \mu\text{A}/\text{cm}^2$ between oxygen and hydrogen evolution in 0.05M NaOH. Figure 1 shows the results obtained on the first cycle after a freshly polished iron electrode is inserted into a cell filled with air-saturated electrolyte which is free of reaction products, and Fig. 2 shows the results obtained on the ninth cycle. Corresponding points (chosen to identify the fully developed features observed on the ninth cycle) bear the same labels in the two figures. The initial cathodic cycle used to reduce the oxide film left after chemical polishing is not shown in Fig. 1. In deaerated borate electrolyte the initial reduction leaves the surface free of any film, but we cannot assume that this is true in air-saturated alkaline electrolyte. The first anodic cycle shows some structure between A and D, but the pronounced arrest between B and C which characterizes later cycles does not show up on the first cycle. Beyond point D, the potential exhibits the linear increase with time which we attributed to field-limited passive-state film growth in our work in neutral borate electrolyte. Oxygen evolution begins at E and continues to the beginning of the cathodic cycle at F. The first cathodic cycle exhibits two major arrests, F-G and H-I, but not the arrest between G and H seen on the ninth cycle. Close examination of the arrest between H and I shows that it is actually composed of two arrests at closely

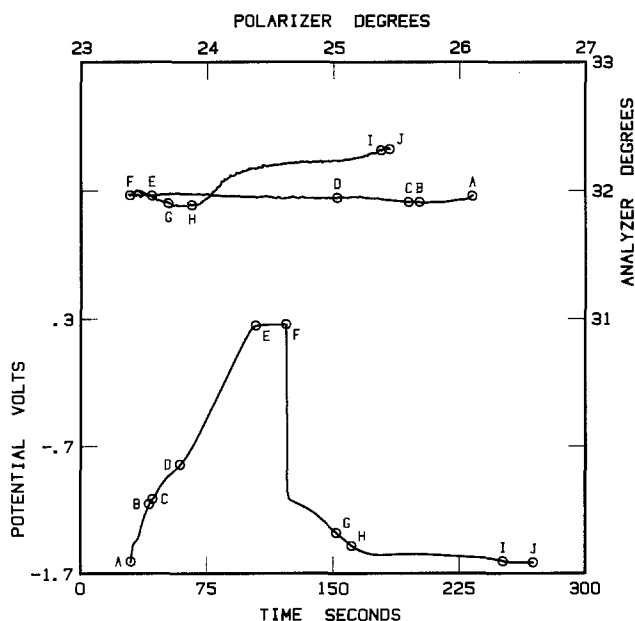

Fig. 1. First galvanostatic cycle at $87 \mu\text{A}/\text{cm}^2$ in 0.05M NaOH

Fig. 2. Ninth galvanostatic cycle at $87 \mu\text{A}/\text{cm}^2$ in 0.05M NaOH

spaced potentials. Hydrogen evolution begins at I and continues to the end of the cathodic cycle at J.

The curves traced out by the null settings of the ellipsometer during the first and ninth galvanostatic cycles are shown in the upper portions Fig. 1 and 2 in the form of plots of polarizer null setting *vs.* analyzer null setting. The optical data exhibit a complex structure which correlates strongly with the structure in the *V-t* curves, but the ninth cycle appears very different from the first cycle, and the reason for the difference is not apparent in Fig. 1 and 2.

The optical data do, however, have a definite pattern, and this pattern can be seen in Fig. 3 where we plot the data from all 18 cycles. A1-F1-J1 identify the first-cycle end points from Fig. 1, and A9-F9-J9 identify the ninth-cycle end points from Fig. 2. (The initial cathodic segment, omitted from Fig. 1, is shown in Fig. 3.) The dominant features of the pattern in Fig. 3 are the "loops" traced out by the cycle end points, and it is these loops which are the starting point for the optical analysis described in the next section.

There are two other ways of plotting the data in Fig. 2 which aid in their interpretation. In Fig. 4, we show the derived dQ/dV *vs.* potential plot we discussed at the beginning of this section. Three anodic processes, O1, O2, and O3, have peaks associated with them, and O4, passive-

Fig. 3. Optical data from 18 galvanostatic cycles at $87 \mu\text{A}/\text{cm}^2$ in 0.05M NaOH. End points of the first and ninth cycles, points A, F, and J in Fig. 1 and 2, have corresponding labels.

Fig. 4. Plot of dQ/dV vs. potential derived from the potential-time plot in Fig. 2. Four oxidation peaks and three reduction peaks can be identified in the figure.

state oxidation, shows up as an offset in the base line. Cathodic processes R1 and R2 have single peaks associated with them, but R3 is really two processes (which we will refer to as R3a and R3b) with closely spaced peaks which are just resolved on the scale in Fig. 4. Figure 4 contains really no information beyond what appears in Fig. 2, but it puts the information in a form which is more closely comparable to a linear sweep plot.

Figure 5, however, contains time-rate-of-change information about the optical data which is not present in the P-A plot in Fig. 2. The "optical tracking rate" plotted vs. time in the figure is the rate at which the null setting of the ellipsometer tracks along the P-A locus on the ninth galvanostatic cycle. Figure 5 uses the same time scale as the potential-time plot in Fig. 2, and corresponding points bear the same labels. Under galvanostatic conditions, film growth by substrate oxidation and removal by cathodic reduction produce optical changes which proceed at a steady controlled rate, whereas a process such as dissolution-precipitation produces changes which start slowly and then build rapidly to a peak before slowing down as the reaction products are consumed. Neither hydrogen nor oxygen evolution produces significant optical changes.

Cycles with restricted anodic or cathodic end points can help a great deal in the interpretation of both optical and electrochemical data. Figure 6 shows the results of a galvanostatic cycling experiment at $87 \mu\text{A}/\text{cm}^2$, in which the cathodic segment of the eighth cycle is terminated at the end of process R2 (point O in the figure). The cathodic segment of the preceding cycle is shown for

Fig. 5. Plot of optical tracking rate vs. time for the ninth cycle data. The time scale and the labeling are the same as in Fig. 2.

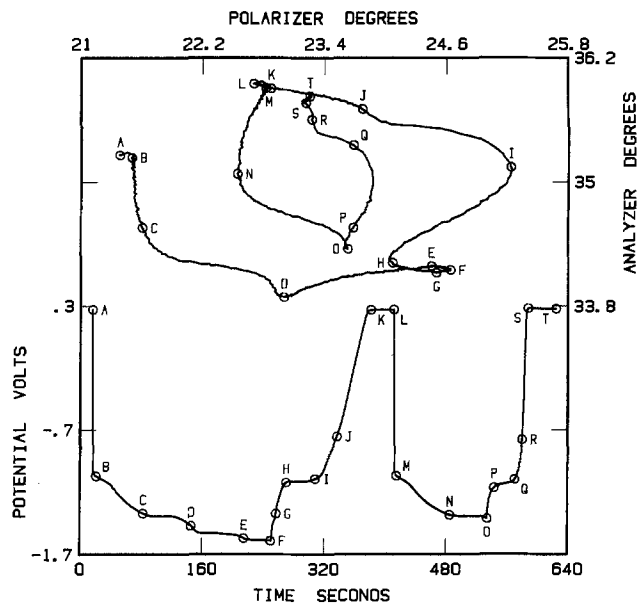

Fig. 6. Galvanostatic cycles at $87 \mu\text{A}/\text{cm}^2$ in 0.05M NaOH showing the effect of stopping the cathodic cycle at point O.

comparison purposes (points A through F), and the anodic segment of the subsequent cycle is plotted from O through T. The experiment was continued by applying three additional cycles with the same cathodic end point, then a complete cycle to gas evolution at each end, and finally a series of cycles with restricted anodic end points. The first cycle with a restricted anodic end point is shown in Fig. 7, along with the cathodic segment of the preceding complete cycle. The anodic cycle is terminated at the end of process O2 at point I, and the subsequent cathodic segment continues to point L.

Discussion

The loops traced out by the cycle end points in Fig. 3 act as the starting point for the optical analysis. An ellipsometer measures the change in polarization resulting from interference between light reflected at the electrolyte-film and film-substrate interfaces, and loops of this type are produced by the growth of a film which does not absorb light very strongly. If the refractive index of the film is only slightly higher than that of the electrolyte, the amplitude of the light reflected at the film-

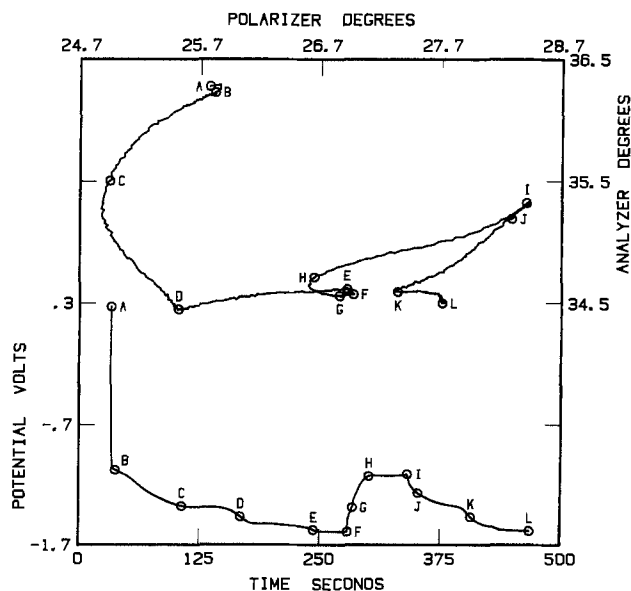

Fig. 7. Galvanostatic cycles at $87 \mu\text{A}/\text{cm}^2$ in 0.05M NaOH showing the effect of stopping the anodic cycle at point I.

electrolyte interface is much smaller than the amplitude of the light reflected at the film-substrate interface, and hence interference does not greatly change the polarization of the reflected light, and the null settings of the instrument trace out a relatively small loop as the film grows. Loop closure will occur when the product of the film thickness, and the cosine of the angle of refraction is equal to half the wavelength of light in the film; hence, the lower the film index, the greater the thickness at which closure occurs.

These considerations enable us to deduce a great deal from the optical data in Fig. 3 without detailed analysis. First, the film grows progressively and is not removed from the surface by cathodic reduction. Second, the film has a very low index (about 1.4), much lower than that of a solid-phase oxide film. Third, the difference in size of the end-point loops shows that the oxidized form of the film must have a higher index than the reduced form. Fourth, the film reaches a considerable thickness (well over 1000Å) after 18 cycles.

We conclude, therefore, that the film which grows progressively on iron in alkaline electrolyte is best thought of either as a very porous film containing considerable electrolyte, or as a film of electrolyte containing partially dissolved reaction products. The cyclic change in film index shows that the the oxidation state of the film is raised and lowered each cycle, and the processes by which this occurs account for the structure in the $V-t$ curves which is enhanced by cycling. We chose to use an unstirred electrolyte in these experiments so that we could study the growth and change in oxidation state of a film which does not adhere strongly to the surface, and we chose 18 cycles to get a thickness range wide enough for unambiguous optical analysis.

We know that an underlying compact oxide must also be present on the iron electrode at the end of an anodic cycle, and we next turn to the problem of how we distinguish its optical effects from those due to the outer layer. The problem is relatively easy to solve because the two layers have greatly different refractive indexes. The scales in Fig. 3 can accommodate only a small segment of the growth loop of a compact oxide and, over the thickness range found in neutral electrolyte, the growth segment appears essentially linear. In Fig. 8, we replot the optical data from Fig. 3, showing only the segments associated with processes O2 and R3b. The loops traced out by the end points of the segments are still an important feature of the figure, but now it is readily apparent that the optical changes associated with process R3b trace out a sequence of parallel linear segments of approximately the same length, whereas those associated with process O2 are of variable length and have changes in slope which reflect the change in the slope of the loop. From this, we

conclude that process O2 involves the progressively growing outer layer, and process R3b involves the underlying oxide layer. The O2 optical data initially parallel the growth curve for the lower oxidation state of the outer layer, then swing rapidly outward toward the curve for its higher oxidation state. From this, we conclude that O2 involves both growth and oxidation of the outer layer. R3b, however, appears to involve only the removal of the compact inner layer by cathodic reduction.

If we use this approach to classify the other processes, we conclude that formation of the compact oxide is begun by process O1 and continued to limiting thickness by process O4. O3 is more difficult to classify, because the rapid optical changes associated the O2 end just as O3 is reached, and the optical effects which can be identified with O3 appear little different from those associated with O4. R1 and R2 appear to be reduction processes involving primarily the outer layer, whereas R3a appears to involve reduction of the inner compact layer as well as continued reduction of the outer layer. The inflection point which divides R3 into R3a and R3b appears to mark the point at which reduction of the outer layer ceases.

The results of a quantitative analysis of the optical data based on the procedure described above for distinguishing between layers are plotted in Fig. 9. The data used in the analysis were taken from a sequence of eight standard cycles followed by the short cycle plotted in Fig. 6. The end-point data, offset slightly in P from the data in Fig. 3 because of a difference in surface roughness, are shown in Fig. 9 identified by cycle number. The short cycle points labeled A, F, L, and O in Fig. 6 are labeled O7, R8, O8, and P9, respectively, in Fig. 9. The bare surface point, point B, was chosen to provide the most consistent fit to the cathodic end-point data. They were found to fit a curve for the growth of a transparent film of index 1.381, and this curve is shown in the figure for growth to a thickness of 1400Å. The point corresponding to an inner layer of maximum thickness on a bare iron surface, point C, was similarly chosen to give a consistent fit to the anodic end-point data. If a value of 2.0 is assumed for N of the inner layer, a value of 0.25 is found for K, and the maximum thickness reached by the layer at point B is 38Å. The anodic end-point data fit a curve through B representing the growth of a transparent film of index 1.411, and this curve is shown in the figure for growth to a thickness of 1400Å. Also passing through B is a curve for growth of the 1.381 index film to a maximum thickness of 1400Å, this time on top of the 38Å inner layer. Points, such as P9, which fall on this locus are reached at the end of the outer-layer reduction processes R1 and R2. The outer layer can be treated as having some optical absorption, but the K values determined in the analysis are com-

Fig. 8. Replot of the optical data in Fig. 3 showing only the O2 (fine line) and R3b (bold line) segments.

Fig. 9. Theoretical analysis of eight complete galvanostatic cycles (reduction end points R1-R8, oxidation end points O1-O8) followed by the short cycle in Fig. 6 (in Fig. 6 L is O8, O is P9).

parable with the estimated error in K; hence, we prefer to treat the layer as transparent.

Figure 9 also shows theoretical curves for models of an outer-layer conversion process with end points at O8 and P9 (actually on the 1.411 index curve at 1192Å and on the 1.381 index curve at 1251Å). In model C1, the conversion takes place by homogeneous proportionate changes in index and thickness, and the corresponding P-A locus is roughly a straight line between the end points. In models C2 and C3, the conversion sweeps across the film from one interface to the other. In model C2, the outer layer has index 1.381, and in model C3 it has index 1.411. All three models can describe oxidation as well as reduction, but the theoretical curves are all drawn for a process which takes place on top of a 38Å inner layer, and these conditions pertain on an anodic cycle only for the short cycle shown in Fig. 6. The phase boundary between the components of the low index film is probably not as sharply defined as the models require, but the counter-clockwise looping of the optical data shows that oxidation generally follows model C3 and reduction follows model C2. This means that both oxidation and reduction sweep inward across the layer from the electrolyte interface. We cannot determine layer composition from our optical measurements, but we see no reason to dispute the identification of the oxidized form of the outer layer as α -FeOOH (13), which converts to ferrous hydroxide on reduction.

We agree also with the identification of the primary passivating layer as Fe_3O_4 (13) rather than Fe_2O_3 , and we regard the evidence in support of this identification to be equally as strong as it is in neutral electrolyte. The short cycle in Fig. 6 presents this evidence most clearly. Reduction is carried to a point where it is universally agreed that any Fe_2O_3 present will be reduced to Fe_3O_4 , then the anodic current is reapplied, and the anodic cycle shows no sign of a process which could possibly correspond to the oxidation of Fe_3O_4 back to Fe_2O_3 . Process O4 is completely absent, and the potential rises rapidly between R and S, in accordance with the predictions of a model in which the current is limited by the electric field in the Fe_3O_4 film. We do expect the outer surface of the Fe_3O_4 to be oxidized to Fe_2O_3 on an anodic cycle, and this likely occurs when the oxidation wave sweeping through the outer layer reaches the oxide surface. (This, finally, is our identification of process O3).

The short cycles are also useful for studying layer growth processes. The short cycle in Fig. 6 shows that outer-layer growth does not occur on an anodic cycle unless the inner layer is reduced on the previous cathodic

cycle, and it shows how process O2 is modified when oxidation takes place without layer growth. The short cycle in Fig. 7 shows that the outer-layer growth is complete and its oxidation is well advanced by the end of O2, and inner-layer growth has the overpotential proportionality expected of a field-limited process. If we trace the path of the iron which ends up in the outer layer, we see that it is removed from the substrate by the field in the inner layer on an anodic cycle, then delivered to the outer layer as dissolved ferrous ions on the next cathodic cycle, and finally incorporated into the outer layer as ferrous hydroxide which is oxidized to FeOOH by the oxidation wave sweeping in from the electrolyte interface.

Resistance of Titanium to Phosphidation and the Reaction Mechanism

Y. Sasaki and Y. Kabuto¹

Department of Synthetic Chemistry, Chiba University, Yayoi-cho, Chiba 260, Japan

ABSTRACT

A study was undertaken concerning the resistance of titanium to phosphidation at 650°-950°C in phosphorus vapor at 1 atm by a sealed-tube method. X-ray diffraction patterns and an electron microprobe analysis of the product films showed that the phosphide layer structure was $\text{TiP}_{1+x}/\text{TiP}/\text{Ti}_3\text{P}_2/\text{Ti}$. All the phosphidation reactions obeyed a parabolic rate law; hence, the rate-determining step was apparently a diffusion process. The parabolic rate constant was given as a function of the absolute temperature by the following expression.

$$K_p = 1.34 \exp(-34.5 \times 10^3/RT) \text{ g}^2\text{cm}^{-4}\text{h}^{-1}, (1 \text{ atm}, 923\text{-}1223 \text{ K})$$

A marker experiment indicated that the component which diffused was not phosphorus, but was titanium. Titanium metal was appreciably superior to iron, nickel, and chromium, which are the main constituent metals of stainless steel, with respect to phosphidation resistance.

Metallic materials such as stainless steel, Hastelloy, and Monel have been widely utilized because they have a corrosion-resistant property. One of the authors has reported previously on the kinetics and mechanism of the phosphidation reactions of iron (1), nickel (2, 3), chromium (4), and copper (5), which are the main constituents of these materials and also of Fe-Ni (6), Ni-Cr (7), and Fe-Cr (8) alloys.

As part of a series of studies on the phosphidation of metals, this study has been undertaken to develop a phosphorus resisting metallic material and to synthesize titanium phosphides; information is provided concerning the layer structure of phosphide films, the relationship between the products and reaction conditions, kinetics, and diffusing species.

Experimental

Materials.—A titanium sheet 0.5 mm thick with a purity of 99.7 mass % was cut into rectangles of approximately 6 mm × 25 mm. According to an analysis by the manufacturer, the impurity level of this sheet was as follows: O, 0.12 mass %; Fe, 0.05; C, 0.02; N, 0.02; H, 0.008. These coupons were abraded through 0/6-0/9 emery papers, then washed with refined toluene. They were chemically polished for 20s at room temperature in a solution consisting of 45 parts by volume 62% HNO_3 , 10 parts 46% HF , and 45 parts distilled water. These polished specimens were then rinsed in distilled water. Their geometric surface areas and weights were measured.

Red phosphorus was treated with a boiling 10% aqueous solution of sodium hydroxide for 5h, then with dilute hydrochloric acid. After being washed with distilled water, the refined red phosphorus was preserved in a desiccator with phosphorus pentoxide.

Apparatus and procedures.—The evacuated- and sealed-tube method (2, 5) was employed for the phosphidation. A sample sheet and an excess of red phosphorus were each placed at an end of the silica tube; this tube was sealed under vacuum. It seems reasonable that red phosphorus with various crystal structures will not give stable pressures of phosphorus vapor. Therefore, a conversion from red to liquid phosphorus is necessary to secure the stable pressures of phosphorus vapor in the closed system. In this study, the phosphorus vapor that evolved by heating the red phosphorus in the sealed tube was condensed by water cooling into liquid phosphorus.

The reaction apparatus consisted of a porcelain tube maintained in two temperature zones, the first zone being used to heat the sample sheet in a sealed silica tube and the second zone being used to control the vapor pressure of phosphorus in this tube. A vapor pressure of phos-

phorus was governed by the minimum temperature in the closed system. A temperature of 280°C gave 1 atm for the phosphorus vapor pressure (9) and was employed for all the phosphidation reactions. The apparatus and experimental methods employed in this study have been described in detail in previous papers (2, 5).

Results and Discussion

Metallic titanium was phosphidized at temperatures of 650°, 750°, 800°, 850°, 900°, and 950°C in phosphorus vapor at 1 atm. Because the sheet of titanium was used as a sample in this study, all the products of the phosphidation were films.

Fig. 1. X-ray diffraction patterns of the surface and reverse side of phosphide films formed on titanium sheets in phosphorus vapor at 1 atm. Effect of temperature and of reaction time: ○ TiP_2 ; ● TiP ; △ Ti_3P_2 ; ▲ Ti_5P_3 ; □ $\alpha\text{-Ti}$.

¹ Present address: Fuji Heavy Industries, Ltd., Nishi-shinjuku 1-7-2, Shinjuku-ku, Tokyo 160, Japan.

Compositions of phosphide layers.—Figure 1 illustrates the x-ray diffraction patterns of the surfaces of the phosphide films formed at 650°, 750°, 850°, and 950°C, employing nickel-filtered copper radiation. Also shown is the x-ray pattern of the reverse side of the film formed at 900°C. The diffraction peaks are identified by comparison with the literature values of diffraction angles of Ti (10), Ti_3P_3 (10), Ti_4P_3 (10), TiP (11), and TiP_2 (12).

Figure 1 shows that the composition of the products changes gradually with the reaction temperature. The reaction starting temperature seems to be somewhat less than 650°C because, in the diffraction patterns at 650°C-reaction for 2h, the diffraction angle $2\theta(CuK\alpha) = 37.6^\circ$ belongs alone to TiP, whereas all the other peaks are due to Ti. In the reaction for 48h at the same temperature, the diffraction peaks belonging to both TiP and the higher phosphide TiP_2 are found, as are those belonging to unaltered Ti. At the elevated temperature of 750°C for 2h, three new diffraction peaks belonging to TiP are observed. In the reaction for 48h at the same temperature, the peaks of Ti disappear completely. This phosphide film was composed of the mixture of mainly TiP and small amounts of Ti_3P_3 , Ti_4P_3 , and TiP_2 . At 850°C-reactions for 2 and 48h, the higher phosphide TiP_2 was not formed, but almost all the peaks were for TiP. Because no data for the equilibrium $TiP_2(s) \rightleftharpoons TiP(s) + 1/4 P_4(g)$ are reported, it is impossible to discuss what is expected to be formed under certain fixed reaction conditions. The pattern of 950°C-24h reveals the product to be TiP alone.

The diffraction pattern of the reverse side of the phosphide film formed at 900°C is in close agreement with that of Ti_4P_3 ; this is the same behavior found at other temperatures. It is worth noting that at the phosphide/titanium interface, the formation of Ti_4P_3 takes place. Lower phosphides Ti_2P (13) and Ti_3P (13) cannot be detected from x-ray diffraction at each temperature.

Composition variations through the phosphide film formed at an advanced stage of reaction were examined by EPMA. The specimens phosphidized at 850°C-48h and 950°C-24h were embedded in a polyester resin, the cross sections were polished with finely divided chromium (III) oxide powder, and the concentration distributions of phosphorus were then examined. These results are shown in Fig. 2.

It is clear from Fig. 2 that at the surfaces of both of the specimens, the concentrations of phosphorus reach about

Fig. 2. Distribution of phosphorus in the titanium phosphide film: A—850°C, 1 atm, 48h; B—950°C, 1 atm, 24h.

Fig. 3. Phosphidation of titanium in phosphorus vapor at 1 atm: ○ 950°C; ● 900°C; △ 850°C; ▲ 800°C; □ 750°C; ■ 650°C.

65 atom percent (a/o) and decrease toward the inner scale layers. It must be noted that two plateaus having constant phosphorus contents of 50 ± 2 and 42 ± 2 a/o are present in the bulk phosphide. The composition of the first plateau should correspond to TiP, and the second plateau adjacent to unchanged titanium should correspond to Ti_4P_3 from the x-ray diffraction patterns. The higher concentration of phosphorus observed at the surface is assumed to represent a dissolution of phosphorus in the TiP matrix. If this layer is tentatively termed TiP_{1+x} , the layer structure of the phosphide scaling film becomes approximately $TiP_{1+x}/TiP/Ti_4P_3/Ti$.

Kinetics and temperature dependence.—Plots of the mass gain per unit area vs. $\sqrt{\text{time}}$ are shown in Fig. 3. The small scatter of the data points is attributed to the fact that each point represents phosphidation of separate specimens.

Fig. 4. Comparison of K_p of Ti with values for Ni, Fe, and Cr (phosphorus pressure: 1 atm).

Table I. Parabolic rate constants for phosphidation of titanium in phosphorus vapor at 1 atm

Temp, °C	K_p , $\text{mg}^2\text{cm}^{-4}\text{h}^{-1}$
650	0.0093 ± 0.0015
750	0.0570 ± 0.0050
800	0.1200 ± 0.0100
850	0.2800 ± 0.0200
900	0.4900 ± 0.0400
950	0.9200 ± 0.0600

All the plots yield approximately straight lines, showing that the phosphidation proceeds according to a parabolic rate law; hence, the rate-determining step is apparently a diffusion or a transport process of titanium or phosphorus. Values of the parabolic rate constants, K_p , obtained from the slopes of these straight lines, are summarized in Table I.

A semilogarithmic plot of K_p vs. the reciprocal of the absolute temperature is shown in Fig. 4. This relationship gives a straight line, which may be approximately expressed as follows

$$K_p = 1.34 \exp(-34.5 \times 10^3/RT) \text{ g}^2\text{cm}^{-4}\text{h}^{-1},$$

(1 atm, 923-1223 K)

There is no effect of the conversion of α -Ti into β -Ti, which occurs at 882°C, on these kinetics. For comparison, the parabolic rate constants of phosphidation of iron (1, 6, 8), nickel (2, 6, 7), and chromium (4, 7, 8), which are the main constituent metals of stainless steel, are included in the same figure. As shown, the K_p of titanium is considerably smaller. Therefore, titanium metal should be superior to these metals with respect to phosphidation resistance.

Determination of diffusing species.—A marker experiment relating to the diffusion process was carried out for the phosphidation of titanium, with the use of alumina powder as a marker. Figure 5A shows a cross section of the specimen phosphidized at 950°C for 24h and the position of the alumina marker; this is confirmed in the SEM by AlK α radiation and is shown in Fig. 5B. Since the marker is situated at the phosphide/metal interface, the reaction is regarded as limited by diffusion of titanium through the phosphide layer. It has been reported previously that metal has diffused in the phosphidation of iron (6), chromium (4), nickel (7), and zinc (14) as in this study.

Impedance Relaxation Spectrum Analysis of Oxidized Silver Electrodes

Maria Hepel* and Micha Tomkiewicz*

Department of Physics, Brooklyn College of The City University of New York, Brooklyn, New York 11210

ABSTRACT

The real and imaginary parts of the impedance of the oxidized silver electrode in 1M KOH solutions have been measured in a frequency range of $1-1.3 \times 10^7$ Hz. When the electrode is oxidized at a potential when only Ag_2O is formed, we were able to isolate three passive elements: the high frequency capacitance and the high and low frequency resistances. On further oxidation, at a potential in which AgO can be formed, we were able to isolate five passive elements: two capacitive and three resistive. Two of these elements were identified as originating from the Ag_2O layer. The functional dependence of all these elements on the amount of charge that is used for oxidation reveals that the Ag_2O layer can be analyzed in terms of a single dielectricum in a parallel-plate capacitor. Parameters such as thickness of the layer, resistivity of the material, and roughness factor could be evaluated. We have found that at the potential in which AgO is formed, a significant fraction of the charge is used for the formation of Ag_2O .

The electrochemical behavior of silver-silver oxide electrode has been extensively studied (1-7) because of the importance of electrochemical storage systems such as silver-zinc, silver-cadmium, silver-iron, and silver-hydrogen batteries. It is known (17) that in alkaline solutions, silver is oxidized in two steps. During first stages of oxidation, silver undergoes dissolution with formation of $\text{Ag}(\text{OH})_2^-$ complexes (18), and Ag_2O is formed, which can be further oxidized to AgO . Impedance measurements (3, 19), in addition to more conventional electrochemical methods, were used extensively to characterize the chemical and morphological mechanism of the oxidation process (20). The technique of relaxation spectrum analysis, in which the impedance is monitored over a wide frequency range and the results are portrayed in terms of a set of parallel, frequency independent, R-C elements, was used in the past to describe the potential distribution at the semiconductor electrolyte interface (21). Recently, the technique was extended to characterize the interface of metallic single-crystal RuO_2 with aqueous electrolytes (22).

The principal condition under which one can apply this mode of interpretation to the frequency dispersion of the impedance of the interface is that the faradaic components will be negligible during the impedance measurements. Thus, if this condition is satisfied, the impedance measurements are used to monitor static characteristics of the interface and changes in these characteristics due to perturbation of the system prior to the impedance measurements. The correlation between the changes in the static characteristics and the perturbations which give rise to them provide the tools for understanding certain aspects of the dynamics of the system. The generalized equivalent circuit, which is based on a network of parallel RC elements and was so useful for the simple interfaces, is clearly not appropriate for the study of the oxidation of the silver electrode.

Ag_2O is a small bandgap [1.2 eV at 293 K (23)] semiconductor which is insulating with resistivities of the order at $10^6-10^8 \Omega \text{ cm}$ at room temperature (24). Although its electronic properties are not as well characterized as those of the better-known semiconductors, and not even as well as the properties of its structural analog, Cu_2O , there is no known method of doping this material to reduce its resistivity to the region in which its semiconducting properties will dominate.

Our knowledge of the solid-state properties of AgO are even less complete than that of Ag_2O . X-ray and neutron diffraction studies (25-27) suggest that AgO has a monoclinic structure, with two different Ag-O distances (2.18 and 2.03Å, approximately) corresponding to the distances Ag(I)-O and Ag(III)-O. AgO was characterized as an n type semiconductor, with a bandgap of ~ 2 eV (28). Unlike

Ag_2O , its resistivity can be reduced considerably to a level of $\sim 10 \Omega \text{ cm}$ (29-31). Since these two oxides vary so much in their transport properties, it is natural that the interpretation of the impedance data should assume their separate contributions to the transport properties to be in series with each other. This simplified assumption should result in two possible RC elements connected in series. If, however, AgO is formed not by direct oxidation of Ag_2O at the oxide electrolyte interface, but is instead through nucleation, then a random distribution of the two oxides may be expected. Such a random distribution cannot be analyzed in terms of well-defined, dielectric materials connected in series, but rather as a changing dielectric constant of a random composite that can be analyzed by utilizing effective medium theories (32). These theories can calculate the frequency dispersion of the dielectric constant of the composite as a function of its changing composition.

In this paper, we present evidence that, under certain experimental conditions, the evolution of the two oxides can be separately monitored. We present evidence that at least Ag_2O behaves as a pure dielectricum with a frequency-independent dielectric constant, and we follow the growth of Ag_2O as it is further oxidized to AgO .

Experimental

Apparatus.—The experimental setup for impedance measurements was similar to the one described elsewhere (11). It consisted of a Hewlett-Packard 3320-B frequency synthesizer, 3575-A gain-phase meter, and dc-bias supply. The system control and data acquisition were performed by a Hewlett-Packard Model 9830A microcomputer. The experimental data, relative magnitude M and phase shift Φ between the two input signals (derived from the impedance of the reference circuit and total impedance), were processed and analyzed by a computer interactive program. The electronic equipment used allowed for measurements up to a frequency of 13 MHz, a limit unsuitable in practice for potentiostatic systems.

Special precautions concerning the electrochemical cell design (as in the case of bridge methods) had to be undertaken. Although balancing the reference impedance and the cell impedance is not required for the method used, a comparable value of the reference impedance was always maintained in order to achieve the best accuracy of readings. The parasitic inductance of leads has been diagnosed, and all the results presented here are corrected for the high frequency inductance effects.

Electrochemical cell and materials.—The electrochemical cell used for measurements was a standard two-compartment plexiglass cell with a capacity of 100 cm^3 . The counterelectrode was made from a large graphite cylinder. A double-junction saturated (KCl) silver/silver chloride electrode with 1M KNO_3 external solution was used

*Electrochemical Society Active Member.

as a reference electrode. A high purity silver rod substrate (Johnson-Matthews, 99.99%) with an exposed surface area 0.385 cm^2 was used as a working electrode. The oxide films were prepared on this substrate according to a procedure described below.

All chemicals used were of analytical-grade purity. Deionized water ($18 \text{ M}\Omega$) was obtained using Mili-Q purification system.

Procedure.—The polycrystalline silver substrate electrodes were polished to a mirror-like surface using $0.05 \mu\text{m}$ alumina. The surface was subsequently degreased in acetone and propyl alcohol, etched in dilute HNO_3 solution, rinsed with deionized water, and dried in air. The bilayer electrodes were prepared in two steps. During the first step, a Ag_2O film was deposited in 1 mol/dm^3 KOH solution at constant potential $E = +300 \text{ mV}$ (vs. Ag/AgCl double-junction reference electrode) using standard electrochemical equipment (an EG&G Model 173 potentiostat, equipped with a Model 179 digital coulometer and Model 175 universal programmer). The deposition was carried out for several hours and was interrupted after a given charge had been passed through the cell. Then the electrode potential was increased to $+600 \text{ mV}$, which is in the region of the AgO formation. The deposition was carried out for different times in order to grow oxide films of different thicknesses. The anodic charge consumed in the second step was from 0.47 to 15.1 C . The electrodes obtained in this way were then subsequently used in the impedance measurements with the network analyzer setup described above.

All the solutions used were deoxygenated by passing argon through the cell. During the experiments an argon purge was maintained.

Results and Discussion

Figure 1 shows the cyclic voltamogram of the oxidation and reduction of the silver/silver oxide electrode with the arrows indicating at which potentials the films were oxidized and the potentials at which the impedance of the system was measured. Figure 2 shows the impedance spectrum of the system when only Ag_2O is deposited, and Fig. 3 shows the impedance spectrum with 0.44 C used for Ag_2O deposition, followed by further oxidation to form AgO . Similar data were taken for different amounts of deposition charge. Next, a generalized way of analyzing these results will be presented, followed by a detailed account of the $\text{Ag/Ag}_2\text{O}$ and $\text{Ag/Ag}_2\text{O/AgO}$ systems.

Fig. 1. The CV characteristic for the polycrystalline silver electrode (geometric area $A = 0.385 \text{ cm}^2$) in 1 mol dm^{-3} KOH solution at 22°C . $V = 10 \text{ mV/s}$. E_{dep}' and E_{dep}'' are potentials of deposition of Ag_2O and AgO , respectively (used in further deposition experiments). E_r' and E_r'' are the rest potentials at which impedance spectra were measured.

Fig. 2. Impedance spectrum for a polycrystalline silver electrode covered by a thin film of Ag_2O deposited at $E = +300 \text{ mV}$ (vs. Ag/AgCl). (I) $Z = \log R$, (II) $Q = \log(2\pi X)$, (III) $Q = -\log f - \log C_f$. Solution: 1 mol dm^{-3} KOH.

Fig. 3. Impedance spectrum for a bilayer $\text{Ag/Ag}_2\text{O/AgO}$ electrode in 1 mol dm^{-3} KOH. Total deposition charge: 2.9 C/cm^2 . (I) $Q = \log R$, (II) $Q = \log(2\pi X)$.

Relaxation spectrum analysis in a series presentation.—The generalized equivalent circuit of the system is presented as a series of passive R-C elements, as shown in Fig. 4(a), where R_s is the series resistance due to the electrolyte, r_s^i the series resistance of phase i , and C_p^i and R_p^i the capacitance and shunt resistance, respectively, of phase i . If phase i behaves like an insulator, then $r_s^i = 0$ and C_p^i and R_p^i will relate, through the geometry of the system and the frequency, to the real and imaginary parts of the dielectric constant. If, on the other hand, phase i behaves like a semiconductor with a space-charge layer which is small compared to the thickness of the material, then only r_s^i relates to the resistivity of the system and C_p^i and R_p^i will relate to the charge distribution at the space-charge layer and will vary with the potential drop across phase i . The impedance of such an equivalent circuit is given by

$$Z = R + jX = R_s + \sum_i Z^i \quad [1]$$

where R and X are the real and imaginary components of the impedance.

$$Z^i = r_s^i + \frac{R_p^i}{1 + j\omega\tau^i} = r_s^i + \frac{R_p^i}{1 + (\omega\tau^i)^2} - j \frac{\omega R_p^i \tau^i}{1 + (\omega\tau^i)^2} \quad [2]$$

where ω is the angular frequency and $\tau^i = R_p^i C_p^i$ is the relaxation time characteristic of phase i . Substituting Eq. [2] into Eq. [1], we will obtain the following expressions for the real and imaginary parts of the total impedance

$$R = R_s + \sum_i r_s^i + \sum_i \frac{R_p^i}{1 + (\omega\tau^i)^2} \quad [3]$$

$$X = -\omega \sum_i \frac{R_p \tau_i^i}{1 + (\omega \tau_i)^2} \quad [4]$$

Thus, as in the parallel case, a function can be formulated, in this case, simply by the imaginary part of the impedance, in which one obtains a line shape which is a superimposition of lorentzian-type peaks. If the various contributions can be resolved, then the number of peaks will indicate the number of components i . Each peak will be centered at $\omega = 1/\tau_i$, and X at the maximum will be equal to $R_p/2$, from which one can readily evaluate C_p^i and R_p^i .

From the high frequency components of the real part, one can evaluate $R_s + \sum_i \tau_s^i$. The individual τ_s^i cannot be evaluated by this technique.

Figure 3 shows the impedance spectra, when both Ag_2O and AgO are present. The imaginary part of the impedance, even in the logarithmic scale, shows clearly two main peaks. It remains to be established whether either of these peaks is due to a single relaxing, passive, RC element, but clearly the procedure that was established here offers the best starting point.

Figure 2 shows the impedance spectra when only Ag_2O is present; it does not show any resolvable peaks in the imaginary part. The behavior here resembles the one observed with single phase interfaces and was analyzed (11) in terms of a network of parallel RC elements as shown in Fig. 4b. We will not attempt a full analysis of the network here and will concentrate only on the fastest relaxing RC element and the shunt resistance $R(O)$.

It should be emphasized that the analysis of the data in terms of parallel or series networks is not unique and is a matter of convenience only. It serves primarily to isolate charge accumulation modes according to their relaxation times.

Ag/Ag₂O system.—Under the conditions in which relaxation spectrum analysis on a parallel network can be performed, there exists a frequency region in which the equivalent circuit can be reduced to a single RC element (11). In this frequency range, the impedance is given by

$$Z_{\text{HF}} = R - \frac{j}{\omega C_f} \quad [5]$$

In this region

$$\log(2\pi X) = -\log f - \log C_f \quad [6]$$

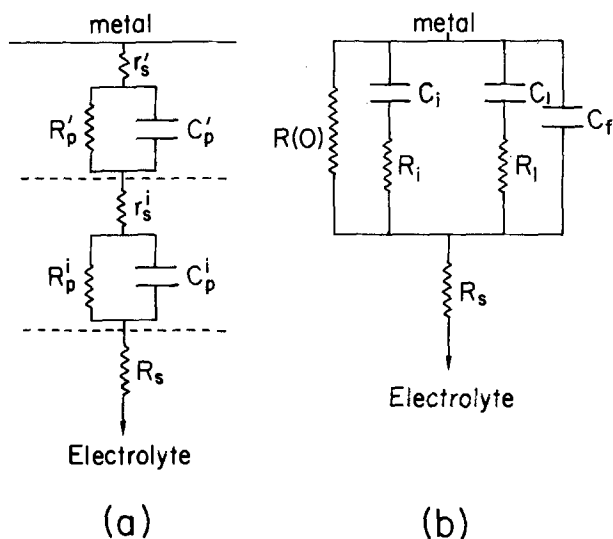

Fig. 4. Generalized equivalent circuit for series (a) and parallel (b) configurations of the passive elements. R_p and C_p are the parallel resistance and capacitance, respectively, for the inner film (prime) and the interface (i); τ_s 's stand for the respective time constants; R_s is the ohmic resistance mainly due to the electrolyte; $R(O)$ is the low frequency resistance; C_f is the film capacitance; and C_i, R_i are the series time constants.

and $\log(2\pi X)$ should be linear with $\log f$ with a slope of -1 and an intercept from which C_f can be extracted. The real part is frequency independent and equal to R_s , the series resistance of the system which is due to the electrolyte. From Fig. 2, the frequency range of 8,000-800,000 Hz satisfies these criteria (curve III in Fig. 2). The exact frequency domain in which these criteria are met varies from experiment to experiment. For each experiment, the entire frequency dispersion of the impedance was measured, the frequency domain with the fastest relaxing RC element identified, and the resistance and capacitance values measured. The variations of these parameters with the amount of charge that was passed to oxidize silver to Ag_2O will be discussed in this section. The oxidation was done at a constant potential of 0.3V vs. Ag/AgCl with different oxidation times, and the measurements were taken at the rest potential which changed little between the limits 0.19-0.24V vs. Ag/AgCl with increasing film thickness. For each experiment, the electrode was freshly polished.

Figure 5 shows the results of the dependence of $1/C_f$ on the oxidation charge Q . Figure 6 shows the dependence of R_s on Q which was taken from the high frequency component of R . The same figure also shows the dependence on Q of $R(l)$, the real part of the impedance at low frequency. The spread in the data is considerable; nevertheless, a few qualitative conclusions can be drawn: (i) R_s is independent of Q and can be shown to be dominated by the resistance of the electrolyte, and (ii) C_f decreases as Q increases, while $R(l)$ remains approximately constant within the large spread of the data. If we attempt to treat the system as a parallel-plate capacitor in which Ag_2O serves as the dielectricum and further assume a unit faradaic efficiency for formation of Ag_2O , then

$$Q = \frac{2Fd\gamma Al}{M} \quad [7]$$

where F is the Faraday constant, d is the density, A the geometric area, l the thickness of the capacitor, γ the roughness factor, and M the molecular weight of Ag_2O . The capacitance will be given by

Fig. 5. Dependence of the reciprocal of the Ag_2O film capacitance $1/C_f$ determined from the impedance relaxation spectra upon the oxidation-charge Q . Coefficients of the linear fit to the experimental points are given.

Fig. 6. Plot of the experimental data R_s and $R(l)$ vs. deposition charge Q for the $\text{Ag}/\text{Ag}_2\text{O}$ electrode in 1 mol dm^{-3} KOH solution.

$$C = \frac{\epsilon_0 \epsilon \gamma A}{l} \quad [8]$$

where ϵ is the dielectric constant and ϵ_0 is the permittivity of free space. The resistance, R_T , which is associated with this dielectricum is given by

$$R_T = \frac{\rho l}{\gamma A} \quad [9]$$

where ρ is the resistivity of Ag_2O . Substituting l from Eq. [7] into Eq. [8] and [9], one gets

$$\frac{1}{C_T} = \frac{MQ}{2Fd\epsilon\epsilon_0 A^2 \gamma^2} \quad [10]$$

$$R_T = \frac{\rho MQ}{2FdA^2 \gamma^2} \quad [11]$$

These equations predict linear behavior of $1/C_T$ and R_T with respect to Q , and they predict also that $\tau = R_T C_T = \rho \epsilon \epsilon_0$ is independent of the geometric factor involved. The data from Fig. 5 can be analyzed in terms of Eq. [10] after correcting for C_e , the capacitive element on the electrolyte side of the interface, such that

$$\frac{1}{C_f} = \frac{1}{C_T} + \frac{1}{C_e} \quad [12]$$

Analysis of Fig. 5 in terms of Eq. [10] and [12] yields an intercept of $8 \times 10^5 \text{ F}^{-1}$, a slope of $8.5 \times 10^6 \text{ C}^{-1} \text{ F}^{-1}$, with a correlation coefficient of 0.92.

The dielectric constant of Ag_2O is not reported in the literature, but the variations in similar solids (oxides and nonoxides) are all within the range of 5-10. If we take the dielectric constant of Ag_2O to be similar to that of Cu_2O , which is its structural analog, then $\epsilon \approx 7$. Taking $d = 7.44 \text{ g/cm}^3$, $M = 232$, and $A = 0.385 \text{ cm}^2$, one can calculate from the slope of Fig. 5 and from Eq. [10] that $\gamma = 14$. From the intercept, we obtain $C_e = 3.2 \times 10^{-6} \text{ F/cm}^2$ (geometric area), and if one takes into account the roughness factor, $C_e = 2.3 \times 10^{-7} \text{ F/cm}^2$. These values are on the low side of the capacitance of the Helmholtz layer, but the quality of the data and the assumptions in the model make further speculation unwarranted.

If, at least qualitatively, the data in Fig. 5 could be analyzed in terms of Eq. [10], it is obvious that the data in Fig.

6 cannot be analyzed in terms of Eq. [11]. $R(l)$ does not represent R_T . We will return to the possible characterization of $R(l)$ in the next section. At this stage, since we do not possess, as yet, information about the resistive component across the oxide, we cannot evaluate the relaxation time of the material. Hence, we cannot evaluate its resistivity.

Ag/Ag₂O/AgO system.—For this set of experiments, the amount of charge used for Ag_2O formation was kept constant at 0.44C. Following Ag_2O formation, we increased the potential to $E = 0.600 \text{ V vs. Ag/AgCl}$, where AgO formation takes place (see Fig. 1). We have measured the impedance at the rest potential of $\text{Ag}_2\text{O}/\text{AgO}$, which is $0.450 \text{ V vs. Ag/AgCl}$. We have measured the impedance as a function of the amount of charge that was used for deposition of AgO . Figure 3 shows a typical result of such a measurement. As mentioned above, even on a logarithmic scale, two peaks, one at high frequency and the other at low frequency, can be seen. The procedure developed above will be used as a basis for interpreting the results. The first step in this process is to establish whether either of these peaks is due to a single relaxing, passive, RC element. Examination of the low frequency peak in Fig. 3 clearly shows that the peak is too broad for a single lorentzian. Figure 7 shows the change of the frequency dispersion of the imaginary part of the impedance with the amount of charge that was used to form the oxide. The amplitude of the high frequency peak increases in direct proportion to the deposition charge, while the high frequency tail of the low frequency peak is little affected by the deposition. Figure 8 shows the numerical fit of the high frequency peak to a normalized single lorentzian. Except at the tail ends of the peak, where an inductance dominates on the high side and low frequency contributions affect the low side, the fit is very good; the peak will be treated as a single lorentzian.

As was mentioned before, the low frequency peak is much too broad for a single lorentzian. We do not want to speculate here about the various processes that might contribute to this peak. Figure 7 shows that the high frequency tail of this peak remains constant with deposition charge. It will be useful to determine whether this high frequency tail corresponds to a single passive RC element. From Eq. [4], the contributions of a single lorentzian to the imaginary part of the impedance is given by

Fig. 7. Frequency dispersion of the imaginary part of the impedance of the bilayer $\text{Ag}/\text{Ag}_2\text{O}/\text{AgO}$ electrode in 1 mol dm^{-3} KOH at various AgO deposition charges [C]: (1) 0.91, (2) 1.05, (3) 1.19, (4) 1.48.

Fig. 8. Computer fit of the high frequency reactance peak to a single lorentzian for different AgO deposition charges [C]: (1) 0.91, (2) 1.05, (3) 1.19.

$$X^i = - \frac{\omega R_p \tau^i}{1 + (\omega \tau)^2} \quad [13]$$

The high frequency tail of this peak is defined for $\omega \tau^i \gg 1$. Under these conditions

$$X^i = -1/\omega C_p^i \quad [14]$$

and the analysis will be similar to that for the high frequency component of the parallel case which was used above.

Figure 9 shows the fit between the experimental points on the high frequency tail of the low frequency peak and Eq. [14]. The fit is good over nearly two orders of magnitude of frequencies. From the intercept of this curve

$$C_p = 4.10^{-5} \text{ F} \approx 1.0 \times 10^{-4} \text{ F/cm}^2$$

based on the geometric area of the electrode.

Based on the absolute value of C_p and particularly the observation that it is nearly independent of the amount of AgO deposition or Ag_2O growth during the deposition of AgO, it is reasonable to associate this capacitive element with the junction between AgO and the electrolyte. It can be dominated by the capacitance of the Helmholtz layer, or by that of the space-charge layer in the conductive oxide or by combination of the two. As long as the width of the space-charge layer is smaller than the thickness of the

Fig. 9. Fit of the high frequency tail of the low frequency peak to a single lorentzian for the bilayer Ag/Ag₂O/AgO electrode.

Fig. 10. Dependence of the reciprocal of the inner film capacitance $1/C_f$ for the bilayer Ag/Ag₂O/AgO electrode in 1 mol dm⁻³ KOH upon the oxide deposition charge Q_1 .

oxide, the value of the capacitance will be independent of charge.

Let us now turn our attention to the fastest relaxing RC element. Figures 10 and 11 show the variation of $1/C_f$ and R_f with the amount of charge Q_1 associated with deposition at 0.6V on top of 0.44C associated with Ag_2O that was deposited at 0.3V vs. Ag/AgCl. Figures 10 and 11 show that both R_f and $1/C_f$ increase with Q_1 , where Q_1 is the total amount of charge deposited at 0.6V vs. Ag/AgCl. They then both saturate at $Q_1 > 5\text{C}$. If we neglect the low coverage (up to 0.5C) where nucleation is known to take place, the functional dependence can be represented by

$$\frac{1}{C_f} = \frac{5.6 \times 10^7 Q_1}{1 + 1.1 Q_1} \quad [15]$$

$$R_f = \frac{187 Q_1}{1 + 0.67 Q_1} \quad [16]$$

The inserts in both figures show the dependence of C_f and $1/R_f$ on $1/Q_1$, from which the constants in Eq. [15] and [16] were evaluated. If we take the saturation in both R_f and C_f to indicate saturation in the formation of the dielectric material that is responsible for the high frequency peak, then, within the parallel-plate approximation

$$\tau = (R_f C_f)_{\text{sat}} \approx 5.10^{-6} \text{ s} = \rho \epsilon \epsilon_0 \quad [17]$$

Taking again, as in Eq. [2] $\epsilon = 7$, we obtain $\rho \approx 8.2 \times 10^6 \Omega \text{ cm}$.

The high resistivity can only be due to Ag_2O . We arrive at the conclusion that at the potential at which we form AgO, the characteristics of the Ag_2O layer changes as well. If AgO is being formed by oxidation of Ag_2O whose thickness does not increase, the expected changes would have been the exact opposite to those actually observed. One can observe a decrease in the thickness of the Ag_2O layer when nucleation of AgO proceeds. This case corresponds to consumed charges for oxidation much less than 0.5C. In our experiments, we were in the region of

Fig. 11. Plot of the reciprocal of the inner film resistance R_f vs. Q_1 for the Ag/Ag₂O/AgO layered electrode in 1 mol dm⁻³ KOH.

charges used for oxidation far behind the nucleation process. In this set of experiments, the electrode was oxidized at $E = +600$ mV vs. Ag/AgCl with charge consumption up to 15C. The observed results in Fig. 10 and 11 can be interpreted that at this potential both oxides Ag₂O and AgO grow simultaneously.

Assuming, as a result, that Fig. 10 and 11 indicate continuous deposition of Ag₂O while Ag₂O is being further oxidized to AgO, we will try to analyze the correlation between R_f and $1/C_f$ with Q in a manner similar to that in the previous section. Let us assume that fraction of the charge, Q_1 , was used for the oxidation of Ag₂O to AgO and that the remaining charge was used for the oxidation of Ag to Ag₂O. The net amount of charge used for deposition of new Ag₂O is given by

$$Q_{\text{net}} = (1 - 2\alpha) Q_1 \quad [18]$$

Following the arguments that led to Eq. [10] and [11] in the previous section, the capacitance and resistance of the newly formed Ag₂O layer will be given by

$$\frac{1}{C_f} = \frac{n(1 - 2\alpha)Q_1}{2Fd\epsilon\epsilon_0 A^2 \gamma^2} + \frac{1}{C_f^0} \quad [19]$$

$$R_f = \frac{\rho M(1 - \alpha)Q_1}{2FdA^2 \gamma^2} + R_f^0 \quad [20]$$

where C_f^0 and R_f^0 are the values for $Q_1 = 0$.

Comparing Eq. [15] and [16] with Eq. [19] and [20] prior to saturation one can evaluate $\gamma/\sqrt{1 - 2\alpha}$. This implies that, if we can evaluate the roughness factor in an independent experiment, then the ratio between the two oxidation reactions can be evaluated. From Eq. [19] and [15], one can calculate that $\gamma/\sqrt{1 - 2\alpha} = 15.3$.

Up to now, we have evaluated all the data that we could extract from the frequency dispersion of the imaginary part of the impedance. From Fig. 3, one can observe that at both ends of the frequency spectrum, the real part of the impedance is frequency independent. Figure 12 shows the dependence of the high frequency component,

Fig. 12. Dependence of $R(\infty)$ and $R(1)$ upon the oxide deposition charge Q_1 for the bilayer Ag/Ag₂O/AgO electrode in 1 mol dm⁻³ KOH.

$R(\infty)$ and the low frequency component, $R(1)$, as a function of deposition charge. The high frequency component exhibits the behavior that was shown in Fig. 6, when only Ag₂O was present and is consistent with the interpretation that $R(\infty)$ is due to the series resistance, R_s , which is due to the electrolyte. $R(1)$, on the other hand, increases with deposition charge in a manner which resembles R_f in Fig. 11. However, the absolute values are considerably smaller than the R_f values. This is in sharp contradiction with Eq. [2], which demands that

$$R(O) = \lim_{\omega \rightarrow 0} R = R_s + \sum r_s^i + \sum R_p^i \quad [21]$$

Since R_f is one component of this sum, Eq. [21] requires that $R(O) > R_f$. Since the low frequency part of the imaginary part of the impedance was shown to result from multiplicity of unresolved processes, we do not feel secure in proposing a definite explanation for this fact. More work is needed before some conclusion about the low frequency regime can be reached.

Conclusions

It was shown that impedance measurements can be used to gain information about the chemical and topological changes that take place during oxidation of the silver electrode. The distinction between perturbation and detection was the key in enabling us to interpret the results using the simplest possible model and to correlate the measurements with the perturbation in a straightforward way.

The technique of relaxation spectrum analysis separates the charge accumulation modes at simple interfaces, according to their relaxation times, expressed in terms of simple, frequency-independent, RC elements. This technique can be extended to systems in which to first approximation, the charge accumulation modes are in series with each other. Under conditions when only Ag₂O is deposited, the impedance spectra behaved similarly to that

of a single interface. Three well-behaved, passive elements were extracted: the high frequency capacitance, the high frequency resistance, and the low frequency resistance. The physical origin of these elements was identified by monitoring their dependence on the amount of charge that was used to oxidize the electrode. The resistive element was found to be independent of charge, while the reciprocal of the capacitive element increased linearly with the amount of charge. The functional dependence of the capacitive element on the amount of charge was consistent with a simple model of a parallel-plate capacitor in which Ag_2O serves as the dielectric material. Based on this model, an "average" roughness factor, which is independent of the thickness of the layer was calculated and found to be ~ 14 . Based on this model, it was determined that, at least for the conditions that were investigated here, Ag_2O behaves as an insulator in which the electric field is distributed across the entire sample and does not concentrate at the interface. The high frequency resistance was associated with the resistivity of the electrolyte, while the low frequency resistance was associated with kinetic effects. At the potential in which the silver can be oxidized to AgO , five well-behaved, passive elements were extracted, and their variation with the amount of deposited charge was monitored. The capacitive and resistive elements of a single dielectricum were isolated. In terms of a parallel-plate model, these two parameters relate to the real and imaginary parts of the dielectric constant of the material through the geometric factor of the capacitor. The relaxation time of this material was found to be $\sim 5 \cdot 10^{-6}$ s from which a resistivity of $\sim 8 \times 10^6 \Omega \text{ cm}$ was evaluated. The high resistivity clearly demonstrates that the material is still Ag_2O . The conclusion was that, at the potential where silver can be oxidized to AgO , a significant fraction of the charge is used to increase the thickness of the Ag_2O layer. For an amount of charge in excess of $\sim 15 \text{ C/cm}^2$, the capacitive and resistive elements which are associated with the Ag_2O saturate, and a steady state is achieved between formation of Ag_2O and oxidation of Ag_2O to AgO .

Nucleation of Pb Electrodeposits on Ag and Cu

Joseph C. Farmer and Rolf H. Muller*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Initial stages in the electrocrystallization of Pb (up to 200Å thick) from 1M NaClO₄, 0.5 and 5 mM Pb(NO₃)₂, pH 3, on Ag(111) and Cu(111) have been investigated by ellipsometry and light scattering during cyclic voltammetry. Optical constants, thickness, valence, and free energy of adsorption of the underpotential deposit have been determined. An optical model which agrees with experimental data for fractional coverage by the underpotential deposit is based on the two-dimensional spreading of islands of monolayer thickness. The bulk deposit immediately following formation of the underpotential monolayer involves three-dimensional growth from nucleation centers, even at the 20Å level of deposit thickness, and results in a particulate, porous film on top of the underpotential deposit.

Two separate steps can often be identified in the early stages of the electrocrystallization of a metal on a dissimilar substrate: the formation of an underpotential deposit (UPD) and that of a bulk deposit (1-3). The properties of these layers are expected to be an important factor for determining the properties of subsequently formed deposits of practical interest with macroscopic thicknesses. This work was undertaken to investigate the transition from the underpotential deposit (the first monolayer) to the bulk deposit and the micromorphology of the two deposits by *in situ* optical techniques. Fast automatic ellipsometry and light scattering during cyclic voltammetry made it possible to separate optical changes due to formation of the first monolayer from those associated with subsequent formation of the bulk deposit. The system chosen for study was the deposition of Pb on Ag and Cu because of the well-known formation of the underpotential layers (4). There are also significant differences in the optical constants of Pb and the substrates, making detection of small amounts of Pb on the electrode surface by ellipsometry possible (5-7).

Schmidt and Gyax (3) have determined the Gibbs free energy of adsorption for Pb electrosorption on polycrystalline Ag and Cu by integrating the cathodic UPD peak in the cyclic voltammogram and deriving coverage as a function of potential. Here, adsorption isotherms for the Pb underpotential deposit have been determined similarly on single-crystal Ag and Cu surfaces. In addition, thickness and optical constants of the underpotential deposit were derived from ellipsometer measurements and a knowledge of surface coverage determined electrochemically. Unusual optical properties of the bulk deposit have been attributed to its morphology.

Experimental Procedure

Experiments were conducted potentiodynamically while simultaneous ellipsometer and light scattering measurements of the electrode surface were performed. A bipotentiostat (Pine RDE 3) was used to drive the electrochemical cell. The potential was swept from 200 to -800 mV (*vs.* Ag/AgCl) at sweep rates varying from 0.1 to 1.5 V/min.

A self-nulling ellipsometer (8) was operated at an angle of incidence of 75° with a stabilized 75W xenon short-arc light source (Oriol C-72-20) and an interference filter for 515 nm (bandwidth 9 nm, transmission 43%). An acrylic electrolytic cell used in an earlier investigation of anodic silver oxidation (9) was employed. The cell had two quartz windows for ellipsometry with an angle of incidence of 75°, a volume of approximately 250 ml, and ports for introduction and draining of electrolyte, for a nitrogen purge stream, and for a reference electrode capillary. A Pt counterelectrode was used and positioned so as not to interfere with the observation of the working electrode.

Ag(111) and Cu(111) working electrodes were used. The single-crystal surfaces were approximately 1.20 × 2.85 cm (3.42 cm²), and were mounted in epoxy. The electrodes

were polished mechanically, ultimately using 0.05 μm aluminum oxide powder suspended in water. The polishing was followed by ultrasonic cleaning, chemical polishing for Ag surfaces (9, 10), a period of soaking in the acidic electrolyte, and pre-electrolysis. Any oxides formed on the electrode surface during transfer to the cell were unstable at the pH and potential used for the experiments and removed during pre-electrolysis at a potential anodic to that for Pb deposition (11, 12). No significant electrochemical or ellipsometric differences were observed between Ag electrodes polished mechanically and chemically and those polished only mechanically, although a smoother surface, important for light scattering measurements, was expected to result from chemical polishing. The chemical polishing step was omitted after scattering measurements were completed.

The reference electrode used was a double-junction Ag/AgCl electrode (Dow-Corning 476067). The inner compartment, containing the electrode, was filled with 4M KCl saturated with AgCl, the outer compartment with 1M KNO₃.

A second cell was used for light scattering studies, and has been described elsewhere (9). This cell used high purity, polycrystalline Ag sheets rather than single crystals. The electrode was 0.5 × 5.0 × 0.2 cm and was 60% immersed in electrolyte. It was located in a cylindrical glass cell of 4 cm diam and illuminated with the beam from an argon laser (515 nm line) at an angle of incidence of 75°.

All experiments used a supporting electrolyte of 1M NaClO₄ at pH 3. Pb²⁺ ion was introduced into the electrolyte as a nitrate at concentrations of either 0.5 or 5.0 mM. The pH was adjusted to the desired level by adding small amounts of dilute HClO₄, and measured with a digital pH meter (Corning 130).

Experimental Results

Potential ramp and cyclic voltammogram data for the deposition of Pb on Ag(111) from a 0.5 mM solution at a sweep rate of 0.1 V/min are shown in Fig. 1 and 2.

Ellipsometer measurements (psi and delta) during two potential cycles for deposition on silver are shown in Fig. 3 and 4 together with the current trace. The separate formation of underpotential and bulk deposits is clearly shown by the relative amplitude parameter psi (Fig. 3). During the anodic part of the potential cycle, the two layers are dissolved in reverse order and the process is repeated in the next cycle. Reversibility and reproducibility are also seen in the relative phase parameter delta (Fig. 4). The response of that measurement to the underpotential deposit is representative of a metal-like layer, while dielectric-like properties are indicated for the bulk deposit. These unexpected optical results for delta are caused by the micromorphology of the deposits: the cathodic UPD peaks have been interpreted as the formation of a complete monolayer of Pb on the substrate; the bulk deposit is shown to be of a particulate, porous nature. Similar results were obtained for potentiodynamic deposition of Pb on Cu(111) at concentrations of 0.5 and 5.0 mM and a sweep rate of 1.5 V/min.

Fig. 2. Potential ramp corresponding to Fig. 1 from $+150$ to -660 mV . Sweep rate: 0.15 V/min .

Light scattering measurements from the electrode surface during cyclic voltammetry are shown in Fig. 5. An argon-ion laser (Lexel 75.2) tuned to 514.5 nm , served as light source (30 mW , 75° angle of incidence). Scattered light was collected 15° from the specular direction with a fiber-optic probe (1° acceptance) and measured with a photomultiplier (RCA R136). The lower oscillogram traces in Fig. 5 represent the current passed through the cell, with cathodic peaks shown negative, anodic peaks positive. The poor cathodic peak waveform is due to the electrode geometry in the scattering cell, which results in nonuniform current distribution. The upper traces represent the photomultiplier current. Figure 5a shows the in-

Fig. 3. Response of current and ellipsometer parameter ψ to potential ramp shown in Fig. 2. Wavelength of light 515 nm , angle of incidence 75° , other conditions as in Fig. 1.

Fig. 4. Response of current and ellipsometer parameter δ , conditions as in Fig. 3.

crease in scattered light intensity with the onset of bulk deposition and its return to the initial level upon stripping the deposit. A particle diameter of 16 \AA , derived from ellipsometer measurements, has been associated with a significant increase in light scattering. No increase in scattering light intensity is observed during formation of the underpotential deposit layer. Light scattering, like the ellipsometer measurements, are reversible and repeatable during potential cycling. Increased light scattering is indicative of the formation of very small three-dimensional nuclei appearing on top of the Pb monolayer which completely covers the substrate. This interpretation agrees with that found for the ellipsometer measurements.

Optical Model of the Initial Stage of Deposit Formation

The general theory for submonolayer ellipsometry has been reviewed by Bootsma (13, 14). Other authors who have written on this topic have paid particular attention to the anisotropic nature of the adsorbate layer (15-17).

As discussed elsewhere (18), it has been found that the ellipsometer measurements of the formation of the underpotential deposit can best be interpreted with a coherent superposition (island) model; the Bruggeman model failed to explain the data. In this model, it is assumed that the surface is partially bare and partially covered with patches or islands of a thin film (19). With the islands having a smaller diameter than the spatial coherence of the incident light, the state of polarization of the reflected light is determined by the coherent superposition of polarization states resulting from reflection on bare and film-covered surface elements.

Application of this island concept to the underpotential deposit implies that (i) metal adatoms adsorbed to the surface, as two-dimensional clusters or individually, can be treated as equivalent thin film islands of some apparent thickness and complex refractive index, (ii) the optical constants and thickness of individual islands are the same as those of the complete monolayer, (iii) the overall reflectance of the surface is due to a coherent superposition of beams reflected from island-covered portions of the electrode and bare portions of the electrode, and (iv) the optical constants of the individual islands and the substrate are potential and coverage independent. Predictions derived from this model agree well with experimental data for the development of the underpotential deposit monolayer as the potential is ramped (Fig. 6). Assumption (i) above requires elaboration. As will be shown in the discussion that follows, the Pb UPD obeys a Langmuirian adsorption isotherm, which indicates that there is minimal lateral interaction between adsorbed Pb atoms, while clustering would require strong attraction. Based upon the isotherm alone, one would expect the Bruggeman optical model for a layer of randomly distributed atoms to fit the data. This dilemma will have to be resolved by future work.

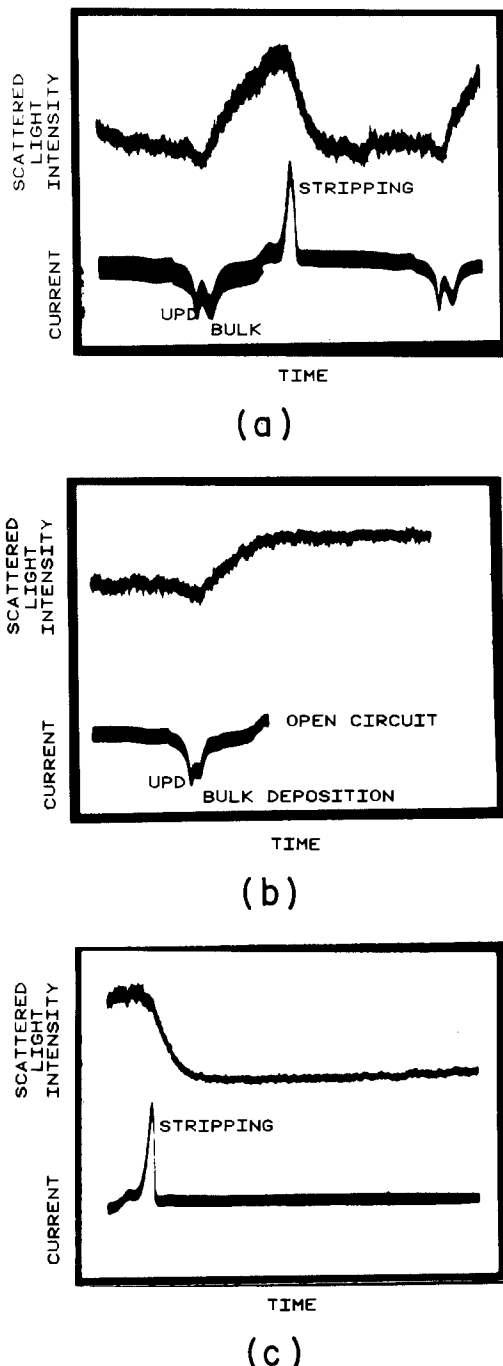

Fig. 5. Light scattering data at conditions similar to those of Fig. 1, except that the experiments were conducted on polycrystalline Ag in a light scattering cell. Top traces, scattered light intensity (increasing in the positive direction); bottom traces, current response to the potential ramp (cathodic peaks negative). The first cathodic peak is UPD deposition; the second is bulk deposition. Light source argon ion laser at 515 nm. (a) Increase of light scattering with onset of bulk deposition, (b) stability of deposit on open circuit, and (c) removal of deposit after open-circuit stand.

An investigation of different optical models to interpret the present *in situ* ellipsometer measurements of the bulk deposit has been reported elsewhere (20). This layer was found to form on top of the first monolayer of Pb adatoms and to be of a granular, porous form. The optical properties of this layer are intermediate between those of metallic Pb and electrolyte and have been determined by use of the Bruggeman theory (21). This approach is analogous to that used by representing microrough surfaces as equivalent films (21-23).

Other investigators have suggested that three-dimensional nucleation occurs on a completely formed monolayer, on the basis of *ex situ* experiments using Auger

Fig. 6. Prediction by optimized coherent superposition model (solid line) and measurement of changes in ellipsometer parameters ψ and δ due to progressive deposition of an underpotential layer of Pb on Ag(111). Properties of the underpotential deposit derived from the optimized data fit given in Table I.

spectroscopy (24), x-ray fluorescence (25), and scanning electron microscopy (26).

To model both the UPD monolayer and the bulk deposit collectively, a two-film model is used, analogous to the approach of Smith and Müller (19, 27). First, one calculates a value of the complex reflection coefficient ratio due to the UPD layer on the electrode. Then, using this ratio, an apparent refractive index is calculated, which includes both the effects of the substrate and the UPD monolayer. The optical effect (δ and ψ) of the porous bulk deposit is then determined on the apparent substrate. The Bruggeman theory is used to compute the effective refractive index of the porous film material.

By minimizing the sum-of-squares error between the model predictions and the measurement of δ and ψ , one determines optimum values of the adjustable model parameters (28, 29). Parameters to be fitted are (i) complex refractive index of the UPD, (ii) apparent thickness of the UPD, (iii) porosity of the bulk deposit, and (iv) thickness of the bulk deposit. Fine tuning of the metal optical constants is done initially to compensate for uncertainty in the optical constants found in the literature or determined experimentally. Equation [1] defines the sum-of-squares error for the model.

$$S_{\Delta, \psi} = \sum_{i=1}^N (\Delta_{M,i} - \Delta_{C,i})^2 + \sum_{i=1}^N (\psi_{M,i} - \psi_{C,i})^2 \quad [1]$$

The parameter variance is then defined by

$$SE(p) = \frac{\sigma^2}{\frac{1}{2} \frac{\partial^2 S_{\Delta, \psi}}{\partial p^2}} \quad [2]$$

Parameter confidence intervals (Eq. [3]) are calculated from this variance and the student-t statistic for $2N-P$ degrees of freedom, where N is the number of δ - ψ measurements and P is the number of adjustable model parameters

$$\delta(p) = t(2N - P, 1 - 2\alpha)[SE(p)]^{1/2} \quad [3]$$

Both the parameter variance and the model variance are required, and are estimated numerically by use of Eq. [4] and [5], respectively

$$\sigma^2 \sim S_{\text{MIN}}/df = S_{\text{MIN}}/(2N - P) \quad [4]$$

$$\frac{1}{2} \frac{\partial^2 S_{\Delta, \psi}}{\partial p^2} \sim \frac{S_{(+)} + S_{(-)} - 2S_{\text{MIN}}}{2(\Delta p)^2} \quad [5]$$

Separate optimizations are performed to determine UPD and bulk optical properties. This is possible since

Table I. Optical properties of the Pb underpotential deposit (UPD) at complete coverage ($\theta = 1$). Wavelength: 514.5 nm. Electrolyte: 0.5 and 5.0 mM Pb^{2+} , 1M NaClO_4 , pH 3. Errors given for 95% level of confidence

Substrates	Ag(111)	Cu(111)	Cu(111)
Pb concentration (mM)	0.5	0.5	5
UPD refractive index	$n_{\text{UPD}} = 1.285 \pm 0.007$	1.225 ± 0.066	0.952 ± 0.417
UPD extinction coefficient	$k_{\text{UPD}} = 4.080 \pm 0.040$	3.520 ± 0.041	3.898 ± 0.021
UPD thickness (\AA)	$d_{\text{UPD}} = 5.149 \pm 0.026$	4.030 ± 0.178	4.777 ± 1.101

potential ramping separates formation of the two layers in time. As the UPD was formed, 19 values of current, delta, and psi were logged by computer during formation of the Pb UPD on Ag; these measurements were used collectively to determine the three parameters needed for the characterization of the UPD (complex refractive index and thickness). These values can be determined from data for a single cathodic sweep with a high degree of accuracy. Optical constants and thicknesses determined thus for the Pb UPD layer on Ag(111) and Cu(111) for a wavelength of 515 nm are given in Table I (18). The error limits are given for a 95% level of confidence, based upon 37° of freedom. The thickness of the layer of 4-5Å compares well with an atomic diameter of about 3.5Å.

Estimates of the parameters for the bulk deposit are more uncertain. Confidence intervals for these parameters can only be derived by averaging comparable values of delta and psi from replicate experiments (or multiple sweeps). Modeling results for the bulk Pb deposit are presented in Table II for different substrates, electrolytes, and potential cycles. From these results, it was concluded that the bulk deposit formed in the experiments conducted with 0.5 mM was approximately 30% porous and about 10Å thick; the bulk deposit formed with 5.0 mM was approximately 40% porous and 200Å thick.

Adsorption Isotherm

Conway *et al.* present general theories of adsorption at liquid-solid interfaces and the proper selection of standard states (30). Conway and Kozłowska also discuss the effects of sweep rate, etc., on the UPD peak in voltammetry (31). Ross has shown that the Langmuir isotherm can be applied to hydrogen adsorption on Pt single crystals with data taken from cyclic voltammograms (32). Swathirajan *et al.* have presented a detailed thermodynamic model for Ag and Pb underpotential deposition on polycrystalline Au, and determined that both of these UPD layers involved electroadsorbed species having valences equivalent to those of their respective dissolved

ions (33). If one assumed that the valence of the electroadsorbed Pb species on Ag(111) and Cu(111) is equivalent to that of Pb^{2+} , the term $RT/F(1/\gamma_{\text{UPD}} - 1/z) \ln a_{\text{M}^{2+}}$ in Eq. [12] of Ref. (33) becomes zero, and the adsorption behavior is therefore independent of the solution activity of Pb^{2+} . The terms γ_{UPD} , z , and $a_{\text{M}^{2+}}$ correspond to the terms z , z_{pb} , and α , respectively, in this paper. By assuming that both the Frumkin and Temkin parameters are zero, and by taking the reference potential $U_{1/2}$, to be that giving $\theta = 0.5$, Eq. [12] of Ref. (33) reduces to the Langmuir isotherm, Eq. [6], which is linear in potential

$$\ln \left(\frac{\theta}{1 - \theta} \right) = - \frac{zF}{RT} (U - U_{1/2}) \quad [6]$$

The Gibbs free energy of adsorption is related to the underpotential at half-monolayer coverage ($U_{1/2}$) through Eq. [7]

$$\Delta G_{\text{ADS}}^{\circ} = -zFU_{1/2} \quad [7]$$

Since Eq. [6] is linear in potential (underpotential scale), it can be applied to experimental data easily by using regression analysis (34). Equation [8] is used for data reduction; the slope m and intercept b are then related to the Gibbs free energy of adsorption

$$\ln \left(\frac{\theta}{1 - \theta} \right) = mU + b \quad [8]$$

$$G_{\text{ADS}}^{\circ} = -bRT \quad [9]$$

The underpotential at half-coverage and the apparent valence are given by Eq. [10] and [11], respectively

$$U_{1/2} = -b/m \quad [10]$$

$$z = -mRT/F \quad [11]$$

Rigorous analysis relates the error in these physical quantities (Eq. [12]-[14]) to the uncertainties in the slope and intercept of the regression line (Eq. [15] and [16]), and to the model variance (Eq. [17])

$$\delta(\Delta G_{\text{ADS}}^{\circ}) = F[(U_{1/2} \cdot \delta z)^2 + (z \cdot \delta U_{1/2})^2]^{1/2} \quad [12]$$

$$\delta(U_{1/2}) = U_{1/2} \left[\left(\frac{\delta b}{b} \right)^2 + \left(\frac{\delta m}{m} \right)^2 \right]^{1/2} \quad [13]$$

$$\delta(z) = \frac{RT}{F} |\delta m| \quad (\text{also written as } \delta z) \quad [14]$$

$$\delta m = S \cdot t(N - 2, 1 - 2\alpha) \left[\sum_{i=1}^N (U_i - \bar{U})^2 \right]^{-1/2} \quad [15]$$

$$\delta b = S \cdot t(N - 2, 1 - 2\alpha) \left[\left(\sum_{i=1}^N U_i^2 \right) / \left(N \sum_{i=1}^N (U_i - \bar{U})^2 \right) \right]^{1/2} \quad [16]$$

Results of the linear regression and error analysis are presented in Table III. The data for the Pb UPD on Ag(111) and Cu(111) were first analyzed separately, then together. The noninteger values of the electroadsorption valence could imply that Frumkin and Temkin parameters should be included in the adsorption isotherm model; however, it is believed that these unusual values are attributable to integration errors at low coverage and have no physical significance. The coverage, which is determined by integration of the cathodic UPD peak, cannot be determined accurately at low values since the current is of the same order as the background noise.

Inspection of the experimental data plotted in Fig. 7 shows that the underpotential at half-coverage is about 155 mV for both substrates, which corresponds to a Gibbs free energy of adsorption of 7.14 kcal/mol for an assumed electroadsorption valence of $z = 2$ (35). Note that a value of 5 kcal/mol has been reported for polycrystalline substrates (3). Theoretical predictions of coverage at different poten-

Fig. 7. Electroadsorption isotherm for Pb UPD on Ag(111) and Cu(111), model predictions for a free energy of adsorption of 7 kcal/mol and a valence of 2 (broken line) and experimental data from cyclic voltammetry. Coverage computed from charge.

Table IV. Comparison of amount of Pb deposit d_a based on charge passed with amount $\theta_{\text{Pb}}d$ derived from ellipsometer measurement

Substrate	Pb ⁺⁺ (mM)	t(s)	$d_a(\text{\AA})$	θ_{Pb} (vol. fract.)	$d(\text{\AA})$	$\frac{\theta_{\text{Pb}} \cdot d}{d_a}$
Ag(111)	0.5	300	29	0.75	16	0.41
		413	42	0.75	26	0.46
Cu(111)	0.5	24	5	0.71	6	0.85
		30	7	0.71	6	0.61
		46	9	0.71	6	0.47
		48	10	0.73	12	0.88

		40	141	0.60	170	0.72
		45	160	0.61	194	0.74

tials can be made by substituting these values into the adsorption isotherm equation. These predictions are represented by the broken line in Fig. 7, which agrees well with experimental data except at very low coverages. Continuous adsorption isotherms have been reported for different Ag faces (36).

Double layer charging currents were subtracted by base-line extrapolation across the base of the UPD peak, assuming the *a priori* separability of charging currents. This method can lead to errors in coverage estimation, but the error for the Pb UPD on Ag and Cu may be small if the points of zero charge (pzc's) of the two materials are nearly equal (37). The concept of partial discharge associated with electroadsorption bonds (38) in the underpotential deposit is not supported by this work.

Charge Balance

Equation [18] was used to calculate the charge passed to the working electrode during deposition

$$Q = \int_0^t i(t) \hat{A} dt = \frac{(xyd_a)\rho_{\text{Pb}}}{MW_{\text{Pb}}} z_{\text{Pb}} e N_{\text{avg}} \quad [18]$$

This charge was used to calculate the coverage of Pb adatoms on the electrode surface. The actual charge required for a complete UPD agreed with that expected for a monolayer with a roughness factor of 1.25.

The thickness of the bulk deposit and the volume fraction of Pb in it, determined from ellipsometer measurements, were used to compute the total amount of Pb on the electrode surface. This quantity was then compared to the amount expected on the basis of charge passed. The ellipsometer measurements consistently predict less Pb on the surface than the charge balance (a discrepancy ranging from 10% to 50%, Table IV). This difference might be due to uneven current distribution on the electrode, with more Pb being deposited around the edge of the electrode, while the ellipsometer measurement was performed at the center.

Conclusions

The initial stages of electrodeposition (0-200 \AA) can be elucidated by the simultaneous use of ellipsometry, cyclic voltammetry, and light scattering measurements. The application of a potential ramp allows one to separate underpotential and bulk deposits in time and thus investigate them separately.

An optical model which fits the data very well involves the two-dimensional growth of monolayer islands during UPD formation and the three-dimensional nucleation and growth of a microporous bulk deposit on top of it. Thickness, optical constants, Gibbs free energy of adsorption, and apparent valence for the Pb UPD on Ag(111) and Cu(111) have been determined.

LIST OF SYMBOLS

\hat{A}	electrode area (cm ²)
\hat{A}, \hat{B}	complex parameters for quadratic equation
a	activity of Pb ²⁺ in solution
b	linear regression intercept
C	concentration
d	thickness of bulk deposit derived from ellipsometer measurement
d_{UPD}	thickness of underpotential deposit
df	degrees of freedom ($2N - P$)
d_q	deposit thickness based on change (\AA)
e	electronic charge (1.602×10^{-19} C)
E	electrode potential vs. Ag/AgCl (V)
F	Faraday's constant (96,487 C/eq)
g	interaction parameter
$u(t)$	time varying current density during cyclic voltammetry (A/cm ²)
k_{UPD}	extinction coefficient of underpotential deposit
k_{Pb}	extinction coefficient of bulk Pb
m	slope of linear regression (V ⁻¹)
MW_{Pb}	atomic weight of Pb (207.2 g/mol)
n_{Pb}	refractive index of bulk Pb
n_{UPD}	refractive index of underpotential deposit
N	number of data points defining experimental electroadsorption isotherm and number of pairs of Δ and ψ measurements
N_{AVG}	Avogadro's number (6.02×10^{23} at./mol)
N_i	atomic number density of component i in the effective medium
p	arbitrary model parameter to be fitted
P	number of model parameters to be fitted
Q	total charge passed to working electrode (C)
r	regression coefficient (Table III)
RT	constant (0.592 kcal/mol)
S	variance between experimental data and prediction of electroadsorption model
$S(\)$	error of quantity in parentheses (except for $\delta\Delta$ and $\delta\psi$)
$SE(p)$	variance of parameter p
$S_{\Delta,\psi}$	sum-of-squares error between theoretical ellipsometer parameters and those measured experimentally
S_{MIN}	minimum value of $S_{\Delta,\psi}$ corresponding to a selection of optimum "p" values
$S_{(+)}$	value of $S_{\Delta,\psi}$ computed at a parameter value of $p + \Delta p$
$S_{(-)}$	value of $S_{\Delta,\psi}$ computed at a parameter value of $p - \Delta p$
t	time
$t(2N - P, 1 - 2\alpha)$	the t-statistic for "2N - P" degrees of freedom at a "1 - 2 α " level of confidence
U	underpotential relative to Nernst potential $E^0(V)$
U_i	measured value of U (controlled) at the i th coverage; the i th data point
$U_{1/2}$	underpotential corresponding to $\theta = 0.5(V)$
\bar{U}	mean underpotential (V)
V	electrode potential (V)
x	electrode dimension (cm)
y	electrode dimension (cm)
z	apparent valence of metal adatom after electroadsorption
z_{Pb}	valence of lead ion in solution (2)
α	level of confidence ($1 - 2\alpha$)
$\delta(p)$	error in parameter "p" at a "1 - 2 α " level of confidence
$\delta\Delta$	change in ellipsometer parameter delta due to underpotential deposit (deg.)
$\delta\psi$	change in ellipsometer parameter psi due to underpotential deposit (deg.)
Δ or delta	ellipsometer parameter, phase difference between p and s electric field components after reflection, relative to the incident (deg.)
Δ_C	calculated value of Δ for bulk deposit
$\Delta_{C,i}$	calculated value of Δ corresponding to $\Delta_{M,i}$
Δ_M	measured value of delta for bulk deposit (deg.)

$\Delta_{M,i}$	the i th measured value of Δ for the UPD at the i th coverage; the i th data point
ΔG_{ADS}^0	Gibbs free energy of adsorption for UPD monolayer (kcal/mol)
θ	fractional coverage of electrode surface by UPD monolayer
θ_f	fraction of surface covered by film of refractive index \hat{n}_f
θ_i	UPD monolayer coverage measured at underpotential U_i
θ_{Pb}	volume fraction of Pb in composite thin film deposit
θ_u	monolayer coverage predicted by electroadsorption model for underpotential U_i
ρ_{Pb}	density of Pb (11.34 g/cm ³)
σ^2	variance of the model predictions for Δ and ψ
ψ or psi	ellipsometer parameter, amplitude ratio of p and s electric field components after reflection (tan ψ), relative to the incident (deg.)
ψ_C	calculated value of ψ for bulk deposit
$\psi_{C,i}$	calculated value of ψ corresponding to $\psi_{M,i}$
$\psi_{M,i}$	measured value of ψ for the UPD at the i th coverage; the i th data point
ψ_M	measured value of psi for bulk deposit (deg.)

Band-Edge Shift and Surface Charges at Illuminated n-GaAs/Aqueous Electrolyte Junctions

Surface-State Analysis and Simulation of Their Occupation Rate

P. Allongue and H. Cachet

Laboratoire "Physique des Liquides et Electrochimie" du CNRS associé à l'Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

Mott-Schottky plots for n-GaAs/aqueous electrolyte junctions under various illuminations show that the semiconductor bandedges are shifted with respect to their position in the dark, the magnitude of the shift increasing with increasing light intensity. Correlatively, the surface-state capacitance $C_{ss}(V)$ presents a sharp peak; its height increases with illumination. A model for the electron occupation rate of a surface-state distribution is described in order to interpret these experimental facts. It is shown that such a kinetic model explains only impedance $C_{ss}(V)$ results; chemical modifications at the surface have to be invoked to account for the flatband-potential shift at the illuminated electrode. The surface-state capture cross sections are pulled from impedance analysis through the relaxation time $R_{ss} \cdot C_{ss} = \tau_{ss}$.

In several papers, it has been reported that in semiconductor liquid junctions, bandedges are shifted under illumination (1-4). For n-type (p-type) semiconductors, the shift is positive (negative) of the flatband potential V_{FB} in the dark; in our case, this shift is experimentally evidenced by impedance measurements under illumination. In a recent model for the photoresponse of the n-GaAs/(Se²⁻/Se₂²⁻) junction, we accounted for this shift by taking a pseudo flatband potential V_{FB}^* as the reference for the band bending $V_b = V - V_{FB}^*$, where V is the external applied voltage (3). We pointed out that impedance measurements under illumination are absolutely necessary to avoid wrong interpretations and reach the real charge-transfer kinetics. A surface-state capacitance distribution on n-GaAs was experimentally determined and surface charges were invoked to interpret the band-edge shift.

In this paper, we intend to specify by using impedance measurements the fundamental role played by the surface states. Experimental results show an increase in the flatband-potential shift and the peak in surface-state capacitance $C_{ss}(V)$, when light intensity increases. A question arises: are these evidenced states responsible for the band-edge shift? In order to answer this question, we present a kinetic model for the filling process of the surface states. It is similar to the model presented by Kelly and Memming, who developed their model to explain the large delay of the photocurrent onset potential with respect to the flatband potential in the dark, at p-GaAs electrodes (1). They performed extensive simulations. A similar model was also developed for metal-GaAs Schottky barriers, to reach the real surface-state distribution from capacitance measurements in the dark (5). And Chazalviel described the impedance and current behaviors of n-Si/acetonitrile junctions by using a very simple model which assumed that the only current pathway was a surface-state distribution over the whole gap (6).

In our model, the surface states may exchange charges with their three surrounding charge reservoirs, which are the conduction and valence bands of the semiconductor and the solution. We do not perform simulations. This

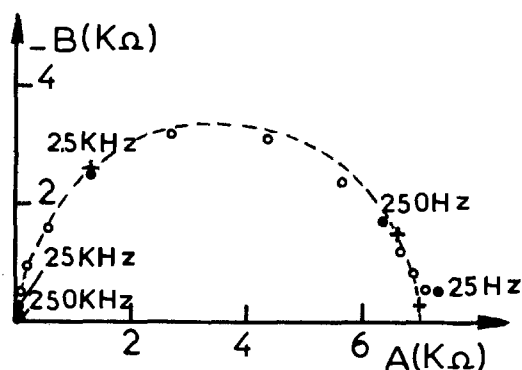

work is based upon experimental data such as surface-state capacitance $C_{ss}(V)$, surface-charge relaxation time $\tau_{ss}(V)$, Mott-Schottky plots, and I-V characteristics. The adjustable parameters are found to be very few, compared to the number of conditions to be satisfied. The aim is to use our theoretical model, for the occupation rate of the surface-state distribution, to fit the calculated $C_{ss}(V)$ and $\tau_{ss}(V)$ curves to the experimental ones for various light intensities. It is shown that a narrow, constant surface-state distribution is sufficient to explain our results and that the surface-charge variation associated with this distribution cannot account for the difference between the Mott-Schottky plots in the dark and these under illumination. The distribution always empties, more or less even in the dark. The way the distribution empties is photon-flux dependent through the minority carrier (hole) surface concentration. Finally, the flatband-potential shift with illumination is discussed in terms of chemical modifications at the surface.

Experimental

Undoped n-type ($2.3 \times 10^{16} \text{ cm}^{-3}$, <100> orientation) GaAs single crystals are purchased from MCP Limited. After polishing, semiconductor electrodes are etched with H₂SO₄:H₂O₂:H₂O, 2:1:1 mixture. All measurements are made in a classical three-electrode electrochemical cell. All potentials are referred to a saturated calomel reference (SCE). Selenide electrolytes 1M KOH + 1M Se²⁻/Se₂²⁻ are prepared by electrochemical reduction of selenium on a mercury cathode (7). A 100W quartz halogen lamp is used for illumination, and light intensity is changed with neutral filters and measured with a MACAM TR 3010 radiometer. Stationary I-V curves and impedance measurements are performed under potentiostatic conditions. At each potential, impedance $Z(\omega, V)$ is determined in the frequency range of 1 Hz-250 kHz by using a 1174 Solartron connected to a data management system. Every $Z(\omega, V)$ diagram is analyzed by means of a nonlinear least squares method, in accordance with the classical electrical equivalent circuit (Fig. 1a). We want to

Fig. 1. (a) Electrical equivalent circuit of a semiconductor-electrolyte junction used in Ref. (3). C_{sc} is the space-charge capacitance in the semiconductor, C_H the Helmholtz capacitance, R_F and R_s the faradic and series resistances. The series $R_{ss}C_{ss}$ circuit accounts for a charge relaxation in surface states. At some potential, a second $R'_{ss}C'_{ss}$ circuit is necessary to fit our impedance spectra. (---) calculated spectrum according to the scheme in (a). The calculated (+) and experimental (●) points correspond to the same frequency indexation. (b) $V = -0.60$ V/SCE; $C_{sc} = 15.1$ nF; $R_f = 7020$ Ω; $R_{ss} = 664$ Ω; $C_{ss} = 4.2$ nF; $R_s = 5.7$ Ω; $C_H = 1$ μF. (c) $V = -1.575$ V/SCE; $C_{sc} = 36.2$ nF; $R_f = 176$ Ω; $R_{ss} = 106$ Ω; $C_{ss} = 181$ nF; $R'_{ss} = 211$ Ω; $C'_{ss} = 1800$ nF; $R_s = 7.9$ Ω; $C_H = 1$ μF.

emphasize that each component of this scheme is not frequency-dependent. Because the series resistance is $R_s \approx 2$ Ωcm², the IR drop is negligible ($I < 10$ mA/cm²) and cannot account for the flatband-potential shift. It is worth pointing out that to obtain a good fit of the impedance diagrams at some potentials, several time constants,

$R_{ss}C_{ss}$, have to be considered. This indicates that a surface-state distribution exists in the bandgap, as is further confirmed by calculations. However, to limit the number of parameters in impedance analysis, we take only two time constants, $R_{ss}C_{ss}$. This is found to be sufficient in most cases. In the following, the surface-state capacitance $C_{ss}(V)$ at a given potential is defined as the sum of the two elementary C_{ss} to account for the whole surface-charge variation (8, 9). In the same way, a mean relaxation time $\tau_{ss}(V)$ is defined as the weighted mean of the two time constants $\tau_{ss} = R_{ss}C_{ss}$, with respect to their associated C_{ss} . It appears that the slower τ_{ss} always corresponds to the greater C_{ss} and then refers to the main surface-charge variation.

Finally, C_H has to be estimated. Because this is not possible using the impedance analysis alone, we use an indirect method. It appears, judging by the equivalent scheme (Fig. 1a), that when $C_{ss} \ll C_{sc}$, the fixed value of C_H does not influence the analysis ($C_H \gg C_{sc}$), and that when $C_{ss} \gg C_{sc}$ (see Fig. 4), the series combination of C_H and C_{ss} is measured. Hence, in the latter case, at a given potential, a value of C_{ss} (or $C_{ss} + C'_{ss}$) corresponds to a fixed C_H . Consequently, the $C_{ss}(V)$ curve is C_H -dependent; the $C_{sc}^{-2}(V)$ is not. Knowing all the capacitances of the circuit, the actual band bending $V_b(V)$ can be calculated at any bias (10). Introducing it into our model for the photoresponse (3), we compare the experimental and theoretical I-V characteristics, especially in the photocurrent-rise region. In fact, the band bending variations deeply influence the calculated slope of the I-V curve at these potentials. The best fits lead to $C_H = 2.8$ μF/cm² in the case of the n-GaAs/selenide junction. It is noted also that C_H represents the series combination of Helmholtz and oxide capacitances if there is an oxide layer.

Results

In the following, the presented results are those of the n-GaAs/selenide junction. However, these results seem to be characteristic of n-GaAs/aqueous electrolyte interfaces because the same behavior has been found for n-GaAs dipped in 1M KOH, 1M KOH + 1M S²⁻/S_n²⁻, and 0.1M Fe^{2+/3+} (citrate) buffered at pH = 9.4 Figure 1b and 1c show two impedance diagrams of the junction in two extreme cases (these are Nyquist plots with the convention of electrochemistry). In the photocurrent plateau region, the only required (R_{ss}, C_{ss}) circuit indicates small ($C_{ss} < C_{sc}$) surface charge variations. The diagram is almost a semi-circular loop (Fig. 1b). However, a second loop appears if the contribution of the surface states is important (Fig. 1c). Here, two time constants are required and $C_{ss} + C'_{ss} \gg C_{sc}$. The latter happens in the photocurrent-rise region. Figure 2 illustrates the I-V characteristics of the junction and their corresponding Mott-Schottky plots under various illuminations. These latter curves are almost straight and parallel over more than 1V and are shifted toward more positive potentials as light intensity is increased. In the dark, $V_{FB} = -2.06$ V/SCE. In the potential region corresponding to the photocurrent existence ($V > -1.55$ V/SCE), the band bending can be defined with respect to a pseudo flatband potential V_{FB}^* . It is the intercept of the $C_{sc}^{-2} - V$ straight line with the potential axis. For potential near V_{FB}^* , all the curves seem to tend toward the "dark" curve. Figure 3 illustrates the shift $\Delta V_{FB} = V_{FB}^* - V_{FB}$ of the flatband potential as a function of the saturation current density. It appears that this shift presents an asymptotic value of ~ 0.370 V for strong illumination.

It is tempting to connect the above result to the change in the surface charge revealed by the surface-state capacitance $C_{ss}(V)$ curves under illumination. Figure 4 presents the "slow" and the "fast" C_{ss} , associated with a long and a short relaxation time constant, respectively (Fig. 5). As stated above, two time constants are required to fit the impedance spectra for potentials close to -1.6 V/SCE. This corresponds to the sharp peak region of the "slow" C_{ss} and indicates a great surface-charge variation for these potentials. For polarizations cathodic of -1.7 V/SCE, the

Fig. 2. (top) I-V curves of the n-GaAs/selenide junction under (a) 1.5 mW/cm², (b) 9 mW/cm², (c) 22 mW/cm², and (d) 50 mW/cm² illumination. (●) experimental data and (—) theoretical curve according to the model in Ref. (3) completed with the present model. Parameters are: $\alpha = 26,000 \text{ cm}^{-1}$; $L = 0.2 \mu\text{m}$; $\tau = 1.45 \times 10^{-10} \text{ s}$; $N_D = 2.3 \times 10^{16} \text{ cm}^{-3}$; $V_{FB} = -2.06 \text{ V/SCE}$; $V_{redox} = -0.96 \text{ V/SCE}$; $\lambda = 1 \text{ eV}$. The surface-state distribution characteristics are those of Fig. 11 at a given light intensity. (bottom) Mott-Schottky plots (a), (b), (c), and (d) correspond to the I-V curves (a), (b), (c), and (d), respectively. In the dark, $V_{FB} = -2.06 \text{ V/SCE}$.

high electron current associated with H₂ evolution might be responsible for the C_{ss} rise. Because measurements in this region are difficult, they are not yet interpreted, and, in the following, the main point we discuss is the peak which is reproducible. For anodic potentials, it is not possible to distinguish two time constants because their associated C_{ss} are very small compared to C_{sc} (the space-charge capacitance) and their determinations become less accurate. That is why we have only evidence of the "fast" C_{ss}. Figure 6 shows the evolution under various illuminations of the C_{ss}(V) curves, as defined in the experimental section. This recalls the admittance peak recently observed at n-GaAs and n-GaP electrodes (11). The peak height increases with light intensity, but it does not exist anymore in the dark. Its location remains almost constant

Fig. 3. Variations of $\Delta V_{FB} = V_{FB}^* - V_{FB}$ vs. saturation current density of an n-GaAs/selenide junction. Light intensity varies from 1.5 to 76 mW/cm².

for the illumination range we use. However, the mean relaxation time $\tau_{ss}(V)$ remains almost independent of the photon flux: it always presents the same abrupt variations around -1.6 V/SCE in correspondence with the C_{ss}(V) peak (Fig. 7). Finally, Fig. 8 shows the polarization resistance of the photocurrent characteristics R_p vs. the applied voltage. R_p becomes smaller when illumination is increased at a given potential.

Model

In a previous paper, we dealt with the direct charge-transfer kinetics between the valence band and the occupied states in solution. A model was presented for the photoresponse of the junction, thanks to the Marcus-Gerischer theory (3). In this section, we intend to explain the increasing peak in C_{ss}(V) and its associated band-edge

Fig. 4. Surface-state capacitances C_{ss} of an n-GaAs/selenide junction vs. applied voltage. (a) "slow" and (b) "fast" capacitances under 22 mW/cm² illumination.

Fig. 5. Relaxation times τ_{ss} vs. potential under 22 mW/cm² illumination. Experimental data for slow (●) and fast (▲) τ_{ss} for an n-GaAs/selenide junction.

shift ΔV_{ss} with increasing light intensity. The contribution in the flatband-potential shift ΔV_{FB} of the surface states giving rise to a $C_{ss}(V)$ will be discussed in the following. In the case of a single surface state, ΔV_{ss} and $C_{ss}(V)$ are defined by

$$\Delta V_{ss} = qN_{ss}\Delta f/C_H \quad [1]$$

$$C_{ss}(V) = -qN_{ss}df/dV_b \quad [2]$$

where V_b is the band bending of the semiconductor, f the electron occupancy of the single surface state with a density N_{ss} , and Δf the total variation of f with potential.

The occupancy f depends on charge exchanges between the surface state, the valence (VB) and the conduc-

Fig. 6. Surface-state capacitance $C_{ss}(V)$ curves of an n-GaAs/selenide junction, under (a) 50 mW/cm² illumination, (b) 22 mW/cm², (c) 9 mW/cm², (d) 1.5 mW/cm², and (e) in the dark.

Fig. 7. Mean relaxation time $\tau_{ss}(V)$ curve of an n-GaAs/selenide junction under 22 mW/cm² illumination. (●) experimental data according to the definition given in the experimental section. (—) theoretical $\tau_{ss}(V)$ according to the model. Parameters are $V_{FB} = -2.06$ V/SCE, $C_H = 2.8$ μ F/cm², and $V_{FB}^* = -1.79$ V/SCE. The surface-state distribution extends between $E_c - 0.2$ eV and $E_c - 0.4$ eV with a constant density $N_{ss} = 1.05 \times 10^{13}$ cm⁻² eV⁻¹, $\sigma_n = 3.10^{-17}$ cm², $\sigma_p = 4.10^{-16}$ cm², $\sigma_s = 10^{-15}$ cm².

tion (CB) bands, and charges on the redox species in solution. For CB and VB exchanges, the Shockley-Read-Hall statistics hold. The conduction (valence) band exchange rate $R_c(R_v)$ expresses

$$R_c = k_c n_s N_{ss}(1-f) - k_c n_1 N_{ss} f \quad [3]$$

$$R_v = k_v p_s N_{ss} f - k_v p_1 N_{ss}(1-f) \quad [4]$$

and a similar equation can be written for the capture rate R_s of a hole, trapped in the surface state, by a reduced species in solution

$$R_s = k_s c_{red} N_{ss}(1-f) - k_s^{-1} c_{ox} N_{ss} f \quad [5]$$

where the k 's are constants as defined in Fig. 9, n_s and p_s are the electron and hole surface concentrations, and $c_{red}(c_{ox})$ are the reduced (oxidized) species concentrations. n_1 and p_1 are given by

$$n_1 = N_c \exp \frac{E_{ss} - E_c}{kT}$$

$$p_1 = N_v \exp - \frac{E_v - E_{ss}}{kT}$$

where E_{ss} is the energy level of the surface state. The capture of an electron by an oxidized species is very unlikely in our case because of coulombic repulsion, the oxidized species being Se_2^{2-} . Thus, in Eq. [5], the second term is

Fig. 8. Polarization resistance R_p vs. potential under various illuminations of an n-GaAs/selenide junction. (a) 1.5 mW/cm², (b) 9 mW/cm², (c) 22 mW/cm², and (d) 50 mW/cm².

neglected. df/dt is given by

$$\frac{df}{dt} = R_c - R_v + R_s \quad [6]$$

From stationary conditions, $df/dt = 0$, one gets f and its derivative df/dV_b

$$f = \frac{k_s c_{\text{red}} + k_c n_s + k_v p_1}{k_s c_{\text{red}} + k_c (n_s + n_1) + k_v (p_s + p_1)} \quad [7]$$

$$\frac{df}{dV_b} = \frac{-k_v f (dp_s/dV_b) + k_c (1-f) (dn_s/dV_b)}{k_c (n_s + n_1) + k_v (p_s + p_1) + k_s c_{\text{red}}} \quad [8]$$

$p_s(V)$ and $n_s(V)$ are provided by I-V analysis, as pre-

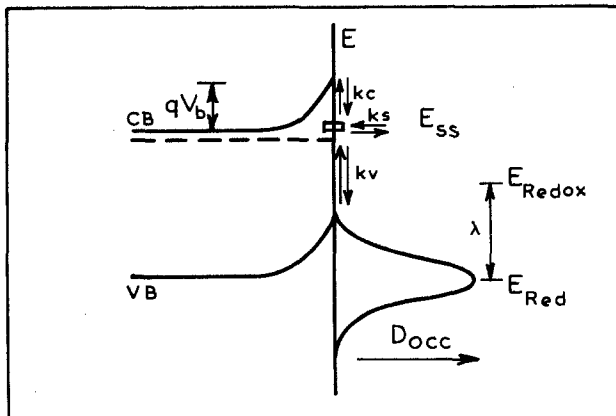

Fig. 9. Energy diagram of an n-type semiconductor/electrolyte interface and the various types of charge exchange mechanisms between a single state at E_{ss} with the conduction band (k_c), the valence band (k_v), and the solution (k_s). The density of the only occupied state in solution is represented for clarification.

sented elsewhere (3). On the other hand, k_s is supposed to follow the Marcus-Gerischer law

$$k_s = \sigma_s v (kT/\pi\lambda)^{1/2} \exp[-(E_{ss} - E_{\text{red}})^2/4\lambda kT] \quad [9]$$

where v is the thermal velocity for holes, and σ_s is the capture cross section of a hole trapped in the surface state by a reduced species. σ_s will be estimated later. Note that $k_s c_{\text{red}}$ remains constant with potential only if the band-edges of the semiconductor are fixed; otherwise the overlap $E_{ss} - E_{\text{red}}$ varies with potential. This possibility is accounted for in the following. Equation [6] allows defining a relaxation time τ_{ss} for f

$$\tau_{ss}(V) = [k_c(n_s + n_1) + k_s c_{\text{red}} + k_v(p_s + p_1)]^{-1} \quad [10]$$

Equations [7], [8], and [10] show that f , df/dV_b , and τ_{ss} are (i) functions of the state localization through p_1 and n_1 , (ii) functions of the applied potential through n_s and p_s , and (iii) functions of light intensity through p_s .

Knowing $k_v = \sigma_p v$ and $k_c = \sigma_n v$ ($v = 1.7 \times 10^7$ cm/s is the thermal velocity for holes and electrons), it is possible to estimate σ_p , σ_n , the capture cross sections for holes and electrons, and σ_s , from the measured relaxation time $\tau_{ss}(V)$. For small band bending, CB exchanges are predominant and τ_{ss} gives information about σ_n . However, at larger band bending, $n_s \ll p_s$ under illumination and $k_v p_s$ dominates in Eq. (10).

As a preliminary remark, assuming that illumination is not responsible for the surface state, it is obvious that if $k_s c_{\text{red}} \gg$ both $k_c n_s$ and $k_v p_s$, f remains equal to 1 at any bias (Eq. [7]). For such states, $C_{ss}(V) = 0$. This is the case if E_{ss} is taken close to E_v , the top of the valence band at the surface, because of a better overlap with the occupied states in solution. However, if E_{ss} is close to E_c , the bottom of the conduction band at the surface, the occupation rate f follows a kind of Fermi statistics; consequently, the surface state empties for sufficiently large bias, leading to a flatband-potential shift ΔV_{ss} independent of light intensity. Finally, if under illumination $k_s c_{\text{red}}$ is of the order of magnitude of $k_v p_s$, our results can be explained. For large enough band bending, f decreases with light intensity because p_s becomes larger; Δf and the associated band-edge shift ΔV_{ss} increase. Equation [8] shows that $C_{ss}(V)$ depends on dp_s/dV_b and dn_s/dV_b . By the hole-transfer current expression, one gets (3)

$$dp_s/dV_b = (dp_s/dV) (dV/dV_b) = (1/R_p^p) (p_s^0/J_p^0) (dV/dV_b) \quad [11]$$

with dV/dV_b given by Eq. [10]

$$dV/dV_b = (C_H + C_{sc} + C_{ss})/C_H \quad [12]$$

R_p^p is the polarization resistance associated with the only photocurrent; J_p^0 and p_s^0 are defined in Ref. (3). In Eq. [12], C_{sc} can be neglected ($C_{sc} \ll C_H$). Using $n_s = N_D \exp(-qV_b/kT)$, its differential, and combining Eq. [8]-[10], [12], and [2], $C_{ss}(V)$ reads

$$C_{ss} = qN_{ss}\tau_{ss} \frac{[k_v f (dp_s/dV) - k_c (1-f) (dn_s/dV_b)]}{1 - qN_{ss}\tau_{ss} k_v f (dp_s/dV_b)/C_H} \quad [13]$$

As a first approximation when $C_{ss} \ll C_H$, $dV/dV_b = 1$ and $C_{ss}(V)$ reduces to the numerator of Eq. [13], and it can be seen that $C_{ss}(V)$ is strongly correlated to $1/R_p^p$. Note that if the electron current may be neglected, $R_p^p = R_p$, the polarization resistance of the junction. Moreover, if the band bending is sufficient, $dn_s/dV_b \ll dp_s/dV$ and $C_{ss}(V)$ is proportional to R_p^{-1} . This fact partly explains the shape of the $C_{ss}(V)$ curves and their evolution with light intensity because it is well known that R_p decreases with increasing photon flux (Fig. 8). When C_{ss} and C_H have the same order of magnitude, the correlation $R_p^{-1} - C_{ss}$ is less evident. The denominator tends approximately to enhance the peak of C_{ss} for given parameters.

As a first conclusion from this model, it appears that the behavior of a single surface state, for given capture cross sections, depends on its location in the gap. This

also shows that only one relation time τ_{ss} at any bias corresponds to a single state.

If a surface-state distribution is considered, Eq. [1-5] have to be integrated vs. E_{ss} , Eq. [6-10] describing the behavior of an elementary state located at E_{ss} with a density $N_{ss}(E_{ss})dE_{ss}$. Each elementary state gives rise to an elementary surface-state capacitance $dC_{ss}(V, E_{ss})$ that has to be integrated to get the whole capacitance $C_{ss}(V)$ associated with the whole distribution (8, 9). Moreover, at a given potential, it becomes obvious that each elementary state has its own time constant $\tau_{ss}(V, E_{ss})$. This shows that in such a case, several time constants, $R_{ss}C_{ss}$ have to be found by impedance measurements. As stated in the experimental section, the calculated $\tau_{ss}(V)$ is defined as the weighted mean of elementary $\tau_{ss}(V, E_{ss})$, with respect to their associated $dC_{ss}(V, E_{ss})$.

Discussion

Surface-state capacitance $C_{ss}(V)$ results allow us to calculate the effective band bending of the semiconductor at any potential, for a given C_H . It appears that the $C_{ss}(V)$ data only cover the region $E_c - 0.1$ eV to $E_c - 1.3$ eV and that the surface-charge variation associated with the $C_{ss}(V)$ peak is too small to yield a band-edge shift ΔV_{ss} of the order of ΔV_{FB} , ΔV_{ss} being calculated by means of Eq. [12].

Analysis of the I-V characteristics gives $p_s(V)$ (3). Then we calculate $C_{ss}(V)$, $\tau_{ss}(V)$, and $f(V)$, thanks to our model, and we compare them to the experimental data. The only adjustable parameters are k_c , k_v , and σ_s ; all the others are determined through experiments. These three simultaneous constraints allow one to obtain reasonable values for the k constants and σ_s . In the case of a single surface state, calculations, show that σ_s has a greater effect upon Δf than upon C_{ss} ; the opposite is true for k_c and k_v . At first, relative values of k_c , k_v , and k_s are obtained by fitting $C_{ss}(V)$ and ΔV_{ss} . Then, to obtain their final values, it is sufficient to adjust $\tau_{ss}(V)$ by multiplying the three parameters by the same factor (Eq. [10]). By doing this, $f(V)$ and $C_{ss}(V)$ are not changed (Eq. [7] and [13]). The following discussion is based upon results concerning the n-GaAs/selenide junction, but the same model would apply to other experimental results with different aqueous electrolytes.

Single surface-state hypothesis.—Simulations based on such a simple hypothesis show that it is possible to fit our experimental results, but without obvious physical significance. If we try to obtain the best agreement for each illumination, it appears that, with increasing light intensity, (i) the state moves up in the gap from $E_c - 0.3$ to $E_c - 0.15$ eV, (ii) the state empties completely for even large $\sigma_s(10^{-14} \text{ cm}^{-2})$, and (iii) the density N_{ss} increases from 7.10^{10} to $2.6 \times 10^{12} \text{ cm}^{-2}$, whereas the capture cross sections σ_n , σ_p , σ_s remain unchanged ($\sim 5 \times 10^{-17} \text{ cm}^2$).

However, these simulations are interesting evidence of the influence of some parameters. It is confirmed that for given cross sections, a state empties less and less as it goes down in the gap, and correlatively, the $C_{ss}(V)$ peak vanishes (Fig. 10a). Moreover, the relaxation time τ_{ss} depends on the electron occupancy. The unusual experimental peak in τ_{ss} vs. V (Fig. 10b) can be explained as follows. For potentials cathodic of -1.60 V/SCE, τ_{ss} increases with the applied potential because of decreasing $n_s = N_D \exp -qV_b/kT$ ($n_s \gg p_s$ in Eq. [10] in such a case). Under illumination, p_s and n_s have the same order of magnitude as soon as $V = -1.60$ V/SCE, and then $p_s \gg n_s$ for more positive potentials. Consequently τ_{ss} begins to decrease if $V > -1.60$ V/SCE (Eq. [10]). Figure 10b also shows that τ_{ss} is much smaller when f remains constant than when f undergoes variations. A factor of ~ 50 exists between the two situations. The latter point means physically that the smaller the surface-charge variation, the shorter the rearrangement. If the state is sufficiently high in the bandgap, it is empty ($f = 0$) at equilibrium. So, even in the dark, when the band bending becomes small enough, the state is fully or partly occupied by electrons. This could explain the slight deviation of the Mott-Schottky plot in

Fig. 10. (A) Evolution of the calculated $C_{ss}(V)$ curve associated with a single surface state, when E_{ss} moves down in the gap: $\Delta E = E_c - E_{ss} = 0.3$ eV (a), 0.4 eV (b), and 0.5 eV (c). In the insert, the corresponding Δf is figured (Δf is the maximum variation of f for a large potential excursion). (B) Calculated $\tau_{ss}(V)$ and $f(V)$ associated with the curve (a) of (A).

the dark for cathodic potentials (Fig. 2b, curve e). Thus, in that case, the shift ΔV_{FB} between illumination and dark conditions cannot be accounted for, even partially, by such a mechanism. On the other hand, if the surface state is close to the valence band, it never empties except for $\sigma_s = 0$. Only in this case could ΔV_{FB} be explained.

Case of a surface-state distribution.—It seems that a single state is too simple an assumption to account for all our capacitance results and, particularly, the light intensity dependence of the peak height. A better description is possible if a surface-state distribution is considered. In this case, each elementary state [density $N_{ss}(E_{ss})dE_{ss}$, energy E_{ss}] of the distribution behaves as a single state, with the same density and energy. This behavior has been discussed above. The increase of N_{ss} with light intensity is physically understood as a surface-state distribution which empties more and more. When the photon flux becomes larger, states located higher in the gap empty earlier. This simply means that for a given surface hole concentration p_s , the required band bending is smaller for a greater light intensity. In this way we explain the increase in the area of the peak in C_{ss} capacitance, which represents the associated surface-charge variation. In the same way, the sharp increase of the surface hole concentration, for potentials close to -1.6 V/SCE, promotes a strong surface-charge variation responsible for the peak existence. Moreover, the greater the illumination, the greater dp_s/dV_b and, correlatively, the peak height increases. In the dark, these states also empty for large enough band bending. However, the much slower variation of p_s in such conditions does not allow observing a peak (Fig. 6). At last, although the peak moves in the bandgap, it remains at almost the same potential in the SCE scale because of the band-edge shift.

The peak magnitude accounts then for the way the surface-state distribution loses its negative charges or traps holes. It does not account for the flatband-potential shift ΔV_{FB} under illumination as it would have been expected to. As a final remark about these simulations, it is worth noting that the solution is not unique. Quite different constant surface-state distributions (N_{ss} density, ΔE width) may give the same result for a given illumination, provided σ_s is changed. However, the simulations we present are performed for a distribution with a constant density $N_{ss} = 1.05 \times 10^{13} \text{ cm}^{-2} \text{ eV}^{-1}$ which extends between $E_c - 0.2$ eV and $E_c - 0.4$ eV. This distribution is

found to be one of the best choices for keeping σ_n , σ_p , and σ_s almost constant when illumination is changed (Fig. 11). Values of $\sim 3.10^{-16}$ cm and 5.10^{-17} cm² are found for σ_p and σ_n , while σ_s can take values in the range of 10^{-16} to 10^{-15} cm² (Fig. 7 and 11). Such values lead to negligible currents through this state distribution. The deviation of the theoretical $\tau_{ss}(V)$ curve from the experimental one for anodic potentials may come from a rough C_{ss} determination in this region (Fig. 7). C_{ss} is very small compared to C_{sc} for potential $V > -1.3$ V/SCE ($C_{ss} < 0.1 C_{sc}$).

Flatband potential shift.—As a consequence of our model, it appears that the band-edge shift under illumination cannot be accounted for by the mechanism we discussed above. This shift has to be related to other mechanisms, such as chemical surface reactions involving surface intermediates. It is the case for the dependence of the flatband potential on pH (12, 13) and on redox concentration (14, 15). Surface modification may also be the result of oxide or hydroxide intermediate formation (2), such as As_2O_3 on n-GaAs (16, 17). If we consider a surface reaction involving surface agent and holes, our experimental result concerning ΔV_{FB} might be explained. In the dark, this chemical equilibrium presents stationary conditions which are fixed by the small surface hole concentration. As soon as the electrode is illuminated, the large

amount of photogenerated holes disturbs this “equilibrium,” leading to new stationary conditions. One can imagine, for example, a transient modification of the surface at the very time when the electrode is illuminated. At the same time, electrical charges may be transferred from the surface to solution or be trapped at the surface, leading to a light dependent change of the Helmholtz potential drop. In fact, there exists a non-negligible time constant (a few seconds) for obtaining a stationary photocurrent when illumination is put on. The variations of ΔV_{FB} with the photon flux show that this modification becomes effective for low light intensities (~ 1.2 mW/cm²). Because the band-edge shift is positive, the surface-charge variation must be positive. For example, the surface may gain holes. Furthermore, as mentioned earlier (3), this shift is reversible. This means that the flatband potential returns to its initial value in the dark, when light is cut off. This fact indicates that the surface reaction is reversible and that *in situ* experiments have to be performed to identify these surface modifications. Note that a shift of $\Delta V_{FB} = 0.20$ V is promoted by only trapping 3.5×10^{12} cm⁻² charges at the surface ($C_H = 2.8$ μ F/cm²). This means that one surface atom out of about three hundred is involved in such a mechanism. We know that the n-GaAs/selenide PEC cell is almost completely stabilized (18), but it is not unreasonable to think that the shift ΔV_{FB} is linked to steps of the photocorrosion process as it was described by Tsubomura *et al.* (2). Similar results exist in various aqueous electrolytes, especially in 1M KOH (19).

Conclusion

From simultaneous I-V and impedance experiments upon n-GaAs/aqueous electrolyte junctions, we proposed a model for mechanisms that take place at the interface. Particularly, impedance measurements showed that two types of surface states have to be considered (i) slow surface states which promote surface-charge variations independent of the potential and due to chemical transformations of the surface because of photogenerated holes. These states are responsible for the flatband-potential shift ΔV_{FB} . (ii) fast surface states which exchange charges with the semiconductor bands and the solution. These charge variations account for the differential capacitance $C_{ss}(V)$ and modify the potential distribution through the junction in the photocurrent rise region.

According to our analysis, the band-edge shift under illumination cannot be induced by surface-charge variations of the second type. This result differs from the one of Kelly and Memming, who attributed the whole shift to the charge variation in a single state close to the midgap region. We believe that the strong variation of the surface charge with potential, according to the mechanism they considered, would completely block the band bending for potential close to -1.6 V/SCE. In that case, a plateau in the photocurrent rise would appear. This is not experimentally observed. Finally, the surface-state distribution we find reinforces the assumption of a direct hole-transfer current to solution via the valence band, as it was assumed by others (20). It appears that the working conditions of the illuminated junction are the consequences of one or several surface modification processes via holes.

Electrochemical Investigation of Hydrogen Storage in Metal Hydrides

C. M. Luedecke, G. Deublein, and R. A. Huggins

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

A new technique has been developed to study and control hydrogen storage in solid metal hydrides. The formation of metal hydrides and their thermodynamic and kinetic properties have been investigated by electrochemical methods employing a low temperature molten salt galvanic cell of the type

The choice of the electrolyte is of great importance in this method. Besides having to be thermodynamically stable when in contact with the electrodes, it must conduct charge by transport of hydrogen containing species. For this purpose, the low temperature organometallic salt NaAlEt₄ (melting point 128°C) has been synthesized. It is saturated with NaH, the hydride ions of which act as hydrogen transmitters. This electrolyte has the additional advantage that its oxygen activity is extremely low, so that no oxide layers form which could block hydrogen reaction with the alloy and thus reduce its apparent capacity. It even cleans the surface of oxide layers which may have been present initially. This technique allows easier investigation of metal hydrides than the conventional pressure-temperature experiments and, in addition, avoids the main problems involved in using aqueous solution electrolytes, *i. e.*, the corrosion of the metal alloys and, especially, the formation of oxide or hydroxide layers. With the aid of this cell, charge/discharge experiments have been carried out and hydrogen has been added to and deleted from the hydride forming metal alloy systems Mg-Ni, Mg-Cu, and Mg-Al at 142° and 170°C. Equilibrium open-circuit voltage measurements provide information about the thermodynamic properties as a function of the overall composition of the electrode material. Thermodynamic data for the different metal hydride systems have been determined as a function of hydrogen content and interpreted in terms of the corresponding ternary phase diagrams (Mg-Ni-H, Mg-Cu-H, and Mg-Al-H, respectively). The Gibbs free energies corresponding to the various reactions of hydrogen with the binary metal alloys measured in this way have been found to be in good agreement with data determined by conventional pressure-temperature experiments. For the Gibbs free energy of formation of MgH₂, for instance, we find $\Delta G_f = -4.8$ kcal/mol at 142°C, whereas the data reported in literature range from -4.2 to -5.0 kcal/mol. The results are also in accordance with a model in which these systems are treated as ternaries rather than as pseudo-binary reactions. Using this new approach, the relevant three-phase triangles and two-phase tie lines of the ternary phase diagrams can be calculated from the Gibbs formation energies of the phases present in these systems. The hydrogen capacities in these several metal alloy systems are also readily interpreted in terms of the phase boundaries of the corresponding three-phase equilibria.

Hydrogen is being looked upon as an ideal energy carrier: it is nonpolluting, light weight, relatively inexpensive, and readily available because it can be produced from water. However, there are a number of problems to be solved, one of them being the storage of hydrogen.

One approach to this is the use of solid metal hydrides, in which the density of hydrogen per unit volume can be greater than in either liquid or gaseous hydrogen, even under quite high pressures. Therefore, metal hydrides are often discussed as potentially useful hydrogen storage media (1-4). They are mostly intermetallic compounds which are generally thought to reversibly absorb hydrogen at convenient temperatures and pressures according to a reaction of the type

where Me is the metal or alloy and MeH_x is its hydride.

Many investigations concerning the formation of metal hydrides have been done by absorption experiments in which hydrogen from the gas phase reacts with solid alloys (1, 2, 5-7). Pressure and temperature are generally the controlling parameters. However, another possible way to investigate metal hydrides is by means of electrochemical methods. According to the Nernst equation, the hydrogen activity or pressure p_{H_2} at the interface between the electrolyte and the solid hydride electrode can be controlled by the electrochemical potential if a suitable electrolyte and cell configuration can be found. Thus, control of the cell voltage E should cause the metal hydride to either absorb or desorb hydrogen.

$$\Delta E = RT/zF \ln p_{\text{H}_2}$$

(R = gas constant, F = Faraday's constant). Therefore, measurements can be done under isothermal conditions

by applying an electrical potential, rather than changing the pressure and/or the temperature.

There are several advantages the electrochemical technique has over the traditional methods. First, as there is no temperature change necessary for adsorption or desorption, the hydrogen activity at the surface of the metal hydride can be changed very rapidly. Second, large variations in hydrogen activity can be attained by relatively small differences in the cell voltage so that the effective pressure can be changed easily over several orders of magnitude, a feature that is not normally possible using the conventional pressure-temperature methods.

However, in spite of these potential advantages, only a few electrochemical investigations of hydride systems have been done thus far (8-10). The reason for this seems to be that aqueous electrolytes have been used. These electrolytes poison the metal hydrides by forming oxide layers on the surface and give rise to a loss of capacity and poor cycling properties. This drawback can be avoided by using nonaqueous electrolytes. In this work, NaH dissolved in a low temperature molten salt is used as the electrolyte. The hydrogen transmitting species in this case are not H^+ ions, but H^- ions.

In addition to this new experimental method, we propose a new theoretical approach to the interpretation of the formation of hydrides from binary metallic alloys, namely, treating them as ternary systems instead of as pseudobinary reactions, as is generally done in the literature, and describing them by means of ternary thermodynamics and phase diagrams. The plateau voltages, or hydrogen pressures, thus correspond to regimes of three-phase equilibria, and the widths of these regions correspond to the lengths of the plateaus and, therefore, the hydrogen capacity of different alloys.

This experimental method and theoretical approach have been applied to three systems: Mg-Ni-H, Mg-Cu-H, and Mg-Al-H. They serve as models to simultaneously test the experimental technique and theoretical interpretation. They are also possible reversible hydrogen storage materials themselves.

Experiments

The electrochemical investigations of the ternary Mg-based alloys were carried out using galvanic cells of the type

The experiments were performed at 142° and 170°C under high purity helium gas in a controlled atmosphere glove box.

An important feature of this cell is the use of a hydride ion conducting nonaqueous electrolyte. The low temperature organometallic salt $NaAlEt_4$ was used as a solvent and saturated with NaH. The $NaAlEt_4$ was synthesized by direct reaction of $AlEt_3$ with Na at 130°-140°C in a glove box.

Elemental sodium is stable in $NaAlEt_4$ and can be used as the reference/counterelectrode (11). This solvent is also stable in the presence of up to 1 atm H_2 . NaH, which has a dissociation voltage of 246 mV at 142°C (12), is soluble in it, and the hydride ions serve as hydrogen carriers.

The sample to be hydrided was used as the working electrode. Several metal alloys were investigated: $Mg_{2.35}Ni$ (99.9 weight percent [w/o], Hy-Stor Alloy 301, Ergenics); $Mg_{2.08}Cu$ (99.6 w/o, Hy-Stor Alloy 302, Ergenics); and Mg-Al alloys of the nominal concentrations Mg_3Al , $MgAl$, and $MgAl_4$. The Mg-Al alloys were prepared by melting the metals in the proper amounts in a small molybdenum bucket. The hydride forming alloys were crushed and ground to fine powder in a porcelain mortar and pestle. The powder was then cold pressed into thin pellets. These were held and electrically connected by means of ribbons of molybdenum which do not show any solubility for hydrogen (13, 14). This whole process was done in a high purity He atmosphere.

This type of hydride electrode proved to be very successful. It provided a high surface area, and while extensive studies of cycling behavior were not undertaken, such electrodes did not show any obvious degradation as a result of a number of hydriding/dehydriding experiments. The thermodynamic results remained consistent during repeated cycling.

The counter and reference electrodes consisted of commercially pure Na. At the temperatures present, it was liquid and was therefore kept in a U-shaped quartz tube. The electrical contact to the Na was provided by a ribbon of molybdenum, which shows good compatibility with Na under these conditions.

The electrochemical experiments involved passing constant currents of about 100 μA through the cell. By this means, hydrogen was added to, as well as deleted from, the hydride forming alloys. Potentials, currents, and charges were measured and controlled by means of a potentiostat/galvanostat (PAR, Model 173) and a digital coulometer (PAR, Model 179). A multimeter and a chart recorder helped with monitoring the data.

Results

With the galvanic cell described above, electrochemical measurements have been done on $Mg_{2.35}Ni$, $Mg_{2.08}Cu$, and three Mg-Al alloys of nominal concentrations Mg_3Al , $MgAl$, and $MgAl_4$ at 142° and 170°C. According to the binary phase diagrams (13-15), these alloys are mixtures of the phases Mg and Mg_2Ni , Mg and Mg_2Cu , Mg and Mg_5Al_4 , Mg_3Al_4 and Mg_2Al_3 , and Mg_2Al_3 and Al, respectively.

Because the potentials are measured with respect to the reference electrode, the EMF of which is determined by the Na/NaH equilibrium, the dissociation voltage of NaH has to be taken into account to convert the cell voltage to the voltage vs. 1 atm H_2 . This is done using the tabulated data (12).

As mentioned above, the starting alloys consist of two phases. By adding hydrogen, a three-phase equilibrium is established so that, according to the Gibbs phase rule, the hydriding reactions should give constant cell voltages. Only if a two-phase tie line is crossed and another triangle entered will the voltage change to a new fixed value. The electrical potentials which have been measured in three-phase equilibria are listed in Table I. They are given vs. Na/NaH and vs. 1 atm H_2 . The hydrogen activities and Gibbs free energies of the reactions calculated from these data are included in the table as well. The EMF spans

Table I. Electrochemical data for various three-phase reactions in the ternary magnesium alloy hydride systems Mg-Ni-H, Mg-Cu-H, and Mg-Al-H, as measured at 142°C. E = equilibrium open-circuit cell voltage; a_{H_2} = hydrogen activity = hydrogen pressure (atm); ΔG = Gibbs free energy of the corresponding reaction

System	Three-phase equilibrium	E [mV] vs. Na/NaH	E [mV] vs. 1 atm H_2	a_{H_2}	ΔG [kcal/mol H_2]
Mg-Ni-H	Mg_2Ni -Mg- MgH_2	140	107	2.4×10^{-3}	-4.9
	Mg_2Ni - MgH_2 - Mg_2NiH_4	168	79	1.1×10^{-2}	-3.7
Mg-Cu-H	Mg_2Cu -Mg- MgH_2	145	102	3.2×10^{-3}	-4.7
	Mg_2Cu - $MgCu_2$ - MgH_2	181	66	2.4×10^{-2}	-3.1
Mg-Al-H	Mg_3Al_4 -Mg- MgH_2	142	105	2.7×10^{-3}	-4.8
	Mg_2Al_3 - Mg_3Al_4 - MgH_2	166	81	1.1×10^{-2}	-3.7
	Al- Mg_2Al_3 - MgH_2	180	67	2.3×10^{-2}	-3.1

from about 140 to 181 mV vs. Na/NaH or from about 107 to 67 mV vs. 1 atm H_2 . Accordingly, the hydrogen activity or pressure changed by about one order of magnitude, from 2.4×10^{-3} to 2.3×10^{-2} . The lower values in all three cases correspond to the formation of MgH_2 , which these systems have in common.

These data can be interpreted in terms of Gibbs triangles. Figures 1-3 show the isothermal sections of the corresponding ternary phase diagrams valid for temperatures in the range 140° to 170°C. The initial compositions of the various alloys are marked by arrows, and the paths of overall concentrations during the addition or deletion of hydrogen are indicated by dotted lines.

Whereas Mg_2Ni forms a stable ternary hydride, namely, Mg_2NiH_4 , the phase diagrams of the systems Mg-Cu-H and Mg-Al-H do not exhibit any ternary hydride compounds. Instead, these alloys react during the uptake of hydrogen to form MgH_2 and an intermetallic compound less rich in Mg than the initial alloys. However, in all three systems, the addition of hydrogen to the magnesium-rich two-phase alloy causes MgH_2 to be formed until

Fig. 1. Ternary phase diagram of Mg-Ni-H valid for the temperature range 140°-170°C. The arrow shows the initial concentration of the alloy, and the dotted line shows the concentration change during the hydriding experiment.

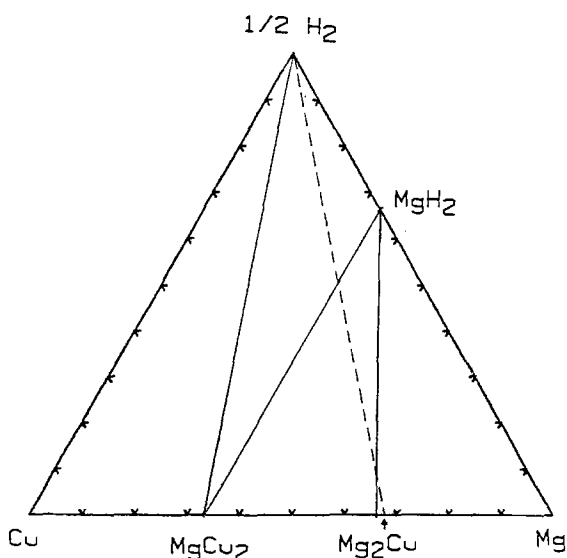

Fig. 2. Ternary phase diagram of Mg-Cu-H valid for the temperature range 140°-170°C. The arrow shows the initial concentration of the alloy, and the dotted line shows the concentration change during the hydriding experiment.

Fig. 3. Ternary phase diagram of Mg-Al-H valid for the temperature range 140°-170°C. The arrows show the initial concentrations of the alloys, and the dotted lines show the concentration changes during the hydriding experiments.

the boundary of the neighboring three-phase equilibrium is reached.

For $Mg_{2.35}Ni$ and $Mg_{2.08}Cu$, the voltages of the second plateaus neighboring the triangle in which MgH_2 is formed have been measured at both 142° and 170°C. The results are given in Table II, which also includes data from the literature (16-18) for comparison. It is seen that these values, as well as their small temperature dependence, are in good agreement.

Discussion

The reaction of hydrogen with binary alloys Mg-Ni, Mg-Cu, and Mg-Al has been studied by use of electrochemical techniques. The results of this approach will be compared to data (available in the literature) obtained by conventional pressure-temperature experiments. They will also be related to thermodynamic calculations based on the corresponding binary phase diagrams.

As the ternary phase diagrams (Fig. 1-3) show, the magnesium-rich two-phase alloys of all three systems will first form MgH_2 during hydrogenation. The plateau voltage and Gibbs free energy change of these reactions correspond to the formation of MgH_2 from elemental Mg according to $Mg + H_2 \rightarrow MgH_2$ [1]. The values obtained are -4.9, -4.7, and -4.8 kcal/mol, from measurements on the Mg-Ni-H, Mg-Cu-H, and Mg-Al-H systems, respectively, at 140°C. The differences between these values are well within experimental error.

The literature contains a number of values for the thermodynamic parameters of this reaction, obtained from experiments performed by the use of conventional methods. These are shown in Table III. It is seen that the enthalpy of formation is about -18 kcal/mol H_2 , and the entropy change is about -33 cal/K mol H_2 (corresponding to the disappearance of 1 mol of gas). The values of the Gibbs free energy of formation of MgH_2 at 140°C range from -4.2 to -5.0 kcal/mol, with an average of -4.6

kcal/mol. We see that the values obtained from the experiments reported here fall well inside this range.

Discussion of the results of each of the three ternary systems follows.

Mg-Ni-H.—Interpreting the hydrogenation of binary alloys in terms of ternary phase diagrams makes possible calculating the thermodynamic data related to various ternary equilibria from data on the corresponding binary systems (13-15), in this case Mg-H, Mg-Ni, and Ni-H. Mg has a very small solubility for hydrogen [< 0.1 atom percent (a/o)] and forms only one binary compound, MgH₂, the Gibbs free energy of formation of which is about -4.6 kcal/mol at 140°C (cf. Table III). Ni and Mg have a very small solubility for each other as well (< 0.1 a/o) and form two intermediate phases, MgNi₂ and Mg₂Ni, both having narrow ranges of stoichiometry (13-15). Their Gibbs free energies of formation at 140°C are about -13 kcal/mol and -10 kcal/mol, respectively (12, 26). Ni has only negligible solubility for hydrogen ($\leq 10^{-4}$ a/o) (13), and the binary compounds are either not confirmed (NiH₄ and NiH₂) or they decompose (NiH) (15). Mg, Ni, and H form only one ternary phase, Mg₂NiH₄. Its Gibbs free energy of formation is -16.6 kcal/mol at 140°C (27). Calculations based on these data confirm the ternary phase diagram presented in Fig. 1.

From the phase diagram in Fig. 1, we can see that hydrogenation of an alloy with initial composition Mg_{2.35}Ni causes MgH₂ to form (the amount of Mg will decrease) until the overall concentration crosses the MgH₂-Mg₂Ni tie line. Thereafter, the intermetallic compound Mg₂NiH₄ begins to form, and the Mg₂Ni gradually disappears. The equilibrium voltage steps from one plateau to another. The first plateau represents the Mg-Mg₂Ni-MgH₂ triangle, which has the same thermodynamic properties as the equilibria along its edges. One of these is the Mg-MgH₂ equilibrium, which can be related to the Gibbs free energy of formation of MgH₂ from Mg and H₂. The second plateau corresponds to the Mg₂Ni-MgH₂-Mg₂NiH₄ triangle, whose thermodynamic properties correspond to the reaction

because both Mg₂Ni and Mg₂NiH₄ are at its corners. These two plateau voltages give the Gibbs free energies of the corresponding reactions to be -4.9 and -3.7 kcal/mol H₂. These results are in good agreement with data gained by conventional methods mentioned earlier for Reaction [1], as well as those listed in Table IV for Reaction [2]. The effect of temperature on the thermodynamic data of Reaction [2] is very small and is in accordance with the literature as well, as is shown in Table II.

Mg-Cu-H.—The thermodynamic parameters of this system have been determined from the data of the corresponding binary phase diagrams.

Mg and Cu have a negligibly small solubility in each other. They form two intermetallic compounds, MgCu₂ and Mg₂Cu; MgCu₂ has compositional ranges of the order of 1 a/o, whereas Mg₂Cu has a very narrow range of stoichiometry (13). Their Gibbs free energies of formation are either -8.2 and -6.3 kcal/mol (26) or -8.49 and -6.75 kcal/mol (28). The solubility of hydrogen in Cu is less than 10^{-4} a/o, and no hydride phases are formed (13-15).

Table IV. Thermodynamic data for the formation of Mg₂NiH₄ measured with conventional methods (T = 142°C)

ΔH [kcal/mol H ₂]	ΔS [cal/K mol H ₂]	ΔG [kcal/mol H ₂]	Ref.
-15.2	—	—	22
-15.0	—	—	29
-15.0	-28.5	-3.2	17
-15.4	-29.2	-3.3	16

From the information on the three binary systems and the assumption that no ternary phases exist (the literature does not indicate the existence of any, and it will be seen later that this assumption is confirmed by measurements), the ternary phase diagram has been determined. It is shown in Fig. 2. The phase diagram shows that during the hydrogenation of an alloy with initial composition Mg_{2.08}Cu, two tie triangles are crossed by the overall composition. The first one represents the formation of MgH₂ according to Reaction [1]; the second one corresponds to the reaction of Mg₂Cu with hydrogen according to

The Gibbs free energies of these reactions have been found from the electrochemical experiments to be -4.7 and -3.1 kcal/mol H₂, respectively.

These data are in very good agreement with data measured by use of *p-T* methods, being -4.6 kcal/mol H₂ in the first case, as mentioned earlier, and -3.3 kcal/mol H₂ ($\Delta H = -17.4$ kcal/mol H₂; $\Delta S = -34.0$ kcal/mol H₂) (18) for the second, respectively. The measured change of the Gibbs free energy of reaction [3] with temperature is again small, in accordance with the literature (Table II).

For reaction [3], the thermodynamic data of the binary compounds available in the literature lead to -3.1 kcal/mol H₂ (26) and -3.9 kcal/mol H₂ (28), which are also in good agreement with the experiments.

Mg-Al-H.—The literature does not give precise enough data, for the Gibbs free energies of formation of the binary Mg-Al alloys, to allow the accurate calculation of the Gibbs free energies of the three-phase reactions in the resulting ternary diagram. However, the phase diagrams of the binary systems are known, so the ternary phase diagram can be mapped out. Mg and Al are both soluble up to 2 a/o in each other and form two intermetallic compounds, Mg₂Al₃ (38-40 a/o Mg) and Mg₅Al₄ (53-60 a/o Mg). Al does not form any hydride phase stable at the temperatures present (12), and it dissolves less than 10^{-6} a/o hydrogen (13, 14). The resulting ternary phase diagram is shown in Fig. 3. This diagram exhibits three triangles which do not contain elemental hydrogen. The thermodynamic parameters of the first, whose corners are at Mg₅Al₄, Mg, and MgH₂, correspond to the formation of MgH₂. The second and third involve the reactions

and

The Gibbs free energy changes resulting from all three reactions have been found from the electrochemical measurements reported here to be

$$-4.8 \text{ kcal/mol H}_2 \text{ for Reaction [1]}$$

$$-3.7 \text{ kcal/mol H}_2 \text{ for Reaction [4]}$$

$$-3.1 \text{ kcal/mol H}_2 \text{ for Reaction [5]}$$

The value for Reaction [1], which corresponds to the Gibbs free energy of formation of MgH₂, is in good accordance with values in the literature for this reaction, as mentioned earlier. There are no available data for Reaction [4]. In the case of Reaction [5], $\Delta H = -16.4$ kcal/mol

Table V. Gibbs free energy of various three-phase reactions in the ternary magnesium alloy hydride systems Mg-Ni-H, Mg-Cu-H, and Mg-Al-H at $T = 142^\circ\text{C}$. H_2 and $\Delta S = -31.9$ cal/K mol H_2 have been found (2), which gives ΔG $142^\circ\text{C} = -3.1$ kcal/mol H_2 , in excellent agreement with our own measurements.

Conclusions

An electrochemical technique has been developed to investigate metal hydrides. As has been pointed out, the choice of the electrolyte is important. In order to avoid the formation of oxides and hydroxides, a low melting organometallic salt of high ionic conductivity has been used, rather than an aqueous solution. In this case, the hydrogen containing species is the hydride anion, H^- . This method has several advantages over the use of the traditional pressure-temperature variables to control the formation of the various possible phases in these systems. Because the hydrogen activity is established by electrochemical means, it can be controlled with ease and high precision over wide ranges. For example, if a solution of NaH is used as the electrolyte, the range can be extended from well over 1 atm down to less than 10^{-5} atm. This span includes several metal alloy systems which are of interest for application as hydrogen storage materials.

In addition to this new experimental technique, a theoretical approach has been presented which interprets the formation of ternary metal hydrides in terms of ternary phase equilibria, rather than as pseudobinary reactions. This has been found to be very useful in explaining observed hydrogenation reactions, as well as in providing a framework for predicting them. In this interpretation, plateaus in traditional pressure-temperature experiments correspond to regimes of three-phase equilibria. The pressures of these plateaus can be directly calculated from the thermodynamic data of the phases present, by consideration of the ternary reactions predicted from the phase diagram. Furthermore, the compositional limits of the observed plateaus correspond to the compositions at which the overall composition crosses a two-phase tie line. Thus, the hydrogen capacity of the metal alloy can readily be read from the phase diagram, and the reactions taking place can readily be seen.

This experimental technique and this theoretical approach have until now been applied to the hydrogen storage alloy systems Mg-Ni, Mg-Cu, and Mg-Al. The measurements are in good agreement with the calculations and with the results of conventional pressure-temperature methods (Table V). With this concept, experimental as well as theoretical, it is possible to investigate several families of new potential hydrogen storage alloys and to design materials with appreciable capacities at desirable temperatures and hydrogen activities.

Molten Carbonate Fuel Cell Electrolyte Structure Fabrication Using Electrophoretic Deposition

Charles E. Baumgartner,* Vincent J. DeCarlo, Paul G. Glugla¹ and John J. Grimaldi²

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Electrophoretic deposition has been evaluated as a technique for preparing porous LiAlO₂ matrices suitable for use as molten carbonate fuel cell electrolyte structures. Although both the technique and the deposited product initially appeared to be well suited for the application, structural fracture resulted during impregnation with the alkali carbonate electrolyte necessary for fuel cell operation. Data are presented comparing and contrasting the physical properties of electrophoretically fabricated and hot-pressed electrolyte structures.

The electrolyte structure of a molten carbonate fuel cell (MCFC) is comprised of a porous ceramic matrix whose interstitial volume is filled with alkali carbonates. This structure plays a pivotal role in determining overall fuel cell performance as it serves both as the carbonate ion conduction path required for cell operation and also as a barrier to prevent gas-phase mixing of the fuel and oxidant. Satisfying both criteria requires the electrolyte structure to remain essentially carbonate filled during its operation, *i.e.*, free of cracks and interconnected voids.

Conventional electrolyte structure fabrication entails hot-pressing an intimate mixture of the ceramic (LiAlO₂) and the electrolyte (typically 62 mole percent [m/o] Li₂CO₃:38 m/o K₂CO₃) at a temperature just below the carbonate's 763 K liquidus to yield a brittle structure of greater than 95% theoretical density (1). The prepressed mixture is obtained by either dry mixing the respective components (2) or preferably from a precursor mixture of an aqueous solution/slurry containing all components (3, 4). Hot-pressed structures suffer from several disadvantages: first, carbonate agglomerates, formed in the mixture prior to pressing, drain into the porous electrodes during cell operation leaving voids in the structure which can act as centers for crack initiation. In addition, owing to the fragile nature of the final compact, structures are typically 0.125 cm or more thick. As the specific conductance of a 0.18 cm thick hot-pressed electrolyte structure is ~ 0.3 ($\Omega\text{-cm}$)⁻¹ at 923 K (5) the electrolyte related voltage drop for a fuel cell operating at a current density of 0.16 A/cm² is, therefore, given by

$$E_{\text{drop}} \text{ (V)} \approx 0.533t \quad [1]$$

where t is the electrolyte structure thickness in centimeters. A fuel cell possessing a 0.025 cm thick electrolyte structure would operate at a potential 82 mV higher than an identical cell possessing a 0.178 cm thick structure, owing to the decrease in required carbonate conduction length. Therefore, electrolyte structures thinner than those readily prepared by hot-pressing are desired. Finally, the economics associated with hot-pressing at temperatures approaching 750 K add greatly to the cost of the final fuel cell package.

Various methods have been suggested as alternative fabrication techniques including tape casting (6), vacuum casting (7), and electrophoretic deposition (ED) (8, 9). Of these, tape casting and ED are especially attractive as they are commercial processes for fabricating thin structures. This communication details our work on ED as a technique for preparing porous LiAlO₂ matrices for use as MCFC electrolyte support structures.

Method

Particle electrophoresis has been known for over a century and has been utilized as a fabrication technique by

*Electrochemical Society Active Member.

¹Present address: Department of Chemistry, University of Colorado, Boulder, Colorado 80309.

²Present address: Michelin, Greenville, South Carolina 29610.

the ceramics industry for several years (10, 11, 16-18). The technique can be separated into the two stages of suspension preparation and electric-field-induced deposition.

Particles suspended in an "inert" vehicle are categorizable, in broad terms, as being either stable or flocculating. In flocculating suspensions, particle-particle collision resulting from Brownian motion leads to permanent contact and thus a decrease in the number and an increase in the size of suspended particles. Particle concentrations have been shown both theoretically and experimentally to decrease at a second-order rate which is dependent upon factors such as particle diameter, vehicle viscosity, and temperature (12, 13). Conversely, in stable suspensions particles exhibit repulsive surface charges resulting from one or more of a variety of mechanisms, such as site-specific solvent adsorption or selective ion dissolution. These repulsive interactions slow particle flocculation rates by reducing the degree of attractive interaction upon collision.

The preparation of stable suspensions is important in electrophoretic fabrication for the following reason. The external electric field in an ED process simply serves to draw particles together onto the mandrel surface. Flocculating suspensions, which already possess an affinity to coalesce, form only a few contact locations during deposition, resulting in a very weak structure. However, deposits from stable suspensions lead to a more idealized, close-packed structure characterized by a higher density and improved strength. The deposit's microstructure and morphology are therefore stringently dependent upon the suspension characteristics. The choice of suspension vehicle and the use of binders or deflocculants are known to affect the suspension stability and electrophoretic mobility, which, in turn, affects the deposit quality.

Experimental

Powder and suspension preparation.—LiAlO₂ powders were prepared by either a molten-salt-mediated synthesis or a high temperature synthetic reaction. The molten salt synthesis (14) reacts high surface area Al₂O₃ (Alcoa) with LiOH in a molten NaCl/KCl solvent. The reaction is carried out at 1073-1273 K in air for 4-8h, depending upon the particle size of the desired product. Following cooling, the alkali chloride solvent is dissolved in water and the γ -LiAlO₂ collected by filtration using a Millipore 0.22 μm filter (Millipore Corporation). The synthesis yields a uniform particle-sized LiAlO₂ with a BET surface area between 6 and 8 m²/g. Lower surface area powders were prepared by reacting Al₂O₃ (Alcoa) with Li₂CO₃ at 1473 K in air for 24h. This reaction yields a highly aggregated γ -LiAlO₂ which must be comminuted to the desired surface area.

Ten solvents (reagent-grade alcohols and ketones) ranging in dielectric constant from 13.1 to 25.7, were evaluated as deposition vehicles. Of these, 2-propanol yielded the best results and was used for the majority of the sample preparations reported here. The deposition behavior in

other vehicles will be detailed later. Suspensions were typically prepared by combining 200g of LiAlO_2 , 540 ml of 2-propanol previously dewatered by passing over molecular sieves, and 400g of dense $\alpha\text{-Al}_2\text{O}_3$ grinding media in a 1 liter plastic bottle. Just prior to this step the LiAlO_2 was heated to 1275 K in air for 1h to remove adsorbed moisture. A vibratory milling (Sweco, Incorporated) of 4-24h yielded an acceptably stable suspension exhibiting less than 5% settling in 10 min.

Deposition and postdeposition.—Flat LiAlO_2 structures were deposited electrophoretically by applying a dc voltage of between 125 and 800V across the suspension. The deposit accumulated on a prepared mandrel (charged negatively for 2-propanol suspensions), the counter-electrode being either the stainless steel container or an additional stainless steel insert. A millisecond timer (Minarik Electric Company) controlled the duration of the applied potential (Sorensen Power Supply, Raytheon Company) (Fig. 1). For example, deposit thicknesses of 0.025 and 0.178 cm were obtained using deposition times of 4.0 and 60.0s, respectively, at 400V from a 2-propanol suspension. Various materials were evaluated as deposition mandrels including graphite, stainless steel, and nickel, and various deposition time/voltage conditions were evaluated.

Following deposition, the mandrel containing the deposit was removed from the suspension for drying. Drying procedures to yield crack-free deposits ranged from air drying for thin (0.013-0.038 cm thick) deposits to controlled 2-propanol vapor pressure conditions for thicker (0.127-0.178 cm thick) structures.

Electrolyte addition.—Following the fabrication of a dried, porous LiAlO_2 layer, the pore volume must be impregnated with alkali carbonates to yield a MCFC electrolyte structure. Electrolyte additions (62 m/o Li_2CO_3 :38 m/o K_2CO_3) were accomplished by heating the deposit containing premelted and ground carbonate on its surface above the 763 K carbonate liquidus. As the carbonates melted, it was drawn into the porous deposit by capillarity. Various impregnation conditions were evaluated.

Sample evaluation.—Following electrolyte filling, structures were examined for fractures by optical microscopy (10-70 \times); crack-free structures were stored in a dry atmosphere. The sample's hermeticity as a function of differential gas pressure (pressure capacity) was measured at 923 K and compared with that of hot-pressed structures (15). The apparatus employed consists of two 304 stainless steel canisters, the faces of which contain a series of 1/16 or 1/8 in. holes arrayed within a 1 in. diam circle (Fig. 2). The sample itself (> 1 in. diam) was held between two pieces of perforated gold foil. A piece of 40 mesh screen was utilized as a bottom support. Alignment of the top and bottom canister was aided by locating pins and assembly within a cradle; the cradle was then placed

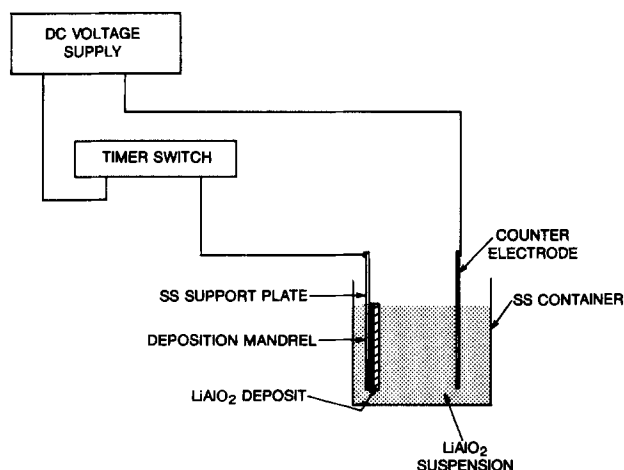

Fig. 1. Electrophoretic deposition apparatus

BUBBLE PRESSURE TEST APPARATUS

Fig. 2. Pressure capacity test apparatus. For clarity, the gold foil and expanded metal mesh are not shown.

inside a N_2 -purged box furnace. A hydraulic ram was used to apply sealing pressure, making a gastight seal between the sample and canister halves.

Each canister half contained both a gas inlet and outlet. The top canister was coupled to a pressure gauge and micrometer valve (cf. Fig. 2). This canister was pressurized, relative to the bottom half, using a N_2 containing gas such as 34% H_2 , 24% CO_2 , and 42% N_2 . The N_2 -free gas (75% H_2 , 25% CO_2) used in the bottom canister exited to a Carle series S analytical gas chromatograph equipped with two thermal conductivity detectors and a Shimadzu C-RIA chromatopac. The pressure capacity of the sample was taken to be the pressure differential at which a N_2 level in excess of background was first detected in the exit gas from the bottom canister. Both the sample's initial pressure capacity and its capacity following thermal cycling below the electrolyte liquidus were measured using this equipment.

In addition, the thermal expansion behavior of both hot-pressed and free standing ED structures was evaluated using a high sensitivity dilatometer. The samples, $2.0 \times 0.33 \times 0.15$ - 0.18 cm, were suspended lengthwise within an Al_2O_3 tube between two gold-foil sheets and held in place by a 10g holding force applied horizontally between one end of the sample and the tube's end. Specimens were heated at $3.3^\circ\text{C}/\text{min}$ from ambient to 973 K for three cycles under a CO_2 atmosphere. A LVTD continuously provided data on the sample's expansion/contraction during each heating and cooling cycle.

Results and Discussion

Matrix fabrication.—The importance of vehicle dielectric constant on suspension preparation and the quality of electrophoretically deposited sodium beta-alumina samples was shown previously by Powers (16). Ten solvents were evaluated here as LiAlO_2 deposition vehicles

ranging in dielectric constant from 13.1 to 25.7. Deposition occurred from all suspensions following a several-hour vibratory milling. The milling step was found to be essential to the preparation of stable suspensions. Milling fractures larger particles and particle agglomerates to yield newly exposed surfaces thereby promoting solvent adsorption and stable suspension formation. For the vehicles examined here, the resulting deposit quality was found not to depend upon vehicle dielectric constant, but rather to be strongly dependent upon the solvent type (Table I). Suspensions prepared with ketones settled significantly more rapidly than those from alcohols indicating more flocculating conditions. As a result, deposits from ketone vehicles were less dense and, on several occasions, slid from the mandrel following deposition. Those that were retrieved successfully invariably cracked upon drying. Alcohols as vehicles gave significantly stronger deposits but the deposits were plagued by extensive bubble-hole formation, *i.e.*, physical holes in the deposit which result from gases evolved as the solvent heats and eventually decomposes at the solvent/electrode interface. This effect was particularly prevalent for primary alcohols and somewhat less apparent for 2-propanol.

Deposition occurred on the negatively charged mandrel for all vehicles investigated with the exception of 3-pentanone. The general mechanism responsible for suspension formation here is believed to be solvent-specific adsorption as shown in reactions [2] and [3] below for a protonated solvent. The ceramic-solvent association is assumed to be dipole in nature (19).

Reaction [3], which possesses an adsorbed solvent sheath with a ceramic-directed negative dipole, is inferred to be predominant in most of the vehicles investigated here since deposition occurred on the negatively charged mandrel. Deposition from ketone-prepared suspensions also occurred on the negatively charged electrode, with the exception of 3-pentanone, in which a reversal in charging mechanism occurred. This charge reversal also occurred in acetone + 1-pentanol mixtures, where deposition obtained on the negatively charged mandrel for either pure solvent, but on the positively charged mandrel for solvent mixtures from 10-90% acetone. The specifics of the mechanism have not been confirmed experimentally.

The structures reported above were all deposited on polished stainless steel mandrels. In addition, mandrels of carbon, polished nickel, and porous nickel were evaluated. Whereas neither deposits on carbon nor polished nickel showed any significant differences from those made on stainless steel, the porous nickel mandrel (Gould Corporation porous nickel, > 60% porosity, 6 μm median pore size) was found to considerably reduce the occurrence of bubble holes within the deposit. The porous mandrel also aided in reducing the frequency of cracked deposits during drying by increasing drying uniformity.

Table I. Solvents investigated as ED vehicles

Material	Resulting structure
Ketones	
2-Pentanone (15.4) ^a	Cracked
3-Pentanone (17.0)	Cracked
2-Butanone (18.5)	Cracked
Acetone (20.7)	Cracked
2,4-Pentadione (25.7)	Cracked
Alcohols	
Benzyl alcohol (13.1)	Extensive bubble holes
1-Pentanol (13.90)	Extensive bubble holes
2-Propanol (18.3)	Some bubble holes
1-Propanol (20.1)	Extensive bubble holes
Ethanol (24.3)	Some bubble holes, cracked

^a The number in parenthesis is the solvent dielectric constant.

All results reported subsequently utilized 2-propanol suspensions deposited on negatively charged, porous nickel mandrels.

Deposition voltages exceeding ~125V were satisfactory for LiAlO₂ deposition, with about 6.0s at 125V or 4.0s at 400V required to produce a 0.025 cm thick matrix, and 60.0s at 400V to produce a 0.18 cm thick deposit. In suspension, each LiAlO₂ particle is surrounded by a solvent sheath or double layer. During deposition, this double layer is retained, in effect separating the individual ceramic particles by one or more monolayers of solvent. Following deposition, this solvent must be removed from the structure; accompanying solvent removal the structure shrinks, owing to a collapse of the solvent occupied volume. Structures on the order of 0.025 cm thick were readily dried in air for 24h followed by vacuum at ~373 K. Thicker structures, *e.g.*, > 0.050 cm thick, however required slower drying under a 2-propanol partial pressure to prevent cracking, because the outer surface of the deposit physically contracted prior to the center. This was accomplished by drying the deposits in a loosely covered container over a 2-propanol soaked towel. The resulting structures, in both cases, were extremely fragile, causing all deposits to be difficult to remove from the deposition mandrel without fracture. Deposits thicker than ~0.05 cm were removable, however, by careful horizontal pressure applied along one edge following complete deposit drying. Examination of density, pore-size distribution, and pore morphology showed these properties to be independent of deposit thickness for identically prepared samples. Therefore, thicker structures, removed from the deposition mandrel, were used in future evaluation when possible to remove influences associated with the porous nickel backing. For studies involving thinner deposits which incorporated the porous mandrel, a MCFC porous Ni anode was used as the deposition mandrel. Such a deposition technique would be necessary for the preparation of thin ED layers for MCFC applications.

Figure 3 displays mercury porosimetry curves for material deposited at 400V for 4s. As the LiAlO₂ surface area increased from 6.8 to 0.3 m²/g, the median pore size increased from ~0.3 to 1.8 μm and the pore diameter distribution broadened. Interestingly, the porosity showed no clear surface area dependence, varying between 55 and 61%. The deposit's pore-size distribution is important in determining its use as a MCFC electrolyte matrix. During fuel cell operation, the electrolyte structure is in intimate contact with both porous electrodes. Although the carbonate electrolyte is initially present within the electrolyte structure matrix, it will redistribute from the matrix to the electrodes, in accordance with the respective pore diameters and wetting characteristics of the individual components. The median pore diameter of the electrodes is between 2 and 6 μm . Since the electrolyte structure must retain sufficient electrolyte within its matrix during cell testing to prevent gas crossover, the electrolyte struc-

Fig. 3. Mercury intrusion porosimetry curves of ED LiAlO₂ layers deposited from various surface area LiAlO₂ powders.

ture's median pore diameter must not overlap excessively with that of the electrodes. The degree of optimum pore overlap has not been quantified; however, as the median pore diameter obtained on the deposit fabricated using $0.3 \text{ m}^2/\text{g}$ LiAlO_2 powder is approaching $2 \mu\text{m}$, it is assumed that this represents a lower limit in surface area for usable LiAlO_2 powders.

Electrolyte addition.—Electrolyte impregnation of deposited matrices was accomplished for both thick ($> 0.05 \text{ cm}$) deposits removed from the deposition mandrel and for thinner deposits (0.025 cm) still retained on the porous substrate by spreading the electrolyte, as a powder, over the matrix surface and heating above the electrolyte's liquidus. Once molten, the electrolyte was drawn into the pores by capillarity. The quantity of electrolyte to be added was determined prior to impregnation from mercury intrusion porosimetry results obtained on a separate, identically fabricated matrix. The influences of heating rates, gas atmospheres, and volume percent electrolyte fills on the propensity for matrix fracture during electrolyte addition were evaluated. A variety of gas atmospheres were chosen, including O_2 , CO_2 , H_2 , N_2 , their combinations, and vacuum, with CO_2 atmosphere-impregnated structures showing the least propensity towards cracking. Although the exact reason for this gas atmosphere influence has not been determined, it is possibly due to alkali carbonate decomposition in non- CO_2 containing environments (20). The incidence of structure fracture during impregnation was also found to decrease with decreasing electrolyte-fill fraction, decreasing heating/cooling rates, and decreasing LiAlO_2 surface area with the surface area influence being the most pronounced of these three (Table II).

Visual observation of 0.18 cm thick, $4 \times 4 \text{ cm}$ free standing ED matrices during electrolyte impregnation revealed at least two different fracture mechanisms to be operating. The specimens were placed on an Al_2O_3 pedestal within a quartz plate covered box furnace under a flowing CO_2 atmosphere. Samples were monitored visually during heating and cooling cycles. Immediately after the carbonate liquidus temperature was exceeded and the molten carbonate was absorbed into the LiAlO_2 matrix, LiAlO_2 particle rearrangement occurred driven by strong capillary forces (several hundred psi). This resulted in an overall structure shrinkage of approximately 1%. Structures which were unable to contract uniformly developed cracks at this time. These cracks were primarily manifest as peripheral wedge-shaped openings, if matrix edge-flaws were present, and otherwise as isolated microfractures covering the entire structure. A photograph showing severe microcracking in a sample impregnated with carbonate under a CO_2 atmosphere is presented in Fig. 4. These fractures, only barely detectable without magnification, extend completely through the thickness of the impregnated matrix imparting a translucency to the otherwise opaque structure.

Table II. Parameter influence on fracture of impregnated ED structures

Parameter	Results
Gas environment (O_2 , CO_2 , H_2 , N_2 , vacuum)	Crack-free structure yield slight better in CO_2 , worst in vacuum.
Impregnation temperature (773-973 K)	Little effect.
Structure cooling rate (60° to $5^\circ\text{C}/\text{h}$)	Slower cool rate moderately improved crack-free yield.
Electrolyte-filled void volume (50% to 100%)	Reducing electrolyte loading improved crack-free yield.
Initial LiAlO_2 surface area (6.8 to $0.3 \text{ m}^2/\text{g}$)	Lower surface area LiAlO_2 greatly increased crack-free yield.
Electrophoretic deposition voltage (175-800V)	Little effect.
Deposited LiAlO_2 thickness (0.178-0.013 cm)	Thinner structures increased crack-free yield.

Fig. 4. SEM micrograph showing microcracking of electrolyte-impregnated, $6.8 \text{ m}^2/\text{g}$ LiAlO_2 ED sample.

The severity and incidence of microcracks formed during electrolyte addition could be lessened by either lightly sintering the LiAlO_2 matrix prior to electrolyte addition or by decreasing the LiAlO_2 surface area. As the fractures result from physical particle rearrangement, lightly sintering the particle microstructure is obviously advantageous. Heat-treatments of at least 1000°C for 1h in air were found to be necessary to fuse the LiAlO_2 particle bridges sufficiently to produce a factor of 2 or 3 reduction in microcrack density. The alternate technique of increasing fracture resistance by decreasing the LiAlO_2 surface area was helpful but less effective. The larger particle size LiAlO_2 is not only more difficult to rearrange, owing to its increased mass, but also generates larger pores, thereby reducing the capillary drawing forces for structural rearrangement. Therefore, fractures associated with electrolyte addition could be partially eliminated by depositing LiAlO_2 powders with a surface area of $< 1 \text{ m}^2/\text{g}$.

No fractures were directly observed in the furnace during cooling through the carbonate solidification region; however, a second fracture mechanism was evident upon examination of cooled electrolyte filled structure. These fractures were concluded to be due to thermal stresses introduced into the now composite structure (electrolyte + LiAlO_2). ED-prepared porous LiAlO_2 structures were measured to possess a linear thermal expansion coefficient of $11.3 \times 10^{-6} \text{ in./in. } ^\circ\text{C}$ in this temperature region (see below). In contrast, the carbonate electrolyte undergoes a 5% volume contraction upon solidification at 763 K and exhibits a 373-673 K linear thermal expansion coefficient of $35.7 \text{ in./in. } ^\circ\text{C}$ (21), more than three times that of the ceramic matrix. The significant stresses generated by this thermal expansion mismatch leads to fractures ranging from long major cracks, several centimeters long, to crazing, similar to glazes placed under tension. Whereas lightly sintering the matrix was found to be beneficial in eliminating particle rearrangement-related fractures, such heat-treatments appear to have little or no impact on thermal stress related fractures. Instead, the microstructure of the porous ceramic layer, as dictated by the LiAlO_2 particle size and morphology, appeared to be the dominating influence. As before, matrices deposited using larger particle size LiAlO_2 powders showed a decreased propensity towards fracture. However, even matrices prepared using $0.3 \text{ m}^2/\text{g}$ LiAlO_2 commonly fractured during electrolyte impregnation. The final "optimized" impregnation procedure, therefore, involves a multistep impregnation whereby approximately 1/2 of the matrix's pore volume is electrolyte filled in each of two steps. Both steps are carried out under a CO_2 atmosphere with a controlled heating/cooling cycle of $\sim 0.75 \text{ K}/\text{min}$ to 873 K.

Using this procedure, approximately one-third of the 3×3 cm samples fabricated using LiAlO_2 powder with a surface area below $1 \text{ m}^2/\text{g}$ could be successfully impregnated to a crack-free status.

Evaluation and comparison to hot-pressed structures.—Electrolyte-impregnated structures were evaluated to determine their compatibility with fuel cell requirements. One of these requirements is that the structure must remain crack-free in the event that the cell undergoes a thermal cycle between the 923 K operating temperature and some temperature below the electrolyte liquidus, for example, 573 K. Structures which were electrolyte impregnated following the "optimized procedure" stated above were microscopically examined for fractures at 70X. Crack-free structures were then evaluated for their ability to prevent gas crossover as a function of differential pressure. This test is a sensitive technique for microcrack detection, and it simulates the fuel cell condition where a differential pressure could arise between the anode and cathode owing to a pressure malfunction on one side of the cell. In the event this occurs, the capillarity of the electrolyte structure alone prevents reactant gas mixing.

The pressure resistance or pressure capacity arises from the capillary force exerted by the electrolyte-filled pores, the relationship between capillary pressure capacity (P) and pore radius (r) is given by Eq. [4]

$$P = \frac{2\gamma_{1,v} \cos \theta}{r} \quad [4]$$

Janz (22) measured a value of 200 dyne/cm for $\gamma_{1,v}$ for molten Li/K carbonate, and contact angle measurements (23) have shown $\cos \theta$ for molten carbonates on most oxides to be equal to 1. Therefore, the theoretical pressure capacity of a molten carbonate-filled LiAlO_2 pore with a radius of $1.0 \mu\text{m}$ would be equal to 58 psi.

Pressure capacity measurements on hot-pressed and ED electrolyte structures were conducted at 923 K, using the apparatus shown in Fig. 2 and described elsewhere (15). Prior to sample heating, gas flow at a few inches of water was initiated through the canister halves to protect the sample. The temperature was increased from ambient to ~ 475 K and held constant for ~ 12 h; temperature was monitored with a Chromel-Alumel thermocouple located adjacent to the apparatus. Following this "drying period" the temperature was raised to 793 K. In general, a 1-1.5 K/min heating rate was maintained from ~ 733 to 793 K so that melting of the eutectic occurred uniformly. At ~ 793 K, the entire "sandwich" was hydraulically sealed from the top with 3-6 psi. Seal quality and background N_2 concentration were determined by monitoring the bottom canister's gas environment with no differential pressure across the sample. The temperature was then elevated to ~ 923 K. Throughout each pressure capacity measurement, the external sealing pressure was maintained greater than the pressure differential between the top and bottom canister. Background N_2 concentration was determined and found to be independent of applied sealing pressure.

Hot-pressed samples (containing 67 volume percent [v/o] electrolyte) successfully withstood a ΔP up to 36 psi, the limit of the apparatus employed. This indicates that the samples neither cracked during heat-up nor possessed sufficient large pores ($\approx 3.2 \mu\text{m}$ diam) to allow blow through at these pressures. A hypothetical hot-pressed structure median pore diameter of $0.3 \mu\text{m}$ calculated from the LiAlO_2 powder surface area and carbonate volume fraction is predicted to possess a pressure capacity in excess of 350 psi based on Eq. [4]. Moreover, these structures were shown to be fracture resistant following thermal cycling below the electrolyte liquidus, as evidenced by a sustained pressure capacity upon reheating. In contrast, the majority of ED structures examined, whether removed from the deposition mandrel or impregnated as a composite on the porous Ni plaque, fractured either prior to or during heat-up in the test apparatus. All

Fig. 5. Percent nitrogen crossover as a function of differential pressure at 923 K for a 0.18 cm thick hot-pressed, a 0.18 cm thick ED, and a 0.025 cm thick ED electrolyte structure. The open and filled symbols represent the initial and post-thermal cycle data, respectively.

samples were examined microscopically prior to testing to insure they were crack-free; however, microcracks were extremely difficult to detect, especially in thinner deposits. Therefore, some of the fractures may have been present prior to testing. Figure 5 shows the N_2 crossover recorded at 923 K for three samples prior to and following one thermal cycle from 923 K to below 623 K. Both ED structures were fully impregnated prior to testing. Whereas the hot-pressed structure retained its resiliency towards gas crossover following the thermal cycle, both ED structures fractured, as evidenced by a substantial N_2 crossover as 1 psi ΔP upon reheating to 923 K. The hot-pressed structure continued to survive a second thermal cycle and exhibited only a slight crossover following the third.

The difference in fracture propensity between ED and hot-pressed structures was further examined by comparing their thermal expansion behavior under a CO_2 atmosphere (Fig. 6-8). The hot-pressed structure, 0.18 cm thick and containing 67 v/o electrolyte, contracted $\sim 1.5\%$ during the initial pass through the electrolyte liquidus (Fig. 6). This contraction is due both to LiAlO_2 particle rearrangement as the structure melts and to the collapse of residual voids entrapped during pressing. Subsequent thermal cycles showed only two regions of fairly linear thermal expansion, the change in slope occurring at ~ 773 K during heating, owing to electrolyte melting, and at ~ 733 K during cooling upon electrolyte solidification. The separation of liquidus and solidus temperatures is explained by the observation of Janz and Lorenz (24) that unless the carbonate is seeded to initiate crystallization, it

Fig. 6. Thermal expansion curve for 67 v/o electrolyte, hot-pressed structure between 373 and 973 K under a CO_2 atmosphere.

supercools to a eutectic liquidus of ~ 733 K. Linear thermal expansion coefficients, derived from these curves at temperatures above and below the liquidus (Table III), are in good agreement with previously reported data on similar systems (21).

The thermal expansion behavior of a nonimpregnated ED structure was linear between 373 and 973 K with a thermal expansion coefficient of 11.3×10^{-6} in./in. $^\circ\text{C}$ (Fig. 7 and Table III). This value is less than one-third the thermal expansion coefficient of 35.7×10^{-6} in./in. $^\circ\text{C}$ published for the free carbonate electrolyte (21). The stresses generated during thermal cycle as a result of the significant differences in thermal expansion behavior of the two materials is likely responsible for the fracture mechanism observed previously during structure cooling following impregnation. This was clearly evident when an

Fig. 7. Thermal expansion curve for a nonimpregnated LiAlO_2 layer between 373 and 973 K under a CO_2 atmosphere. Prepared using $1.8 \text{ m}^2/\text{g}$ LiAlO_2 powder.

Fig. 8. Thermal expansion curve for an ED LiAlO_2 matrix electrolyte filled within the dilatometer during the initial heating cycle between 373 and 973 K under a CO_2 atmosphere. Prepared using $1.8 \text{ m}^2/\text{g}$ LiAlO_2 powder.

ED structure was electrolyte filled within the dilatometer (Fig. 8). Upon initially passing through the liquidus (region 1 in Fig. 8), approximately 0.5h was required for the electrolyte to melt and be absorbed into the porous structure. At that time, the structure shrank approximately 0.4% (region 2) owing to LiAlO_2 rearrangement. This is in agreement with the observation of the first fracture mechanism (microcracking) discussed previously. Cooling from 973 K to the electrolyte liquidus gave an initial contraction very similar to that observed for the nonimpregnated matrix, indicating that the electrolyte did not contribute significantly to the expansion characteristics while in the molten state. A small perturbation was seen as the electrolyte solidified (region 3), accompanied by a change in thermal expansion slope, showing that the electrolyte now dominated the expansion characteristics. At approximately 663 K, an abrupt 0.5% expansion resulted from thermally induced stresses (region 4). This is consistent with the second fracture mechanism identified earlier. A second thermal cycle yielded almost identical results, with the exception that the fracture which opened during the initial cooling cycle closed as the temperature exceeded the electrolyte liquidus (region 5). Microscopic examination of the sample following testing showed branched fractures, similar to those observed previously during cooling of electrolyte-filled structures.

At first glance, hot-pressed and electrolyte-filled ED structures appear similar in that both are ceramic/alkali carbonate composites of roughly the same volume proportions. The above comparison of the structure's thermal behavior, however, clearly illustrates that significant differences exist between these two structures; these dif-

Table III. Linear thermal expansion coefficient of hot-pressed and electrophoretically deposited electrolyte structures

^a Nonreproducible curves due to structural fracture on cooling led to a range of calculated expansion coefficients.

ferences are associated with the fundamental differences in their fabrication routes. A hot-pressed structure, fabricated in an integral step, is analogous to a particle reinforced body in which at temperatures above the electrolyte liquidus, the LiAlO_2 particles are surrounded by liquid. In contrast, impregnated ED samples, fabricated in a two-step process, are typified as a porous ceramic exhibiting particle-particle contact and whose interstitial volume is electrolyte filled. As the exact microstructure of either sample is unknown, precise fracture modeling of either system is impossible. However, it is well known that the thermal properties of a composite structure are a complex function of each material's thermal expansion characteristics and bulk modulus, as well as the extent that each phase is continuous. ED and hot-pressed structures differ considerably in this last category, *i.e.*, hot-pressed structures are assumed to be continuous only in the carbonate phase, whereas ED structures are continuous in both the carbonate and LiAlO_2 phases. It is believed that this difference is responsible for the poor thermal expansion resiliency found here for carbonate-filled ED structures. Following electrolyte filling, high tensile stresses develop in the cooling matrix as the lower thermal expansion LiAlO_2 framework prevents the electrolyte from contracting. As was seen in the thermal expansion curves, these stresses are apparently sufficient to fracture not only the brittle, solidified carbonate but the weak ceramic matrix as well.

Conclusions

High quality porous LiAlO_2 layers are easily deposited electrophoretically from 2-propanol suspensions. The deposited layers are approximately 60% porous exhibiting a uniform thickness with a median pore diameter and pore size distribution which can be tailored by varying the initial powder's surface area.

Comparison of ED fabrication to hot-pressing for MCFC use shows ED to be considerably easier, faster, and more economical. In addition, thin ED LiAlO_2 layers are easily deposited allowing thinner electrolyte structure fabrication and, therefore, lower in-cell ohmic losses associated with the electrolyte. However, the application of these layers for use in MCFCs relies on their successful impregnation with Li/K carbonate electrolyte. The difficulties associated with crack-free impregnation of these structures has been demonstrated. In addition, the results of the pressure capacity and thermal expansion evaluations reported here clearly show the fragility of impregnated ED LiAlO_2 layers. This fragility leads one to seriously question the utility of this fabrication technique for MCFC usage.

Acknowledgments

Improved Nickel Anodes for Industrial Water Electrolyzers

C. K. Dyer*¹

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A method of increasing the energy efficiency of hydrogen production by alkaline water electrolysis is described. An ac activation of sintered Ni anodes leads to reductions in the oxygen evolution overpotential of ~230 mV at 100-250 mA/cm². The resulting reduction in cell voltage yields an increased energy efficiency and a significantly lowered cost of hydrogen production. Compared with other processes to raise anode efficiency, ac activation provides a fourfold improvement.

Hydrogen production by water electrolysis is already a well-established industrial process. To meet increasing demands for hydrogen (1-4), it is widely recognized that improved energy efficiencies and reduced capital costs are necessary. A major goal in developing advanced electrolyzer technology for high purity hydrogen is to reduce the cell voltage at a given current density (5). Electrical energy accounts for 78% of the cost of producing electrolytic hydrogen (based on 30 mil/kWh). Nickel and its alloys are the preferred anode materials in alkaline electrolysis owing to their high corrosion resistance at anodic potentials in alkaline electrolyte (up to 30 weight percent [w/o] KOH) and their low cost. However, the overpotential for oxygen evolution on Ni is higher than several expensive alternatives. There is evidence that a thin initial surface coating of Ni(OH)₂ on a porous Ni electrode lowers the oxygen overpotential at 200 mA/cm² by 40-60 mV in 30 w/o KOH at 80°C (6). At high loadings of Ni(OH)₂, the overpotential increases due to the plugging of pores in the porous electrode during the electrochemical impregnation.

A new method of producing a very uniform layer of active Ni(OH)₂ within a porous Ni structure without pore plugging was described recently (7). This method should be very suitable for activating oxygen electrodes for the hydrogen production industry. A highly uniform film, free of blockage of electrolyte channels within the electrode, was demonstrated in that work (7).

Experimental

Sintered Ni electrodes having an average porosity of 77.5% and mean pore size of 12.7 μm were supported on a Ni wire mesh. The projected area was 1 cm². The test electrodes were subject to "activation" pretreatments using ± 125 mA (p-p) ac current (square wave) at 0.25 Hz in a 1M KCl aqueous solution. This was one of several ac treatments which has yielded conversions of Ni to electrochemically active material [Ni(OH)₂] with relatively high coulombic efficiency (~ 60%). The details of the technique and other ac conditions which are expected to yield comparable results are reported elsewhere (7).

After different amounts of activation, consisting of 25, 50, 100, 200, or 300 ac cycles, electrodes were washed in distilled water, then charged and discharged at 250 mA/cm² in 30 w/o KOH to determine their coulombic capacity and hence the loading level of active Ni(OH)₂. Each electrode was recharged to oxygen evolution potentials in 30 w/o KOH at a given constant current in the range of 25-250 mA/cm² at 25° or 80°C, and the electrode potential was measured at its surface by means of a Luggin capillary probe with a Hg/HgO reference electrode [+0.926V (RHE)]. The position of the probe tip on the electrode surface was changed, and a new set of readings was taken in order to average out potential measurement errors due to different distances between the probe tip and the surface, nonuniformity in current flow especially near edges, etc. Counterelectrodes on either side of the porous Ni electrode were made of a sintered Teflon®

and Pt powder mixture supported on a Ni screen, of area ~50 cm², and similar to electrodes used to generate H₂ in the Ni/H₂ secondary cell. The cell was a closed Pyrex® beaker; recombination of evolved oxygen and hydrogen occurred within the cell nonexplosively above the electrolyte level, on the exposed portion of the Pt counterelectrodes. Thus, the KOH concentration was maintained over long periods (6h) of testings at 200 mA/cm². Temperature was held at 80° ± 1°C using a temperature-controlled hot plate.

Results

Reduction of the oxygen evolution potential on Ni (at 25°C).—The discharge capacities in coulombs per square centimeter (C/cm²) are proportional to the number of cycles of activation applied to the different electrodes (Fig. 1) and indicate the amount of electrochemically active Ni(OH)₂ produced ("loading level") on the surfaces of the sintered Ni particles comprising the electrode.

During oxygen evolution at a given current density, the variation of electrode potential from point to point on the exterior surface of a particular electrode is relatively small compared with the overall effect of an increase in loading level. Table I shows the average electrode potential for six probe positions at each current density at 25°C after 0, 25, 50, 100, 200, or 300 cycles of the ac square-wave current activation. The data are not corrected for the iR drop between the probe tip and the electrode surface. This is very small [Hall (8) estimates 10-20 mV] and potentials are generally constant to less than ± 10 mV (Table I). The average electrode potentials for anodic current densities of 100, 200, and 250 mA/cm² are shown in Fig. 2 as a function of the number of ac cycles applied. Reductions of ~200 mV were achieved for the oxygen evolution reaction (OER) after a 200 cycle (800s) pretreatment, while even 25 cycles (100s) gave a substantial improvement of ~125 mV.

Stability of the lowered oxygen evolution potentials (at 25°C).—Increasing cell voltage with time is a problem in

Fig. 1. Discharge capacities of ac activated electrodes in 30 w/o KOH at 250 mA/cm² after charging at 250 mA/cm² to oxygen evolution. Dependence on activation pretreatment is shown as the number of ac cycles at 0.25 Hz, ± 125 mA/cm² in 1M KCl.

present hydrogen production (1). Table II shows that there is a trend towards higher electrode potentials at all current densities after prolonged gassing, but that this is also a function of the electrode pretreatment. An unactivated Ni sintered electrode showed as much as a 40 mV increase after 1h of gassing at 100 mA/cm², although at higher loading levels there was a smaller increase with time and so the electrode potential was more stable. This phenomenon was partially reversible on open circuiting: e.g., the 25 cycle electrode showed only ~6 mV increase in potential after 20 min on open circuit, previous to which there had been an average 17 mV increase at all current levels. The recovery after open circuiting unactivated Ni was also ~10 mV (Table II).

Fig. 2. OER potentials (V vs. Hg/HgO) in 30 w/o KOH at 25°C of Ni electrodes with different amounts of activation. ●: 100 mA/cm². ◇: 200 mA/cm². ○: 250 mA/cm².

Oxygen evolution potentials at 80°C.—In order to obtain a comparison with previously published work under commercial electrolyzer conditions (6), results were obtained at 80°C in 30% KOH for the ac activated electrodes over a 6h period of gassing at 200 mA/cm².

The data after 5h at 200 mA/cm² are shown in Fig. 3 and 4. As expected, the higher temperature initially produced lower OER potentials for all electrodes at each current density (compare Fig. 3 with Fig. 2) and the potentials of activated electrodes rose by no more than ~5 mV/h at any current density over the 6h test period of continuous gas-

Fig. 3. OER potentials (V vs. Hg/HgO) in 30 w/o KOH at 80°C after 5h at 200 mA/cm² (at 80°C). Symbols as in Fig. 2. □: Data from Ref. (6) at 80°C after 6h at 200 mA/cm² (electrochemically impregnated electrodes).

Fig. 4. Tafel plots after 5h at 200 mA/cm² in 30 w/o KOH at 80°C for Ni sinter which was unactivated (●), or activated with: 25 (■), 50 (△), 100 (○), 200 (□), or 300 (▲) ac cycles.

sing (Table III) and therefore generally rose less than during the first hour at 25°C and 100 mA/cm² (Table II). The largest reduction in potential, ~230 mV, was again shown by the 300 ac cycle electrode and is about 20 mV larger than the improvement at 25°C.

These reductions in electrode potential at 80°C are significantly larger than the 40-60 mV reductions previously reported (6) for other activation procedures, which were by impregnation of Ni(OH)₂ using either the chemical (9) or electrochemical technique (10) to similar loading levels (namely, 1.6-6 mg/cm², which would have an equivalent discharge capacity of ~1.6-6 C/cm²).

Discussion

Methods of producing the nickel hydroxide catalyst on Ni surfaces have either been by prolonged anodic pretreatment in KOH (11) or, more recently, by electrochemical impregnation (6). Neither of these two methods seems to have produced the degree of improvement demonstrated by the ac activation. Hall (6) found that loadings of Ni(OH)₂ in the range 1.6-6.1 mg/cm² (projected area) gave the minimum OER potentials for 50% porous Ni electrodes impregnated electrochemically (10). Higher loading levels gave higher OER potentials, owing to "pore plugging." The loading levels of 1.6-6.1 mg/cm² correspond to discharge capacities of 1.7-6.3 C/cm² (based on 0.289 Ah/g Ni(OH)₂). The actual initial surface areas of Hall's electrodes were 140-180 cm² per cm² (projected), which were higher than the 120-140 cm² per cm² electrodes used in the present work. Note that both estimates are based on BET measurements. For direct comparison with ac activation, Hall's data, which were taken after 6h of gassing at 200 mA/cm² in 30% KOH at 80°C, are plotted on Fig. 3 at ac cycle numbers corresponding to the coulombic capacities of ac activated electrodes from Fig. 1, with the unactivated data superimposed to compensate for the iR corrections in Hall's work.

A much larger drop in OER potential results from equivalent Ni(OH)₂ loadings by ac activation. Also, no "blockage" effects appear at high loading levels up to 21.4 mg/cm², partly owing to the higher level of porosity (80%) of electrodes used in this work, but mostly to the uniform "nonblocking" nature of ac conversion of Ni to Ni(OH)₂ and the high surface area of the film produced (7). Higher sinter porosity does not account for the fourfold greater reduction in OER potentials compared with 50% porous structures (6). A uniform film thickness produced by ac

Table III. Maximum rate of electrode potential change (m V/h), after the first hour, of activated sintered electrodes during 6h of oxygen evolution at 200 mA/cm² in 30 w/o KOH at 80°C. Data at different current densities were taken every hour with the reference electrode probe in the same position

activation should allow most of the surface of the hydroxide film to participate in the OER. However, Appleby *et al.* (12) demonstrated that there was little difference in overpotentials for the OER on smooth, woven, or sintered Ni, so that the present results might be due to the smaller percentage of the total hydroxide film surface surrounding unblocked passages towards and at the outside of the activated sinter. It is these outer regions of the sinter that are particularly susceptible to blockage during electrochemical and chemical impregnation but are not blocked during the ac process (7). Experimental Tafel slopes for the 80°C data decreased with increase in the amount of ac activation from 100 to 65 mV per decade below 100 mA/cm² and from 135 to 95 mV per decade above 100 mA/cm² (Fig. 4). At 25°C, Tafel slopes were higher but also decreased with increase in ac activation, from 120 to 90 mV per decade below 100 mA/cm² and from 160 to 105 mV per decade above 100 mA/cm². Exchange current density determinations were not made. The OER mechanism is thought to involve Ni⁴⁺ in the surface of the oxyhydroxide (11, 13), to which Ni(OH)₂ has converted before the OER starts

So, in addition to the effect of a larger or more available surface area in lowering the true current density, the observed lower potentials of the OER on ac activated electrodes would promote more efficient reduction of Ni⁴⁺ to Ni³⁺ and hence oxygen evolution.

The rise of the OER potentials after 1h of gassing at 25°C (Table II) was greater for unactivated Ni sinter electrodes at all current densities than for activated electrodes. This, apparently, is related to the thickness or amount of the active Ni(OH)₂, originally deposited, since the 21.4 mg/cm² electrode (300 ac cycles) only gave a ~5 mV rise in OER potential after 1h, compared with ~17 mV for the 1.4 mg/cm² electrode (25 ac cycles). Since the rise in potential is partially reversible on open circuiting, a surface area decrease of the hydroxide films in these electrodes is unlikely. The effect could be due a rising Ni⁴⁺:Ni³⁺ ratio, which would inhibit the OER by converting active Ni³⁺ sites to inactive Ni⁴⁺ sites (11). It seems reasonable that a higher ratio of Ni⁴⁺ to Ni³⁺ would be more rapidly attained in the thinner films since, on average, the ions experience a higher field.

At 80°C, the rates of rise of OER potentials during the first hour at all current densities and for all electrodes was lower than at 25°C. For the unactivated electrode the rate was +6 to +10 mV/h during the first hour at all c.d.'s, while for the activated electrodes the rate was +2 to +6 mV/h. Table III shows the maximum increases in OER potentials after the first hour up to 6h of continuous gassing. The rates of rise were generally lower than during the first hour. These rates at 80°C for the activated electrodes are lower than for commercial electrodes during 5h of operation. An unactivated Ni-plated steel anode in 28% KOH at 70°C gave initial rates of increase in the OER potential of ~12 mV/h after 2h at 135 mA/cm², which fell to ~2 mV/h after 6h (1).

The generally lower rates of OER potential rise at 80°C even for unactivated Ni may be due to a rapid initial at-

tainment of a stable and higher surface activity (higher $\text{Ni}^{3+}:\text{Ni}^{4+}$) at the higher temperature.

Finally, a large part of the overall improvement in performance compared with electrochemically impregnated electrodes is due to the characteristic uniformity of thickness of films produced by the ac process (7), which ensures uniform film conductance. This uniformity of film thickness is due to a high effective "throwing power" caused also by the local nature of the dissolution/precipitation process. Dissolution of Ni is enhanced by adsorption of Cl^- ions from solution during the anodic half-cycle, causing Ni to dissolve rapidly then reprecipitate as hydroxide during the cathodic half-cycle (7) as the pH of the surface rises (14). This process also removes the risk of pore blockage endemic with electrochemical deposition of Ni hydroxide, where throwing power is much lower because deposition is dependent upon diffusion of Ni^{2+} ions within the highly tortuous pore structure to internal deposition sites.

Chloride ions were not detected in the ac produced films at levels above the detection limit of 0.1 atomic percent using Auger-electron spectroscopy and ion milling (7). Backscattered electron images from scanning electron microscopy showed a significant change in atomic-number contrast towards the ac produced film surfaces, indicating a very low density of Ni. The surfaces of the films are therefore probably highly porous with a high true surface area, allowing a lower $\text{Ni}^{4+}:\text{Ni}^{3+}$.

Application of ac activation to other types of Ni anode should be a straightforward extension of the technique. The high throwing power and small amount of Ni converted to catalytic oxyhydroxide would ensure the structural integrity of nickel substrates.

Further improvements in anode efficiency and life might be attainable through the presence of other components, such as cobalt ions, in the active $\text{Ni}(\text{OH})_2$ film. NiCo_2O_4 has been shown to be a good catalyst for the OER (15) and 1-10% of cobalt hydroxide codeposited with $\text{Ni}(\text{OH})_2$ has been shown to reduce film stress in battery plates (16). Other cations can be introduced into $\text{Ni}(\text{OH})_2$ films made by ac activation through additions to the electrolyte. Deposition, as the pH rises during the cathodic half-cycle, would include nickel ions dissolved during the preceding anodic half-cycle together with cations from the bulk solution.

Practical application of ac activation will probably make use of low voltage power-FET technology which, in the near future, should be able to provide the low frequency (< 1 Hz), large alternating currents needed, with high efficiency (17).

Conclusions

Ac activation is a simple and most effective method of raising energy efficiencies of Ni anodes for electrolytic hydrogen production. AC activated sintered Ni electrodes have demonstrated a 230 mV reduction in OER potential at normal operating current densities of a commercial water electrolyzer.

This reduction in cell voltage would translate into a considerably lowered cost of electrolytic hydrogen production, where 80% of the cost arises from electrical energy consumption within the cell.

ABSTRACT

Composites consisting of inert fiber substrates coated with metallic silver were shown to be potentially useful as a source of silver ions for infection control. Using an *in vitro* system, the ability of six silver-coated nylon fabrics to support an electric current was studied, and the resulting silver levels up to 23h after initiation of the current were measured. In four fabrics, $1.7 \mu\text{A}/\text{cm}^2$ for 16h produced fabric corrosion that prevented further current flow. Comparable changes in two other fabrics did not occur until $16 \mu\text{A}/\text{cm}^2$. At fixed current densities, the fabrics produced differing solution silver concentrations. For one fabric, the measured silver concentrations approached the theoretically predicted level. The results indicated that silver-nylon fabrics could produce antimicrobially significant silver levels at relatively low currents and voltages, and that the rate of ion production can be predicted on the basis of electrochemical considerations.

Silver compounds are used in clinical medicine because of their antiseptic properties (1). The prophylaxis of ocular infections and prevention and treatment of burn-wound sepsis are two examples. Beginning in the late 19th century, metallic silver in the form of sutures and foils was used to produce bacteriostatic effects via the passive disassociation of silver from the metallic phase into tissue (2). Metallic silver continued to be used clinically until the systemic antibiotics were introduced in the 1930's.

Interest in the possible use of metallic silver as a topical antimicrobial agent developed again in the 1970's, when a series of studies showed that electrically generated silver ions inhibited the growth of bacteria and fungi (3-8). The first attempt at clinical application of this concept involved the treatment of osteomyelitis (9). To increase the area of tissue actually exposed to silver ions, silver-coated nylon fabric as well as thin silver wire were used.

The concept of applying an antiseptic agent by passing a current through a metallized fabric has clinical appeal: (i) the dose can be regulated by controlling the current; (ii) the textile characteristics of the substrate can be chosen to produce an occlusive or nonocclusive dressing, as needed; (iii) since a typical wound dressing would contain only a few milligrams of silver, the cost of the dressing would be low.

To pursue this idea, the *in vitro* electrical properties of a commercially available class of silver-coated nylon fabrics were studied. Our aim was to elucidate the electrochemical response of the fabrics under conditions that simulated actual clinical use.

Methods

Six fabrics (Swift Textile Metalizing Corporation, Hartford, Connecticut) were studied. The fabric designations and some of their physical properties are listed in Table I. The fabrics consisted of woven or knitted nylon fibers, 20-50 μm diam, that had been uniformly coated with pure silver to a calculated average thickness of 0.02-0.4 μm , depending on the fabric. The coating process did not affect the handling characteristics or mechanical strength of the fabrics.

For dc studies, the fabrics were prepared as annular electrodes with tabs to permit introduction of the current (Fig. 1A). The fabrics were not treated prior to use except for a brief rinse in distilled water. In most experiments, the tabs were coated with an insulating material (Paraplast, Lancer, St. Louis, Missouri) to prevent wick action.

The Paraplast was applied to the tabs at 56°C and allowed to harden at room temperature; it did not affect the pertinent physical properties of the fabrics. In some cases, to increase the current per unit area of the fabric, part of the annular ring was removed (Fig. 1A). The fabrics were operated as anodes against silver-wire cathodes (23 cm of 0.5 mm diam silver wire) in the configuration shown in Fig. 1B. The cathode material and configuration were chosen for convenience, and they had no specific effect on events within the anodic chambers which did not vary when stainless steel, copper, or silver-nylon fabrics (surface area 0.16-60 cm^2) were used.

Silver measurements were made by atomic absorption spectroscopy using standard methods (10). Briefly, aliquots of the solution under study, after dilution if needed, were directly aspirated into an air-acetylene flame. Silver concentrations were determined by absorbance measurements (Perkin-Elmer 306, with a silver hollow-cathode lamp) with the use of standard curves generated by adding known concentrations of silver to the same medium as the test solution. The 328.0 nm resonance line of silver was used, and all measurements were made in triplicate and the results averaged.

Current was applied using a variable power supply (EICO 10645) and measured with an electrometer (Keithley, 610C) or a digital multimeter (Beckman 3020) (see Fig. 1). A second such multimeter was used for resistance

Fig. 1. The experimental system. (A) Geometry of the annular electrode. Two additional electrode geometries were used in some measurements. The semi-annular electrode produced by cutting the fabric at X-X₁ (and discarding the distal portion); the tab electrode produced by cutting the fabric at Y-Y₁. The surface areas were, respectively, 19, 9.5, 1 cm^2 . (B) For passage of current, the portion of the electrode distal to the junction was immersed in 50 ml of medium—either saline or tryptic soy broth—contained in 400 ml beakers. Electrical connection to the cathodal beaker was made via a tryptic-agar bridge.

measurements. The voltages reported were the potential differences applied between the chambers; they were monitored with a high impedance voltmeter (RCA WV 510-A). For scanning electron microscopy (SEM), 1 cm squares of fabric were cut out and adhered to aluminum scanning stubs with copper-impregnated tape. The specimens were examined and photographed in an AMR 1200 scanning electron microscope at an accelerating voltage of 25 kV.

The unmetallized fabrics did not undergo detectable changes in resistance when subjected to the conditions of immersion employed in this study. The electrical changes observed are, therefore, attributed to changes in the silver coating, and not the nylon itself.

Results

The fabrics exhibited changes in surface resistance following immersion in saline (Table II). A typical current *vs.* time curve for fabric HRS is shown in Fig. 2. At 1V after 9-10h, the current dropped precipitously. When the average current density was increased using a semi-annular or tab anode (the total current was unchanged), the current drop-off occurred at proportionately earlier times (Table III).

For immersion times greater than 24h, the resistance between any two points on the annular portion of the

HRS anode (or between any two points, one of which was in the annular portion) was essentially infinite regardless of whether it had been used to pass current or not. But for immersion times sufficiently short that the passive disassociation of silver from the fabric did not affect the total system current, the pattern of resistance measurements was related to the current density passed through the fabric and, more particularly, to the occurrence of the drop-off phenomenon. Before the drop-off, all resistance measurements, including those having a path across the junction, were on the order of 1Ω. Immediately after the drop-off, however, only resistance paths that did not cross the junction yielded low values; all paths through the junction showed essentially infinite resistance.

The sequence of measurements was repeated with IT which, unlike HRS, underwent negligible changes in resistance due to immersion in saline (Table II), and again the current drop-off was observed (Table III). Before the current drop-off occurred, all resistance measurements were on the order of 1Ω; after the drop-off, essentially infinite resistance across the junction was again measured.

The extent of the region at the junction manifesting the electrolytic effects on surface resistance depended on

electrode geometry and voltage. Generally, it was 1-3 cm², which corresponded to 10-100% of the electrode surface actually exposed to the solution.

4H and LRS exhibited behavior qualitatively similar to that of IT; they were stable (Table II) and exhibited both a current drop-off (Table III) and a corresponding high resistance in the neighborhood of the junction. R and SN were also stable, but were able to support a current for 24h for all but the highest current density (Table III).

SEM showed that the formation of surface-adhering crystals — presumed to be silver chloride — accompanied the passage of current. Figure 3, which depicts the crystal formation in the junction region of IT, is typical of the observed surface corrosion. By SEM, the density of crystal formation appeared to be greater in the junctional region compared to that in the opposite portion of the electrode (Fig. 4), but actual measurements were not performed. Al-

though the effect of the passage of current through the fabrics could be readily detected by SEM, there were no corresponding macroscopic changes in any of the fabrics.

To explore the role of the geometry of the junction itself when the average current density was held constant, we prepared electrodes having the same surface area but widely different junction geometries (Fig. 5). The narrowest junction exhibited both the most rapid onset of the current drop-off, and lowest base-line current. The 50 mm junction exhibited a diffuse current drop-off with the longest onset and highest base-line level. The 10 mm junction was intermediate with respect to both characteristics.

Knowledge of the electrical characteristics of the silver-nylon fabrics is important with regard to their contemplated clinical uses for infection control. Data regarding the fabrics' silver-ion releasing properties is also needed, because clinical efficacy requires tissue silver levels of 5-20 $\mu\text{g/ml}$ (6). We therefore measured the silver concentrations in tryptic soy broth (a standard medium that supports microbial growth).

The fabrics themselves did not undergo significant changes in resistance following immersion in the medium (Table IV). The silver measurements were made using annular anodes. At 1V, the total system current was approximately 22 μA (average current density: 1.2 $\mu\text{A/cm}^2$ of fabric). The silver levels released into solution by both passive disassociation and electrolysis (1 and 2V) up to 23h are shown in Table V.

Discussion

Previous work showed that HRS can be effective against micro-organisms (11); silver dissolved from the fabric's surface diffused through the medium and inhibited growth. This movement of silver has been confirmed indirectly by the present measurements of fabric resistances, which rise with immersion time, suggesting that silver ions are being liberated. It has also been confirmed by the direct measurement of silver in solution. After 23h, HRS liberated 2.6 $\mu\text{g/ml}$ of silver, which is essentially the same concentration deduced in the earlier study (11).

* Current drop-off observed.

All the fabrics produced silver when immersed in the medium, and the resulting silver levels varied by about a factor of 6 during the first 8h; at 23h, the range was greater than a factor of 10 (LRS compared to SN). Silver levels produced by silver wire under identical experimental conditions were below the level of detection (0.01 $\mu\text{g/ml}$). The surface area of the silver-wire anode was 3.6 cm^2 . The geometric surface of the fabrics was 19 cm^2 , but the actual surface area varied depending on the particular fabric. Based on the fabric properties listed in Table I, and assuming a fiber diameter of 20 μm (50 μm for 1T), it can be shown the actual surface area, depending on the fabric, was 0.8-22 times as great as the corresponding geometric area. Thus the fabric anodes had 4-116 times the surface area of the silver anodes. Consider SN, which is the most extreme case. It had a calculated actual surface area 22 times that of its geometric area. The area of the SN anode was, therefore, $22 \times 19/3.6 \approx 116$ times that of the silver-wire anode. Although there was a difference of two orders of magnitude in the surface areas, there was a difference of at least three orders of magnitude in the corresponding silver levels produced by passive disassociation (Table V). This indicated that the metallic silver coating on SN was significantly more labile than silver wire. Similar calculations for the other fabrics lead to the same conclusion.

The passage of current through the fabrics resulted in increased silver levels. When the silver levels at 1 and 2V were corrected for the base-line levels, the materials ranked as follows in decreasing order of relative electrolytic efficiency with regard to liberating silver: 1T, 4H, LRS, silver wire, R, SN, HRS, at 1V up to 7h; 1T, 4H, R, HRS, SN, silver wire, at 2V up to 4h. Faraday's law gives as the upper limit for silver production 4 $\mu\text{g}/\mu\text{A}\cdot\text{h}$. In Fig. 6, the range of measured silver levels produced by the fabrics and silver wire is compared to the theoretical level. 1T was the most faradaic of the materials in that it produced silver levels close to the predicted values.

It is the total silver concentration that determines whether microbial growth will be inhibited. Under the conditions we employed, the threshold of such an effect (approximately 5 $\mu\text{g/ml}$) occurred after 2h at 1V and after 1h at 2V. Under different but realistic experimental conditions, this threshold could probably be achieved even more quickly.

1T was one of the most interesting of the fabrics studied. Even though it was the lightest and least-silvered fab-

ric (Table I), it produced high silver concentrations (Table V). Its major drawback was that it was among the fabrics most prone to exhibit the current drop-off (Table III).

The current drop-off phenomenon apparently arises from the preferential liberation of silver ions at the junction zone. We know of no theoretical reason to expect that the current density would be greater near the junction, but such an occurrence would explain both the high resistance region found at the junction and the SEM observations of increased corrosion at that location.

We have shown that the fabrics will electrolytically liberate silver ions into solution, producing silver levels that would be expected to inhibit the growth of micro-organisms. Studies to be published elsewhere have established this activity against gram-positive and gram-negative bacteria and fungus (12). Clinical application of the silver-nylon fabrics will require attention to both the design of the electrode and its geometric relationship to the treatment site. The current drop-off phenomenon exhibited by the fabrics will probably not impede their development for clinical use.

Current Efficiency Losses in Indirect Electrochemical Processing

Ch. Comninellis, Ch. Griessen, and E. Plattner

Institut de génie chimique, Ecole Polytechnique Fédérale de Lausanne, CH-1015 Lausanne, Switzerland

ABSTRACT

The loss of current efficiency in the indirect two-stage electrochemical process using the Mn^{2+}/Mn^{3+} system is due to the oxidation of organics present in the recycled electrolyte. There is no evidence of electrode poisoning under the experimental conditions studied (88% H_2SO_4 ; Pt anode, 85°C).

At the present time, there is considerable industrial interest in the indirect two-stage electrochemical process ("ex-cell" process) for the synthesis of organic compounds. In this process, a carrier (M^{n+}) is electrochemically oxidized (or reduced) and then allowed to react with the organic compound in a separate vessel. When reaction is complete, a separation of product takes place and the spent liquor is returned back to the electrochemical cell, where the carrier is regenerated

This method and its advantages have been described in a number of publications (1, 2), but its application on an industrial scale is limited. One reason why this process has not become common is the loss in current efficiency observed in working process due to organic matter present in the recycled electrolyte (3, 4). In this paper, the reason for current efficiency losses in the indirect two-stage process using the Mn^{2+}/Mn^{3+} system has been studied by cyclic voltammetry and by preparative electrolysis.

Mechanisms of Current Efficiency Losses

Current efficiency losses observed in the indirect two-stage electrochemical process can occur by two main mechanisms: oxidation of the organic compound carried over with the recycled electrolyte (mechanism I), and electrode poisoning (mechanism II).

Current efficiency losses due to oxidation of the organic compound.—In this mechanism, the only reason for current efficiency loss is the oxidation of the organic compound (mainly to CO_2) at the anode and/or with the carrier $M^{(n+m)+}$ formed electrochemically. The loss of coulometric charge is defined as the charge of induction period [Q_{ind}] and can be estimated from the charge needed for complete combustion of the organic compound [Q_{comb}] from the relation

$$[Q_{ind}] = K[Q_{comb}] \quad [1]$$

The constant K in this relation is equal to 1 if the organic compound is completely oxidized to CO_2 and is smaller than one if the oxidation is not complete (formation of CO, fatty acids, and others). This type of inefficiency can

be characterized as reversible because after the partial or complete oxidation of the organic compound, the electrochemical regeneration of M^{n+} is carried out as in the absence of organics.

Current efficiency losses due to electrode poisoning.—In this mechanism, the organic compound forms a film at the anode, modifying its electrochemical properties; it may change the standard rate constant (k_s) for the couple $M^{n+}/M^{(n+m)+}$ and/or influence the overpotential for oxygen evolution. For example, if k_s for the couple $M^{n+}/M^{(n+m)+}$ is strongly decreased and the overpotential for oxygen evolution is not changed, the oxidation of water competes with the oxidation of M^{n+} producing a large amount of oxygen. In this type of inefficiency, it is difficult to establish a quantitative relationship to estimate the loss of charge due to oxygen generation. This type of inefficiency can be characterized as irreversible if the poison is electrochemically inactive and as reversible if it can be oxidized.

Both of these mechanisms have already been discussed by Kuhn (3), who has studied the electrochemical regeneration of Cr^{6+} in the oxidation of o-toluene sulfonamide to saccharin. He has shown that two main reasons contribute to current efficiency losses: namely oxidation of organics (mechanism I), and oxygen evolution due to the formation of a film at the anode (mechanism II). Lin-Cai and Pletcher (5) have studied the influence of organics (benzyl alcohol) in the electrochemical oxidation of Cr^{3+} using cyclic voltammetry. They concluded that an organic film was formed at the electrode which increases the current due to oxygen evolution (mechanism II).

In preliminary work (6), the volume of gas evolved during the anodic oxidation of Mn^{2+} in the presence of organics (bibenzanthrone) was measured and a partial analysis of CO_2 was made. We assumed that the remainder was oxygen. In this paper, the reason for current efficiency losses in the indirect two-stage process using Mn^{2+}/Mn^{3+} has been studied using cyclic voltammetry and analyzing the gas evolved during electrolysis by gas chromatography.

Experimental

Preparative electrolysis was carried out in an electrolytic cell of 150 ml capacity. The anode was made of a

Table I. Classification of organic compounds according to their action on the selectivity of Mn(II) oxidation

Class of compounds	Studied compounds	Group
Paraffins	Octane	A

^b Tartaric acid is also decomposed in hot concentrated H₂SO₄.

platinum sheet (10 cm² area), and the cathode was a platinum spiral enclosed in a 10 ml porous porcelain pot (ABS); the anolyte was a slurry of MnSO₄ · H₂O (0.66 mol dm⁻³ suspension) and Ag₂SO₄ (6 × 10⁻³ mol dm⁻³) in 88% w/w H₂SO₄; the catholyte was H₂SO₄ 88% w/w. The electrolysis was carried out at constant current density (100 mA cm⁻²) and temperature (85°C). The amount of Mn³⁺ formed in the anolyte was determined by potentiometric titration with Fe²⁺. Gas evolved during electrolysis was stripped from the electrolyte with helium, and analyzed by gas chromatography with a TC detector at regular intervals by automatic injection in a column separating O₂, N₂, CO₂, and CO.

The voltammetric experiments were performed in a conventional three-electrode cell. A platinum wire (0.55 cm² area) was used as working electrode, and a platinum sheet (10 cm² area) as counterelectrode. Hg/Hg₂SO₄ · sat K₂SO₄ [0.656V (NHE) at 25°C] was used as reference electrode. All potentials in this paper are quoted against this electrode. A Tacussel potentiostat and a PAR 175 signal generator were used for the experiments, and voltammograms were recorded either on a Honeywell X-Y recorder or a Tektronic X-Y memory oscilloscope. All voltammetric experiments have been carried out in 88% w/w H₂SO₄ at 85°C. The concentration of MnSO₄ was 2 × 10⁻² mol dm⁻³ when present and concentrations of or-

ganic compounds were varied between 1 × 10⁻³ and 5 × 10⁻² mol dm⁻³ when present.

Results and Discussion

Preparative electrolysis. — In order to study the influence of organics on the selectivity of Mn²⁺ oxidation (in presence of Ag⁺ as catalyst), the electrochemical oxidation of Mn²⁺ to Mn³⁺ was carried out in the presence of different organic compounds. It was found that the behavior of organics toward the selectivity of Mn²⁺ oxidation can be related to the stability of the organic toward oxidation. Thus, compounds which are stable toward oxidation in the potential range of Mn³⁺ do not influence the selectivity of Mn²⁺ oxidation (group A compounds in Table I), as opposed to compounds which are easily oxidized and which influence very strongly the selectivity of the reaction, decreasing the current efficiency of Mn³⁺ formation (group B compounds in Table I). In order to study the mechanism of current efficiency losses, benzoic acid was chosen as model aromatic compound (group B).

The electrochemical oxidation of Mn²⁺ to Mn³⁺ in the presence of benzoic acid has an induction period (Fig. 1a), which means that some time is required before the maximum rate of Mn³⁺ formation occurs. The loss of charge observed in the induction period [Q_{ind}] is proportional to the benzoic acid concentration (Fig. 1b) and increases the applied current density (Fig. 2). The increase of [Q_{ind}] with the applied current density is due to oxygen evolution, which is favored at high current density even in the absence of organics. The constant K in the relation [1] is smaller than 1, indicating a partial oxidation of benzoic acid.

Figure 3 shows the composition of gases obtained during the electrochemical oxidation of Mn²⁺ in the presence of benzoic acid. Three regions can be distinguished.

Region I.—In this region, the charge is mainly consumed for the oxidation of benzoic acid (to CO and CO₂) at the anode and/or with Mn³⁺ (and/or Ag²⁺) formed electrochemically.

Region II.—The oxidation of Mn²⁺ to Mn³⁺ occurs with the same instantaneous yield as in the absence of organics.

Region III.—The conversion of Mn²⁺ to Mn³⁺ is complete and oxygen evolution is the main reaction.

The fact that in region I the amount of oxygen formed is the same or less as that obtained in absence of organics and that there is a good agreement between the loss of

Fig. 1. a(left): Variation of induction periods for different concentrations of benzoic acid. Volume of electrolyte: 135 ml; T : 85 °C; current density: 300 mA cm⁻²; 88% H₂SO₄; Ag₂SO₄ 5 × 10⁻³ mol dm⁻³; MnSO₄ 0.66 mol dm⁻³; benzoic acid: 0, 1.23 × 10⁻³, 1.64 × 10⁻³, 4.92 × 10⁻³, and 6.56 × 10⁻³ mol for curves 1-5, respectively. **b(left):** Reported values of [Q_{ind}] as a function of concentration of benzoic acid.

Fig. 2. Influence of current density on $K = [Q_{ind}/Q_{comb}]$ for benzoic acid $2.43 \times 10^{-2} \text{ mol dm}^{-3}$, in a solution of MnSO_4 0.66 mol dm^{-3} in $88\% \text{ H}_2\text{SO}_4$, at 85°C .

charge and the charges for the oxidation of benzoic acid to CO and CO_2 (Table II) indicates that the losses in current efficiency are due to an oxidation mechanism (mechanism I).

Reaction of organics with Mn^{3+} .—The chemical reaction of Mn^{3+} in excess with organic compounds has been studied by measuring the concentration of Mn^{3+} and by analyzing the gas evolved during the reaction. It has been found that only organics of group B react with Mn^{3+} , producing mainly CO_2 and CO . Figure 4 shows the rate of oxidation of benzoic acid (taken as model aromatic compound) by means of disappearance of Mn^{3+} .

Electrochemical measurements.—Figure 5a shows typical cyclic voltammograms (at different sweep rates) for the $\text{Mn}^{2+}/\text{Mn}^{3+}$ couple in presence of organics of group A, while Fig. 5b shows reported values of i_p vs. the square root of sweep rate ($v^{1/2}$). The diffusion coefficient of Mn^{2+} can be calculated from the linear dependence of $i_p - v^{1/2}$ using the relation (Randles-Sevcik equation)

$$i_p = kn^{3/2}D^{1/2}cv^{1/2}$$

where $k = 2.45 \times 10^5$ for the experimental conditions.

Fig. 3. Evolved gases during electrolysis of Mn^{2+} to Mn^{3+} in presence of benzoic acid. Volume of electrolyte: 135 ml ; $T: 85^\circ\text{C}$; MnSO_4 0.44 mol dm^{-3} ; benzoic acid $1 \times 10^{-3} \text{ mol}$; current density: 100 mA cm^{-2} .

Fig. 4. Conversion of Mn^{3+} in excess with benzoic acid. Volume of solution: 135 ml ; $T: 85^\circ\text{C}$; benzoic acid $2.43 \times 10^{-2} \text{ mol dm}^{-3}$.

Fig. 5. a(left): Cyclic voltammograms of $\text{Mn}^{2+}/\text{Mn}^{3+}$ couple, in presence of acetic acid, at different sweep rates. $88\% \text{ H}_2\text{SO}_4$; $T: 85^\circ\text{C}$; MnSO_4 $2 \times 10^{-2} \text{ mol dm}^{-3}$; acetic acid $1 \times 10^{-2} \text{ mol dm}^{-3}$; scan rate: 5, 10, 20, 50, 100, 200, and 400 mV s^{-1} for curves 1-7, respectively, b(right): Reported values of peak current as a function of $v^{1/2}$.

Fig. 6. Cyclic voltammogram of $\text{Mn}^{2+}/\text{Mn}^{3+}$. 88% H_2SO_4 ; T : 85°C; MnSO_4 2×10^{-2} mol dm^{-3} . (1): In absence of benzoic acid. (2): In presence of benzoic acid $\sim 1 \times 10^{-3}$ mol dm^{-3} .

The calculated value ($1.4 \pm 0.3 \times 10^{-6}$ $\text{cm}^2 \text{s}^{-1}$) agrees well with that given from Mn^{2+} in absence of organics (7).

From the separation of anodic and cathodic peak potential (ΔE_p), the constant (k_s) for the $\text{Mn}^{2+}/\text{Mn}^{3+}$ couple (in the presence of organics of group A) can be calculated using the relation proposed by Nicholson (8)

$$\psi = \gamma^{\alpha} k_s / \sqrt{\pi a D_0}$$

where $a = nFv/RT$, and $\gamma = (D_0/D_R)^{1/2}$ is approximately 1. Voltammograms obtained in Fig. 5a show a $\Delta E_p = 140$ mV at 100 mV s^{-1} ; thus, the value for k_s obtained in the presence of organics of group A is

$$k_s = 1.0 \pm 0.3 \times 10^{-3} \text{ cm s}^{-1}$$

This value of k_s for the $\text{Mn}^{2+}/\text{Mn}^{3+}$ couple is almost the same as that obtained in absence of organics ($1.2 \pm 0.3 \times 10^{-3}$ cm s^{-1}).

Chemistry	21 ± 2	15.4	1.8	0

Organic compounds of group B are electrochemically active. Figure 6 shows cyclic voltammogram for the oxidation of Mn^{2+} in presence of benzoic acid (curve 2), in reference to the oxidation of Mn^{2+} without an organic (curve 1). The peak of reduction is affected by the presence of benzoic acid, that being the result of the chemical reaction, and the value of ΔE_p for $\text{Mn}^{2+}/\text{Mn}^{3+}$ is slightly increased. The standard rate constant for $\text{Mn}^{2+}/\text{Mn}^{3+}$ couple is approximately identical to the k_s obtained in presence of an organic of group A.

For a larger concentration of benzoic acid (in presence of Mn^{2+}) the reduction peak of Mn^{3+} is completely absent, as shown in Fig. 7a, and the anodic peak for the oxidation of Mn^{2+} is no longer visible, but Mn^{2+} is still active: the diffusion coefficient for Mn^{2+} calculated from the slope of $i_p - c_{\text{Mn}^{2+}}$ has been found to be the same as in the absence of benzoic acid. In Fig. 7b are reported values of $i_p - v^{1/2}$ for the oxidation of benzoic acid in presence of Mn^{2+} , showing that the oxidation of organic compound is effected in a diffusion-controlled process. Values of $i_p - v^{1/2}$ for the oxidation of Mn^{2+} are reported for comparison.

Conclusions

It has been shown that, under the experimental conditions studied, the current losses were due to oxidation of the organic compound at the anode or with Mn^{3+} . Evolved oxygen is never greater than that obtained in absence of organics during the electrolysis, and is never present during chemical reactions. Compounds which are stable in presence of Mn^{3+} are electrochemically inactive at the studied potentials (group A); compounds which are unstable in presence of Mn^{3+} are electrochemically active (group B). Oxidized products of group B, resulting from electrochemical or chemical reaction, are approximately

the same. The standard rate constant for the oxidation of Mn^{2+} (k_s) is slightly affected by the presence of the organics of both groups A and B, but there is no poisoning of the electrode to permit oxygen evolution.

LIST OF SYMBOLS

c	concentration of electroactive species (mol cm^{-3})
i	current density (A cm^{-2})
i_{pa} , i_{pc}	current density of anodic and cathodic peaks
k	Randles and Sevcik constant
k_s	standard rate constant (cm s^{-1})
n	number of electrons exchanged
v	potential sweep rate (V s^{-1})
w/w	weight/weight
ABS	porous porcelain diaphragm
D_o , D_R	diffusion coefficient of the oxidized and reduced species ($\text{cm}^2 \text{s}^{-1}$)
E	potential (V)
ΔE_p	separation between E_{pa} and E_{pc}
F	Faraday's constant
K	Q_{ind}/Q_{comb}
M^{n+}	charge carrier at the reduced state
$M^{(n+m)+}$	charge carrier at the oxidized state
NHE	normal hydrogen electrode

Q	electrical charge (F) (here reported to 1 mol or 1 dm^{-3})
Q_{ind}	charge passed to destruct the active organic compound
Q_{comb}	charge for complete combustion of the organic compound
R	gas constant ($8.31 \text{ J mol}^{-1} \text{ K}^{-1}$)
T	temperature ($^{\circ}\text{C}$)
TC	thermal conductivity

Greek symbols

α	charge transfer coefficient
γ	$(D_o/D_R)^{1/2}$
ψ	charge transfer parameter

Some Aspects of Large Frequency Dispersion of Mott-Schottky Plots in TiO_2 Electrodes

Gyoichi Nogami

Department of Electrical Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu 804, Japan

ABSTRACT

The origin of large frequency dispersion in Mott-Schottky plots was studied for TiO_2 electrodes, the surface structure of which was analyzed by x-ray photoelectron spectroscopy (XPS) and impedance measurements. XPS spectra revealed that the atomic composition at the surface was different from that in the bulk. Impedance measurements showed that a Bode plot had a slope of $-1/2$. The results were analyzed in terms of a thick interfacial layer, in which interface states distribute in the forbidden gap. A new model was proposed in order to explain above results: the interface states were in quasi-equilibrium with the Fermi levels of the semiconductor and electrolyte. Charging and discharging of the interface states by ions in the electrolyte causes a large frequency dispersion in Mott-Schottky plots.

The primary method to characterize a semiconductor electrode is based on capacitance-voltage measurements (1-7). A Mott-Schottky relationship gives a theoretical background. However, it has not been rigorously confirmed that the Mott-Schottky theory could be applicable to an electrolyte-semiconductor contact. Does the electrolyte play the same role as the metal electrode in a metal-semiconductor contact?

With capacitance-voltage characteristics, a large Helmholtz layer capacitance (C_H), which is in series with a depletion layer capacitance (C_D), is generally neglected in evaluating a total capacitance. The large Helmholtz layer capacity is partly owed to a rapid "dielectric" relaxation by solvent molecules such as H_2O molecules in an aqueous electrolyte.

With current-voltage characteristics, on the other hand, it is generally accepted that the surface state plays a decisive role in electrode reaction and is a key parameter in determining cell performance. The presence of the surface state enables a rapid charge transfer between the semiconductor and electrolyte, mainly because charge transfer can take place equienergetically. It is assumed that charge exchange between the surface state and the electrolyte occurs quite easily. However, one says that the surface states are in equilibrium with the Fermi level of

the semiconductor bulk in the interpretation of the C-V characteristics. Nonlinear Mott-Schottky plots have been ascribed to the surface state. The Fermi level scans the surface state in accordance with an applied bias, which gives information about the energy level of the surface state. If this is the case, a large energy difference between the Fermi level of the electrolyte and the top of the filled surface state will result under a large anodic bias; charge transfer from an ion in the electrolyte to the surface state might easily occur in an anodic bias. Surface state charging will occur, and potential drops across the Helmholtz layer will change. In other words, the surface states are pinned to the redox energy level in the electrolyte. In this case, a frequency dispersion due to surface states could not be observed if the energy level of the surface states (E_A) is deep because the charge-transfer process can be characterized by the Boltzmann factor of $\exp(E_A/kT)$. The electrolyte plays quite the same role as the metal electrode.

What is the cause of large frequency dispersion frequently observed in oxide semiconductors such as TiO_2 and Fe_2O_3 ? Dutoit *et al.* (6, 7) have developed an empirical theory to explain a dispersive Mott-Schottky plot, the physical origin of which has not been clarified. The dispersive Mott-Schottky plots are not unusual in a semicon-

ductor-electrolyte contact (6-13). Especially in a TiO₂ electrode, it is an important problem to obtain the electrode which shows less dispersive C-V characteristics (5).

The present author has explained a nonlinear Mott-Schottky plot in terms of a thick interfacial layer (14-16). There must be a relatively thick interfacial layer of ~0.1 μm, which contains the interface states, probably because the semiconducting property of the oxide semiconductors is obtained by defect doping. The model does not include the frequency dispersion of the Mott-Schottky plots.

The objective of the present study is to elucidate the origin of the frequency dispersion of Mott-Schottky plots in a semiconductor electrode.

Two types of experiments were performed: XPS and impedance measurements. XPS study revealed that there existed a relatively thick interfacial layer, the atomic composition of which is certainly different from that in the bulk. Impedance measurements showed that the Bode plots had the slope of -1/2, the cause of which could not be ascribed to the semiconductor only. The slope of -1/2 in Bode plots is characteristics for a Warburg impedance: a diffusion impedance of the electrolyte. Combining these results, a band model for the electrolyte-semiconductor interface was proposed.

Experimental

Sample preparation.—A single crystal of TiO₂ was purchased from Fujititan. C-cut wafers were mechanically polished and then etched in NaOH at 500°C for 1h. NaOH was removed with boiling distilled water and then HCl. Two samples as a pair were reduced under the same conditions: reducing conditions were varied from pair to pair, typically $2 \sim 10 \times 10^{-5}$ torr, 800° ~ 900°C, and 6 ~ 10h; one of the pair was for the impedance measurements and the other for the XPS measurements. Many pairs (more than ten pairs) were prepared.

XPS and impedance measurements.—A Shimadzu-Pont Model 650B was used in the XPS measurements.

Energy in our system was calibrated by setting Cu 2P_{3/2} at 932.0 eV and Au 4f_{7/2} at 84.0 eV. Al Kα radiation was used. The scan rate was 0.05 eV/s. Depth profiles of XPS spectra were obtained by an Ar ion etching technique. Unfortunately, the precise ion etching rate is quite difficult to determine in our system and could not be ascertained. A dual phase lock-in amplifier (PAR Model 5204) was used in the impedance measurements. The electrolyte used was 1M KOH solution. The quantities measured were the equivalent series capacitance C and resistance R, which were determined by measuring the out-of- and in-phase components of the complex impedance.

Results

X-ray photoelectron spectroscopy.—Figure 1a and 1b show the XPS spectra for the paired sample reduced under the same conditions as the sample which gave the most favorable data in interpreting the present result unambiguously: namely, the slope of the Bode plot was -1/2 (see Fig. 3 and 4). However, nearly the same XPS spectra were observed for another sample; no appreciable difference could be found between two measurements. The peaks at 465.0 and 459.5 eV are due to 2P_{1/2} and 2P_{3/2}, respectively, while the peak at 531.0 eV is due to O 1s. The binding energy difference of the O 1s and Ti 2p_{3/2} bands is 71.5 eV, the value of which agrees with that reported elsewhere (17, 18). The peak at 459.5 eV suggests the formation of TiO₂. With increasing ion etching time, a shoulder at 457 eV appears. Usually, the peak due to TiO appears at ~455 eV. Therefore, the shoulder may be a sign of coexistence of Ti³⁺. The peak heights for 2P_{1/2} (465.0 eV) and 2P_{3/2} (459.5 eV) are plotted as a function of ion etching time in Fig. 2, where the background intensity is subtracted. It is clearly seen that the peak intensity shows a gradual increase as a function of ion etching time. This fact implies that the atomic composition at the surface is certainly different from that in the bulk: Ti content at the surface is smaller than that in the bulk, probably owing to the reduction process. Some Ti atoms might be evaporated.

Fig. 1. a(left): The XPS spectra of Ti 2p region. The peaks at 465.0 and 459.5 eV are due to 2p_{1/2} and 2p_{3/2} of Ti, respectively. b(right): The XPS spectra of O 1s region.

Fig. 2. Depth profiles of $2P_{3/2}$ and $2P_{1/2}$. It is clearly seen that the atomic composition at the surface is different from that in the bulk. Based on this figure, the existence of the thick interfacial layer is assumed.

Impedance measurements.—Impedance measurements were made for every pair prepared. All the samples studied showed more or less a large frequency dispersion in Mott-Schottky plots. A typical example is shown in Fig. 3. Nonlinear Mott-Schottky plots like Fig. 3 are not unusual in a TiO_2 electrode. Nearly the same result has been also shown by Wilson *et al.* (19, 20), although they have not shown the frequency dependence. Dutoit *et al.* (7) have obtained a linear Mott-Schottky plot for a TiO_2 electrode. However, they have only shown the C^{-2} -V plots under large anodic biases, far from the flatband potential [Fig. 1 and 2 in Ref. (7)]. Nonlinear Mott-Schottky plots are, in the author's opinion, to be observed near the flatband potential (19, 20). In the course of a variety of attempts, we observed a linear Mott-Schottky plot for the sample

Fig. 3. Mott-Schottky plots for a TiO_2 electrode. Large frequency dispersion is observed.

which was merely mechanically polished and not chemically etched by NaOH. In this case, too, a large frequency dispersion was observed. These results may suggest, as was pointed out by Cooper *et al.* (5), that a linear Mott-Schottky plot without any dispersion might be obtained after removing the damaged surface layer. Even in that case, some dispersion may be observed if the electrolyte concentration is low enough (5).

A Bode plot, a log-log plot of the impedance $|Z|$ vs. frequency, showed complicated behavior. Some samples showed an ideal Bode plot at low frequencies (below ~ 1 kHz), where a slope precisely equals -1 . At higher frequencies, however, the slope deviated from -1 , where the Mott-Schottky plot showed a large frequency dispersion, such as appears in Fig. 3. Other samples gave more complicated Bode plots. Under cathodic biases with larger capacity, a slope typically approaches $-1/2$ and deviated from $-1/2$ with increasing anodic biases, as shown in Fig. 4. The sample shown in Fig. 3 and 4 was reduced in vacuum of 5×10^{-5} torr at $850^\circ C$ for 8h. However, the same preparation conditions did not necessarily give the same result. The electrode was quite sensitive to its history. Figure 4 shows that each plot can be represented as a straight line with a slope of about $-1/2$, which is characteristic for a Warburg impedance. If the rate-determining step is a diffusion, the impedance of the system is characterized by the Warburg impedance. Therefore, some sort of a diffusion process might be the cause of large frequency dispersion in Mott-Schottky plots. The equivalent series resistance R is also plotted against frequency in Fig. 4. A slope of $\log R$ vs. $\log f$ is precisely equal to $-1/2$. As our total system is regarded as a series connection of R and C , a resistance component of our system can be characterized by a diffusion resistance of the electrolyte. The value of R observed seems to be too large to be regarded as the diffusion resistance of $1M$ KOH solution used. We feel, therefore, that electroactive species may penetrate into the defective interface layer and their effective concentration may be reduced as a result of charge rearrangement when the electrolyte and semiconductor are brought into contact. The defective interface layer may also serve as a resistive layer for diffusion. Cooper *et al.* (5) have found that even the sample which shows the ideal Mott-Schottky relation begins to show a large frequency dispersion if the electrolyte concentration is reduced below $0.25M$. They ascribed this phenomenon to dielectric relaxation in a disturbed surface layer.

Discussion

One way to realize a dispersive Mott-Schottky relation with an equivalent circuit diagram is to consider a relaxa-

Fig. 4. Bode plots with an external dc bias as a parameter. The slope of Bode plots is nearly equal to $-1/2$ and approaches closer and closer to $-1/2$ with decreasing anodic bias. The equivalent series resistance R is also plotted. The slope of $\log R$ vs. $\log f$ plot is equal to $-1/2$.

tion impedance of a series connection of R_s and C_s , which is in parallel with the depletion layer capacitance. C_s is so called surface-state capacitance. The product of $C_s R_s$ performs the relaxation time. This configuration has a crucial defect because their relaxation time is characterized by the Boltzmann factor typically expressed as $\tau = \tau_0 \exp(E/kT)$. If we assume that the surface states equilibrate with the semiconductor, τ increases exponentially and then drastically with increasing anodic bias. Frequency dispersion could not be observed at large anodic biases (21). Experimental results show, however, that the large frequency dispersion is observed over the potential range examined.

Another way to explain the large frequency dispersion is to consider dielectric relaxation in a disturbed surface layer (5). Observed frequency dispersion seems to be too large, in the author's opinion, to be ascribed to the dielectric relaxation of the surface layer.

We consider here the interaction between the thick interfacial layer and the electrolyte.

An equivalent circuit analysis.—We consider here the equivalent circuit and the energy band diagram as shown in Fig. 5(a) and 5(b), respectively. The basic ideas proposed here are as follows: (i) The interface states are principally in thermal equilibrium with the Fermi level of the semiconductor bulk E_F . (ii) With increasing anodic bias, electrons which lie above E_F must transfer from the interface state to the conduction band by thermal excitation. This process proceeds quite slowly because the interface state is deep. (iii) The interface states which emitted electrons into the conduction band are rather "quickly" filled by the electrons transferred from the electrolyte. The interface states are always occupied by electrons. (iv) Consequently, the interface states in the l region of Fig. 5(b) lie below the quasi-Fermi level E_{Fn} which is extended horizontally from the redox level of the electrolyte E_{FE} across the l region. (v) Electrons injected from the interface state into the conduction band of the semiconductor pass through the external circuit and appear at the counter-

electrode, where cathodic reaction takes place. In this situation, reaction products such as H₂ and O₂ may be produced. As a result, charge neutrality condition is maintained in the electrolyte: potential drop across the Helmholtz double layer remains unchanged. (vi) Even in this case, an appreciable reaction current might not be observed because a rate-determining step is assumed to be the thermal excitation of electrons from the interface state to the conduction band, the rate of which is assumed to be quite slow. (vii) Under a low amplitude ac excitation, the interface state exchanges charges with the electrolyte. With increasing frequencies, a relaxation phenomenon takes place. The relaxation phenomenon is characterized by the relaxation time τ , which is equivalent to the product $C_s R_s$ in an equivalent circuit diagram. (viii) At low frequencies, a capacitance in the l region, C_l , is shunted by the impedance of C_s and R_s in series. Then, the total capacitance is given by that in an L region, C_l , if C_s is sufficiently large. At high frequencies, however, the charge transfer (diffusion) cannot respond to an external excitation so that C_l contributes to the total capacitance. (ix) Pure "dielectric response" is characterized here by the series connection of C_l , C_1 , and C_H (C_H is the Helmholtz layer capacitance). The charge transfer process is characterized by the series connection of C_s , R_s , C_w , and R_w , where C_w and R_w are the capacitance and resistance components of the Warburg impedance.

We make here additional assumptions that $C_w \gg C_s$, $C_H \gg C_l$, and $R_w \gg R_s$. The impedance is then expressed as

$$Z = \frac{1}{j\omega C_L} + \frac{1 + j\omega\tau_{sw}}{j\omega(C_s + C_l)(1 + j\omega\tau_{mw})} \quad [1]$$

$$\frac{1}{C} = \frac{1}{C_L} + \frac{1}{C_s + C_l} \cdot \frac{1 + \omega^2\tau_{mw}\tau_{sw}}{1 + \omega^2\tau_{mw}^2} \quad [2]$$

$$R = \frac{\tau_{sm} - \tau_{mw}}{(C_s + C_l)(1 + \omega^2\tau_{mw}^2)} \quad [3]$$

where $\tau_{sw} = C_s R_w$ and $\tau_{mw} = C_l R_w / (C_s + C_l) < \tau_{sw}$. If $\omega\tau_{sw} \gg 1 \gg \omega\tau_{mw}$, then $|Z|$ is given by

$$|Z| = \sqrt{R_w^2 + \frac{1}{\omega^2 C_L^2}} \quad [4]$$

Therefore, a Bode plot will be characterized by the diffusion resistance R_w in a frequency range where $R_w > 1/\omega C_L$, as is exemplified in Fig. 4. C_L becomes larger, and then $1/\omega C_L$ becomes smaller with increasing cathodic biases, so that above condition $R_w > 1/\omega C_L$ is well satisfied under cathodic biases, as is also exemplified in Fig. 4, where $|Z|$ approaches R , and the slope to $-1/2$ with increasing cathodic bias. If R_w is always small enough to be $R_w \ll 1/\omega C_L$, then the resultant Bode plot may have a slope of -1 , as usually observed. Even in this case, a large frequency dispersion in Mott-Schottky plots can be explained, as shown later. Moreover, in the potential range where $R_w \sim 1/\omega C_L$, a slope may range from $-1/2$ to -1 , and is typically about -0.7 , as shown in Fig. 4: R_w and $1/\omega C_L$ depend on $\omega^{-1/2}$ and ω^{-1} , respectively. One may ascertain a slope of ~ -0.7 for two decades if he plots Eq. [4] in the frequency range of $R_w \sim 1/\omega C_L$. It is noteworthy here that a slope of $-1/2$ in a Bode plot may be observed only when $R_w \gg 1/\omega C_L$, while a large frequency dispersion in a Mott-Schottky plot can be observed even when $R_w \ll 1/\omega C_L$, if C_s is sufficiently large, in an equivalent circuit diagram. C_l is shunted by the surface-state capacitance C_s at low frequencies, while C_s is not effective at high frequencies, owing to a relaxation effect.

Model calculation.—Our system is quite complicated. The purpose of the present study is not to explain the observed C^{-2} -V characteristics in detail but to elucidate the origin of large frequency dispersion in Mott-Schottky plots. Therefore, we make here simplified assumptions in order to derive analytical expressions for dispersive

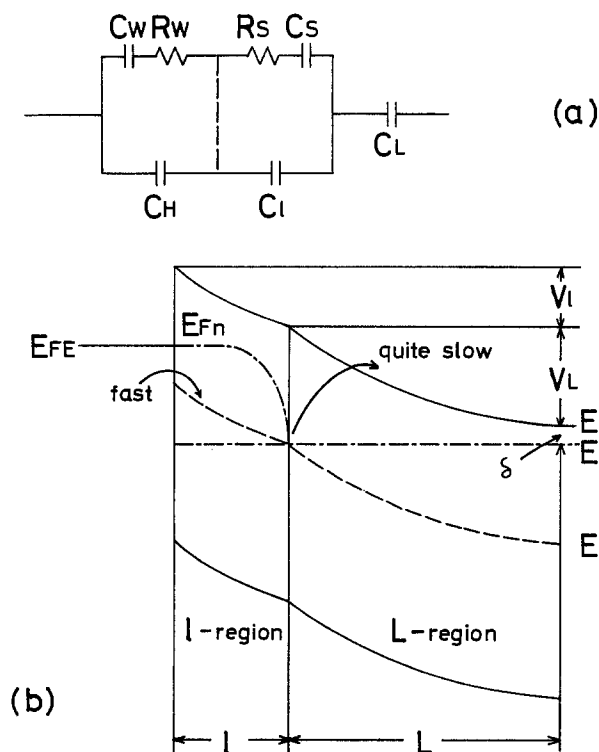

Fig. 5. (a): An equivalent circuit for an electrolyte-semiconductor contact with a thick interfacial layer. A series connect of C_L and C_1 , and C_H represents the dielectric response, while that of C_s , R_s , C_w , and R_w represents the usual relaxation of charges. (b): Assumed energy band diagram. The interface state is assumed to lie below E_{FE} and to be occupied by an electron.

Mott-Schottky plots. The interface states are assumed to distribute rather deep into the semiconductor bulk with the concentration of N_s , while the shallow impurities distribute uniformly throughout the electrode with the concentration of N . Figure 5(b) shows the energy band diagram for an electrode anodically biased by V from its flatband condition. If the expressions must be expressed in terms of a flatband potential V_{FB} , then V or V_D in the following expressions must be replaced by $(V - V_{FB} - kT/q)$. Potential drop across the L and l layers, V_L and V_l , are given, respectively, by

$$V_L = \frac{qN_c}{2\epsilon} L^2 \quad [5]$$

$$V_l = \frac{qN_c}{2\epsilon} \{(l^2 + 2lL) - \alpha l^2\} \quad [6]$$

where $N_c = N - N_s$ and $\alpha = N_s/N_c$. N_c denotes the net charge density in the depletion layer. These situations are quite the same as the preceding result (21). The potential drop across the depletion layer V is given by

$$V = V_L + V_l = \frac{qN_c}{2\epsilon} \{(L + l)^2 - \alpha l^2\} \quad [7]$$

Derivation of the admittance of the electrode is now straightforward. Hereafter, we denote the dc and ac component by subscripts D and A, respectively. Applying the same procedure as the preceding study, the ac components of l_{AO} , l_A , and L_A are given by

$$l_{AO} = \frac{1}{L_D + (1 - \alpha)l_D} \cdot \frac{\epsilon}{qN_c} V_A \quad [8]$$

$$l_A = \frac{1}{1 + j\omega\tau} l_{AO} \quad [9]$$

$$L_A = \frac{L_D + (1 - \alpha)l_D}{L_D + l_D} \cdot \frac{j\omega\tau}{1 + j\omega\tau} l_{AO} \quad [10]$$

where subscript o denotes the quasi-static value.

Then, the small signal ac admittance Y_A can be expressed by the following relation

$$I_A = Y_A V_A = \frac{dQ_{sc}}{dt} = j\omega q N_c (L_A + l_A) \quad [11]$$

Combining Eq. [11] with Eq. [8], [9], and [10] leads to

$$Y_A = \frac{j\omega}{1 + j\omega\tau} \cdot [C_o + C_\infty j\omega\tau] \quad [12]$$

where

$$C_o = \frac{\epsilon}{L_D + (1 - \alpha)l_D} \quad [13]$$

$$C_\infty = \frac{\epsilon}{L_D + l_D} \quad [14]$$

An equivalent length of the l region reduces by a factor of $(1 - \alpha)$. If the interface state density N_s is large enough to be $\alpha = 1$, then the capacitance at a low frequency limit is determined only by the thickness of the L region, L_D . The capacitance C and the conductance G are given by

$$C = \frac{C_o + C_\infty \omega^2 \tau^2}{1 + \omega^2 \tau^2} \quad [15]$$

$$G = \frac{\omega^2 \tau (C_o - C_\infty)}{1 + \omega^2 \tau^2} \quad [16]$$

where C_o and C_∞ are the capacitance at the low and high frequency limit, respectively. In order to obtain a Mott-Schottky relation, C must be expressed as a function of a dc bias V_D . The dc component of Eq. [7] is expressed as

$$(1 - \alpha)l_D^2 + 2l_D L_D - \frac{\epsilon}{qN_c} (V_D - V_o) = 0 \quad [17]$$

where

$$L_D^2 = \frac{2\epsilon}{qN_c} V_D = \frac{2\epsilon}{qN_c} (E_A - \delta) \quad [18]$$

Combining Eq. [17] and [18] with Eq. [13] and [14] leads to

$$\frac{1}{C_o^2} = \frac{2(1 - \alpha)}{qN\epsilon} \left\{ V_D + \frac{\alpha}{1 - \alpha} V_o \right\} \quad [19]$$

$$\frac{1}{C_\infty} = \frac{1}{1 - \alpha} \cdot \frac{1}{C_o} - \frac{\alpha}{1 - \alpha} \sqrt{\frac{2}{qN\epsilon}} V_o \quad [20]$$

where the relation $N = N_c(1 + \alpha)$ is used.

Equations [19] and [20] show that a slope of a Mott-Schottky plot at the low and high frequency limit gives $2(1 - \alpha)/qN\epsilon$ and $2/(1 - \alpha)qN\epsilon$, respectively. Large frequency dispersion of a Mott-Schottky plot is characterized by a factor of $1/(1 - \alpha)^2$. If $\alpha = 0.5$, then the slopes differ by a factor of 4. The model calculation in this chapter indicates that the origin of a large frequency dispersion in the Mott-Schottky plots does not necessarily depend on a Warburg impedance. The main origin of a dispersive Mott-Schottky plot is ascribed to the interface or surface state, as was conventionally accepted. However, the role played by the interface state is considered here to be somewhat different from that usually accepted: the interface state is also in equilibrium with the electrolyte. A lot of C-V measurements enabled us to observe some characteristic Bode plots: a slope of $-1/2$ could not be ascribed to the semiconductor alone.

Conclusions

A dispersive Mott-Schottky plot frequently observed in an electrolyte-semiconductor contact has been explained in terms of the interface states, which distribute rather deep into the electrode. The interface states could exchange charges with the electrolyte. The relaxation phenomenon of charge transfer between the interface state and the electrolyte can be characterized by a single relaxation time because charge transfer could take place energetically: the relaxation time is independent of a Boltzmann factor.

In other words, the relaxation time is considered to be constant and independent of an applied dc bias. This is one of the most important conclusions drawn here. The assumption that the energy level which lies above the Fermi level of the semiconductor bulk is occupied by an electron may offer a new concept in the interpretation of the Mott-Schottky plot.

In a usual metal-semiconductor contact, rather "clean," well-defined semiconductors and metals are used; the thick interfacial layer considered here may be absent. However, in an electrolyte-semiconductor contact, both the semiconductor and electrolyte are quite complicated; semiconductors used are generally "reduced" oxides such as TiO_2 and $SrTiO_3$, which are structure sensitive or processing dependent. Large frequency dispersion in Mott-Schottky plots frequently observed in these semiconductors could not be explained because the electrolyte has been regarded as playing the same role as the metal electrode. The large Helmholtz layer capacitance which is in series with the small depletion layer capacitance can be surely neglected in so far as we consider the dielectric response, *i.e.*, dielectric relaxation. However, if we are forced to consider the interface state, the energy level of which lies below the redox energy level of the electrolyte, an additional relaxation effect such as a Warburg impedance must be taken into consideration because charge exchange between the interface state and the electrolyte is possible. Charges are supplied to or taken out from the interface states by the bulk of the electrolyte, where a motion of charge carriers is controlled by diffusion.

Acknowledgments

The author wishes his sincere thanks to Professor T. Ohshige for his continuous encouragement in carrying out this work. He is also grateful to Professor W. P. Gomes and Professor W. H. Laflere for their stimulating discussions. He wishes to thank Dr. T. Nakamura and Mr. H. Ito for their help in XPS measurements as well as stimulating discussions. This work was supported in part by Meisenkai 80 Fund.

The Power Conversion Efficiency of the Thionine Photoelectrochemical Cell Containing Uncoated and Thionine Coated Photoelectrodes

T. I. Quickenden and I. R. Harrison

Department of Physical and Inorganic Chemistry, The University of Western Australia, Nedlands, Western Australia, 6009, Australia

ABSTRACT

The power conversion efficiencies, voltage efficiencies, and current efficiencies of thionine cells containing various combinations of thionine coated and uncoated gold and SnO₂ electrodes have been determined. Cyclic voltammetry was used to determine coating thicknesses and to ascertain whether the thionine/leucothionine couple or the Fe³⁺/Fe²⁺ couple was reversible on the various electrodes. The power conversion efficiency of the thionine cell containing two uncoated gold electrodes was $(4.1 \pm 0.9) \times 10^{-4}\%$, and contrary to previous predictions, when the photoelectrode was coated with thionine, the efficiency did not increase, but was reduced by a factor of 19. Larger decreases in efficiency were observed when SnO₂ photoelectrodes were coated with thionine. Previous electrochemical studies have suggested that the thionine coating suppresses the Fe³⁺/Fe²⁺ couple and is reversible towards the thionine/leucothionine couple in solution, these being the requirements for optimal power output. This study has shown that both solution couples are substantially suppressed, the reported reversibility toward the thionine couple arising from facile oxidation and reduction of thionine in the dye coating, the latter producing negligible photoelectrochemical activity.

The thionine photoelectrochemical cell has often been suggested as a possible transducer of solar energy to electricity (1-4). This cell usually comprises two identical inert electrodes which are immersed in a solution containing a ferric/ferrous couple and a light-sensitive thionine/leucothionine couple. In normal use, only one electrode is illuminated; at that electrode, leucothionine is oxidized to thionine. At the dark electrode, ferric ion is reduced to ferrous ion. The detailed mechanism of the processes which occur at the electrodes and in the bulk of the electrolyte solution has been discussed elsewhere (5).

The power conversion efficiency, ϕ_p , of a photoelectrochemical cell is the ratio of the photoelectric output power to the optical input power, and it can be expressed as

$$\phi_p = \phi_v \cdot \phi_q \cdot f \quad [1]$$

where f is the fill factor, ϕ_v is the open-circuit voltage conversion efficiency, and ϕ_q is the quantum efficiency of current production in the short-circuit condition. The voltage conversion efficiency is effectively the ratio of the mean energy per photoelectron to the energy per inci-

dent photon, and it is given by

$$\phi_v = \frac{V_{oc}F}{N_a} \left/ \frac{hc}{\lambda} \right. \quad [2]$$

where V_{oc} is the open-circuit photovoltage, F is the Faraday constant, N_a is Avogadro's number, h is Planck's constant, c is the velocity of light, and λ is the wavelength of the incident light (6).

The quantum efficiency of current production in the short-circuit condition is given by

$$\phi_q = \frac{dn_e/dt}{dn_p/dt} \quad [3]$$

where dn_p/dt is the number of incident photons per unit time and dn_e/dt is the number of electrons fed to the external circuit per unit time by the light-induced cell reaction when the cell is short circuited. The fill factor is unity in a cell with rectangular photovoltage-photocurrent characteristics (6), but in practice it is usually fractional, due to the various types of overvoltage which lead

to deviation from the rectangular cell characteristics (7). The fill factor can be expressed as

$$f = \frac{V_p I_p}{V_{oc} I_{sc}} \quad [4]$$

where I_{sc} is the short-circuit current delivered by the cell, and V_p and I_p are the cell voltage and current, respectively, at the point of maximum power on the voltage-current characteristic curve of the cell (6). If the latter curve is linear, then $f = 0.25$.

Although over 45 papers have been published on the thionine photoelectrochemical cell, only six of these papers (2, 4, 8-10, 14) present explicit determinations of the cell's power conversion efficiency. The other papers lack one or another of the quantities (*e. g.*, irradiance, current-voltage characteristics, fill-factor) necessary for the determination of power conversion efficiency. However, in four of these cases (12, 14, 15, 17) it has been possible to estimate power conversion efficiencies from the published data by assuming a fill-factor of 0.25. The values obtained are included with the six direct determinations in Table I. The fill-factor of 0.25 is probably a reasonable estimate. As indicated previously, it arises from linear V - I characteristic curves and is not greatly different from the practical values of 0.25, 0.22-0.33, and 0.33 which have been observed in various photoelectrochemical systems (6, 9, 10, 16).

The performance data aggregated into Table I provide a useful profile of the thionine cell. In particular, the data placed in perspective some of the more optimistic claims regarding the cell's efficiency. Such claims probably stem from the prediction by Rabinowitch (1) that the cell may be capable of reaching a power conversion efficiency of 1%. Table I shows that no practical determination for incident light comes anywhere near this value: most power conversion efficiencies lie within the 10^{-4} - $10^{-3}\%$ range, and the only system reaching into the $10^{-2}\%$ region is the nonaqueous solvent cell of Hall *et al.* (9, 10). Some workers have presented efficiencies with respect to absorbed light, and these are naturally higher than those for incident light because the photoelectrochemically active region near the photoelectrode is much thinner

than the path length of the absorbed light (18). However, power conversion efficiencies determined with respect to absorbed light are of little practical value because they do not represent the practical performance of the device and because they can be inflated at will by reducing the cell thickness (because the absorption path length of the electrolyte is usually greater than the thickness of the region of photoelectrochemical activity). The practical efficiency of the device with respect to the light incident upon it is, of course, unchanged by such mathematical manipulations, and the absorbed efficiency has practical significance only if cells are to be stacked optically in series, as done by Hall *et al.* (9).

Some variation in efficiency may result from variations in the spectral distribution of the "white light" used by the various workers in Table I. Ideally, the spectral distribution should be defined; otherwise, monochromatic light should be used. In either of these cases, efficiencies with respect to sunlight can be precisely calculated if desired.

The power conversion efficiencies in Table I have been accompanied by values for ϕ_v , the open-circuit voltage conversion efficiency, and ϕ_a , the quantum efficiency of production of the short-circuit current by following the procedure adopted by Potter and Thaller (2). These quantities have been defined in Eq. [2] and [3]. ϕ_v would assume a value of unity if all the energy of the absorbed photon were transferred to the relevant photoelectron, but in practice, energy is lost in the various photochemical and electrochemical steps that intervene between absorption of light and electrodic electron transfer. The value of ϕ_v is mediated by the efficiencies of the photochemical steps and by activation polarization, but not by ohmic considerations or mass transport limitations. However, the value of ϕ_a does depend on the latter two quantities, and it is normally dominated by the rate of mass transport because ohmic limitations can usually be minimized easily in any optimal cell design.

Table I shows that the ϕ_v values for the thionine cell are relatively high and are surprisingly similar from worker to worker, despite the wide variety of cell designs. Thus, if the value of the photovoltaic-assisted cell from Mountz and Tien (14) is excluded, all the ϕ_v values lie between 4%

Table I. Published power conversion efficiencies of the thionine photoelectrochemical cell with respect to incident white light

and 11%. On the other hand, the ϕ_a values are much more dependent on cell design, and they vary between 0.0015% and 3%, most of the values lying in the 10^{-2} - 10^{-10} % range. The highest value obtained for ϕ_a in a single thionine cell is that of about 1% from the work of Hall *et al.* (9, 10). The high quantum efficiency may result from the presence of acetonitrile (50% by volume) in the aqueous electrolyte because this solvent enables the thionine concentration to be raised to 10^{-3} mol dm $^{-3}$, thus facilitating the absorption of light close to the photoelectrode. Shigehara *et al.* (15) have suggested that some of the high photocurrents observed to be coming from the thionine cell may be short-lived transients which have little relevance to long-term energy output; the authors suggest that this may explain their lack of success in replicating the high currents reported by Clark and Eckert (8). It is also possible that the semiconductive characteristics of the SnO $_2$ electrodes vary considerably from worker to worker and are responsible for such variations.

It should be noted that two basic types of thionine cell are listed in Table I. The first type (2, 4, 11, 13, 16, 17) employs well separated dark and light electrodes. In the other type (8-10, 12, 14, 15, 17), both electrodes are illuminated, but each electrode is preferentially reversible to a different redox couple in the electrolyte solution. In general, the latter type of cell possesses the higher efficiencies shown in Table I and has been developed from the experiments of Clark and Eckert (8) and the theory of Albery and Archer (3).

Albery and Archer (18-20) have discussed extensively the electrochemical processes which occur in the thionine cell and have shown that a major electrochemical condition for optimal power output is a large difference between reversibilities of the light sensitive and non-light sensitive redox couples in the cell. Albery *et al.* (21-23) have further argued that the Fe $^{3+}$ /Fe $^{2+}$ couple can be rendered irreversible, without greatly affecting the reversibility of the thionine/leucothionine couple, by anodically coating the photoelectrode with a layer of thionine. They have argued that this should enhance the power conversion efficiency, but they have not determined whether this is truly the case, though they have confirmed that the reversibilities are affected in the required manner by the surface coating.

The aim of this study is to determine whether as predicted by Albery *et al.* (21-23), the power conversion efficiency of the thionine cell is enhanced by anodically coating the photoelectrode with thionine. This work follows a previous study by Quickenden and Bassett (25) which shows that the power conversion efficiency of the rhodamine B photoelectrochemical cell is enhanced by as much as 14 times following anodic deposition of dye on to the gold photoelectrode.

Experimental

Chemicals.—All reagents used in the present study were of analytical reagent grade, except for SbCl $_5$, which was of reagent grade, and thionine, which was of biological grade (Gurr). Thionine purity was checked by paper chromatography and by thin layer chromatography on a silica substrate. Only one chromatographic spot was observed under both visible and ultraviolet illumination after four effluents of differing polarities had been used to develop the chromatograms. Further purification was thus considered unnecessary, apart from filtration to remove insoluble impurities.

The cell electrolyte used for photoelectrochemical measurements was prepared by adding to water the calculated amounts of solutes required to give 0.0100 mol dm $^{-3}$ FeSO $_4$, 0.010 mol dm $^{-3}$ H $_2$ SO $_4$, and 2.1×10^{-4} mol dm $^{-3}$ thionine (80% of saturation at 298 K). As is usual Fe $^{3+}$ ion was provided by the impurity level (about 5×10^{-4} mol dm $^{-3}$) present in the FeSO $_4$ (9, 10). When necessary, the electrolyte was deoxygenated by bubbling with high purity N $_2$ which had been presaturated with water vapor. FeSO $_4$ was always stored as a deoxygenated solution to avoid significant oxidation by atmospheric oxygen. All

solutions used in this study were prepared with water which had been redistilled once after distillation from alkaline permanganate.

Cell construction.—Figure 1 shows the array of photoelectrochemical cells designed to facilitate rapid determination of the power conversion efficiency and to enable extensive reproducibility checks of the latter to be carried out. This type of cell construction also permits dye layers to be electrochemically deposited on the photoelectrode and provides a convenient arrangement for carrying out cyclic voltammetry on the photoelectrode.

The photoelectrode was either a semitransparent layer of gold or transparent SnO $_2$ glass doped with Sb. In the first case, high purity (>99.99%) gold was vacuum deposited on one face of a sheet of Perspex (8.5 cm \times 5.0 cm \times 0.15 cm). The thickness of the gold was kept in the range of 25-35 nm to avoid layers which were too thin (< ca. 5 nm) to ensure electrical continuity but not so thick as to prevent a substantial portion (ca. 40%) of the incident light reaching the gold/electrolyte interface (24). The Perspex-backed layer of gold acted as a semitransparent photoelectrode which was common to all 20 cells in the array (Fig. 1) and acted as their base. Five uncoated strips of Perspex (5.0 cm \times 1.5 cm \times 0.2 cm), each bored with 4 holes of diameter 0.63 cm, were then attached to the gold-coated Perspex base with an acrylic resin glue (Acrifix 92, Röhm). Extensive cyclic voltammetric studies using the Fe $^{3+}$ /Fe $^{2+}$ couple showed that cells manufactured with this glue exhibited identical behavior to those constructed without the glue.

When conducting SnO $_2$ glass was used as the photoelectrode material, the same mode of construction was adopted, except that a previously used (6, 25, 26) vinyl-acrylic mixed resin glue (Selley's Plastic Glue) replaced

Fig. 1. Schematic diagram (not to scale) of the array of photoelectrochemical cells and associated optical and electrical equipment.

the acrylic resin glue, and the gold-coated Perspex was replaced by a sheet of SnO₂ glass (5.0 cm × 8.0 cm × 0.50 cm). The latter was prepared by spraying (5) the surface of borosilicate glass, heated to a temperature of 933 K, with a solution made by mixing 10 cm³ of SnCl₄ with 0.60 cm³ of SbCl₃ and 20 cm³ of ethyl acetate. A moist atmosphere was necessary for the production of satisfactory SnO₂ glass which had a conductivity of about 70 Ω cm⁻¹.

Electrical connection was made to the SnO₂ glass or gold photoelectrode by attaching a wire to the surface with an electrically conducting glue (Silver Dag, Acheson) mechanically strengthened by a superficial layer of epoxy resin glue (Araldite). Each cell in the array of 20 cells contained 80 mm³ of electrolyte solution, which was introduced with a micrometer controlled syringe. Each cell and its solution was thermostated at 298 ± 0.5 K during measurements by placing the cell array on the surface of a large transparent tank through which thermostating water was passed. When required, a cell in the array could be maintained in an oxygen-free atmosphere by covering it with a small plastic "tent" equipped with a thin tube to pass N₂ over the surface of the electrolyte solution. The array of cells and the associated equipment were contained in a light-proof enclosure.

Photoelectrochemical measurements.—The dark electrode used in photoelectrochemical measurements comprised a 0.70 mm diameter wire of 99.99% purity gold or a thin SnO₂-coated rod of similar dimensions. The dark electrode dipped vertically into the electrolyte solution with its lower end accurately located 1.00 ± 0.01 mm from the photoelectrode by means of a precision height gauge (Mitutoyo 506-201). It was shown that the small amount of light transmitted by the solution to the dark electrode produced a negligible photovoltage.

During photoelectrochemical work, an individual cell was illuminated from below (Fig. 1) by light from a voltage-stabilized tungsten lamp (Bausch and Lomb, 33-86-39-01) which had been monochromated by passage through a Bausch and Lomb High Intensity Monochromator equipped with a UV-visible grating (33-86-02). The incident light was focused by a lens system to provide uniform illumination of the base of the cell. The absolute irradiance of the light incident on the base of the cell and of the light incident on the gold/electrolyte interface was measured with a calibrated photometer (United Detector Technology, 181). The lamp intensity was adjusted in each case to ensure a constant irradiance of 6.4 × 10⁻⁴ W m⁻² at the gold/electrolyte interface.

The voltages and currents developed by the cells across various resistive loads (Jay-Jay 0.1% precision resistance box) were measured with a calibrated electrometer (Keithley 610C) connected to a chart recorder. Photovoltages and photocurrents were separated from dark voltages and dark currents by the graphical procedure described previously (26). The maximum output power from the photoelectrochemical cell was obtained from the rectangle of greatest area (6) under the voltage-current characteristic curve.

Cyclic voltammetry and chronopotentiometry.—Cyclic voltammograms were produced on an X-Y recorder (Houston 2000) using a ramp generator (H. B. Thompson DRG 16) and a potentiostat (H. B. Thompson "Ministat"). The cell arrangement was the one used for the photoelectrochemical measurements, except that the cell was not illuminated and the straight wire dark electrode was replaced by a small Ag/AgCl reference electrode (Microelectrodes MI 401) around which was wrapped the counterelectrode in the form of a coil containing 20 cm of 0.25 mm diameter gold wire (purity > 99.99%). The surface area of the counterelectrode (1.57 cm²) was about five times greater than that of the working electrode deposited on the base of the cell. The reference electrode housing contained a liquid junction separator comprised of a single fiber asbestos frit, which prevented thionine dye from entering the Ag/AgCl compartment. When necessary, the counterelectrode was cleaned separately in boil-

ing concentrated nitric acid. The reference electrode/counterelectrode assembly was accurately located in the electrolyte by the height gauge described in the previous section. IR compensation was not necessary during cyclic voltammetry measurements because of the slow sweep rates, small electrode separation, and relatively high H⁺ concentration.

Chronopotentiometry was carried out with the same cells and electrodes used for cyclic voltammetry, but with the potentiostat operated in the galvanostatic mode. The potential was recorded as a function of time on a chart recorder. All chronopotentiometry and cyclic voltammetry was carried out with the cell inside the darkened enclosure, at a temperature of 298 ± 0.5 K.

UV-visible spectrophotometry.—Transmittances of solutions and of gold layers were determined with a Hewlett Packard HP 8450 spectrophotometer at a temperature of 298 ± 0.3 K.

Results and Discussion

Dye layer deposition.—Previous workers (21-23, 25) have deposited dye layers on metal electrodes by maintaining the electrode at some empirically selected potential while it was immersed in a solution of the dye. This method is inconvenient if a number of different dyes are to be deposited because each must be separately investigated in order to determine the optimum deposition potential. The present method of depositing dye layers by repetitive cycling has been developed¹ in order to overcome this difficulty and has been tested on several different dyes. It possesses another advantage too, in that the thickness of the coating can be monitored from the progressive expansion of the cyclic voltammograms obtained during the deposition process.

Figures 2 and 3 show the cyclic voltammograms (CV's) obtained during the deposition of thionine on Au and

¹Since submitting this work for publication, we have received a copy of a recent paper (in *Electrochim. Acta*, 28, 1515 (1983)) which also describes the electrochemical deposition of thionine layers by repetitive cycling and speculates that the layers are held together by covalent bonds formed in a polymerization mechanism.

Fig. 2. Cyclic voltammogram of applied potential, E , vs. current, I , showing the process of thionine deposition on Au during successive potential cycles. Oxidative (anodic) currents are shown as positive. Every second trace has been recorded. Sweep rate = 100 mV s⁻¹, area of working electrode = 0.31 cm², temperature = 298 ± 0.5 K [thionine] = 6 × 10⁻⁵ mol dm⁻³, and [H₂SO₄] = 0.050 mol dm⁻³ in water. The leucothionine oxidation peak occurs at 540 mV, and the thionine reduction peak occurs at 490 mV (vs. NHE).

SnO₂ electrodes, together with the CV's obtained from the same electrodes after the thionine solutions used for depositions are removed and replaced by background electrolyte after washing 5 times in 0.050 mol dm⁻³ H₂SO₄. The depositions are carried out in the same cells (Fig. 1) used for the power conversion measurements, but the electrolyte comprises 80 mm³ of aqueous 6 × 10⁻⁵ mol dm⁻³ thionine containing 0.050 mol dm⁻³ H₂SO₄. The voltage limits of 0.05-1.40V (NHE) shown in Fig. 2 and 3 are chosen so as to stay between the reductive region of hydrogen production and the region (> 1.6V) where oxidative destruction of the thin gold electrodes becomes important.

The heights of the characteristic thionine oxidation and reduction peaks in Fig. 2 and 3 increase with the number of cycles to asymptotic limits after about 70 cycles, in the case of a gold electrode, and after about 500 cycles, in the case of SnO₂. The areas within the CV's similarly reach plateau values. Because the areas ($\int Idt$) are also independent of cycling speed, it can be concluded that complete oxidation and reduction of the electroactive species occurs during each cycle, thus validating the use of areas under peaks for determining layer thicknesses.

Determinations of dye layer thickness.—Dye layers deposited on the gold electrodes are not discernible to the eye, apart from the appearance of a slight scoring on the electrode surface. The measured optical absorption of the layers is also negligible, thus indicating that the layer thickness is less than 1-2 nm if the molar decadic absorption coefficient of solid thionine is 2.6 × 10³ m² mol⁻¹.² This thickness corresponds to less than 3-6 monolayers if the molecules lie flat on the surface and have a thickness of 0.325 nm (27).

The layers deposited on the SnO₂ electrode are visible to the eye and give a broad absorption around 475-640 nm (cf. 598 nm for an aqueous thionine solution). The weak absorption indicates a layer thickness somewhat greater than 6 monolayers.

The CV's in Fig. 2-4 permit a more accurate determination of thickness to be carried out, via Eq. [5]

$$c_s = \int Idt / (2nFA) \quad [5]$$

where c_s is the surface concentration in mol m⁻², n is the number of electrons transferred in the redox process [= 2 in the present case (21)], F is the Faraday constant, and A is the electrode area in m². $\int Idt$ is the total charge, in coulombs, contained under the relevant oxidation and reduction peaks after the background charge (determined with the background electrolyte only) has been subtracted.

Table II shows the layer thicknesses obtained from Eq. [5] and from the charge deposited in chronopotentiometric reduction of the layer. It is seen that the thicknesses determined by these two methods agree well and are consistent with the thickness limits established by absorption spectrophotometry. Table II also shows that the thicknesses of the layers deposited by the static potential method and the cycling potential method are similar. The layer thicknesses determined by CV and chronopotentiometry require that the thionine molecules lie flat on the electrode surface and that the cross-sectional area of a molecule is 1.08 nm² and that its thickness is 0.325 nm (27).

Analysis of voltammogram peaks.—During the cyclic deposition process on Au (Fig. 2), the thionine reduction and leucothionine oxidation peaks which are originally at 430 and 490 mV, respectively, shift in turn to 490 and 540 mV, and a small shoulder appears at about 430 mV. How-

²The value of 2.6 × 10³ m² mol⁻¹ for the molar decadic absorption coefficient of solid thionine is obtained (21) by halving the value measured for an aqueous solution. This approach assumes that if the thionine in the deposited layers is polymerized (see footnote 1), its absorption coefficient is not substantially altered from that given by the above procedure. Corresponding electrochemical assumptions apply to the thicknesses determined by cyclic voltammetry and chronopotentiometry. It is noted that the optical and electrochemical methods yield similar values for the layer thickness.

Fig. 3. Cyclic voltammogram showing thionine deposition on SnO₂. Same conditions as in Fig. 2, except that the trace was recorded at 56s intervals for 20 min and at 5 min intervals thereafter. The electrolyte solution was replenished twice during this deposition. Leucothionine oxidation: 535 mV. Thionine reduction: 435 mV.

ever, during the deposition on SnO₂, the thionine reduction peak at 435 mV does not shift. But the oxidation peak moves from 535 to 550 mV, and the shoulder on the reduction peak appears only temporarily during the middle stages of the deposition.

It is clear from a comparison of the CV's obtained when the thionine-coated electrodes are immersed in background and thionine containing electrolytes (Fig. 4 and 5) that the thionine and leucothionine peaks observed with the coated electrodes originate almost entirely from the dye coating, rather than from any thionine in solution. Furthermore, the peak current separation observed for the thionine-coated Au and SnO₂ electrodes in Fig. 4 and 5 increases linearly with sweep rate, as is expected for surface bound species (28). This result means that it is difficult to ascertain the reversibility of dissolved thionine/leucothionine at a thionine-coated electrode because of the swamping of the solution couple by the couple in the deposited layer. Previous reports (5, 21) of the reversibility of the solution couple on thionine-coated electrodes thus need to be viewed with some caution. This observation also has implications in photoelectrochemical studies, as photovoltage generation in the thionine system arises mainly from the photochemical reactions of dissolved thionine, rather than from adsorbed thionine, because of the small amount of light absorbed in the dye layer. This matter is discussed further in the section on power conversion efficiencies.

Albery *et al.* (21) have reported that the Fe³⁺/Fe²⁺ couple is suppressed on thionine-coated Pt and SnO₂. Figure 7 confirms this result for the thionine-coated SnO₂ elec-

Fig. 4. Cyclic voltammograms of the thionine-coated gold electrode from Fig. 2 in aqueous $0.050 \text{ mol dm}^{-3} \text{ H}_2\text{SO}_4$ (no thionine). (a), (b), (c), and (d) are traces at sweep rates of 25, 50, 100, and 200 mV s^{-1} , respectively. (e) is a trace recorded in $6 \times 10^{-5} \text{ mol dm}^{-3}$ thionine and $0.050 \text{ mol dm}^{-3}$ aqueous H_2SO_4 at 100 mV s^{-1} . Other conditions are as in Fig. 2.

trode, but Fig. 6 shows that the situation is more complicated on the thionine-coated gold electrode. In the latter case (Fig. 6), though the $\text{Fe}^{3+}/\text{Fe}^{2+}$ peaks are absent from their usual positions, the height of the thionine reduction peak is substantially increased by the presence of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple and the leucothionine oxidation peak is substantially decreased. This surprising result may arise from a shift (rather than suppression) of the Fe^{3+} reduction peak into the region of thionine reduction, thus augmenting the thionine peak.

Measured power conversion efficiencies.—Table III shows the power conversion efficiencies obtained for the thionine cells used in the present investigation and lists the measured voltage conversion efficiencies and quantum efficiencies of current production. Each value in Table III is the mean of a number of replicate determinations on different cells, and the error ranges represent 50% confidence intervals in these means.

Fig. 5. Cyclic voltammograms of the thionine-coated SnO_2 electrode from Fig. 3 carried out in aqueous $0.050 \text{ mol dm}^{-3} \text{ H}_2\text{SO}_4$ (no thionine). (a), (b), and (c) are traces run at sweep rates of 25, 50, and 100 mV s^{-1} . (d) is a trace of the same electrode when 6×10^{-5} thionine is also present and the sweep rate is 100 mV s^{-1} . Other conditions are as in Fig. 2.

Deoxygenation of the cell electrolyte results in a three-fold increase in the power conversion efficiency, due mostly to an increase in the voltage efficiency and probably arising from decreased oxidation of leucothionine or semithionine in the electrolyte solution. All the subse-

quent measurements in Table III are performed under a N_2 atmosphere. The light intensity transmitted to the dark electrode by the solution is about 8% of that incident on the gold-electrolyte interface of the photoelectrode, but is shown to have negligible effect on the cell photocurrent and photovoltage by an experiment in which the dark electrode is located in a shadowed configuration. This result is not surprising because only about 5% of the dark electrode (the end of the wire) receives even this small illumination.

Fig. 7. Cyclic voltammograms of Fe^{3+} on SnO_2 electrodes in aqueous $0.050 \text{ mol dm}^{-3} \text{ H}_2\text{SO}_4$ at a sweep rate of 100 mV s^{-1} . The efficiencies in Table III are determined with monochromatic ($598 \pm 5 \text{ nm}$) light whose irradiance is measured at the gold-electrolyte interface after passage through the semitransparent gold photoelectrode. The use of the interface irradiance in the calculation of the power conversion efficiency represents a departure from the previous policy (6, 25) followed by this laboratory in calculating efficiencies relative to irradiances incident on the outside of semitransparent gold electrodes. The new procedure is more comparable with the procedures used in the literature determinations reported in Table I for the thionine cell.

The data in Table III serves the prime purpose of this study—testing the prediction of Albery *et al.* (21-23) that on electrochemical grounds, the deposition of a thionine

^b Direction of cell EMF reversed.

layer on the photoelectrode of the thionine cell should significantly increase the power conversion efficiency of the thionine cell. It is clear from Table III that whether the photoelectrode is coated with thionine by the fixed potential or cycling potential methods, the prediction is not supported because the efficiencies fall substantially, rather than increase, when the dye layers are deposited. In the case of the Au photoelectrode, the efficiency drops by about 19 times, and in the case of the SnO₂ photoelectrode, the somewhat thicker thionine layer drops the efficiency by about 200 times.³

It is important to note that the thionine coating reverses the direction of the electron flow, which is originally from the photo- to the dark electrode in the external circuit of the cell containing gold electrodes. This observation suggests that the coated gold electrode is preferentially selective (18-20) toward the Fe³⁺/Fe²⁺ couple, rather than the dye couple, and that the small electron flow obtained is due to the residual amount of light striking the uncoated dark electrode. This order of reversibility is opposite to the condition predicted by the electrochemical measurements of Albery and Archer (18-20) and considered by them desirable for optimal power output.

The reason that Albery and Archer's (18-20) electrochemical predictions are not borne out in terms of photoelectrochemical performance is that whereas CV or similar measurements show facile thionine reactivity in thionine-coated electrodes, these redox processes arise almost entirely from the thionine in the coating and not from thionine in solution, as shown in the previous section. However, the main photoelectrochemical activity does not occur within the thionine coating, but occurs mainly in the bulk of the solution, as shown by the negligible power conversion efficiency in Table III for thionine-coated gold electrodes immersed in background electrolyte containing no thionine.

Other points of interest also arise from the data in Table III. The power conversion efficiency of the thionine cell equipped with an uncoated SnO₂ photoelectrode and a gold dark electrode is about one thirtieth of that for a cell containing uncoated gold electrodes. Most of this difference arises from the low voltage efficiency of the SnO₂/Au cell, which suggests that the voltage difference between the two redox couples may be less on an SnO₂ electrode than on a gold electrode. When the electrode arrangement is reversed so that SnO₂ becomes the dark electrode and gold becomes the photoelectrode (the gold wire dark electrode is replaced by a SnO₂-coated glass rod of similar dimensions), the power conversion efficiency is increased by about four times. This result presumably indicates that the SnO₂ electrode is more selective toward the Fe³⁺/Fe²⁺ couple than the gold electrode and is thus more suitable for use as a dark electrode.

Table III also indicates that the power conversion efficiencies of thionine cells containing thionine-coated SnO₂ photoelectrodes are very low indeed, being about 0.6% of the value for an uncoated SnO₂/Au cell and an Au/Au cell with a coated photoelectrode. The dye coating on the SnO₂ is much thicker than on the gold electrode, and Fig. 5 and 7 show that this thick layer effectively suppresses the Fe³⁺/Fe²⁺ and thionine/leucothionine couples in solution, thereby decreasing the power conversion efficiency, though the thionine/leucothionine couple in the dye layer is electrochemically active.

ABSTRACT

Water-vapor absorption and conductivity in spin-cast poly(ethylene oxide)-lithium tetrafluoroborate films were investigated near 21°C by *in situ* near-infrared spectroscopy and ac conductance measurements. The film conductivity was $\leq 2 \times 10^{-5} \Omega^{-1} \text{cm}^{-1}$ until the water content exceeded that corresponding to $\text{LiBF}_4 \cdot 3\text{H}_2\text{O}$. It increased with additional water, reaching $3 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$ at the composition equivalent to $\text{LiBF}_4 \cdot 20\text{H}_2\text{O}$. Most of the water above the trihydrate level was unstably absorbed, however, and began to escape from the film within a few minutes. This syneresis was attributed to spontaneous restructuring or crystallization of the polymer. The conductivity data were interpreted on the basis of a two-phase model, in which one portion of the salt remained in a nonconductive solid region, while the other portion dissolved in a more fluid conductive polymer-water region.

Complexes of salts with aliphatic poly-ethers are a relatively new class of solid electrolytes (1, 2). Some of these materials can attain conductivities of the order of $10^{-5} \Omega^{-1} \text{cm}^{-1}$ at room temperature, and the conduction is known to increase greatly on absorption of water. Because of their potential importance for lithium battery electrolytes, most research on such complexes has been done with carefully dried preparations. For other types of batteries and electrochemical devices, however, some water is acceptable, or even required, and the higher conductivity is advantageous. The influence of water on these solids is, in any case, a point of scientific interest which has received only cursory treatment in previous studies.

This paper describes results of conductance measurements near 21°C on thin solid films of poly(ethylene oxide) (PEO) complexed with lithium tetrafluoroborate, and containing various amounts of water. The water content of the films was monitored *in situ* by near-infrared absorption spectroscopy, while the ac conductance at 1000 Hz was determined on an impedance bridge. This thin film technique permitted much faster acquisition of data than conventional bulk methods for investigation of polymers. Both the water content and the conductance showed a peculiar but repeatable time dependence, which probably was caused by spontaneous restructuring of the polymer.

Experimental

The PEO preparation, with an average molecular weight of 4,000,000, was from Polysciences, Incorporated. The LiBF_4 was from Ozark-Mahoning. Electrolyte films of the order of 1 μm thick were prepared on single-crystal sapphire plates by spin casting from a viscous aqueous solution containing 4.5 polymer repeating units per molecule of LiBF_4 . These plates had, near one edge, a pair of narrow-line electrodes formed from conductive silver paste, with an interelectrode spacing of 0.4 mm. Margins around the film were defined by masking tape, which was removed after the casting process.

The films were dried under vacuum at room temperature for 24h and transferred, without air exposure, to a helium-atmosphere glove box, where they were mounted in the double cell shown in Fig. 1. For the measurements of conductance and water absorption, the cell was placed in a Beckman DK-2A spectrophotometer, with the electrical leads connected to a Fluke Model 710B impedance bridge. Nitrogen containing known partial pressures of water was passed into the optical reference compartment of the cell and out through the sample compartment. The water pressure was controlled at known levels by passing

the nitrogen through water in a cooled, thermostated gas washing bottle. The moist nitrogen then traveled through a long copper tube to reach room temperature, near 21°C, before entering the cell.

Resistances and near-infrared (IR) spectra of the films were determined at various times up to 2h and, in some instances, the transmittance at the characteristic wavelength of the OH stretching band near 2.9 μm was recorded continuously as a function of time. The amount of water present per unit film area during an experiment was found by comparing the IR absorbance of the film with that of a known thickness of liquid water retained between two glass slides. Following a systematic run, the cell could be placed, open, in the vacuum chamber to redry the film in preparation for the next set of measurements.

Two methods were used to determine the original thickness of the PEO- LiBF_4 film after completion of the conductance measurements. The polymer electrolyte was too soft for measurement with a profilometer. For a rough thickness estimate ($\pm 40\%$), the used film was redried, then dissolved in water, and the resulting weight loss noted. For a more accurate evaluation, the lithium content of the dissolved film was determined by atomic absorption. The density of the anhydrous PEO- LiBF_4 preparation was found to be 1.23 g/cm^3 by weighing a known volume of the bulk solid packed into a glass tube.

Results and Discussion

The system PEO-LiBF₄-H₂O.—The PEO- LiBF_4 system at the 4.5:1 mole ratio was selected for investigation primarily because the anhydrous complex of this composition was known to have the comparatively high conductivity

Fig. 1. Experimental cell

*Electrochemical Society Active Member.

Fig. 2. Infrared spectra of PEO-LiBF₄-H₂O film recorded 30 min after changes of ambient water vapor pressure.

of $10^{-5} \Omega^{-1} \text{cm}^{-1}$ at 20°C (1). This suggests a tendency toward amorphous behavior which could be conducive to the incorporation of water in the organic phase.

The PEO-LiBF₄-H₂O films were colorless and highly transparent. As expected, water was readily absorbed from the vapor phase with an immediate increase in conductivity. Figure 2 shows a typical set of near-infrared spectra recorded after 30 min exposures to each of the indicated partial pressures of water. The maximum absorption due to OH stretching occurred at 2.90 μm in pure liquid water. This band acquired a doublet character in the PEO-LiBF₄-H₂O films, with increased absorption near 2.85 μm , which was more evident at the lower water levels. The shift to the shorter wavelength apparently was due to binding of water with the lithium ion, since it did not occur with PEO in the absence of the salt.

Conductances ($1/R$) of two PEO-LiBF₄ films are plotted as functions of the water absorbance in Fig. 3 and 4. The symbol R represents the measured resistance of the film specimen. The anhydrous film thickness was roughly 1.8 μm for film 1 and, more accurately, 0.88 μm for film 2. The circles and other symbols represent different runs which covered a wide range of water pressures and standing times, as well as different predrying conditions. It is noteworthy that the data for each film can be adequately represented by a single line, even though many non-equilibrium points are included. The significance of the slopes of these lines is discussed later. The absorbance in-

tercept for film 2 in Fig. 4 corresponds to the composition LiBF₄ · 2.9H₂O. The approximate composition LiBF₄ · 2.5H₂O was found in a similar way for film 1 in Fig. 3. Two hydrates of LiBF₄ have been characterized in the literature (3, 4). LiBF₄ · H₂O is stable above 23°C in the presence of an aqueous solution of the salt, while LiBF₄ · 3H₂O crystallizes below 23°C. In the present study, near 21°C, the measured film conductances dropped abruptly to $< 10^{-7} \Omega^{-1}$ as the water content fell below the trihydrate composition. It is thus apparent that the initial portion of the absorbed water was utilized primarily in hydration of the salt. The "free" water above the trihydrate level was responsible for the higher magnitude of conductivity discussed in this paper.

The absorption of water by the PEO-LiBF₄ films displayed an unusual time dependence. Figure 5 illustrates this behavior in the IR absorbance recorded under a constant water vapor pressure of 18.7 torr. After 24h of predrying under vacuum, the film added water rapidly at first. The absorbance then reached a maximum in 7-10 min, after which it gradually decayed toward the level corresponding to LiBF₄ · 3H₂O. This behavior was repeatable with thorough drying between runs. Less extensive drying produced a related, but distinctly different, result shown by the lower curve in Fig. 5. With a vacuum drying time of 0.5h the initial absorbance again was essentially zero. The water uptake also was quite rapid at first, but the loss set in after only 1 min, and the IR absorbance approached the asymptotic value much earlier than it did with 24h of drying.

The change of conductance with time closely paralleled that of the water content, as one can infer from Fig. 3 and 4. This is shown explicitly by Fig. 6 for the same runs that are represented in Fig. 5.

Fig. 5. Time dependence of water absorbance in PEO-LiBF₄-H₂O film recorded continuously under water pressure of 18.7 torr after different predrying times. All curves start at zero absorbance.

Fig. 6. Time dependence of conductance of PEO-LiBF₄-H₂O film under conditions of Fig. 5. All curves start at zero conductance on this scale.

The system PEO-H₂O.—It was of great interest to know whether the spontaneous water loss was a property of the salt or the polymer. A spin-cast film of PEO without the salt was prepared for this purpose and dried under vacuum 24h. Its infrared absorption under 18.7 torr of water vapor was then examined.

Infrared spectra recorded at various exposure times under constant water pressures are shown in Fig. 7. This group of spectra differs in several ways from the PEO-LiBF₄-H₂O spectra of Fig. 2. The salt-free film was visually cloudy, and infrared light scattering is evident in the lower transmission range of the spectra. Although the absorption maximum shifted slightly with water content, any doublet character of the OH band is not obvious. Finally, the salt-free spectra showed isosbestic points at 2.76 and 3.21 μm . Such points are characteristic of a fixed stoichiometry between initial and final species in a chemical process. They were not observed with the non-scattering films containing LiBF₄. Figure 8 indicates a time-dependent gain and subsequent loss of water by the PEO which is very similar to that for PEO-LiBF₄ in Fig. 5. The final water absorbance was relatively closer to zero, however, in the salt-free film.

Although the scattering effect prevented an absolute determination of water in the PEO, it is clear that the major time dependence was associated with the polymer. A comparable syneresis, or loss of solvent component, was reported by Weiss and Lenz for water in phosphonate esters derived from PEO oligomers (5). Those authors deter-

mined the absorbed water gravimetrically on bulk samples in experiments lasting several days. With the thin film technique used here, the time dependence could be detected in a few minutes and well characterized in about an hour. An apparently related heat-induced syneresis in cross-linked PEO-H₂O gels was attributed by Graham *et al.* to increased ordering of the polymer, with some water still attached (6).

Further correlations.—Conductivity relationships in the PEO-LiBF₄-H₂O system can be examined in greater detail by means of Fig. 9, in which the total thickness of the swollen film is considered, and Fig. 10, which treats the free water, with its incremental thickness, as a separate region supporting of all the observed conduction.

For calculating the bulk conductivity σ plotted in Fig. 9, the total film thickness was taken, as a first approximation, to be the sum of the dry PEO-LiBF₄ thickness, based on bulk density, and the liquid water thickness equivalent to the IR absorbance of the film. This estimated total thickness ranged from 0.88 μm in the dry state to 2.26 μm for the swollen film at a ratio of 21 mol of H₂O per mole of LiBF₄. All of the smoothed data points for film 2 fell close to a straight line intersecting the mole-ratio axis at 3.1. The corresponding plot for film 1 was a slightly curved line with a similar intercept; it is not shown because of uncertainty in the dry-film thickness.

The cause of the linear relationship in Fig. 9 is not obvious. In a very simple model for the system, it could be en-

Fig. 9. Conductivity of swollen PEO-LiBF₄-H₂O film as a function of the mole ratio of H₂O to LiBF₄. Points are smoothed data from Fig. 4.

visioned that all of the salt dissolves in a homogeneous conductive phase, with water acting only as a diluent. The conductivity would then decrease with increasing water content. Factors opposing this effect could be the dissociation of ion pairs and the lowering of viscosity on addition of water. However, those trends, superimposed on the dilution, would not account for the straight line in Fig. 9. The actual behavior was more consistent with a system of two microphases, one a conductive fluid or amorphous region containing dissolved salt, and the other a nonconductive solid including the remainder of the LiBF₄ · 3H₂O. The linear relationship could then occur if the dissolved-salt concentration in the film as a whole were proportional to the free-water content and the mobilities of Li⁺ and BF₄⁻ remained constant. This model treats the conductive microphase as an aqueous region saturated with both PEO and LiBF₄ and disregards effects of porosity or tortuosity created by the solid PEO-salt matrix.

A lower limit for the apparent equivalent conductance of LiBF₄ can be estimated as follows from the plot in Fig. 9. At the mole ratio of 20, the concentration *c* of LiBF₄ dissolved in the entire film had to be ≤ 1.65*M*. With the corresponding experimental conductivity σ of $3.1 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$, the equivalent conductance Λ_{LiBF_4} , expressed as $1000 \sigma/c$, would have been $\geq 1.9 \Omega^{-1} \text{cm}^2 \text{mol}^{-1}$. It may be noted from the work of Radchenko and Ryss that LiBF₄ completely dissolves in pure water at a ratio as low as 5.35

mol of water per mole of salt (7). In the presence of PEO, however, the salt probably is much less soluble. The lower limit of $1.9 \Omega^{-1} \text{cm}^2 \text{mol}^{-1}$ for Λ_{LiBF_4} is two orders of magnitude less than typical equivalent conductances of salts in water, but it is not inconsistent with their behavior in viscous polymer-water mixtures. For example, a paper by Isono *et al.* indicates an equivalent conductance of $7.9 \Omega^{-1} \text{cm}^2 \text{mol}^{-1}$ for NaCl in a concentrated poly(ethylene glycol)-water mixture at 25°C (8).

Figure 10 accentuates the contrast between the two types of film behavior encountered in this study. An incremental conductivity σ_{aq} was calculated by taking the effective film thickness as that equivalent to the free water. This incremental thickness was found from the IR absorbance term $A-A'$, where A is the measured absorbance and A' is the intercept from Fig. 3 or 4. These are nonequilibrium data. The pronounced difference between the plots in Fig. 10 may reflect a difference in the rates of syneresis for the two films: the polymer apparently rearranged readily in film 1 to an ordered, or crystalline, phase, forming an aqueous region with a constant conductivity σ_{aq} of $6.2 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$. This water was subsequently lost by evaporation. With slower crystallization in film 2, the data included some intermediate stages, where σ_{aq} was lower due to more polymer in solution. The same limiting level was eventually reached by film 2, however, and water loss occurred, as represented in Fig. 5.

Further research is planned to characterize related polymer-salt-solvent electrolyte systems.

The Application of Linear Sweep Voltammetry to a Rotating Disk Electrode with a Catalytic Process

S. L. Lanny Ng*¹ and H. Y. Cheh*

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

The current response of a catalytic process to a linear sweep of the potential on a rotating disk electrode is analyzed with the aid of a Nernst diffusion model. Special solutions for a fast chemical reaction are obtained for reversible, quasi-reversible, and irreversible electrode reactions. Results for the reversible case are compared with experimental data.

Theoretical and experimental studies concerning the application of linear sweep voltammetry (LSV) to a rotating disk electrode (RDE) for simple charge-transfer reactions have been reported recently (1-6). Natural convection is diminished by using a RDE. By applying a LSV to the RDE system, it is expected that both kinetic and mechanistic information on the electrode process can be attained in a relatively simple and fast experiment. Furthermore, it permits an extension in the range of rate constants to be measured. Kinetic and catalytic processes in electrochemistry have been studied in stagnant systems by a wide variety of electrochemical techniques, such as chronopotentiometry and ac polarography. The initial investigation of catalytic systems was carried out by Bricka and Wiesner (7) in polarography. Reviews on this subject are available in several monographs (8-10) and in an article by Nicholson and Shain (11).

This paper reports our investigation on the application of LSV to a RDE for an electron charge-transfer reaction coupled to an irreversible and homogeneous chemical reaction in which the product of the electrode reaction reacts with an electroinactive species to regenerate the initial species. This type of reactive system is often called a catalytic process in the electroanalytical literature, and the resulting current is called a catalytic current (12). Theoretical calculations were conducted by using a Nernst diffusion model, in which the concentration change occurs within a diffusion layer of thickness δ . The same model was used by Andricacos and Cheh (3). An experimental investigation was carried out for the case of a reversible electrode reaction. A similar problem has been studied by Saveant and Vianello (13) in a stagnant system.

Theoretical

Consider the following catalytic mechanism

in which A is reduced to B at the electrode surface and B undergoes a catalytic, homogeneous chemical reaction with an electroinactive species Z to regenerate A. The limiting current density for species A is increased by the presence of species Z, and its magnitude depends on the kinetics of the chemical reaction and mass transport of all the species. In general, the chemical reaction is of the second order. However, it is assumed that the amount of the species Z exists in large quantity. The second-order reaction degenerates to a pseudo-first-order reaction.

By assuming a Nernst diffusion model in the absence of double-layer and adsorption effects, and equal diffusion coefficients for A and B, the governing partial differential equations and the boundary conditions are as follows

$$\frac{\partial c_A}{\partial t} = D \frac{\partial^2 c_A}{\partial x^2} + kc_B \quad [3]$$

$$\frac{\partial c_B}{\partial t} = D \frac{\partial^2 c_B}{\partial x^2} - kc_B \quad [4]$$

$$c_A = c_A^0, c_B = c_B^0 \approx 0 \text{ at } t = 0, x \geq 0 \quad [5]$$

$$c_A = c_A^0, c_B = c_B^0 \approx 0 \text{ at } t > 0, x \geq \delta \quad [6]$$

$$\frac{\partial c_A}{\partial x} = -\frac{\partial c_B}{\partial x} = \frac{i}{nFD} \text{ at } t > 0, x = 0 \quad [7]$$

with

$$\frac{i}{nF} = k^0 \left\{ c_A(0, t) \exp \left[-\frac{\alpha nF}{RT} (E(t) - E_0) \right] - c_B(0, t) \exp \left[\left(1 - \alpha\right) \frac{nF}{RT} (E(t) - E_0) \right] \right\} \quad [8]$$

and

$$E(t) = E_i - vt \quad [9]$$

where c_A and c_B are the concentrations of species A and B, c_A^0 and c_B^0 are the bulk concentrations, D is the diffusion coefficient, k is the rate constant of the catalytic chemical reaction, i is the current density, x is the distance from the electrode surface, t is the time, k^0 is the standard rate constant of the heterogeneous electrode reaction, n is the number of electrons involved in the electrode reaction, v is the sweep rate, α is the transfer coefficient, E is the electrode potential, E_i is the initial potential at which polarization of the electrode begins, and E_0 is the standard electrode potential. R , T , and F have their usual significance.

Let us introduce the following dimensionless parameters

$$C_A = c_A/c_A^0 \quad [10]$$

$$C_B = c_B/c_A^0 \quad [11]$$

$$\theta = Dt/\delta^2 \quad [12]$$

$$X = x/\delta \quad [13]$$

$$z = k\delta^2/D \quad [14]$$

$$\phi = i/i_1 \quad [15]$$

$$s = nFv\delta^2/RTD \quad [16]$$

$$u = (E_i - E_0)nF/RT \quad [17]$$

$$p = k^0\delta/D \quad [18]$$

where i_1 is the limiting current density. According to Levich (14), i_1 and δ for a RDE system can be calculated by

$$i_1 = nFDc_A^0/\delta \quad [19]$$

$$\delta = 1.61D^{1/3}\nu^{1/6}\omega^{-1/2} \quad [20]$$

where ν is the kinematic viscosity and ω is the rotation speed of the RDE. Equations [3]-[7] can now be rewritten as

*Electrochemical Society Active Member.

¹Present address: AT&T Technologies, Engineering Research Center, Princeton, New Jersey 08540.

$$\frac{\partial C_A}{\partial \theta} = \frac{\partial^2 C_A}{\partial X^2} + zC_B \quad [21]$$

$$\frac{\partial C_B}{\partial \theta} = \frac{\partial^2 C_B}{\partial X^2} - zC_B \quad [22]$$

$$C_A = 1, C_B = 0 \text{ at } \theta = 0, X \geq 0 \quad [23]$$

$$C_A = 1, C_B = 0 \text{ at } \theta > 0, x \geq 1 \quad [24]$$

$$\phi(0) = \frac{\partial C_A}{\partial X} = -\frac{\partial C_B}{\partial X} \text{ at } \theta > 0, X = 0 \quad [25]$$

The above equations are solved by Laplace transform (15), and the solution is

$$\frac{\psi(\xi)}{[\Lambda \exp(\alpha\xi)][1 + \exp(-\xi)]} = \frac{1}{1 + \exp(-\xi)} - \frac{2}{\sqrt{s}} \int_{-u}^{\xi} \psi(\xi) \exp[-\lambda(\xi - \eta)] \times \sum_{n=1}^{\infty} \exp\left[\frac{-(2n-1)^2\pi^2(\xi - \eta)}{4s}\right] d\eta \quad [26]$$

where

$$\psi = \phi/s^{1/2} \quad [27]$$

$$\xi = s\theta - u \quad [28]$$

$$\Lambda = p/s^{1/2} \quad [29]$$

$$\lambda = z/s \quad [30]$$

For sufficiently large values of u ($u > 10$), the lower limit of the integral can be replaced by negative infinity. The current-potential behavior no longer depends on u . This situation can be arrived at in practice by allowing the initial potential to be 300 mV more anodic than the half-wave potential, $E_{1/2}$.

Note that when $\xi \rightarrow \infty$

$$\phi \rightarrow \sqrt{z} \coth \sqrt{z} \quad [31]$$

At $\sqrt{z} > 3$, Eq. [31] further reduces to

$$\phi \rightarrow \sqrt{z} \quad [32]$$

Therefore, when the potential is highly cathodic, i/i_1 is independent of both the potential sweep rate and the electrode kinetics but is a function of the catalytic reaction-rate constant and the bulk concentrations of species A and Z. Equation [32] thus provides a simple method to determine the rate constant for the catalytic reaction. Unfortunately, the application is limited due to the interference of side reactions at large values of the overpotential.

For reversible electrode reactions ($\Lambda \rightarrow \infty$, or $k^0 \rightarrow \infty$), Nernstian behavior is obtained. Equation [26] reduces to

$$\frac{1}{1 + \exp(-\xi)} = \int_{-u}^{\xi} \frac{2}{s} \phi(\eta) \exp[-\lambda(\xi - \eta)] \times \sum_{n=1}^{\infty} \exp\left[\frac{-(2n-1)^2\pi^2(\xi - \eta)}{4s}\right] d\eta \quad [33]$$

Alternately, the following expression for the dimensionless current function can be derived explicitly by using the Duhamel theorem (15)

$$\frac{\phi(\xi)}{\sqrt{s}} = \int_{-u}^{\xi} \frac{[1 + \lambda + \lambda \exp(\eta)]}{4 \cosh^2(\eta/2)} \exp[-\lambda(\xi - \eta)] \times \frac{\left\{1 + 2 \sum_{n=1}^{\infty} \exp[-n^2s/(\xi - \eta)]\right\}}{\sqrt{\pi(\xi - \eta)}} d\eta \quad [34]$$

The integral can be calculated by cautious adaptive Romberg extrapolation (16). Figures 1 and 2 illustrate the results at $s = 100$ and $s = 1$, respectively. At high sweep rates ($s > 10$), current peaks are observed for $\lambda \leq 0.3$. How-

Fig. 1. Current-potential behavior for a reversible electrode reaction at $s = 100$.

Fig. 2. Current-potential behavior for a reversible electrode reaction at $s = 1$.

ever, i - E curves resemble polarographic waves at large values of the catalytic rate constant and at low sweep rates. From the characteristics of the peak current and the wave height, it is possible to describe the dependence of the peak current on $\lambda^{1/2}$. The results are shown in Fig. 3. The rate constant of the catalytic reaction can be obtained by applying these results to experimental measurements. The half-wave potential² can also be deduced from the i - E curves and be related to the chemical rate constant, as shown in Fig. 4.

In the case of an irreversible electron charge-transfer reaction ($k^0 \rightarrow 0$), Eq. [26] reduces to

$$1 - \psi^*(\xi^*) \exp(-\xi^*) = \int_{\ln H}^{\xi^*} \frac{2\psi^*(\eta)}{\sqrt{s^*}} \exp[-\lambda^*(\xi^* - \eta)] \times \sum_{n=1}^{\infty} \exp\left[\frac{-(2n-1)^2\pi^2(\xi^* - \eta)}{4s^*}\right] d\eta \quad [35]$$

²For the case where a current peak exists, the half-wave potential is defined to be the potential at which the corresponding current density is half the peak current density.

Fig. 3. Dependence of the catalytic peak current density on the catalytic rate parameter.

Fig. 4. Dependence of the half-wave potential on the catalytic rate parameter.

where

$$\psi^* = \psi/\alpha^{1/2} \tag{36}$$

$$\xi^* = s^*\theta + \ln H \tag{37}$$

$$s^* = \alpha s \tag{38}$$

$$H = p(s^*)^{-1/2} \exp [-(E_1 - E_0)\alpha nF/RT] \tag{39}$$

$$\lambda^* = \lambda/\alpha \tag{40}$$

The dimensionless current is a complicated function of the kinetic parameters for the irreversible electrode reaction and the dimensionless sweep rate. The integral can be calculated numerically. Figures 5 and 6 show the i - E characteristics at $s = 100$ and $s = 1$, respectively.

Theoretical investigation of polarographic waves for simple charge-transfer processes in the absence of chemical reaction was studied in detail by Matsuda and Ayabe (17). These authors classified the electrode reactions into three cases: reversible, quasireversible, and irreversible reactions. The homogeneous chemical reaction can be ignored when $\lambda \rightarrow 0$. The application of LSV to a RDE in this case has been reported in detail by Andricacos and Cheh (3-5), and by Quintana *et al.* (6). However, when $\lambda \rightarrow \infty$, the rate of the chemical reaction is fast relative to the sweep rate, and the resulting current is called the catalytic current.

Fig. 5. Current-potential behavior for an irreversible electrode reaction at $s^* = 100$.

Fig. 6. Current-potential behavior for an irreversible electrode reaction at $s^* = 1$.

In the case of a reversible electrode reaction, there is no current peak and the dimensionless current is derived from Eq. [34]

$$\phi(\xi) = \frac{\sqrt{z} \coth \sqrt{z}}{1 + \exp [-\xi]} \tag{41}$$

The current is independent of s , with the ratio of the catalytic to the mass transport current density i_d (4) (in the absence of the chemical reaction) given by

$$\frac{i}{i_d} = \sqrt{z} \coth \sqrt{z} \tag{42}$$

For a quasireversible electrode reaction, with $\xi \rightarrow \infty$ and large values of λ , Eq. [26] reduces to

$$\phi(\xi) = \frac{1}{[1 + \exp (-\xi)] \frac{\tanh \sqrt{z}}{\sqrt{z}} + \frac{\exp (-\alpha\xi)}{p}} \tag{43}$$

The dimensionless current $\phi(\xi)$ and the dimensionless half-wave potential are both controlled by the rates of the electrode and the chemical kinetics, but not by s . At highly cathodic potential, Eq. [43] reduces to Eq. [31].

If the electrode reaction is an irreversible one, Eq. [35] simplifies to

$$\phi(\xi) = \frac{1}{\frac{\tanh \sqrt{z}}{\sqrt{z}} + \frac{\exp(-\alpha\xi)}{p}} \quad [44]$$

To summarize, one may conclude that when $\lambda^{1/2} < 0.5$, the process is controlled by mass transport with $i_{p,c}/i_{p,d} \approx 1$, where $i_{p,c}/i_{p,d}$ is the ratio of the catalytic peak current to the mass transport peak current. The effect of the catalytic reaction is negligible. On the other hand, when $\lambda^{1/2} > 1$, the system is dominated by the catalytic reaction with

$$i_{p,c}/i_{p,d} \approx z^{1/2} \text{ at } 1 < s \leq 5 \quad [45]$$

and

$$i_{p,c}/i_{p,d} \approx 2.2z^{1/2} \text{ at } s \geq 7 \quad [46]$$

The system is under mixed reaction and transport control at $1.0 > \lambda^{1/2} > 0.5$.

Experimental

Experiments were conducted for the case of a reversible electrode reaction with a catalytic and irreversible chemical reaction on a Au RDE (area = 0.461 cm²). The system Fe⁺⁺⁺/Fe⁺⁺/H₂O₂ was chosen to apply the theory for the determination of the catalytic rate constant. The experimental setup was similar to that reported by Andriacos and Choh (3) except that a function generator (Tacussel, GSTP2) connected to a potentiostat (ECO) instead of the potential scanner (Pine Instrument, RDE3) was used. The electrolyte consisted of 0.75 mM Fe⁺⁺⁺ from FeCl₃ in a 0.5M KCl solution. The pH of the electrolyte was adjusted to 2 by adding HCl. Nitrogen gas was passed through the electrolyte for at least 15 min prior to the experiment and was kept above the solution during measurements.

Initially, a blank solution of 0.5M KCl with a pH of 2 was run at several sweep rates ranging from 1 to 0.005 V/s and at rotation speeds ranging from 0 to 2550 rpm. The initial voltage was set at 600 mV vs. SCE, and the sweep potential range was 500 mV. The stock solution with 0.75 mM Fe⁺⁺⁺ in 0.5M KCl was run at corresponding sweep rates and rotation speeds. A small amount of H₂O₂ was added to the fresh stock solution, and the measurements were repeated. The concentration of H₂O₂ in the Fe⁺⁺⁺ stock solution was determined by titration with 6×10^{-3} N KMnO₄.

Before each experiment, the electrode was polished, cleaned, and cycled for a few times using LSV in the Fe⁺⁺⁺ solution to assure the reproducibility of the results.

Results and Discussion

A significant amount of residual current was observed at high sweep rates ($v > 10$ V/s) in the blank solution. The magnitude of the residual current decreased exponentially as the sweep rate was decreased. The addition of a small amount of H₂O₂ and the variation of the rotation speed did not affect significantly the magnitude of the residual current in the voltage range studied in this work. All currents reported here are net currents, i.e., the observed minus the residual current.

The limiting current density for the reduction of ferric ion to ferrous ion was plotted against the square root of the rotation speed, and the result obeyed satisfactorily the Levich equation, as shown in Fig. 7 for $c_{\text{H}_2\text{O}_2} = 0$. The diffusion coefficient of 4.6×10^{-6} cm²/s was taken from the literature (18), and the kinematic viscosity was calculated to be 8.5×10^{-3} cm²/s which is in agreement with literature values.

The reversibility of the system Fe⁺⁺⁺/Fe⁺⁺ was tested by applying the method of LSV to a RDE. The quantity i_p/i_l was measured at several values of s , where i_l is the limiting current density corresponding to the s value at which i_p was measured for the electrode reduction of Fe⁺⁺⁺. Current-potential curves showed current peaks at $s > 3$ and plateaus at $s < 3$. The peak current-sweep rate dependence is shown in Fig. 8, which shows the theoretical line with a slope of 0.447 and the experimental data for the re-

versible electrode reaction. One may therefore conclude that the Fe⁺⁺⁺/Fe⁺⁺ system satisfies the requirement of reversibility in the potential scan range examined.

With the addition of hydrogen peroxide into the solution, a catalytic reaction occurs. The peroxide reacts with ferrous ion and regenerates ferric ion. The following mechanism was proposed by Haber and Weiss (19)

The first step is the rate-determining step, and the reaction rate can be expressed by

$$\text{rate} = k'c_{\text{H}_2\text{O}_2}c_{\text{Fe}^{++}} \quad [51]$$

where k' is the rate constant for reaction [47]. All experiments were carried out with a relatively large excess of H₂O₂. The rate constant measured is therefore $k'c_{\text{H}_2\text{O}_2}$.

When H₂O₂ is present, the catalytic current does not increase at high sweep rates, and $i_{p,c}/i_{p,d} = 1$. The result is close to that for the case without a coupled chemical reac-

Fig. 9. Dependence of the catalytic rate parameter on voltage sweep rates at various concentrations of hydrogen peroxide. $c_{\text{H}_2\text{O}_2}$ (M): ● = 0.052, ■ = 0.036, ▲ = 0.0167.

Fig. 10. Rate of the catalytic reaction

tion. When s is decreased, polarographic waves are formed and $i_{p,c}/i_{p,d}$ is increased. Eventually, the current is dominated by the chemical reaction kinetics. The half-wave potential was observed to shift to a more positive direction. This can be shown by considering the Nernst equation

$$E = E_0 - \frac{RT}{nF} \ln \frac{c_B}{c_A} \quad [52]$$

As B is converted to A by the catalytic reaction, c_B/c_A decreases, leading to a more positive potential.

By applying the theoretical results presented in Fig. 3 to the experimental data, values of λ at different experimental conditions are determined. A plot of λ vs. $1/s$ with different concentrations of H_2O_2 is presented in Fig. 9. Values of the dimensionless parameter z are then calculated from the slope. Knowing the rotation speed and the physical properties of the solution, the rate constant can then be determined. Figure 10 shows the dependence of $k'c_{\text{H}_2\text{O}_2}$ on the concentration of H_2O_2 . The slope gives k' a value of 83.2 liter/mol-s.

At sufficiently large values of λ or low sweep rates, Eq. [42] is applicable. This condition implies that a quasi-steady state is established within the diffusion layer. This equation has been derived by Haberland and Landsberg (20) to a RDE at a steady-state condition. At $v = 0.01$ V/s, this steady state is established. The experimental results lead to a linear relationship between $z^{1/2}$ and $\omega^{-1/2}$. From a plot of $k'c_{\text{H}_2\text{O}_2}$ vs. $c_{\text{H}_2\text{O}_2}$, shown in Fig. 11, the slope gives a

Fig. 11. Rate of the catalytic reaction

rate constant of 83.6 liter/mol-s. Table I summarizes the literature values of the rate constant measured by different methods and under different conditions for the system $\text{Fe}^{3+}/\text{Fe}^{2+}/\text{H}_2\text{O}_2$.

It is unfortunate that literature results on the rate of the ferrous ion-hydrogen peroxide reaction are all based on different electrodes as well as electrolytes. This makes a quantitative comparison difficult. Our results are close to those by Aoki *et al.* (18), and are self-consistent between transient and steady-state measurements.

Conclusions

An analysis of the transient LSV-RDE using the Nernst diffusion model has been developed for an electrode reaction followed by a catalytic, homogeneous chemical reaction. An experimental system involving $\text{Fe}^{3+}/\text{Fe}^{2+}/\text{H}_2\text{O}_2$ was used to demonstrate the applicability of the theoretical results.

The Application of Linear Sweep Voltammetry to a Rotating Disk Electrode with a Kinetic Process

S. L. Lanny Ng*¹ and H. Y. Cheh*

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York, New York 10027

ABSTRACT

The current response of a kinetic process to a linear sweep of the potential on a rotating disk electrode is analyzed with the aid of a Nernst diffusion model. An experimental study involving the reaction of oxidized, N,N-dimethyl-p-phenylenediamines with hydroxide ion is used to test the applicability of the theoretical results.

Recently, Ng and Cheh (1) reported a detailed study on the application of linear sweep voltammetry (LSV) to a rotating disk electrode (RDE) for a catalytic process in which the electrode reaction is followed by a homogeneous chemical reaction to regenerate the reacting species. The present paper is concerned with a similar study ex-

cept that the chemical reaction generates a new product. The resulting current which is influenced by the chemical reaction is known as a kinetic current (2). Nicholson and Shain (3) and Saveant and Vianello (4) studied the application of LSV to the same problem in stagnant systems. In flow systems, this problem was studied by Galus and Adams (5) and by Kir'yanov and Filinovskii (6), based on the concept of a reaction layer. Tong *et al.* (7) applied the Nernst diffusion layer model to a RDE to study

*Electrochemical Society Active Member.

¹Present address: AT&T Technologies, Engineering Research Center, Princeton, New Jersey 08540.

rapid and irreversible reactions of oxidized *N,N*-dialkyl-*p*-phenylenediamines with hydroxide ion and with phenolates. In the present paper, theoretical calculations based on the application of linear sweep voltammetry to a rotating disk electrode are conducted and an experimental investigation is reported for the case of a reversible electrode reaction using *N,N*-dimethyl-*p*-phenylenediamines as an example.

Theoretical

Consider an electrode reaction which is followed by a homogeneous chemical reaction

where A is the only electroactive species in the potential range of interest. B, which is produced by the electrode reaction, is transformed to C by a homogeneous chemical reaction.

When the chemical reaction is slow, the effect of chemical polarization is negligible and the current-potential behavior resembles that of a single electrode reaction. However, the effect of the chemical reaction is predominant when the chemical reaction is fast and irreversible and the electrode reaction is reversible.

By adopting the Nernst diffusion model and by assuming that the diffusion coefficients of all ions are equal, the governing differential equations and the boundary conditions are as follows

$$\frac{\partial c_A}{\partial t} = D \frac{\partial^2 c_A}{\partial x^2} \quad [3]$$

$$\frac{\partial c_B}{\partial t} = D \frac{\partial^2 c_B}{\partial x^2} - kc_B \quad [4]$$

$$\frac{\partial c_C}{\partial t} = D \frac{\partial^2 c_C}{\partial x^2} + kc_B \quad [5]$$

$$c_A = c_A^0, c_B = 0, c_C = 0 \text{ at } t = 0, x \geq 0 \quad [6]$$

$$c_A = c_A^0, c_B = 0, c_C = 0 \text{ at } t > 0, x \geq \delta \quad [7]$$

$$\frac{\partial c_A}{\partial x} = -\frac{\partial c_B}{\partial x}, \frac{\partial c_C}{\partial x} = 0 \text{ at } t > 0, x = 0 \quad [8], [9]$$

with

$$\frac{i}{nF} = k^0 \left\{ c_A(0, t) \exp \left[-\frac{\alpha nF}{RT} (E(t) - E_0) \right] - c_B(0, t) \exp \left[(1 - \alpha) \frac{nF}{RT} (E(t) - E_0) \right] \right\} \quad [10]$$

and

$$E(t) = E_i - vt \quad [11]$$

where c_A , c_B , and c_C are the concentrations of species A, B and C, respectively, c_A^0 and c_B^0 are bulk concentrations, D is the diffusion coefficient, k is the first-order rate constant of the homogeneous chemical reaction, δ is the thickness of the Nernst diffusion layer, i is the current density, x is the distance from the electrode surface, t is time, k^0 is the standard rate constant of the electrode reaction, α is the transfer coefficient, v is the sweep rate, E is the electrode potential, E_i and E_0 are the initial and standard electrode potentials, respectively, and R , T , and F have their usual significance.

By introducing the following dimensionless parameters

$$C_A = c_A/c_A^0 \quad [12]$$

$$C_B = c_B/c_A^0 \quad [13]$$

$$\theta = Dt/\delta^2 \quad [14]$$

$$X = x/\delta \quad [15]$$

$$z = k\delta/D \quad [16]$$

$$\phi = i/i_1 \quad [17]$$

$$s = nFv\delta^2/RTD \quad [18]$$

$$u = (E_i - E_0)nF/RT \quad [19]$$

and

$$p = k^0\delta/D \quad [20]$$

Equations [3]-[11] can be recast into a dimensionless form, and the following solution can be obtained by using Laplace transform

$$\frac{\psi(\xi)}{\Lambda \exp(\alpha\xi)} = 1 - \int_{-u}^{\xi} \psi(\eta) \{1 + \exp(-\xi) \exp[-\lambda(\xi - \eta)]\} \times \frac{\left\{1 + 2 \sum_{n=1}^{\infty} (-1)^n \exp[-n^2s/(\xi - \eta)]\right\}}{\sqrt{\pi(\xi - \eta)}} d\eta \quad [21]$$

where

$$\psi = \phi/s^{1/2} \quad [22]$$

$$\xi = s\theta - u \quad [23]$$

$$\Lambda = p/s^{1/2} \quad [24]$$

$$\lambda = z/s \quad [25]$$

and i_1 is the limiting current density.

For a RDE, i_1 and δ can be calculated by (8)

$$i_1 = nFDc_A^0/\delta \quad [26]$$

and

$$\delta = 1.61D^{1/3}\nu^{1/6}\omega^{-1/2} \quad [27]$$

where ν is the kinematic viscosity of the solution and ω is the rotation speed of the RDE.

For a reversible electron transfer reaction ($\Lambda \rightarrow \infty$), Eq. [21] reduces to

$$1 = \int_{-u}^{\xi} \psi(\eta) \{1 + \exp(-\xi) \exp[-\lambda(\xi - \eta)]\} \times \frac{\left\{1 + 2 \sum_{n=1}^{\infty} (-1)^n \exp[-n^2s/(\xi - \eta)]\right\}}{\sqrt{\pi(\xi - \eta)}} d\eta \quad [28]$$

The integral equation was solved numerically. Figures 1-3 are the current-potential curves for various values of λ and s . Similar to results reported previously (1, 9, 10), current peaks are observed for $s \geq 3$.

Fig. 1. Current-potential behavior for a reversible electrode reaction at $s = 100$.

Fig. 2. Current-potential behavior for a reversible electrode reaction at $s = 1$.

Fig. 3. Current-potential behavior for a reversible electrode reaction at $\lambda = 100$.

When $\lambda \rightarrow 0$, Eq. [28] simplifies to

$$\frac{1}{1 + \exp(-\xi)} = \int_{-\infty}^{\xi} \psi(\eta) \frac{\left\{ 1 + 2 \sum_{n=1}^{\infty} (-1)^n \exp[-n^2 s / (\xi - \eta)] \right\}}{\sqrt{\pi(\xi - \eta)}} d\eta \quad [29]$$

which is identical to the result presented by Andricacos and Cheh (10) for the case of a reversible electrode reaction without a following chemical reaction.

When $\lambda \rightarrow \infty$, Eq. [28] simplifies to

$$\phi(\xi) = \frac{1}{1 + \frac{\tanh \sqrt{z} \exp(-\xi)}{\sqrt{z}}} \quad [30]$$

with the half-wave potential², $E_{1/2}$, given by

$$E_{1/2} = E_0 + \frac{RT}{nF} \ln(\sqrt{z} \coth \sqrt{z}) \quad [31]$$

²For the case where a current peak exists, the half-wave potential is defined to be the potential at which the corresponding current density is half the peak current density.

For large values of z , $\coth \sqrt{z}$ approaches unity (e.g., at $\sqrt{z} = 3$, $\coth \sqrt{z} = 1.005$), Eq. [31] further reduces to

$$E_{1/2} = E_0 + \frac{RT}{nF} \ln \sqrt{z} \quad [32]$$

Tong (7) obtained a similar result without assuming equal diffusion coefficients for species A and B. The expression is

$$E_{1/2} = E_0 + \frac{RT}{nF} \ln \frac{D_A}{D_B} + \ln(\sqrt{z} \coth \sqrt{z}) \quad [33]$$

where D_A and D_B are the diffusion coefficients for species A and B, respectively.

Figure 1 shows the current-potential behavior for a reversible electrode reaction at various values of λ . As $\lambda \rightarrow 0$, the i - E characteristics approach that for a simple reversible electrode reaction. As λ increases, the peak as well as the half-wave potentials shift to more anodic values with little change in the peak current density. A plot of $\xi_{1/2}$ vs. $\log \lambda$ at various s values, shown in Fig. 4, allows one to determine the rate constant for the homogeneous chemical reaction. The same figure can also be used to define several regimes of interest. For instance, it is reasonable to consider the process to be controlled by mass transfer for $\lambda < 0.1$, and the process controlled by chemical kinetics at $\lambda > 1$. Furthermore, at $\lambda > 3$, one may derive the following equations

$$\xi_{1/2} = -1.148 \log \lambda - 1.088, \quad s > 10 \quad [34]$$

$$\xi_{1/2} = -1.15 \log \lambda - 1.044, \quad s = 7 \quad [35]$$

$$\xi_{1/2} = -1.15 \log \lambda - 0.859, \quad s = 3 \quad [36]$$

$$\xi_{1/2} = -1.15 \log \lambda - 0.160, \quad s = 1 \quad [37]$$

Finally, for $s > 10$, the current-potential curve approaches that of a stagnant system.

Experimental

Experiments were conducted for the rapid and irreversible reaction of oxidized *N,N*-dimethyl-*p*-phenylenediamines (PPD) with hydroxide ion at 23°C. The experimental setup and procedure were similar to those described earlier (1, 10). At Pt-RDE (area = 0.461 cm²) was used. The electrolyte contained 10⁻⁴M PPD in a 0.188M dipotassium hydrogen phosphate buffer solution which was adjusted to a pH of 11.2 by adding NaOH. The buffer solution was saturated with N₂ before the addition of PPD. The viscosity of the solution was determined by a Canon-Fenske viscometer to be 0.0103 cm²/s. The diffusion coefficient of PPD and PPD radical were found from the literature to be 0.678 × 10⁻⁵ and 0.567 × 10⁻⁵ cm²/s, respectively (7).

LSV at different scan rates was performed at rotation speeds ranging from 0 to 191 rpm. The half-wave potentials were determined from the current-potential curves. The accuracy of measurements decreased at scan rates greater than 0.1 V/s.

Results and Discussion

The kinetics of deamination of PPD have been studied by Tong spectrometrically (11) and by Tong *et al.* electrochemically on a RDE (7).

The reaction mechanism is as follows

Fig. 4. Dependence of the half-wave potential on the kinetic parameter

In the presence of an excess of OH⁻, the redox potential for the electrode reaction is

$$E = E_o + \frac{RT}{nF} \ln \left\{ \frac{[PPD^*]}{[PPD][OH^-]} \right\} \quad [40]$$

$$= E_o' + \frac{RT}{2F} \ln \left\{ \frac{[PPD^*]}{[PPD]} \right\} \quad [41]$$

where

$$E_o' = E_o - \frac{RT}{2F} \ln [OH^-] \quad [42]$$

and

$$E_o = -0.063V \text{ vs. SCE (7)} \quad [43]$$

Fig. 5. Experimental results on the dependence of the half-wave potential vs. SCE on the sweep rate.

Fig. 6. Experimental results on the dependence of the half-wave potential vs. SCE on the dimensionless sweep rate.

At $\omega = 0$, the system is stagnant, the measured current decreases, and the half-wave potential is shifted cathodically as the scan rate decreases. The half-wave potential $E_{1/2}$ is plotted against $\log v$, as shown in Fig. 5. A linear relationship is obtained with a slope of 12.31 mV as compared to the theoretical value of 14.79 mV. The average rate constant obtained by applying Eq. [34] is 70.9 s^{-1} .

By applying LSV to the RDE, the current decreases and the half-wave potential is shifted first cathodically and then anodically as s is decreased. A plot of the half-wave potentials vs. $\log s$ is shown in Fig. 6. Since the pH of the solution and E_o are known, Fig. 4 can be used to determine λ . A plot of λ vs. $1/s$ at different rotation speeds is illustrated in Fig. 7. The average rate constant is found to be 44.9 s^{-1} .

At $s < 1$ (i.e., at very slow scan rate and fast rotation speed), the experimental half-wave potential is shifted anodically as the rotation speed is increased. A plot of $E_{1/2}$ vs. $\log \omega^{1/2}$ is shown in Fig. 8. The slope is 32.8 mV, as compared with the theoretical value of 29.6 mV. The average rate constant calculated by using Eq. [33] is found to be 70.4 s^{-1} .

A quantitative determination of the rate constant requires a high degree of accuracy in the experimental data. A 1 mV error in the half-wave potential leads to an error of the rate constant of about 15%. This is the reason for the difference in the measured rate values.

Fig. 7. Experimental results on the dependence of the kinetic parameter on the dimensionless sweep rate.

Fig. 8. Experimental results on the dependence of the half-wave potential vs. SCE on the rotation speed at a sweep rate of 7 mV/s.

Conclusions

An analysis of the transient LSV-RDE by using the Nernst diffusion model was developed for an electrode reaction followed by an irreversible and homogeneous chemical reaction. Mathematical expressions were derived to relate the kinetic current to system parameters. An experimental study of the deamination of N,N-dimethyl-p-phenylenediamines was conducted to test the applicability of the theoretical results. It was found that minor experimental error could lead to a considerable variation in the rate constants. Nevertheless, the application of LSV to RDE is useful in estimating the order of magnitude of the chemical rate constant and in the analysis of reaction mechanisms.

Oxygen Evolution and Corrosion on Ruthenium-Iridium Alloys

R. Kötz and S. Stucki

Brown Boveri Research Center, CH-5405 Baden, Switzerland

ABSTRACT

The initial stages of O_2 evolution and anodic corrosion on ruthenium-iridium alloys have been investigated in 1N H_2SO_4 using voltammetry and x-ray photoelectron spectroscopy (XPS). The alloys were prepared by mixed RF sputtering onto glass substrates. Cyclic voltammetry shows that the corrosion of the Ru component is significantly reduced with increasing Ir content. Simultaneously, the activity for O_2 evolution decreases as a consequence of increased Tafel slope and overpotential. The XPS studies show that the reduced corrosion of Ru is paralleled by an increased tendency to oxide formation of the Ir component. The stabilization of Ru by admixtures of Ir is assigned to the formation of a protective oxide layer with increased Ir content. In addition, a shift of redox potentials for oxide formation is observed.

The excellent catalytic properties of RuO_2 for O_2 evolution are well known and have initiated a series of studies on the electrochemical behavior of metallic oxide electrodes (1, 2). In acidic electrolytes, however, RuO_2 suffers from heavy corrosion during anodic polarization. As a consequence, many efforts were undertaken to stabilize the ruthenium dioxide without losing too much of its catalytic performance.

In the authors' laboratory, mixed oxides of ruthenium and iridium have turned out to be the best catalysts for O_2 evolution in Membrel electrolyzer cells, where a proton conducting membrane serves as the electrolyte (3, 4). While admixtures of iridium significantly increase the stability of the catalyst, only a minor increase in overpotential was observed (3-6). Although, for catalytic application, the mixed oxides are of higher interest than the alloys, we believe that, in a first approximation, the behavior of the alloys is qualitatively comparable to that of the mixed oxides. The stabilizing effect of Ir on Ru has been observed for the oxides (3-6) as well as for the metal alloys (7, 8). This similarity can be understood as a consequence of oxide formation on the metals preceding O_2 evolution (9-11).

There are, however, significant differences between Ru-Ir alloys and the mixed oxide catalysts. Firstly, the anodic oxides formed on the metals are hydrous and most probably amorphous. Secondly, the mixed oxides form a solid solution over the entire composition range, while the phase diagram of Ru-Ir alloys shows a two-phase region, between 43% and 54% Ru and two solid solutions with face-centered cubic structure for low Ru content and hexagonal structure for low Ir content (12). These differences have to be considered before transferring the results, obtained on the alloys, to mixed oxides because the importance of structural parameters for catalysis is well known.

In order to understand the mechanisms leading to a stabilization of Ru by Ir, it is inevitable to know the processes governing the anodic O_2 evolution and corrosion on the single components. This has been the subject of recent investigations (10, 11, 13). In the present paper, we report on the anodic performance of Ru-Ir alloys in an acidic electrolyte. The investigation was limited to the initial stages of O_2 evolution and corrosion. Within these limits, significant changes in surface roughness and morphology can be neglected and the electrode surface remains relatively well defined. Long-term stabilities and time dependences of O_2 evolution and corrosion are beyond the scope of this paper. In view of our results, we shall address the question of whether replacement of the high cost Ir component by other low cost metals is advisable.

Experimental

The metal electrodes were prepared by RF sputtering onto glass substrates in a Balzers Sputron II chamber. In order to produce films with different Ru-Ir compositions, the disk-shaped sputtering target was divided into two half-circles, one made of Ru the other made of Ir. By placing a circular stop excentrically in front of the target

the ratio of effective Ru to Ir target area could be varied continuously. The thickness of the films was about 2000Å. In agreement with known phase diagrams for Ru_xIr_{1-x} alloys (12), the x-ray diffraction patterns exhibited the hexagonal structure for $x = 0.86$ and $x = 0.45$. The face-centered cubic structure of Ir was observed for $x = 0.15$.

All electrochemical measurements were performed in 1N H_2SO_4 using the standard three-electrode potentiostatic arrangement, with the saturated calomel electrode serving as the reference electrode and a platinum wire as counterelectrode. The sputtered working electrodes were used shortly after preparation without further cleaning procedure. All electrochemical measurements were performed at room temperature.

XPS measurements were performed in a Kratos ES 300 photoelectron spectrometer using nonmonochromized Mg $K\alpha$ radiation. Binding energies were calibrated with respect to the Au $4f_{7/2}$ line at 84.0 eV.

After electrochemical treatment, the electrodes were rinsed with triply distilled water and dried in a nitrogen gas stream. Transfer from the electrochemical cell to the UHV chamber of the spectrometer was achieved within 1 min through the fast insertion lock. Experiments performed with the electrochemical preparation chamber, described previously (14), under controlled argon atmosphere showed identical XP-spectra of the metal core levels.

Results

Voltammetry.—In a recent investigation (15), we demonstrated that the species formed during anodic corrosion of Ru is reduced in the cathodic scan of the cyclic voltammogram. The reduction peak, observable in unstirred electrolytes, corresponds to the reduction of RuO_4 being the only corrosion product (15). Figure 1 shows the cyclic voltammogram of pure iridium and the corresponding cathodic scans for three different alloys Ru_xIr_{1-x} and pure ruthenium. The anodic scan limit was $1.3 V_{SCE}$. The curves shown in Fig. 1 correspond to the first scans up to $1.3 V_{SCE}$ after five cycles of the electrodes between $-0.25 V_{SCE}$ and different anodic scan limits (below $1.3 V_{SCE}$) during a window opening experiment. The pronounced reduction peak of 0.75V for the ruthenium electrode ($x = 1$) is strongly diminished with decreasing x . The major decrease of the reduction peak occurs for $Ru_{0.86}Ir_{0.14}$. Further increase of the iridium content has only minor influence. Taking the height of the reduction peak as a measure for the amount of RuO_4 formed, it is obvious that, already, small admixtures of iridium to ruthenium inhibit the corrosion of ruthenium, i.e., formation of RuO_4 in solution, significantly. This effect becomes especially pronounced if the anodic scan limit is shifted to more anodic values.

Unfortunately, the reduced corrosion of Ru is coupled with a reduced activity of the alloy for O_2 evolution. The O_2 evolution current drops considerably with the admixture of iridium to ruthenium. For the alloy $Ru_{0.86}Ir_{0.14}$, the current for oxygen evolution at $1.25 V_{SCE}$ is already reduced to one-fifth of the current measured for pure Ru.

Fig. 1. Cyclic voltammogram of an iridium electrode ($x = 0.0$) and cathodic scans for different alloys $Ru_x Ir_{1-x}$. x is given at the respective curve. Anodic scan limit: $1.3 V_{SCE}$; scan rate: 100 mV/s . No electrolyte stirring. The cathodic scans are displaced by -0.05 mA each.

Again, increasing the amount of iridium above 50% has only negligible influence on the activity for O_2 evolution.

In order to obtain more information about the anodic O_2 evolution on Ru-Ir alloys, we measured the Tafel slope as a function of alloy composition. The results are plotted in Fig. 2. For the alloys $Ru_x Ir_{1-x}$ with $x < 0.5$, the measured Tafel slope of $\sim 50 \text{ mV}$ corresponds to that of pure iridium. The transition from the Tafel slope of 37 mV for Ru to 50 mV occurs for $1 > x > 0.5$.

Fig. 2. Anodic Tafel slopes as a function of alloy composition, scan rate: 2 mV/s , first scan up to $1.4V$.

The catalytic activity of an O_2 evolution catalyst is mainly determined by the onset potential for the O_2 evolution reaction. This potential can be determined from the measured Tafel curves at low current densities. The O_2 evolution potential at 0.1 mA cm^{-2} is shown in Fig. 3 as a function of composition. There appears to be a linear correlation between the O_2 evolution potential and the alloy composition. Thus, the reduced O_2 evolution activity is a consequence of an increased potential for the onset of the O_2 evolution reaction. At higher current densities, the increased Tafel slope reduces the activity (O_2 evolution current at a certain potential) even further.

The data of Fig. 2 and 3 were taken from the first anodic scan for a fresh electrode up to $1.4 V_{SCE}$ (2 mV/s). During this procedure, oxide growth is limited and the changes in surface composition are relatively small, as will be shown below.

X-ray photoelectron spectroscopy.—Before drawing any conclusions from the macroscopic, electrochemical parameters, it is important to know the actual state of the electrode surface. For this purpose, we have applied x-ray photoelectron spectroscopy (XPS). The spectra of the Ru3d and Ir4f levels after O_2 evolution at $1.7 V_{SCE}$ (i.e., current densities of $50\text{--}100 \text{ mA cm}^{-2}$) for 5 min are shown in Fig. 4 for different alloy compositions. On pure ruthenium, the formation of a thick oxide layer gives rise to a shift in binding energy of the Ru3d_{5/2} level to 281.0 eV (10). This shift is strongly reduced for the alloy with the composition $Ru_{0.86}Ir_{0.14}$ ($E_B = 280.2 \text{ eV}$). No shift of the Ru level could be observed for $Ru_{0.45}Ir_{0.55}$ and $Ru_{0.15}Ir_{0.85}$. For the latter alloys the position of the Ru3d level corresponds to that of the metal. Thus, the formation of the thick anodic oxide on ruthenium is inhibited by the presence of iridium.

However, oxide formation on Ir is enhanced. While on pure iridium only a thin oxide layer is formed during O_2 evolution, which could only be detected by deconvolution of the spectra recorded at a low electron emission angle ($\theta = 20^\circ$) (11), the presence of Ru leads to a distinct shift of the Ir4f_{7/2} level to higher binding energies. For Ru mole fractions $x = 0.45$ and $x = 0.86$, the Ir4f_{7/2} binding energies were determined to be 61.5 and 61.9 eV , respectively, which have to be compared to a binding energy of 60.9 eV for the metal (11, 16). Oxide formation on Ru is inhibited at the expense of an increased tendency to oxide formation on Ir.

The actual surface composition of the electrodes can deviate significantly from that of the bulk, especially at

Fig. 3. O_2 evolution potential at 0.1 mA cm^{-2} as a function of alloy composition. Open circles are taken from Ref. (6).

Fig. 4. XP-spectra of the Ru3d and Ir4f level for the pure metals and three different alloys after O_2 evolution at 1.7V for 5 min.

potentials where O_2 evolution and corrosion occurs. We therefore determined the surface composition by use of XPS. The surface sensitivity of XPS, which is a consequence of the limited mean free path of the electrons in the solid, can be increased further by lowering the electron emission angle θ (see Fig. 4). In Fig. 5, the surface composition of the three alloy electrodes is shown as a function of the electrode potential for electron emission angles $\theta = 90^\circ$ and $\theta = 20^\circ$. The results in Fig. 5 were independent of whether a fresh electrode was used for each data point or one electrode was used for a sequence of

Fig. 5. Surface composition x of Ru_xIr_{1-x} alloys after electrochemical treatment at various electrode potentials after 5 min. The asterisk indicates the bulk composition of the alloy.

measurements with anodically increasing potentials. For the three alloys, a change in surface composition in favor of a higher Ir content can be observed for potentials anodic of 0.9V vs. SCE. While the increase in Ir surface concentration is evident for $\theta = 90^\circ$ and $\theta = 20^\circ$ in the $Ru_{0.86}Ir_{0.14}$ alloy, the change in surface composition for the alloys with higher Ir content is detected only with $\theta = 20^\circ$. This indicates that the surface layer on the latter samples is very thin.

The thickness of a surface layer on a substrate can be calculated from the relative intensities of the photoelectron emission from the surface layer and the substrate under certain assumptions using Eq. [3] of Ref. (16). We assume that a homogeneous oxide layer covers the metal substrate and there is no metallic Ir or Ru within the oxide layer. The electron mean free path was assumed to be 20Å, and the ratio of metal to oxide density was 1.7. In Fig. 6, the measured relative intensity of oxidized Ru plus Ir over metallic Ru plus Ir is plotted as a function of the electrode potential. The data were obtained by deconvolution and integration of the metals' 3d and 4f levels. Also given is the calculated thickness, which should be regarded as qualitative only, owing to the uncertainty of the above assumptions. It turns out that the thickness of the oxide layer, formed during O_2 evolution, is strongly dependent on the alloy composition. For the alloy with the highest Ir content, the oxide thickness ($\sim 4\text{Å}$) is close to that on pure Ir (11). As the Ir content of the bulk material decreases, the oxide thickness increases. For $Ru_{0.45}Ir_{0.55}$, a limiting oxide thickness of $\sim 8\text{Å}$ is reached at 1.8V, while for $Ru_{0.86}Ir_{0.14}$, the oxide thickness increases with anodic polarization up to 2.2 V_{SCE} .

From Fig. 6, it is also obvious that oxide formation starts at electrode potentials cathodic of the O_2 evolution potential. This is in agreement with the results obtained on Ir (9, 11) and compares well with the results of Fig. 5, where the initial changes in surface composition occur at a potential of about 0.9 V_{SCE} , far below the O_2 evolution potential.

Discussion

The results presented above demonstrate clearly that the corrosion of ruthenium is considerably inhibited after alloying with iridium. The major inhibition effect occurs for rather low iridium admixtures. Similar observations were made before by Miles *et al.* (7) and Gottesfeld *et al.* (8). These authors, however, analyzed the alloy's stability just by the coloration of the electrolyte after heavy O_2 evolution. After alloying Ru with Ir, the lack of electrolyte coloration due to RuO_4 indicated higher stability. The method used in the present study allows the detection of RuO_4 formation at low current densities during the initial stages of corrosion (15).

The decrease in Ru corrosion of the metal electrode is achieved, however, at the expense of activity for O_2 evolution. Apparently both the corrosion rate as well as the O_2 evolution activity drop in the same qualitative manner with increasing iridium content. The loss in activity for O_2 evolution is a consequence of increasing Tafel slope and increasing overpotential. Taking the Tafel slope as an indicator for the reaction mechanism, one has to conclude (see Fig. 2) that O_2 evolution on Ru_xIr_{1-x} alloys with $x < 0.5$ proceeds via the mechanism assumed for Ir anodes and no longer via that for Ru (1).

The simultaneous inhibition of ruthenium corrosion and O_2 evolution is not too surprising because it has been shown that both processes have a common reaction intermediate (5, 17, 18). If the formation of this intermediate—most probably RuO_4 (15)—is inhibited, both the O_2 evolution rate and corrosion rate will be diminished. The question, however, remains of how the formation of RuO_4 is suppressed.

On the basis of our XPS results, we conclude that segregation and preferential corrosion of ruthenium leads to a surface layer with considerably increased iridium content. Whether the topmost layer is only iridium oxide or still a mixture of ruthenium and iridium oxide cannot be

Fig. 6. Relative integrated intensity of the surface oxide and substrate metal contributing to the Ir4f and Ru3d spectra measured for $\theta = 20^\circ$ as a function of the electrode potential. For estimation of the corresponding oxide thickness, refer to the text.

distinguished on the basis of our results. It is clear, however, that the electrochemical performance of the alloys shifts towards that of iridium as a consequence of a change in surface composition. With respect to the measured Tafel slopes, one could assume that for alloys with $x < 0.5$ the topmost layer is pure iridium oxide.

The growth of this surface layer is rationalized as follows. Oxide formation on both metals occurs at potentials far below the O_2 evolution potential. This is evidenced in Fig. 6 where the oxide layer on the alloys has a measurable thickness already at 0.9V. As can be seen in Fig. 5, the oxide formation, preceding the O_2 evolution, leads to some segregation at the surface in favor of a higher Ir content. At more anodic potentials, where O_2 evolution and corrosion set in, the surface composition changes even further, now being a consequence of preferential corrosion of the Ru component. The thickness, as well as the surface composition, reaches a limiting value for the Ru_xIr_{1-x} alloys with $x = 0.15$ and $x = 0.45$, indicating that film formation and corrosion are equilibrated and that Ru no longer corrodes preferentially. This situation is different for the alloy with $x = 0.86$, where no limiting film thickness is reached within the potential range under investigation. In all three cases, the electrochemically formed overlayer is enriched in iridium and, therefore, the electrochemical performance is much closer to that of pure iridium than would be expected on the basis of the bulk composition. However, ruthenium is removed from the interface, and its contribution to the overall electrochemical reaction becomes negligible.

Upon inspection of Fig. 2 and 3, it becomes evident that the O_2 evolution reaction on the alloys with high iridium content ($x = 0.45$, $x = 0.15$) is not totally identical to the reaction on pure iridium with respect to macroscopic electrochemical parameters. While the Tafel slope is equal to that measured on Ir, the O_2 evolution onset potential is shifted to more cathodic values. In addition, the oxides formed on the alloys are thicker than those formed on pure iridium during O_2 evolution. In order to be sure that the decrease of the onset potential for O_2 evolution is a real effect and not just due to an increase in real surface area we have measured the charge enhancement factor (CEF) (19) for the $Ru_{0.45}Ir_{0.55}$ alloy after O_2 evolution at po-

tentials up to $2.0 V_{SCE}$. The CEF was about 1.5 and too small to explain the observed shift with the increased surface area.

On the basis of the results obtained by Stucki and Müller (6) in combination with the present results, we assume that a general shift of the oxidation potentials of iridium, due to the presence of ruthenium, is responsible for the observed shift in O_2 evolution potential. These authors investigated the electrochemical behavior of thick anodic oxide films grown on Ru-Ir alloys. They found a shift of the highly reversible redox reaction at $0.7 V_{SCE}$, which can be assigned to a change in Ir-valence state from III to IV, as well as a shift of the O_2 evolution potential as a function of alloy composition. As is evident from Fig. 3, the results obtained in the previous study (6) are in complete agreement with those of the present investigation obtained on "thin" oxide layers. Most probably, the addition of ruthenium makes the iridium oxide less noble and shifts the redox potential of the surface oxides.

A shift of the redox potential for the initial stages of oxidation [$M \rightarrow M_x(OH) \rightarrow M_{x-n}(OH)$ in Ref. (9)], which are rather reversible on Ru and Ir, is also observed on the metal alloys. In Fig. 7, the cyclic voltammograms of Ru, Ir, and $Ru_{0.45}Ir_{0.55}$ are compared for anodic scan limits below $0.8 V_{SCE}$. The most interesting result is that the alloy shows only one reduction feature at a potential between those of pure metals. It is clear that the voltammogram of the alloy is not a superposition of the two compounds but it represents a homogeneous phase with a shifted redox potential. This result strongly supports the idea of shifted redox potentials due to alloying in the case of Ru and Ir. The shift of the O_2 evolution onset can be rationalized along these lines, if the O_2 evolution process is under-

Fig. 7. Cyclic voltammograms of Ru, $Ru_{0.45}Ir_{0.55}$, and Ir for a cathodic potential limit $-0.25V$ and different anodic potential limits below $+0.8 V_{SCE}$. $1N H_2SO_4$, scan rate: $100 mV/s$.

stood as the formation and decomposition of "higher oxides" (6, 7, 10, 11). Our results are in good agreement with observations made on alloys like Pd-Au or Pt-Rh (20). Different results have been observed for Pt-Au alloys which, however, do not form solid solutions (21). Most probably, the formation of a solid solution is a prerequisite for the observation of shifted redox potentials in alloys. In the case of O₂ evolution, it is not clear whether the metal substrate or the oxides, from which O₂ is released, or both have to form solid solutions in order to show a shifted O₂ evolution potential. For the system under investigation, however, both the metals as well as the oxides do form solid solutions.

The observed shift in redox potentials is assumed to be a consequence of charge transfer or band mixing of the metal's d band (22) as well as the d derived t_{2g} band of the surface oxides (23). The correlation between the number of valence electrons and the O₂ evolution potential by Miles and Thomason (24) might be fortuitous but may well play an important role in determining the O₂ evolution potential in mixed systems assuming the rigid band model to be applicable (20). Another way of explaining the shift in redox potentials might be the assumption of coadsorption and exchange lateral interaction between surface dipoles (25).

The question whether the iridium component can be replaced by some other low cost component is of importance for industrial application of O₂ evolution catalysts. In view of the present results replacement of Ir does not appear to be advisable. The iridium component does not only stabilize the ruthenium component, while O₂ evolution still proceeds on Ru, but it becomes also the O₂ evolving component. The idea of keeping the advantageous properties of both metals, i.e., the catalytic activity of Ru and the relative stability of Ir, by alloying did not come true.

In order to determine the minimum amount of Ir in the alloy, necessary for a reasonable stabilization effect, more data are needed. The present investigation, however, shows that an iridium content of about 30% may be sufficient.

Application of the results obtained on metal alloys to powder catalysts made of mixed Ru-Ir oxides may appear premature. Investigations in our laboratory, however, indicate a similar behavior of metal alloys and Ru-Ir mixed oxides with respect to O₂ evolution potential in practical cells and Tafel slope as a function of the composition. While surface segregation effects during O₂ evolution on the mixed oxides seem to be negligible, the shift in redox potentials is still observed (23).

Conclusions

The catalytic properties of Ru-Ir alloys for anodic O₂ evolution are determined by two effects (i) surface segregation and (ii) redox potential shifts.

Surface segregation in favor of a higher iridium content starts at potentials cathodic of the O₂ evolution potential. The thickness of the oxide layer formed during O₂ evolution increases with decreasing Ir content of the alloy.

The potentials for O₂ evolution and for the initial steps in oxide formation on the alloys shift to more cathodic values with increasing Ru content of the alloys. This result is in complete agreement with previous investigations (6) showing a similar shift of the potential for O₂ evolution and the reversible oxidation state change on thick anodic oxide films formed on the alloys by potential cycling.

As a consequence of both effects the corrosion of and O₂ evolution on ruthenium is significantly inhibited by alloying with iridium. For alloys with a composition of 50% and more iridium, anodic O₂ evolution proceeds with

a Tafel slope equal to that of pure iridium but with a reduced overpotential

Adsorption at the Solid/Solution Interface

An FTIR Study of Phosphoric Acid on Platinum and Gold

M. A. Habib* and J. O'M. Bockris*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

The paper represents an FTIR study of the adsorption from aqueous solutions of phosphoric acid onto Pt and Au electrodes at various concentrations and potentials. The experimental method utilizes parallel polarized light; the light path through the solution is around 10^{-4} cm. The signal-to-noise ratio was made acceptable by subtracting spectra obtained in regions in which H_3PO_4 was known from radiotracer measurements not to be adsorbed from the spectra at potentials at which adsorption occurs. It was found that there is one main peak at 1074 cm^{-1} which varies parabolically with potential. Values of the electrode coverage, θ , were obtained by calibrating the peak heights against the results of parallel radiotracer measurements. Plots of θ against $\log C$ are linear. The adsorption maximum on Au was *ca.* 300 mV more positive than that on Pt. The validity of the measurements is supported by the rational trends of the data obtained, in particular, the relation to the spectroscopic data separately obtained for H_3PO_4 in solution. H_3PO_4 in solution is 99% molecular and 1% ionic. It is shown that the coverage data can be evaluated in such a way (solvation of H_3PO_4) that $0.2 < \theta < 0.6$, so that a Temkin isotherm may be applicable. The difference in results on Au and Pt may not be interpreted unambiguously in terms of displacement by oxide: accounting for water bonding appears necessary. The method offers an alternative to SERS.

One of the current approaches to improve fuel cell performance is the use of phosphoric acid as an electrolyte. These cells employ 85%-100% (aqueous) phosphoric acid at a temperature of 175° - 200°C (1). The mechanism of the cell is not understood. It may be that the main reason for the good performance is an $e^{+E/RT}$ effect: the acid makes possible the use of elevated temperatures. Cathodic polarization limits the performance.

Although the Arrhenius factor contributes to an increase in efficiency, other factors must be taken into account.

The dissociation constants of H_3PO_4 at 25° , 100° , and 200°C are $10^{-2.15}$, $10^{-2.6}$, and $10^{-3.5}$, respectively (2). The corresponding degrees of ionization for more than 85% concentrated H_3PO_4 ($>14.7\text{ mol dm}^{-3}$), are 0.02, 0.01, and 0.005. Hence, H_3PO_4 electrolyte under fuel cell condition remains 99% molecular. The occupancy of reaction sites by adsorbed acid molecules may be high. If this is the case, O_2 reduction would, in fact, actually be impeded, compared with an electrolyte at the same temperature, which is ionic and which would be expected to occupy only a small fraction of the electrode surface owing to anion repulsion.

If this view is applicable, the high efficiency of fuel cells using H_3PO_4 would indeed be due to the Arrhenius factor but still better results (*e.g.*, higher electrochemical rate constants) might be obtained with an acid equally refractory as H_3PO_4 , but existing predominantly as ions so that a greater degree of surface is left unblocked.

Other factors affecting the oxygen reduction rate may be associated with a change of environment. For example, it may be possible that another acid may increase the activity of protons at a given concentration and thereby increase the rate of O_2 reduction. Alternatively adsorbed layers of some species on the electrode surface may give rise to improved resonance tunneling (3) of electrons at the electrode/solution interface. Similarly, the solubility of O_2 may be increased in certain aqueous solutions, and this would give rise to higher exchange current densities and limiting currents and, hence, increased performance in energy conversion.

Recently, trifluoromethane sulfonic acid (TFMSA) (CF_3SO_3H), which is completely dissociated in aqueous solution (4), and its homologs have been introduced as fuel cell electrolytes (5). These acids produce remarkable results. The exchange current density for the oxygen reduction reaction at 1 atm pressure and ordinary temperature is 3 orders of magnitude greater than that in 85% orthophosphoric acid (5); this leads to a reduction of the

overvoltage by 0.25V and an increase of fuel cell efficiency by 35%. Thus, in the trifluoromethane sulfonic acid fuel cells, fuel cell efficiencies close to 80% would be possible.

Yeager *et al.* (6) investigated the effects of additions of CF_3SO_3H and CF_3SO_3K to H_3PO_4 . From a comparison of limiting currents, they concluded that, while addition of CF_3SO_3H increases O_2 transport to the electrode, the simultaneous addition of $CF_3SO_3K + CF_3SO_3H$ results in only a small increase. Hence, the O_2 reduction kinetics do not appear to be dependent on the proton activity in the H_3PO_4 electrolyte (6). Ross *et al.* (7) found a dramatic decrease of O_2 reduction rate in TFMSA solution by the addition of H_3PO_4 and inferred that, in addition to geometric blocking, a small increase in activation energy may be responsible. Although infrared reflectance spectroscopy has been used to detect organic radicals and carbon containing species as electrochemical reaction products in nonaqueous solvents (8-12), because of high IR absorption by water, the applicability of this method for the study of electrochemical phenomena in aqueous solutions remains limited (13-18). However, a fast Fourier transform infrared (FTIR) spectrometer with higher energy throughput, in combination with a highly polished electrode surface having a thin film of solution between the electrode surface and IR transparent window, brings new promise to the field of electrochemical adsorption studies (8, 10, 19). We report here the electrochemical adsorption of phosphoric acid on platinum and gold electrodes from an aqueous solution, as measured with an FTIR spectrometer system.

Experimental

The working electrode used was a highly polished Pt or Au disk of 0.6 cm diam and 1 mm thick attached to a copper rod clad with heat shrinkable Teflon tube supplied by Small Parts, Incorporated (Miami, Florida). The electrode surface was polished with $0.05\text{ }\mu\text{m}$ alumina. Owing to the necessity of having an optically flat surface, the electrode surface was kept parallel to the polishing surface by mounting it in a vertical aluminum cylinder of 3.1 cm od and 1 cm id (see Fig. 1). The aluminum cylinder with the mounted electrode was then attached to the lever of a Buehler Minimet polisher (Fig. 1), and the electrode was polished until a mirror finish was obtained. The polished electrode was cleaned with conc. HNO_3 , and rinsed thoroughly with tridistilled water. Any traces of aluminum from the holder was found to be removed by conc. HNO_3 cleaning, since the voltammograms of the clean Pt or Au were the same as those previously taken with pure Au or Pt wire electrodes in clean acid solution.

*Electrochemical Society Active Member.

Fig. 1. The electrode polisher

The polished electrode was positioned in the cell very close to the IR-transparent ZnSe cell window, leaving only a very thin film of solution in front of it (Fig. 2) (8). The ZnSe window, supplied by Foxboro (North Haven, Connecticut), was 3 mm thick and of 25 mm diam. The cell window was cleaned with toluene, dried thoroughly, and rinsed with tridistilled water. A Pt counterelectrode and a saturated calomel reference electrode were used. All potentials mentioned in this paper are referred to the normal hydrogen electrode (NHE).

The phosphoric acid, supplied by MCB, was purified by refluxing with 10% v/v of 30% H_2O_2 . Excess water was removed by distillation. Phosphoric acid electrolyte of the desired concentration was then made by addition to a 1 mol dm^{-3} solution of $HClO_4$ in tridistilled water. The electrode was subjected to a fast potentiodynamic cycling of 1 V s^{-1} for 5 min. A voltammogram was taken at 100 mV s^{-1} to determine the surface area of the electrode from the charge due to hydrogen reduction. The cell was then placed in the FTIR spectrometer, so that the electrode surface was in the optical path of the IR beam (Fig. 3). Boil-off of liquid nitrogen was used for purging the system. N_2 gas from a cylinder was used for deaerating the solution.

A HI-TEK potentiostat (Model DT2101) and HI-TEK waveform generator (Model PPR1) were used for controlling the electrode potential. The electrode surface was irradiated with the incident IR beam in the sample com-

Fig. 2. The electrochemical cell

partment of a Digilab FTS-20E FTIR spectrometer system equipped with a Data General Nova 4 computer. A versatile reflection attachment (Harrick Model VRA S5D) with retromirror accessory (RMA-4DG) was used to guide the incident IR beam to the electrode surface and the reflected beam back to the detector. The angle of incidence was $\approx 67^\circ$. The optical configuration is shown in Fig. 3. A Moletron IGP228 gold grid polarizer was used to plane polarize the beam.

The stability of the infrared source (glowbar) is extremely important for the reproduction of the peak intensities. The voltage corresponding to the current passing through the glowbar during experimentation must be stable within ± 1 mV. The power supply for the glowbar showed the voltage to be 1.000V. The fluctuation of this voltage, which corresponds to the variation of the source signal, was monitored by a digital voltmeter and an X-t recorder. When the glowbar voltage fluctuation was more than 1 mV from its adjusted value of 1.000V, then the variations of peak heights for the same experiments were more than 5%; in such cases, the results were rejected.

Constancy of the spectral intensity also depended on the constancy of the flow of nitrogen for purging the spectrometer system. It was noticed that when the flow rate of purging N_2 was changed, the glowbar voltage also changed by about 5 mV and thus affected the spectral intensity. Therefore, the flow rate of N_2 was always kept constant during any given experiment. A gas flowmeter, Gilmont Model F1500, was used, and a flow rate of 30 liter/min was maintained during the experiment.

The electrode was polarized potentiostatically in the range of 0.0 V (NHE) to 1.2V (NHE) for Pt and 0.0 V-1.6V (NHE) for Au, at intervals of 200 mV. A total of 1000 scans were collected at each potential. All spectra at each potential were added together and signal averaged to improve the signal-to-noise (S/N) ratio. Synchronization between the application of the potential step and the beginning of data collection was made by tapping a TTL signal accompanying the beginning of data collection at the Digilab A/D converter and applying the signal to trigger the appropriate potential step at the potentiostat (HI-TEK DT2101). The spectra reported here represent the difference between the spectra at a given anodic potential and that at 0.0 V, where no adsorption of H_3PO_4 molecule is detected by FTIR¹ or in the corresponding radiotracer measurements (20, 21).

All spectra were measured with parallel polarized IR radiation, because the perpendicular polarized light is not absorbed by the adsorbed layer on a reflecting surface and hence does not carry information from the adsorbed layer (22, 23). The calculated spectra are thus termed p-polarized differential spectra, which give information about the adsorbed layer, provided no new species in solution is formed.

Results

Results before subtraction of solution spectra.—In Fig. 4a and 4b, the p-polarized spectra at 800 mV and 0.0 V for Pt, before the subtraction of the spectra at 0.0 V, are shown. Because these broad bands include information from the solution, the two spectra appear to be very much the same. However, when the spectrum at 0.0 V is subtracted from the spectra at 800 mV, the resultant differential spectrum of Fig. 5a is obtained.

Influence of light polarization.—When the IR light was polarized parallel to the plane of incidence, the spectra were taken at 0.0 V and at 800 mV, and the former was subtracted from the latter, the resultant spectrum, as shown in Fig. 5a, distinctly shows the peak due to a P-O

¹Since $(\Delta R/R_{ref}) \ll 1$, the spectra reported here are in the absorbance mode which is equivalent to $-(\Delta R/R_{ref}) = -(R - R_{ref})/R_{ref}$, where R is the reflected intensity at a desired potential and R_{ref} is that at a reference potential. Absorbance = $-\log(R/R_{ref}) = -\log[(R_{ref} + R - R_{ref})/R_{ref}] = -\log(1 + \Delta R/R_{ref}) = -\Delta R/R_{ref}$.

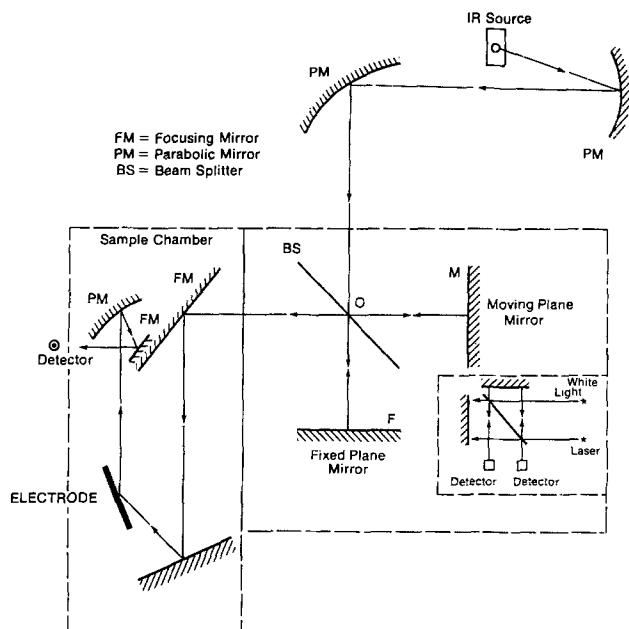

Fig. 3. Optical arrangements for the FTIR spectrometer with the reflection attachments for the electrochemical experiments.

vibration, the area and height of which changes with potential (Fig. 6). With perpendicular polarization, no such peak was observed (Fig. 5b). Hence, when the plane of po-

Fig. 4. *In situ* IR spectra of Pt surface in $1 \text{ mol dm}^{-3} \text{ HClO}_4 \text{ (aq.)} + 6.6 \times 10^{-3} \text{ mol dm}^{-3} \text{ H}_3\text{PO}_4 \text{ (aq.)}$ at (b) 0.0V and (a) 800 mV, before the subtraction of the solution spectrum.

Fig. 5. Differential spectra of the electrode surface at 800 mV with (a) parallel and (b) perpendicular polarization of the IR beam with respect to 0.0 V [solution = $1 \text{ mol dm}^{-3} \text{ HClO}_4 + 6.6 \times 10^{-3} \text{ mol dm}^{-3} \text{ H}_3\text{PO}_4 \text{ (aq.)}$] and (c) spectra in the absence of H_3PO_4 .

larization of the IR light was oriented parallel to the plane of incidence, the spectra recorded were then indeed the spectra of H_3PO_4 adsorbed on the electrode as a function of potential.

Adsorption as a function of potential.—In Fig. 6, the p-polarized differential spectra of the Pt electrode surface at 200, 600, 800, 1000, and 1200 mV (NHE) are shown. The absorbance peak at 1074 cm^{-1} is hardly visible at 200 mV, but increases with increasing anodic potential, and reaches a maximum at 800 mV. With further increase of anodic potential, this peak decreases. This peak was not detectable when H_3PO_4 was absent from the solution (Fig. 5c) and, hence, must originate from H_3PO_4 ; the observed peaks are in the characteristic group frequency range of the P-O stretching vibrations in H_3PO_4 (24). The adsorption peak areas as a function of potential are plotted and compared with coverages measured by the radiotracer method (21) in Fig. 7. Some smaller peaks seem to appear at 1110, 1090, and 1025 cm^{-1} and seem to vary with potential (Fig. 6) but the magnitude of these peaks is really comparable to the noise level as discussed in the Discussion section.

Adsorption as a function of concentration.—In Fig. 8, the absorption peak at 1074 cm^{-1} as a function of the logarithm of H_3PO_4 concentration in solution with the electrode at 800 mV are shown. The peak heights correspond-

Fig. 6. *In situ* differential IR spectra of H_3PO_4 species adsorbed on Pt at different potentials [solution = $1 \text{ mol dm}^{-3} \text{ HClO}_4 + 6.6 \times 10^{-3} \text{ mol dm}^{-3} \text{ H}_3\text{PO}_4$ (aq.)].

ing to surface concentrations are found to vary linearly with $\log C$.

During the experiment, the change of concentration was carried out in the following way: first, the cell was filled with the most dilute concentration of H_3PO_4 solution ($10^{-4} \text{ mol dm}^{-3}$), and the spectra were recorded in the way described in the previous section. Since it is impor-

Fig. 7. Surface concentration, Γ , of H_3PO_4 on Pt as a function of potential. (a): Γ as normalized area of IR peak at 1074 cm^{-1} . The highest peak area is assumed to be the highest surface concentration, as obtained from (b), the radiotracer measurements. The scoring on the Y-axis is in units of 5. Solution as in Fig. 6.

Fig. 8. Variation of the surface concentration of H_3PO_4 on Pt with logarithm of the concentration of H_3PO_4 in solution.

tant not to disturb the position of the electrode or the cell, so that comparison of different spectra can be made, the solution concentration was changed by adding a defined amount of a 25% (aq.) solution of H_3PO_4 to the existing solution in the cell, with the help of a Hamilton microsyringe. Since sufficient diffusion time is needed² for the entire solution to attain a uniform desired concentration, the next set of data collection was started at least 1.5h after the addition of H_3PO_4 to the solution.

Adsorption on gold.—The p-polarized differential spectra of adsorbed H_3PO_4 on Au at various potentials are shown in Fig. 9. The H_3PO_4 peak at 1074 cm^{-1} , due to P-O vibrations, is distinctly visible (Fig. 9).

In Fig. 10, the H_3PO_4 adsorption peaks are shown as a function of potential. The adsorption increases up to 1.2V and then decreases upon further increase of potential.

Discussion

Significance of signal relative to noise.—The amplitude of the signal of interest from the adsorbed layer being extremely small relative to the total light energy hitting the detector, there may be a considerable noise level associated with the main signal from the adsorbed layer. It is, therefore, desirable to determine the noise level before one may ascribe any apparent peak to molecular vibrations. When the incident IR beam was polarized perpendicularly, the main peak at 1074 cm^{-1} was not observed, but there appeared to be several smaller peaks (Fig. 5b). Since the perpendicularly polarized light does not carry information from the surface layer, the extent of these peaks is then only to be associated with the noise level. The magnitude of the noise level is thus 2×10^{-4} (Fig. 5b), and, therefore, any peaks in $\Delta R/R$ smaller than or equal to 2×10^{-4} may not be ascribed to any molecular bond vibration. In Fig. 5 and 6, thus, only one peak, that at 1074 cm^{-1} , may be safely identified. Some peaks, however, appear periodically, but these are smaller than the noise level and hence are assumed to originate in some experimental artifacts. Experiments giving rise to these results were repeated at least twice.

Spectra such as that shown in Fig. 6 are obtained by subtracting the intensities obtained at 0.0 V from those obtained at the potential shown, the light being parallel polarized. The absorbance peak height or area increased with anodic potential first, reached a maximum at 800 mV, and then decreased with further increase of poten-

²The time required for the diffusion of material for the newly concentrated H_3PO_4 into the space between the electrode and the window may be obtained by applying the equation (25)

$$C_1 = \frac{C_0}{(\pi Dt)^{1/2}} \exp\left(\frac{-x^2}{4Dt}\right) \quad [1]$$

where x is the radius of the electrode, with $x = 0.25 \text{ cm}$ and $D = 10^{-5}$, it is easy to see that C_0/C_1 would be 1 in less than 1h.

Fig. 9. *In situ* differential IR spectrum of adsorbed H_3PO_4 on Au electrode at various potentials.

tial, as shown in Fig. 7. This behavior could not be due to species in solution, and, hence, what we are looking at is the adsorbed layer, as is also supported by the linear variation of the peak height with $\log C$ (Fig. 8). The absorbance peak at 1074 cm^{-1} is due to the P-O vibration in the H_3PO_4 molecule, as discussed in the "Assignment of peaks" section below.

Intensities of IR light reflected from the electrode surface are taken here as a measure of the amount of adsorbed species on the electrode. From gas-phase measurements (26, 30), it is known that the intensity is linearly proportional to the surface concentration, up to a surface coverage of 0.5 for most compounds studied. In the present case of H_3PO_4 adsorption, independent measurements by the radiotracer method in this laboratory (20) show

Fig. 10. Areas of IR peaks at 1074 cm^{-1} on Au normalized to 1 at maximum as a function of the electrode potential.

that in the concentration range studied, the fraction of the surrounding coverage is well below 0.5, and, therefore, the spectral intensities here can be assumed to be linearly proportional to the surface coverage.

Spectral intensities may be used for quantitative determination (30), provided that the extinction coefficient of the IR absorbing species is known. For IR measurements in electrochemistry, the extinction coefficients as a function of surface coverage are unknown. Owing to the difference in refractive indexes in the IR window, in the aqueous solution layer, and in the adsorbed layer, the determination of the extinction coefficient is difficult. However, if the maximum intensity is normalized with respect to the maximum coverage determined independently, *e.g.*, by the radiotracer method (20, 21), then the variation with respect to potential or concentration may be obtained (Fig. 7 and 8).

State of H_3PO_4 in solution.—The possible states of phosphoric acid in aqueous solution are molecular H_3PO_4 and H_2PO_4^- , HPO_4^{2-} , and PO_4^{3-} ions, according to the following dissociation reactions (2)

where K_1 , K_2 , and K_3 are the respective dissociation constants at room temperature. Since the second and third dissociation constants are very low, it may be assumed that the presence of HPO_4^{2-} and PO_4^{3-} in solution is negligible. Owing to the presence of an excess of H^+ ions in solution from the base electrolyte 1M HClO_4 , about 1% of the dissolved H_3PO_4 will dissociate to give $\text{H}_2\text{PO}_4^{2-}$ ions at room temperature. Thus, in solution, there are 99% H_3PO_4 molecules and 1% H_2PO_4^- ions which are to be considered for adsorption.

Assignment of peaks.—According to spectral data, H_3PO_4 has a spectral band at $900\text{--}1100\text{ cm}^{-1}$ due to the P-O stretching vibration (24). The differential spectra of the platinum electrode surface at different potentials with H_3PO_4 in solution are shown in Fig. 6. A major peak appears at 1074 cm^{-1} , which is in the region of P-O stretching frequency. First, confirmation that the peaks originate in H_3PO_4 was obtained by carrying out the same set of experiments without H_3PO_4 in solution. None of the peaks in Fig. 6 appeared (Fig. 5c). Lower noise level in Fig. 5c than Fig. 5a and 5b may be due to reflected light intensity loss due to absorption by H_3PO_4 in the bulk electrolyte.

The major peak at 1074 cm^{-1} first increases with increase of anodic potential, reaches a maximum, and then decreases with further increase of potential (Fig. 7), and, thus, this peak is assigned to the P-O vibrations in molecular H_3PO_4 . If it were due to the P-O vibrations in the H_2PO_4^- ion, then the decrease of this peak with further increase of anodic potential would be difficult to justify.

Horanyi *et al.* (27), in their earlier work on the adsorption of H_3PO_4 on Pt by the radiotracer method, mentioned H_2PO_4^- as the adsorbed species, while, in their later paper (21), the adsorbed species was said to be H_3PO_4 . Since during the radiotracer measurements the P atom was tagged, the amount of adsorption detected by the counter gives the total amount, including both the ionic and molecular species containing P^{32} , and no distinction could be made. However, measurement on gold shows that the IR peak at 1074 cm^{-1} starts decreasing at potential higher than that on Pt: namely, above about 1.1V (Fig. 10), at which oxide formation is significant, and hence the decrease in coverage of the H_3PO_4 species due to the displacement by the oxide layer is consistent. Reasonable symmetry of the curve is suggestive of displacement by the adsorbed water molecules. Although the main spectral peak on Pt and Au appear at the same frequency, namely, at 1074 cm^{-1} , the noise level in spectra on Pt (Fig. 6) is far higher than on Au (Fig. 10). This may be due to a greater degree of adsorption of H_3PO_4 on Au than on Pt.

Calibrating radiotracer measurement was only done on Pt, but not on Au, so that this observation remains without confirmation.

Precise calculation of the relative displacement of molecular and ionic species in any reasonable way is impeded by the absence of dipole moment data on H_3PO_4 [cf. Ref. (31)]. The necessary dipole moment to fit the result is 2.5 D (cf. $\mu_{\text{HNO}_3} = 2.16$ D) (31). With respect to the ionic model, the same number of water molecules have to be replaced. A rough calculation (neglecting lateral repulsion and imaging) of the electrostatic bond for ions at 0.8V (i.e., ca. 0.5V positive to the pzc) would be $E_{\text{FI}} = (4\pi qe_0 r_i)/\epsilon$, where q , e_0 , r_i , and ϵ represent electrode charge, charge of an electron, radius of the ion, and dielectric constant at the interphase, respectively. With $\epsilon = 6$, $r_i = 3\text{\AA}$, $q = 10 \mu\text{C cm}^{-2}$, the field ion interaction energy is $E_{\text{FI}} = 9 \times 10^{-13}$ erg. The field dipole interaction is $E_{\text{FD}} = 4\pi\mu q/\epsilon \approx 1.6 \times 10^{-13}$ erg, i.e., about 6 times less than the ion field interaction. Thus, the ions will be preferentially attracted to the electrode. But the number of H_2PO_4^- ions is about 6.6×10^{-5} mol/liter, while that of H_3PO_4 molecules is 6.6×10^{-3} mol/liter. From the radiotracer measurement, the coverage at 0.8V is 2×10^{-10} mol/cm², which corresponds to 1.2×10^{14} phosphorous containing species per centimeter squared. But the ionic H_2PO_4^- present in solution at a concentration of 6.6×10^{-5} mol/liter corresponds to 1.13×10^8 ion/cm², which seems negligibly small compared to the surface concentration. However, ions may diffuse into the double layer from the solution, and from Eq. [1], and with $x = 10\text{\AA}$, one may see that H_2PO_4^- diffusion will take ca. 25 min to diffuse into the diffuse layer to correspond to the amount of the observed amount of adsorption. While this is plausible, the adsorption of molecular H_3PO_4 which was present at 2 orders of magnitude higher concentration seems favorable, and the experimental results fit reasonably well with the theoretical adsorption model (29) based on the molecular nature of the adsorbing species (cf. next section).

The adsorption isotherm.—As shown in Fig. 8, the surface concentration of H_3PO_4 varies linearly with the logarithm of concentration of H_3PO_4 in solution at constant potential. A Temkin isotherm may be applicable. Thus

$$f(\theta) = A \log KC$$

where A is a constant, θ is the fraction of the surface covered, C is the concentration of H_3PO_4 in solution, and K is the adsorption equilibrium constant.

At 800 mV, the surface concentration is 20×10^{-11} mol/cm², and if the area occupied by a single H_3PO_4 molecule is 12\AA^2 based on the molecular dimension of the H_3PO_4 molecule, then the maximum fraction of the surface covered is only 0.15 and then the validity of the application of the Temkin isotherm becomes questionable. But molecular adsorbed species may be laid down on second nearest neighbor platinum sites (28) with water molecules in between (Fig. 11); then the area occupied by each H_3PO_4 molecule would be closer to 35\AA^2 , so that the surface coverage would really be ~ 0.42 in 6.6×10^{-3} mol dm⁻³ H_3PO_4 solution with the electrode at 800 mV. This is within the Temkin-type isotherm range. Surface heterogeneity also contributes to the Temkin-type behavior.

Decrease of surface coverage at potentials higher than 800 mV may be caused by two factors: (i) displacement by the oxide layer on Pt, and (ii) displacement by the water.

Pt-O starts forming from 800 mV, and, if the oxide layer were responsible for the decrease of θ , then the near symmetry of the θ -V curve around θ_{max} seems unexpected; the coverage should decrease more rapidly with the increase of the oxide layer.

However, measurement on gold shows that θ starts decreasing from a higher potential (Fig. 10) of about 1.1V, the potential of gold oxide formation. This is consistent with the suggestion that the adsorbed species are being displaced by the strongly adsorbed O species. However, the symmetry of the θ -V curve still remains and suggests that molecular H_3PO_4 continues to adsorb on the oxide

POSITIVE TO P.Z.C.:

layer and that the gradual decrease of θ occurs by the displacement of H_3PO_4 by the adsorbed water molecules. The adsorption isotherm may, thus, be represented by

$$\ln \frac{\theta}{e^{n-1}(1-\theta)^n} - r\theta = \frac{X_{\text{H}_3\text{PO}_4} K_{\text{H}_3\text{PO}_4}}{X_{\text{H}_2\text{O}}^n K_{\text{H}_2\text{O}}^n} \quad [5]$$

where the logarithmic term is the configurational term given by Dhar *et al.* (28) for the process of adsorption by water displacement, r is the Temkin factor representing lateral interactions between the adsorbed H_3PO_4 mole-

Fig. 12. Fraction of the surface covered, $\theta = \Gamma/\Gamma_{\text{max}}$, where Γ_{max} is the maximum surface concentration obtained on the basis of 35\AA^2 area occupied by one H_3PO_4 molecule as a function of potential. a: Experimental data obtained from the normalized IR peak at 1074 cm^{-1} . b: θ obtained from Eq. [5] with adsorption equilibrium constants obtained from the water displacement theory of Bockris *et al.* (29) with $En/RT = 2$, $\Delta\Delta G_s = 2RT$, and $r = 1$, where E is the lateral interaction energy between the adsorbed water molecules and $\Delta\Delta G_s$ is the difference in the free energies of adsorption for the solvent molecules having different orientation at the pzc.

cules, n is the number of water molecules displaced by one phosphoric acid molecule, X is the mole fractions, and K is the adsorption equilibrium constant.

The ratio of the equilibrium constants was calculated from the "adsorption with competition with water" theory of Bockris *et al.* (29). Equation [5] was used to obtain the surface coverage, θ , and is represented in Fig. 12. The nature of adsorption of H_3PO_4 regarding its variation with potential is thus explainable in terms of the molecular theory based on water displacement.

Conclusions

1. The combination of radiotracer and FTIR measurements allows quantitative determination of adsorption of IR absorbing species in aqueous solution on electrodes.

2. H_3PO_4 adsorbs on Pt, giving IR peaks from the P-O vibrational mode.

3. The potential dependence of the adsorption depends at least partly on water desorption, although an influence from oxide film formation at anodic potentials would be consistent with the results.

4. The concentration dependence of $\theta_{H_3PO_4}$ is temkinian.

Acknowledgments

The authors are grateful to Dr. S. Pons for his introduction to them of the principles of the FTIR method in electrochemical systems, and for several discussions. Discussions with Dr. John Appleby in respect to H_3PO_4 orientation and modeling has proved fruitful. Dr. Kunimatsu's comments on the experimental setup are acknowledged. Thanks are also due to Mr. J. Carbajal for the radiotracer measurements. Financial support for this work from the Electrical Power Research Institute and the National Foundation for Cancer Research is acknowledged. This work would not have been possible without the continued interest of Dr. Hampton Robinson, Jr., in scientific work associated with improvement in environmental quality and the corresponding financial support in the purchase of equipment.

Electrochemical Behavior of Organic Compounds at the (SN)_x Paste Electrode

Graham Cheek* and Pamela A. Horine

Naval Research Laboratory, Surface Chemistry Branch, Chemistry Division, Washington, DC 20375

ABSTRACT

The electrochemical characteristics of several types of organic compounds have been investigated at the (SN)_x paste electrode in acetonitrile/TEAP solution. The current density for reduction of benzoquinone in the presence of protons, formed either by hydroquinone oxidation or by addition of HClO₄ to benzoquinone, was found to be considerably less than that for this process at platinum or vitreous carbon. A similar effect was observed for proton reduction at (SN)_x paste, indicating, as for (SN)_x single-crystal electrodes, a high hydrogen overpotential for the electrode surface. Comparative experiments investigating the redox behavior of the benzoquinone/hydroquinone system in aqueous media at (SN)_x paste indicate that slow protonation kinetics are involved in the voltammetric behavior observed for this system. Electrochemical oxidation of representative aromatic amines and hydrocarbons (including phenothiazine, N,N-dimethyl-o-phenylenediamine, N,N-dimethylaniline, 2,3-diphenylindole, 2,3-benzanthracene, and perylene) involved behavior similar to that observed at platinum, showing that the oxidized species produced, both stable and unstable, undergo no specific interaction with the electrode surface. Oxidation of pyrrole occurs at the anodic background limit of (SN)_x paste, producing a black film on the electrode surface which has voltammetric properties similar to those of polypyrrole films formed at other electrodes. Although the heterocyclic compounds pyridine, quinoline, and acridine are not themselves oxidizable in the (SN)_x paste potential range, addition of these compounds caused the appearance of an oxidation process at a potential approximately 100 mV negative of the (SN)_x anodic background oxidation. The dependence of the current observed for the process upon heterocycle concentration indicates that the process corresponds to a shift of the (SN)_x oxidation caused by a nucleophilic interaction of the heterocycles with the (SN)_x as it undergoes oxidation. Further negative shifts in the potential for (SN)_x oxidation were observed in the presence of several alkylpyridines having greater nucleophilicities than that of pyridine itself. Addition of the less nucleophilic compound thiazole did not produce this effect. These results indicate that the oxidation of (SN)_x itself leads to the formation of rather reactive products, while the (SN)_x surface behaves essentially as a noninteracting, metallic electrode in the potential region between +0.95 and -0.40V vs. SCE, over which (SN)_x is electrochemically stable in acetonitrile.

Polythiazyl, or (SN)_x, has been studied extensively over the past several years and has been found to possess very interesting physical and chemical properties (1, 2). The high conductivity of this substance allows its use as an electrode material, and several reports have appeared describing electrochemical investigations at (SN)_x single-crystal electrodes (3-5). These studies have involved characterization of the electrodes in aqueous media by establishing potential limits for anodic and cathodic background processes (3, 4), studying the effect of alkali metal cations on these potentials (4), surface modification by metal cations (5), and observation of the electrochemical behavior of both inorganic (Pb, Ru systems) and organic species (hydroquinone) in solution (4). Recently, a more convenient electrode system has been devised in which the (SN)_x fibrils are thoroughly mixed with Apiezon M grease (6). The background potential limits for this (SN)_x paste electrode are similar to those of the (SN)_x single-crystal electrode, although the background currents are much lower at the (SN)_x paste electrode (6). Initial work on this system has shown that the cathodic background process involves the depolymerization of (SN)_x, while the anodic background process involves the oxidation of (SN)_x to as yet undetermined products (6).

It was decided to study the electrochemical behavior of a wide range of organic compounds at the (SN)_x paste electrode in order to compare the results to those obtained at other electrodes, including the (SN)_x single-crystal electrodes. It is evident from the available potential range at (SN)_x paste [+0.95 to -0.40V vs. SCE in AN/TEAP (6)] that certain classes of organic compounds which are difficult to oxidize or reduce, such as ketones, halogen-substituted compounds, conjugated π systems, etc. (7, 8), cannot be studied at this electrode. However, several classes of organic compounds, electrochemical studies of which abound, can be investigated, including aromatic amines, quinones, and certain heterocyclic systems (7, 8). Of particular interest in this study is the possibility of specific interactions between the (SN)_x paste and the organic compounds or their redox products and the corresponding effect on their electrochemical behavior. The results of these investigations are reported herein.

Experimental

Cyclic voltammetric experiments were carried out using a PAR 173 Potentiostat/Galvanostat with Model 179 Digital Coulometer (affording iR compensation), a Model 175 Universal Programmer, and a Houston 2000 X-Y recorder. Some experiments utilized a Bioanalytical Systems CV-1B electrochemical instrument and produced the same results. A PAR Model 174A Polarographic Analyzer was used for normal pulse and differential pulse voltammetric experiments. Potentials in this work are reported with respect to a NaCl SCE reference electrode.

Pyridine (99+%, Gold Label), thiazole, perylene (99+%), and 2,3-benzanthracene (tetracene) were used as received from Aldrich Chemical Company. Phenothiazine, acridine, chloranil, p-benzoquinone, and hydroquinone were recrystallized from absolute ethanol or ethanol/petroleum ether mixture. N,N-dimethylaniline and quinoline were purified by reduced-pressure distillation. 2,3-Diphenylindole was prepared and purified as described previously (9).

Acetonitrile (Burdick and Jackson) was dried over 4Å molecular sieves prior to use. Tetraethylammonium perchlorate (Southwestern Analytical Chemicals) was dried under vacuum at 70°C and stored in a desiccator over calcium sulfate.

Polythiazyl, (SN)_x, was synthesized as described previously (10). Owing to the explosion hazard associated with the S₄N₄ intermediate involved in this preparation (11), appropriate safety procedures should be followed (12). (SN)_x paste electrodes were prepared by mixing a 2:1 ratio of (SN)_x to Apiezon M grease, a composition previously found to produce optimum results (6). The paste was then packed into disposable pipettes, electrical contact being made with a platinum wire.

Results and Discussion

Quinones.—As seen in Fig. 1, the electrochemical behavior of hydroquinone (H₂Q) at the (SN)_x paste electrode is in many ways similar to that observed at platinum (13). Both curves show the oxidation of H₂Q, followed by a process on the return sweep for reduction of BQ in the presence of protons liberated upon H₂Q oxidation. In pre-

Fig. 1. Cyclic voltammograms of hydroquinone in AN at (a) $(\text{SN})_x$ paste and (b) platinum. $\text{H}_2\text{Q} = 3.0 \text{ mM}$; scan rate = 100 mV/s .

vious work at platinum (13), this reduction process was described as a "Q/H⁺ wave," indicating that the existence of protonated BQ as the predominant species in solution is in doubt. Since the same general situation is presumably involved at $(\text{SN})_x$ paste, this description of the reduction process will also be used in this work. As at platinum and vitreous carbon, the H_2Q oxidation process was found to be diffusion controlled at $(\text{SN})_x$ paste, a plot of i_p vs. $v^{1/2}$ being linear over the range $10\text{--}350 \text{ mV/s}$. In comparison to the behavior seen at platinum, however, the current response for the reduction process at $(\text{SN})_x$ paste is greatly diminished relative to that for the oxidation process. This phenomenon was also observed using reverse normal pulse voltammetry, scanning toward more negative potentials from an initial potential corresponding to E_p for H_2Q oxidation. Further experiments were carried out in order to determine the cause of the rather low current observed for the Q/H⁺ reduction process.

The proximity of the H_2Q oxidation process to the anodic background limit suggested the possible interaction of $(\text{SN})_x$ oxidation products with the oxidized quinone, thereby lowering the amount of quinone (oxidized form) available for reduction and giving rise to the above effect. In order to determine whether any of the various possible H_2Q oxidation products were involved in such an interaction, an $(\text{SN})_x$ paste electrode was cycled (100 mV/s) several times in a 2.0 mM H_2Q solution between the H_2Q redox processes. No new peaks appeared during these scans, and it was noted that the oxidation peak current on the second and successive sweeps were only slightly lower than that seen on the first sweeps. After cycling, the electrode was transferred to a fresh AN/TEAP solution. A voltammogram taken in this solution, while having a somewhat higher background current than that usually observed at a freshly prepared electrode, did not reveal any well-defined processes, the observation of which would indicate the presence of electroactive surface-bound species (14). These results indicate that a decrease in the amount of quinone at the electrode surface, caused by interaction with anodic breakdown products, does not seem to be the cause of the low current observed for Q/H⁺ reduction.

This reduction process was further investigated in both acetonitrile (AN) and aqueous media, adding 0.1 M HClO_4 as a proton source to benzoquinone (BQ) solutions. In AN, the effects of HClO_4 addition were followed at vitreous carbon and platinum electrodes and were similar to those found by previous workers (15). After addition of a 2:1 molar ratio of HClO_4 :BQ, only the Q/H⁺ process was observed at vitreous carbon and platinum. At $(\text{SN})_x$ paste, a very ill-defined reduction wave, corresponding to that seen on the return sweep in Fig. 1, was seen, the current density of which was smaller by a factor of 7 compared to that at vitreous carbon and platinum. In this study, it was assumed that the geometrical and electrochemical areas of the $(\text{SN})_x$ paste electrodes were essentially the same (6); addition of hydroquinone (H_2Q) to the solution and observation of the relative peak currents for H_2Q oxidation at the various electrodes supported this assumption. Considering the results observed at single-crystal $(\text{SN})_x$ electrodes in aqueous solutions, at which well-defined reduction processes for the protonated quinone were seen (4), it is clear that either the medium involved or the presence of the hydrocarbon (Apiezon M) in the $(\text{SN})_x$ paste has profoundly affected the reduction of the protonated quinone. It was deemed necessary to carry out further experiments in order to differentiate between these factors.

Voltammetric experiments of the $\text{H}_2\text{Q}/\text{Q}$ system at $(\text{SN})_x$ paste electrodes were also performed in aqueous media, both to allow comparison with results at $(\text{SN})_x$ single crystals (4) and to more clearly define the effect of solvent in reduction of the protonated quinone. In 1.0 M acetate buffer (pH 5) at $(\text{SN})_x$ paste, the cyclic voltammogram for the H_2Q system in Fig. 2 shows that the peak current ratio of Q/H⁺ reduction to H_2Q oxidation is similar to that for the H_2Q system at $(\text{SN})_x$ single-crystal electrodes (pH 5 acetate buffer) (4), and is much greater than that observed at $(\text{SN})_x$ paste in AN/TEAP.

Other experiments involved quinone reduction in aqueous 0.1 M KClO_4 solutions with variation of solution acidity by addition of 0.1 M HClO_4 . Cyclic voltammograms of BQ reduction at vitreous carbon (Fig. 3a), as well as at platinum, revealed a 105 mV peak separation for the reduction and oxidation processes, behavior which has been noted at platinum (16) and at carbon paste electrodes (17, 18). At $(\text{SN})_x$ paste, the voltammogram in Fig. 3b shows that the quinone reduction process is somewhat broader than that seen at vitreous carbon or platinum, while the following oxidation process is very poorly defined. It appears, however, that oxidation back to the quinone occurs very gradually during the passage through this region, since the height of the quinone reduction peak observed in the second sweep is only slightly less than that observed in the first sweep. This behavior is thought to be due to slow deprotonation kinetics at the $(\text{SN})_x$ paste electrode surface, since the corresponding results at vitreous carbon and platinum are rather uncomplicated (Fig. 3a).

Addition of 0.1 M HClO_4 to the above solution (1:1 HClO_4 :BQ) caused a shift of the reduction process at vit-

Fig. 2. Cyclic voltammogram of hydroquinone in pH 5 acetate buffer at $(\text{SN})_x$ paste. $\text{H}_2\text{Q} = 92 \text{ mM}$; scan rate = 20 mV/s .

Fig. 3. Cyclic voltammograms of benzoquinone in aqueous 0.1M KClO_4 . Scans taken at: (a) vitreous carbon; (b) $(\text{SN})_x$ paste; (c) vitreous carbon, 1:1 HClO_4 :BQ; (d) $(\text{SN})_x$ paste, 1:1 HClO_4 :BQ. BQ = 1.6 mM; scan rate = 100 mV/s.

reous carbon to a more positive potential, as seen in Fig. 3c. The rather large potential separation for the redox processes indicates considerable irreversibility in the associated protonation equilibria. Voltammetry at $(\text{SN})_x$ paste (Fig. 3d) shows a very gradual reduction process, the current density for which is much higher than that seen for the Q/H^+ process at $(\text{SN})_x$ paste in AN. The reduction process consists of a broad peak, the potential of which corresponds to that for Q/H^+ reduction at vitreous carbon. Oxidation of H_2Q formed in the reduction occurs immediately before the anodic background limit, resulting in nearly identical behavior in the second cathodic sweep to that seen in the first sweep. Further addition of acid (2:1 HClO_4 :BQ) did not improve the resolution or change the relative sizes of the redox processes.

Comparison of the results found in different media provides some insight into the nature of the Q/H^+ process at $(\text{SN})_x$ paste. An important observation is that Q/H^+ reduction proceeds easily both at platinum in AN and at $(\text{SN})_x$ paste in aqueous media. It appears, then, that neither the presence of the nonpolar grease (Apiezon) used in the $(\text{SN})_x$ paste nor the relatively nonpolar AN medium can account entirely for the diminished current observed for the Q/H^+ reduction at $(\text{SN})_x$ paste in AN. The most likely explanation for this behavior is that the effects of the lower dipole moment of AN and the nonpolar character of the Apiezon grease combine to create a situation (*i.e.*, a general nonpolar environment) in which the protonation kinetics in the Q/H^+ system are slow at the electrode surface. Unfortunately, the amount of quinone not involved in the Q/H^+ process at $(\text{SN})_x$ paste could not be determined since its reduction potential (observed at vitreous carbon and platinum) is negative of the $(\text{SN})_x$ paste cathodic background limit. Further investigation in AN/ NaClO_4 solutions produced results which are similar to those in AN/TEAP, indicating that the nature of the supporting electrolyte cation is not critically involved in this effect. It is also possible that the electrode kinetics for Q/H^+ reduction are slow, as observed at platinum (13). The fact that reduction of other positively charged species (*e.g.*, *N,N*-dimethyl-*p*-phenylenediamine cation radical) at $(\text{SN})_x$ paste occurs readily, however, favors the involvement of slow protonation kinetics in the benzoquinone system.

p-Chloranil was chosen as another example in this study, since the reduction of the quinone to its anion radical is observable within the $(\text{SN})_x$ paste potential range (19). Cyclic voltammetric investigations of chloranil at $(\text{SN})_x$ paste showed reversible behavior ($\Delta E_p = 60$ mV) for the first reduction process of this system.

Aromatic amines.—In view of the wide variety of aromatic amines which have been studied at other electrodes (7, 20), a survey was also undertaken of several of these systems at $(\text{SN})_x$ paste. These systems were chosen on the basis of stability of their cation radicals, examples of both stable and unstable species being included.

Two reversible one-electron systems were observed for *N,N*-dimethyl-*p*-phenylenediamine at $(\text{SN})_x$ paste, the potentials for which were similar to those observed at Pt (Table I) (21). This result indicates that the oxidized species involved do not undergo chemical reaction with the $(\text{SN})_x$ paste surface in the potential range studied; in other words, the surface is acting as a metallic conductor with no particular affinity for the radicals produced during oxidation of this compound.

The electrochemical behavior of *N,N*-dimethylaniline (DMA) at $(\text{SN})_x$ paste was found to be very similar to that previously observed at platinum (22). The principal aspects of this oxidative pathway involve the initial production of the cation radical by oxidation, followed by a rapid coupling reaction to form benzidine, which is itself oxidized at the potential for *N,N*-dimethylaniline oxidation. At both $(\text{SN})_x$ paste and Pt electrodes, this behavior is manifested by a large DMA oxidation process, with two one-electron reversible systems at slightly less positive potentials, corresponding to benzidine redox processes. Although the peak currents for the benzidine processes at $(\text{SN})_x$ paste were slightly lower in relation to that for the primary oxidation than is the case at platinum, it is again apparent that the $(\text{SN})_x$ paste surface itself does not dramatically alter the electrochemical oxidation pathway for this system.

Heterocyclic aromatic systems.—For this class of compounds, it was found that the electrochemical behavior of those compounds electroactive within the potential range of $(\text{SN})_x$ paste was usually similar to that observed at other electrodes. Phenothiazine (Table I), for instance, was oxidized in two reversible one-electron steps at potentials close to those found at platinum (23). 2,3-Diphenylindole, the cation radical of which undergoes a rapid coupling reaction at platinum (9), was also found to be irreversibly oxidized at $(\text{SN})_x$ paste, although the product oxidation process [+1.2V at Pt (9)] could not be observed at $(\text{SN})_x$ paste.

Pyrrrole oxidation was observed at a potential corresponding to the anodic potential limit and, while no clear oxidation process was seen, led to the formation of a black deposit on the $(\text{SN})_x$ paste electrode surface. It has long been known that electrochemical oxidation of pyrrole at other electrodes produces a polymeric film on the electrodes (24), and recent work by Diaz *et al.* (25, 26) has demonstrated the formation of a conducting polypyrrole film under these conditions.

Investigation of this system on platinum by cyclic voltammetry has shown fairly well-defined processes for the redox behavior of the polypyrrole (26). The cyclic voltammetric behavior of the film on $(\text{SN})_x$ paste was found to be qualitatively similar to these previous results, the redox processes being much broader and less well-

defined in the present case. Other characteristics of the film, such as its physical adherence and stability upon exposure to air, were similar to those of the film formed at platinum. One interesting possibility in the present work is that the concurrent oxidation of $(\text{SN})_x$ and pyrrole may have some effect on the nature of the film produced, possibly explaining the broader redox processes for the polypyrrole film formed on $(\text{SN})_x$ as compared to that at platinum.

Other heterocyclic systems, the electrochemical behavior of which were not directly observable in the $(\text{SN})_x$ paste potential range, were nevertheless found to produce an interesting effect on the anodic background process. For heterocycles such as pyridine, quinoline, and acridine, addition of these compounds to AN/TEAP solution caused the appearance of an oxidation process approximately 100 mV negative of the usual anodic potential limit. Cyclic voltammetric responses for this process were poorly resolved from the background oxidation; however, better resolution was obtained using differential pulse voltammetry (Fig. 4), the peak currents increasing linearly with increasing concentration of the heterocycles. Since the potentials ($E_{p/2}$) for quinoline and acridine oxidation at platinum occur at +1.97 and +1.58V vs. SCE (27), respectively, while pyridine gives rise to a very poorly defined oxidation process at these potentials (28), it seems likely that the observed responses at $(\text{SN})_x$ paste are not due to the oxidation of the heterocycles themselves, but are due to a lowering of the potential necessary for $(\text{SN})_x$ oxidation, caused by some sort of interaction between the $(\text{SN})_x$ and the added heterocycles. The most likely form of this interaction involves a nucleophilic attack of the heterocycle on the oxidized $(\text{SN})_x$ species, which would be positively charged. This phenomenon is analogous to the oxidation of mercury in the presence of various anions and chelating agents (29-31). This sort of "complexation" should cause the $(\text{SN})_x$ to be more easily oxidized, the extent of this effect being proportional to the amount of the heterocycle at the surface, accounting for the concentration dependence of the current observed for the process. This phenomenon was further investigated by observing the oxidation processes caused by individual pyridines in a series of alkylpyridine derivatives having various nucleophilicities. The compounds chosen for study are given in Table II, along with differential pulse voltammetric peak potentials for $(\text{SN})_x$ oxidation in the presence of these pyridines. Figure 4 illustrates the effect of these pyridines on the $(\text{SN})_x$ oxidation process. As in the case of pyridine itself, the peak heights for the processes depend linearly on concentration in the range 1-20 mM. None of these pyridines was found to be itself electrochemically active at platinum or vitreous carbon in the potential region of interest. The negative shift in peak potential for $(\text{SN})_x$ oxidation in the presence of 4-methylpyridine compared to that in the presence of pyridine itself is apparently due to the greater nucleophilicity of 4-methylpyridine with respect to that of pyridine, as has been observed in other reactions (32-33). An even larger decrease in the potential for $(\text{SN})_x$ oxidation is observed in the presence of 2,4,6-trimethylpyridine, which is expected if the trend in nucleophilicity follows that in basicity (32) [$pK_a = 5.21$ for pyridine and 7.51 for 2,4,6-trimethylpyridine in water (34)]. The potential value in the case of 2,6-dimethylpyridine seems somewhat anomalous in this

Table II. Differential pulse voltammetric peak potentials for $(\text{SN})_x$ oxidation. Effect of pyridine addition

Differential pulse voltammetric conditions are as described for Fig. 4.

Fig. 4. Electrochemical behavior of $(\text{SN})_x$ paste in AN containing various pyridines. Differential pulse voltammograms at $(\text{SN})_x$ paste containing (a) no added pyridine (background curve), (b) 0.62 mM pyridine, (c) 0.51 mM 4-methylpyridine, and (d) 0.38 mM 2,4,6-trimethylpyridine. Scan rate = 5 mV/s; modulation = 25 mV; drop time = 0.5s.

series [$pK_a = 6.65$ in water (34)] and may reflect the predominance of steric effects for this molecule (33). The fact that addition of thiazole [$E_{1/2} = +2.2\text{V}$ at platinum (35)], a weaker nucleophile than those studied above (36), produced only a slight negative shift in the anodic potential limit (i.e., with no discernible peak) supports the above explanation that the observed shifts in potential are due to an interaction between the nucleophiles and the oxidized $(\text{SN})_x$.

Aromatic hydrocarbons.—The potentials for oxidation of aromatic hydrocarbons in nonaqueous media generally are greater than +1.0V vs. SCE (37), greatly restricting those amenable to study at $(\text{SN})_x$ electrodes. It was found, however, that oxidation of both perylene and 2,3-benzanthracene (tetracene) could be observed at +0.98 and +0.82V vs. SCE, respectively, at $(\text{SN})_x$ paste, in fairly good agreement with results obtained in the same medium at platinum electrodes (38) (Table I).

The reversible nature of the one-electron oxidation of perylene, observed in this work at platinum and vitreous carbon and in nitrobenzene by others (39), was also evident at $(\text{SN})_x$ paste, although measurements of relative anodic and cathodic peak currents could not be made, owing to the proximity of the process to the anodic potential limit. Under the present conditions, oxidation of 2,3-benzanthracene was found to be irreversible at $(\text{SN})_x$ paste as well as at platinum and vitreous carbon.

Conclusions

From the preceding discussion, it is evident that, for the $(\text{SN})_x$ paste electrode, there is no apparent interaction between the $(\text{SN})_x$ in the electrode and the oxidized or reduced solute species studied, regardless of the stability of

the initially generated species. Specific effects are observed, however, upon oxidation of the (SN)_x itself, as seen with the interaction between nitrogen heterocycles and the (SN)_x oxidation product. The low reduction current for protonated benzoquinone at (SN)_x paste in acetonitrile is thought to be due primarily to a medium effect, while the high overpotential observed for proton reduction seems to be a more general characteristic of (SN)_x since it is also observed at single-crystal (SN)_x electrodes.

Characterization of Chloroclosoborane Acids as Electrolytes for Acid Fuel Cells

M. W. Rupich,* J. S. Foos,* and S. B. Brummer*

EIC Laboratories, Incorporated, Norwood, Massachusetts 02062

ABSTRACT

The perchloroclosoborane acids, H₂B₁₂Cl₁₂ and H₂B₁₀Cl₁₀, were prepared in high purity and investigated as alternative electrolytes to H₃PO₄ in moderate temperature acid fuel cells. Procedures were developed for the purification of the acids prepared from commercially available salts. The purified acids were characterized by infrared, electronic, NMR, and mass spectroscopy. Concentrated aqueous solutions of the acids were found to have low ionic conductivity and a moderate water vapor pressure. The mono anions, B₁₂Cl₁₂⁻ and B₁₀Cl₁₀⁻, formed from reactions of concentrated aqueous solutions or the solid hydrates of the acids. The B₁₂Cl₁₂²⁻ and B₁₀Cl₁₀²⁻ anions were also found to adsorb on electrocatalytic Pt surfaces.

One approach to improving fuel cell performance is to find an electrolyte which is superior to H₃PO₄. In particular, it would be advantageous to find an electrolyte which would allow for more efficient oxidation of H₂/dirty H₂ and more efficient reduction of O₂. This would result in superior fuel cell performance and expand the range of

* Electrochemical Society Active Member.

acceptable fuels. In addition, any electrolyte which replaces H₃PO₄ in an acid fuel cell must meet the following requirements: good ionic conductivity, thermal stability in solution to ≥200°C, electrochemical stability between 0.0 and 1.0V (RHE), low vapor pressure and high viscosity, and preferably compatibility with existing fuel cell components.

Two materials we have evaluated as alternative electrolytes are the inorganic acids $H_2B_{12}Cl_{12}$ and $H_2B_{10}Cl_{10}$. The chloroclosoborane anions, $B_{12}Cl_{12}^{2-}$ and $B_{10}Cl_{10}^{2-}$, are two examples of a unique class of inorganic compounds characterized by their exceptional stability. The structure of the anions consists of clusters of borons each attached to a terminal Cl^- , as shown in Fig. 1. The reported properties of the chloroclosoboranes include exceptional thermal stability (some alkali metal salts are stable to $>600^\circ C$), good chemical and electrochemical stability, and high solution conductivities (1-7). The acids, $H_2B_{12}Cl_{12}$ and $H_2B_{10}Cl_{10}$, have been characterized as stronger than H_2SO_4 (1). The reported properties of these chloroclosoborane anions suggested that their acids may be useful as electrolytes in acid fuel cells. In this paper, we report on the preparation, purification, and characterization of $H_2B_{12}Cl_{12}$ and $H_2B_{10}Cl_{10}$.

Experimental

Synthesis and purification of $H_2B_{12}Cl_{12}$.— $H_2B_{12}Cl_{12}$ was prepared from $Li_2B_{12}Cl_{12}$ purchased from Callery Chemical Company. Analyses of two lots of as-received $Li_2B_{12}Cl_{12}$ found B-to-Cl stoichiometries of $B_{12}Cl_{11.6}$ and $B_{12}Cl_{9.4}$, indicating incomplete chlorination of the B_{12} cage. The samples also contained varying amounts of organics, which were predominantly decomposition products of triethylamine used in the synthesis of $Li_2B_{12}Cl_{12}$ (8).

$Li_2B_{12}Cl_{12}$ was purified and converted to the acid as follows: an aqueous solution of $Li_2B_{12}Cl_{12}$ was passed over neutral alumina resulting in the removal of the organic contaminants. The resulting solution was then converted to the acid by passage over an acidic Dowex 50W-X8 cation exchange resin ($<30\%$ of the column capacity was utilized) or by electrolysis across a Nafion 125 membrane (du Pont). Chlorine gas was then passed through the aqueous acid solution at $85^\circ-90^\circ C$ for 6h, resulting in complete chlorination of the B_{12} cage. Excess Cl_2 was removed by purging the solution with N_2 at $85^\circ C$. The H_2O and HCl were removed under vacuum at $\leq 80^\circ C$, leaving a white, hygroscopic solid. Elemental analysis of the white solid established a B-to-Cl stoichiometry of 1.0. A potentiometric titration and gravimetric analysis established the overall composition of $H_2B_{12}Cl_{12} \cdot 8H_2O$. (Infrared (cm^{-1}): 3620(S), 3440(M), 1610(M), 1220(W), 1030(S), 850(M), 730(W), 650(W), and 540(S). ^{11}B NMR (CD_3CN): $\delta + 12.9$).

Synthesis and purification of $H_2B_{10}Cl_{10}$.— $H_2B_{10}Cl_{10}$ was prepared from $Li_2B_{10}Cl_{10}$ (Callery Chemical Company) using the same procedure as described for $H_2B_{12}Cl_{12}$. The chlorination step was not necessary with the $Li_2B_{10}Cl_{10}$. The composition of the final product was $H_2B_{10}Cl_{10} \cdot 7.5H_2O$. (Infrared (cm^{-1}): 3620(S), 3420(M), 1610(M), 1160(M); sh. at 1190), 1010(S), 855(M), and 535(S). ^{11}B NMR (CD_3CN): $\delta + 5.3$ and 10.6 with a ratio of 1:4.)

Vapor pressure and conductance measurements.—The water vapor pressure-saturation concentration relationship and conductance measurements of aqueous solutions of $H_2B_{12}Cl_{12}$ were obtained at temperatures between 110° and $150^\circ C$. During an experiment, $N_2(g)$ was saturated with a specified H_2O vapor pressure, and then bubbled through a solution of the acid contained in a sealed cell thermostated at a set temperature. The $N_2(g)$ finally

passed through a trap, where any volatile acidic species were trapped. A capillary conductance cell (cell constant of 220 cm^{-1}) built into the flask allowed *in situ* measurement of the ionic conductivity of the $H_2B_{12}Cl_{12}$ solution. Standardization measurements with H_3PO_4 were in excellent agreement with literature values.

Instrumental analysis.—Infrared spectra were recorded on a Beckman Acculab II spectrophotometer. Solid samples were analyzed in KBr disks or Nujol mulls. Mass spectral data were obtained with a Nuclide 1290G mass spectrophotometer at Biomeasure, Incorporated (Hopkinton, Massachusetts). NMR spectra were acquired with a Joel FX-90Q spectrophotometer in either D_2O or CD_3CN (also at Biomeasure). Chemical shifts were referenced to TMS (1H and ^{13}C spectra) or external $^{11}BF_3 \cdot O(C_2H_5)_2$ (^{11}B spectra). Conductivity data were recorded on a YSI Model 30 conductivity bridge at 1000 Hz. Electronic spectra were recorded on a Cary 14 or Shimadzu 210 spectrophotometer in 1 cm matched quartz cells.

Cyclic voltammetry experiments were performed with a PAR Model 173 potentiostat and a PAR Model 175 universal programmer. Data were recorded on a Bascom-Turner Model 4120 electronic recorder. The electrochemical cell consisted of a three-neck flask with a volume of approximately 15 ml. The working electrode was a Pt wire, and the counterelectrode was a Pt loop. The reference electrode was a H_2 gas electrode.

Chemical analyses.—The concentration of $H_2B_{12}Cl_{12}(aq)$ and $H_2B_{10}Cl_{10}(aq)$ was determined by potentiometric titration with standard 0.1N NaOH. The $B_{12}Cl_{12}^{2-}$ ion was also determined gravimetrically as $[(C_2H_5)_4N]_2B_{12}Cl_{12}$. Chloride (to ~ 0.1 ppm) was detected by precipitation as $AgCl$ in alcoholic solution. Elemental analyses were performed by Galbraith Laboratories, Incorporated, Knoxville, Tennessee. All water used was doubly distilled from Barnstead tin stills, then distilled from alkaline permanganate in an all glass system and stored under N_2 .

Results and Discussion

Characterization of $H_2B_{12}Cl_{12}$ and $H_2B_{10}Cl_{10}$.—The purity of the acids was established by chemical and spectral methods. The infrared spectrum of $H_2B_{12}Cl_{12} \cdot 8H_2O$ is shown in Fig. 2. The absence of a B-H absorption in the 2400 cm^{-1} region and the sharpness of the absorption at 540 cm^{-1} confirm the complete chlorination of the B_{12} cage (1, 5). The ^{11}B NMR spectrum of $H_2B_{12}Cl_{12}$ displays only the absorption at 12.9 ppm reported in the literature for $B_{12}Cl_{12}^{2-}$ (1, 9). 1H and ^{13}C NMR spectra of concentrated solutions of $H_2B_{12}Cl_{12} \cdot 8H_2O$ in CD_3CN indicated the level of organics was $<0.01\%$. The electronic spectrum of $H_2B_{12}Cl_{12}(aq)$ prepared with the described procedure, has a weak absorption at 224 nm ($\epsilon < 200\text{ M}^{-1}\text{ cm}^{-1}$).

The complete chlorination of the B_{10} cage was confirmed by the absence of any absorption due to B-H in the infrared spectrum of $H_2B_{10}Cl_{10} \cdot 7.5H_2O$ (1, 5) and by the absence of any B-H resonance in its ^{11}B NMR spectrum (1, 9). The electronic spectrum of $H_2B_{10}Cl_{10}(aq)$ has a maximum at 224 nm ($\epsilon 10,900\text{ M}^{-1}\text{ cm}^{-1}$).

Conductivity and vapor pressure measurements.—Water vapor pressure-saturation-concentration relationships and conductivity measurements were obtained on aqueous solutions of $H_2B_{12}Cl_{12}$ at temperatures between 110° and $150^\circ C$ and water vapor pressures of 250-600 torr. The results are presented in Table I. At $140^\circ C$ and a water vapor pressure of <600 torr, the solution was very viscous. At temperatures $>145^\circ C$, the solution solidified.

No volatile, acidic species were detected coming from the solution during the measurements below $145^\circ C$. During the measurements, the initially colorless solution darkened. The solution, at the end of the measurements, had the electronic spectrum shown in Fig. 3. Gel permeation chromatography (Bio-Beads S-X8 resin) of the aqueous solution did not indicate multiple components. Chemical tests for Cl^- were negative. The infrared spectrum of the solid, after removal of the excess H_2O , is virtually identical to that of the starting material.

Fig. 1. Structures of the $B_{12}Cl_{12}^{2-}$ and $B_{10}Cl_{10}^{2-}$ anions

Fig. 2. Infrared spectrum of $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$ in KBr

After extended measurements at $>150^\circ\text{C}$ a water-insoluble, black material formed along with free Cl^- . The infrared spectrum of the insoluble, black material contains absorptions at 1030 cm^{-1} , indicating retention of the B_{12} cage structure (1, 3). In addition, the infrared spectrum shows absorptions characteristic of B—O bonds at $\sim 1450\text{ cm}^{-1}$. The material was not characterized further, but is probably a polymeric oxygen bridged species such as $(-\text{B}_{12}\text{Cl}_{10}\text{O})_n$ (3, 7).

Chemical and thermal stability.—The solid hydrates and concentrated solutions of both $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10}$ partially decompose when heated above 100°C . $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$, which is initially colorless, turns tan within 1-2h, then progressively darkens when heated to 150°C under vacuum. No infrared detectable gases form during this process. The resulting brown, hygroscopic solid analyzes as the tetrahydrate $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 4\text{H}_2\text{O}$. The infrared spectrum of $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 4\text{H}_2\text{O}$ is virtually identical to that of $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$, except for the O—H bands in the $3400\text{--}3600\text{ cm}^{-1}$ region. The ^1H and ^{11}B NMR spectra of the tetrahydrate are indistinguishable from those of $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$.

When $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 4\text{H}_2\text{O}$ is dissolved in H_2O , the initially brown solution turns violet over a 24h period. The UV spectrum of the tetrahydrate has a maximum at 224 nm , with an intensity that varies from sample to sample.

$\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$ behaves similarly. Heating of $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$ to between 100° and 160°C results in a violet solid that analyzes as the tetrahydrate, $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 4\text{H}_2\text{O}$. The infrared spectrum of the tetrahydrate is virtually identical to that of $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$.

The violet color of the tetrahydrate rapidly disappears upon dissolution in H_2O or exposure to air. However, the color remains for 5-10 min in acetonitrile. The violet solution has maxima at 596 and 421 nm , in a ratio of 2.1 to 1, and at 224 nm . This is the same as that of the monoanion, $\text{B}_{10}\text{Cl}_{10}^-$ which can be prepared by the $1e^-$ oxidation of $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ in acetonitrile (4).

Table I. Specific conductivity ($1/\Omega\text{-cm}$) of $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ and H_2O vapor pressure (mm Hg) over $\text{H}_2\text{B}_{12}\text{Cl}_{12}$

110°C			133°C		
Vapor pressure	w/o $\text{H}_2\text{B}_{12}\text{Cl}_{12}$	Specific conductivity	Vapor pressure	w/o $\text{H}_2\text{B}_{12}\text{Cl}_{12}$	Specific conductivity

500	47.5	0.360	600	51.3	0.239
600	47.0	0.373			

We believe the changes in $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10}$ during heating result from dehydration of the acids. To verify this, solutions of $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$ and $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$ in acetonitrile were dried by passage over 4 \AA molecular sieves. The spectra of the resulting pale violet solutions were that of the $\text{B}_{10}\text{Cl}_{10}^-$ and presumably the $\text{B}_{12}\text{Cl}_{12}^-$ monoanions, respectively.

$\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$ can also be dehydrated to the tetrahydrates at room temperature by storing them over P_2O_5 under vacuum. Over a 1-2 week period, the solids obtain the violet color of the monoanions. The violet color rapidly fades upon exposure to the atmosphere.

In contrast, dilute ($0.2M$) aqueous solutions of $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ are indefinitely stable when stored in sealed tubes at 110°C .

The intensities of the visible absorptions of the monoanions indicate that $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 4\text{H}_2\text{O}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 4\text{H}_2\text{O}$ are not quantitatively converted to the monoanions under any of the above conditions. The formation of the monoanions can be explained by the disproportionation reactions

Reactions that may involve similar mechanisms have been reported with the hydrides, $\text{H}_2\text{B}_{12}\text{H}_{12}$ and $\text{H}_2\text{B}_{10}\text{H}_{10}$ (10).

The insoluble precipitate observed in the conductivity-vapor pressure measurements of $\text{H}_2\text{B}_{12}\text{Cl}_{12}(\text{aq})$ likely

Fig. 3. Electronic spectrum of an aqueous solution of $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ after conductivity and water vapor pressure measurements at temperatures between 110° and 140°C .

Fig. 4. Cyclic voltammograms of 50 mM $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ in 0.5M H_2SO_4 (—) and 0.5M H_2SO_4 (---) on a Pt wire electrode at a scan rate of 20 mV/s vs. RHE.

formed from reactions of the monoanion such as (6, 10, 11)

The differences in the reaction of $\text{HB}_{12}\text{Cl}_{12}$ and $\text{HB}_{10}\text{Cl}_{10}$ with water and the resultant products reflect the differences in the electronic properties of the B_{12} and B_{10} structures which have been found with the hydrides (1, 10, 11). The final products of these reactions, which depend on the experimental conditions, were not investigated.

The formation of the violet color upon dehydration of $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$ to the tetrahydrate has been reported previously, but was attributed to unknown impurities in the material (12, 13).

Solid-probe mass spectral analysis of $\text{H}_2\text{B}_{12}\text{Cl}_{12} \cdot 8\text{H}_2\text{O}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10} \cdot 7.5\text{H}_2\text{O}$ shows that both decompose below 200°C. The most intense mass ion peaks in the $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ spectrum correspond to HCl (m/e of 36) and B_8Cl_6 (m/e of 298). The major mass ion peaks from $\text{H}_2\text{B}_{10}\text{Cl}_{10}$ correspond to HCl (m/e of 36), BCl_2 (m/e of 81), and B_9Cl_7 (m/e of 344). Both compounds show other mass peaks which can be assigned to various B_xCl_y fragments. It should be noted that the experimental setup prohibited measurement of m/e values of <20 . Thus the formation of H_2 , as suggested in Eq. [1] and [2], was not verified.

Electrochemical characterization of $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10}$.—A cyclic voltammogram of a solution of 50 mM $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ and 0.5M H_2SO_4 on a Pt electrode is shown in Fig. 4, along with a cyclic voltammogram of 0.5M H_2SO_4 . The suppression of the formation of the oxide layer on the Pt and the shift in the potential of the hydrogen reduction and oxidation peaks is characteristic of anionic absorption on the Pt surface.

The electrochemical behavior of solutions of $\text{H}_2\text{B}_{10}\text{Cl}_{10}$ is similar to that of $\text{H}_2\text{B}_{12}\text{Cl}_{12}$. The $\text{B}_{10}\text{Cl}_{10}^{2-}$ anion can be oxidized at very anodic potentials in aqueous media on a Pt electrode. The oxidation product is the violet monoanion $\text{B}_{10}\text{Cl}_{10}^-$, which rapidly decomposes in aqueous media.

Conclusions

The low decomposition temperature of the acids is in contrast to that of the alkali metal salts which are stable to $>200^\circ\text{C}$ (1) and to previous reports on the thermal stability of the acids (7, 13). The greater stability of the alkali metal salts is the result of the cations which are not easily reducible (10). Thus the analogous reactions [1] and [2] do not occur at $<200^\circ\text{C}$, even with the anhydrous salts. However, with H^+ as the cation, these reactions become favorable as the water of hydration is removed. It can also be expected that similar reactions may occur with alkali metal salts when used in reducible, nonaqueous solvents such as $\text{SO}_2(\text{l})$ under the proper conditions (14).

In conclusion, it appears that $\text{H}_2\text{B}_{12}\text{Cl}_{12}$ and $\text{H}_2\text{B}_{10}\text{Cl}_{10}$ are not attractive for use as alternative electrolytes to H_3PO_4 in acid fuel cells.

Electrical Conduction in AgI-Al₂O₃ Composites

P. Chowdhary, V. B. Tare, and J. B. Wagner, Jr.*

Center for Solid State Science, Departments of Chemistry, Mechanical, and Aerospace Engineering and Physics, Arizona State University, Tempe, Arizona 85287

A dispersion of submicron size γ -Al₂O₃ particles in the matrix of an ionic solid is known to enhance the electrical conductivity of such a matrix by several orders of magnitude (1, 2). Although the importance of surface area of the dispersoid has been realized, the precise mechanism of enhancement of conduction has not yet been established. Recently, Khandkar and Wagner (3) suggested that the enhanced condition in AgCl-Al₂O₃ composites is possibly due to the presence of additional silver ion vacancies at the AgCl-Al₂O₃ interface because of the space-charge layer. The effect of the dispersion of γ -Al₂O₃ in AgI on the electrical conductivity of the composite has been investigated by Shahi and Wagner (4). The work reported in the present paper is an extension of that work and involves measurement of ac electrical conductivity as a function of temperature and concentration of Al₂O₃ of 0.06 and 0.3 μ m diam, with an emphasis on the changes in the transformation temperature of β -AgI to α -AgI during heating and cooling cycles for various AgI-Al₂O₃ compositions.

AgI, 99.999% pure, was purchased from Aldrich Chemicals. Agglomerate-free γ -Al₂O₃, 0.06 and 0.3 μ m diam and 99.8% pure, was obtained from Adolf Meller Company. The surface area of this alumina was determined independently by the BET method and was 80 and 22 m²/g for 0.06 and 0.3 μ m diam alumina, respectively. The sample preparation technique and the cell assembly used for conductivity measurements were the same as reported in Ref. (4), except that in the present study all the Al₂O₃ was used in the as-received condition, *i.e.*, not dried. The Al₂O₃ contains about 3 weight percent (w/o) moisture. Before starting measurements the pellets were annealed under argon in the cell at 160°C for 24h. For the measurements, the temperature was varied at random while cooling as well as while heating. The conductivity was measured at each temperature after allowing at least one hour after the previous change in temperature. Measurements were found to be reproducible with respect to several heating and cooling cycles for the same pellet in the temperature range 25°-200°C. Similarly, the conductivity was measured on at least two pellets of the same composition.

Figure 1 shows the variation of $\ln \sigma T$ (σ is the conductivity, and T the temperature in K) of pure AgI and AgI containing 10 and 20 mole percent (m/o) (0.06 and 0.3 μ m) as a function of reciprocal temperature in the temperature range 25°-200°C. The arrows indicate the heating and cooling cycles. Although the conductivity data for a large number of AgI-Al₂O₃ compositions with concentration of Al₂O₃ varying from 0 to 40 m/o have been obtained, data for only two compositions are shown in Fig. 1 for clarity. The sudden change in conductivity at \sim 148°C is due to the transformation of β -AgI to α -AgI. Log σ of (β -AgI + Al₂O₃) at 25°C as well as (α -AgI + Al₂O₃) at 200°C is shown in Fig. 2 as a function of mole percent as well as volume percent Al₂O₃ of 0.06 and 0.3 μ m particle sizes. As expected, the dispersion of Al₂O₃ increases the conductivity of the composite at 25°C with a maximum in conductivity at 30 m/o Al₂O₃. For a given amount of Al₂O₃ added, enhanced conduction is larger for composites containing

0.06 μ m particles than for the 0.3 μ m particles. At 200°C, where only α -AgI is stable, the dispersion of Al₂O₃ decreases the conductivity. The absolute magnitude of the decrease in conductivity is, however, much smaller than the corresponding increase in conductivity of β -AgI at 25°C under similar conditions. Similarly, this decrease appears larger than can be accounted for by the decrease in the volume fraction of AgI as a result of dispersion of Al₂O₃. The conductivities of all the composites are less than that of pure α -AgI. However, the conductivities are of the order of 1 Ω^{-1} cm⁻¹ so small experimental errors and resistances of lead wires contribute significantly. Consequently, two of the decreases for α -AgI(Al₂O₃) are not in the same order as the increases for β -AgI(Al₂O₃) (see Fig. 1). The temperature of transformation of β -AgI as noted from the sudden change in conductivity remains unchanged at 148°C during the heating cycle for pure AgI as well as the AgI-Al₂O₃ composites. During cooling, however, this temperature is found to be lower than 148°C for the composites. The difference in the transformation temperature obtained from heating and cooling cycles, ΔT , increases linearly with increase in mole percent of Al₂O₃ (see Fig. 3). For the same concentration of Al₂O₃, ΔT is smaller for samples containing 0.3 μ m Al₂O₃ than for samples containing 0.06 μ m Al₂O₃. Figure 4 shows the variation of ΔT with the surface area of Al₂O₃ per gram of AgI for samples containing 0.06 μ m as well as 0.3 μ m Al₂O₃. The linear change in ΔT indicates that, irrespective of the particle size, the ΔT is same for same surface area of the

*Electrochemical Society Active Member.

Fig. 2. Log σ vs. v/o and m/o Al_2O_3 ($0.06 \mu\text{m}$)

dispersoid. The role of interfacial area in two-phase mixtures in explaining the enhancement in conduction has been realized by earlier investigators. Khandkar and Wagner (3) suggested that additional silver ion vacancies are generated at the $\text{AgCl}/\text{Al}_2\text{O}_3$ interface and these contribute significantly to the enhancement in conduction. Thermoelectric measurements on $\text{AgI}-\text{Al}_2\text{O}_3$ composites reported by Shahi and Wagner (4) also suggest that at lower temperatures ($\sim 25^\circ\text{C}$) enhancement in conduction is predominantly due to the presence of silver ion vacancies.

Rice *et al.* (5) suggested that the interaction of the cation interstitials with the strain field associated with the volume change was the principal factor responsible for the phase transition. Consequently, a critical concentration of silver ion interstitials is essential to drive the transition from α - AgI to β - AgI , or conversely.

AgI exhibits a Frenkel disorder. We assume that the dispersion of Al_2O_3 in AgI is associated with additional cation vacancies at the $\text{AgI}/\text{Al}_2\text{O}_3$ interface for both the α - and the β - AgI . At high temperatures, α - AgI has the so-

Fig. 3. ΔT as a function of m/o Al_2O_3

Fig. 4. ΔT as a function of surface area of Al_2O_3 per gram of AgI .

called "average structure," in which all the silver ions are moving in between relatively immobile iodine ions in a bcc arrangement. The silver ion mobility in this phase is so high that equilibrium between various defects is readily attained. Consequently, when Al_2O_3 is introduced into α - AgI , the cation vacancies generated at the interface act as sinks for some of the mobile silver ions and hence, the conductivity decreases. On cooling the composite from above 148°C , the smaller concentration of interstitials in the composite relative to the α - AgI without Al_2O_3 results in a lowered phase-transformation temperature because of the requirement of critical concentration of interstitials to drive the transition. However, at lower temperatures the increased conductivity in β - $\text{AgI}-\text{Al}_2\text{O}_3$ composites is due to the increased vacancy concentration. These vacancies are localized at or near the Al_2O_3 interface and do not affect chemical equilibrium in the bulk matrix. The concentration of vacancies in the bulk matrix is given by the square root of the Frenkel constant at each temperature, so the bulk phase transformation β to α occurs at 148°C , the same as for AgI without Al_2O_3 dispersoids.

Because the decrease in the number of interstitials is dependent on the number of additional vacancies at the $\text{AgI}/\text{Al}_2\text{O}_3$ interface and these in turn depend on the interfacial area or the mole percent Al_2O_3 added, the decrease in transformation temperature is expected to be proportional to the concentration of Al_2O_3 , as is observed.

Electroneutrality must be preserved. At present, we do not know what compensates the suggested presence of the additional cation vacancies. The mechanism suggested above is a working hypothesis which is consistent with the observed experimental data, but further study is required to test this suggestion.

Galvanic Action Between MnO₂-Metal Couples and Its Effect on the Discharge of Li/MnO₂ Cells

Niles A. Fleischer^{*,1} and Ronald J. Ekers*

RAYOVAC Corporation, Madison, Wisconsin 53711

The Li/MnO₂ primary battery system delivers energy via a reaction where lithium ions are inserted into the host MnO₂ cathode (1). This insertion reaction has been argued to be responsible for the voltage profile during discharge. After a relatively fast drop from the open-circuit value, the voltage decreases slowly but continuously during a significant fraction of the useful life of the battery. At the end-of-life, the cell voltage drops precipitously. In addition, the conductivity of the MnO₂ decreases so that the cell impedance slowly but continuously increases during discharge, with a rapid increase occurring near the end of cell life. However, we conclude from laboratory experiments and testing of actual cells that a corrosive interaction between the MnO₂ cathode and metal cell case exists and contributes to the declining cell voltage and increasing internal cell resistance during discharge. The magnitude of this corrosive contribution is a function of the composition of the metal cell case.

Galvanic activity between beta MnO₂ and various metal case materials was measured with a galvanic couple current test (GCCT) (2). MnO₂ cathodes (3), 1.48 cm diameter, were initially saturated with an organic electrolyte of LiClO₄-propylene carbonate/dimethoxyethane. These cathodes were installed in the fixture of Fig. 1 along with the metal coupon, and the fixture was filled with 1.0M LiClO₄-PC/DME with initial water content of less than 50 ppm. The MnO₂ and the metal coupon were connected externally with a 300 kΩ resistor.

The metals and alloys studied are shown in Table I, where the galvanic corrosion current at $t = 0$ and $t = 8$ h were recorded at room temperature. The coupons were degreased and dried but otherwise used as received in order to compare the results with later cell tests.

The data in Table I indicate that the stainless steels most resistant to galvanic action with MnO₂ under these conditions generally have a chromium content above 18%, 1-4% molybdenum, and no nickel. Cold rolled steel (CRS) with a surprisingly low GCC, and 29-4 were exceptions to this trend. The 29-4 is differentiated from the more resistant 29-4-C by its lack of a titanium stabilizer. Perhaps, the poorer than expected performance of 29-4 can be explained by the apparent improved protection provided by titanium stabilizers (T-439 vs. 430 and 29-4-C vs. 29-4). Molybdenum was found to be necessary as a minor component; its complete absence increased the GCC (444 vs. T-439). The Ni-Cr alloy Inconel 600 was more resistant to galvanic action than the Ni 200.

Some of the materials in Table I were fabricated into CR2016 coin cells. Open-circuit voltage and impedance were measured after 21-25 days (Table II). These cells were then discharged on 15 kΩ at room temperature. The time

required to reach a 2.4V cutoff voltage and a 50Ω impedance level were recorded.

There was good correlation between galvanic activity and the hours to 2.4V, delivered capacity and open-circuit impedance. That is, case materials with higher galvanic currents delivered less energy than materials with lower galvanic currents. Additionally, the internal impedance of these cells increased at a more rapid rate than did the other cells. Similar correlation between open-circuit voltage and galvanic activity was not apparent. The galvanic activity is

taken as the time averaged GCC using the readings at $t = 0$ and $t = 8$ h from Table I.

Corrosion of the case material seems to be the most likely cause of the galvanic activity measured in these experiments. Changes of the inner surface of the case due to the accumulation of corrosion products might interfere with contact to the MnO_2 , which could account for the higher predischARGE impedance levels for case materials with larger GCC. The simplest explanation is that the additional impedance contributed to the cell by the corrosion process is additive with the increase in impedance due to the lithium insertion process. Thus, cells built with materials exhibiting a high GCC reach the 50Ω impedance cutoff sooner than cells built with corrosion resistant case materials, e.g., Shomac 30-2. High cell impedance and the degraded con-

tact between the MnO_2 and the case can also be used to explain the lower discharge capacity generally found in cells built with materials having high levels of GCC (Table II). The lower capacity is due to slope of the discharge curve which shortens the discharge time.

In the course of the development of ambient temperature Li secondary cells, it has been pointed out that the choice of an electrolyte system is of special importance in the efficient cycling characteristics of the Li electrode (1, 2). It is generally agreed that suitable solvents for the Li secondary electrode are 1,3-dioxolane (DOL) and 2-methyltetrahydrofuran (2Me-THF) (3). As electrolytic salts, LiClO_4 and LiAsF_6 have been used for DOL and 2Me-THF, respectively. The Li cycling efficiencies are sufficiently high in these solvent-salt systems, but some problems are still left. For instance, it has been shown that DOL/ LiClO_4 solutions are susceptible to detonation (4), and the solubility of LiAsF_6 in 2Me-THF is at most $1.5M$ (mol dm^{-3}), which leads the relatively low conductivity ($\sim 4.0 \times 10^{-3} \text{ S cm}^{-2}$) of the solution (5, 6). Therefore, various solvent-salt combinations are now under investigation (3).

Previously, the authors proposed the use of the mixed DOL-THF (1:1 vol)/ LiBF_4 system as an electrolytic solution for Li secondary cells (7). The principal advantages of the mixed solution are its high conductance, compared with DOL/ LiBF_4 and THF/ LiBF_4 (7, 8), and a slight potential change of the Li electrode during the charge-discharge cycle (7). In the present paper, influences of the charge-discharge current densities and the electrolyte concentration on the Li cycling efficiency were investigated in DOL-THF/ LiBF_4 solutions. Furthermore, 2-substituted-1,3-dioxolanes such as 2-methyl-1,3-dioxolane (2Me-DOL) and 2,2-dimethyl-1,3-dioxolane (2,2Me₂-DOL) were examined as a cosolvent with THF instead of DOL, which was subject to polymerize at high LiBF_4 concentration (3, 8).

Experimental

The purification of DOL (Tokyo Kasei Kogyo) and THF (Toyo Soda Manufacturing), and preparation of LiBF_4 (Morita Chemical Industries) solutions were carried out as described previously (7, 8). 2Me-DOL and 2,2Me₂-DOL were synthesized at the Central Research Laboratory, Ube Industries, and were purified in a similar manner as DOL.

Li cycle efficiency was measured by Koch's method (9). A beaker-type glass cell (volume = 100 cm^3) was used for the measurement. The test substrate was a Ni sheet mounted on a Teflon holder. Apparent surface area of the Ni substrate exposed to the solution was 0.95 cm^2 . The counterelectrode was a Li sheet with a Ni mesh ($2.5 \times 3 \text{ cm}$). A Li fragment on the tip of Ni wire was used as the reference electrode, which was connected to the test electrode

through a Luggin capillary. The plating and stripping current densities (i_p, i_s) were normally 2 mA/cm^2 , and the plated charge (Q_p) was 0.2 C/cm^2 . The cycle efficiency was evaluated by $Q_s/Q_p \times 100$ (%), where Q_s is stripped charge.

The current-potential curves of the Li electrode were also measured by using the same apparatus as described above, except for the Li test electrode. A Li foil disk (Kyokuto Metal Industries; $1.33 \text{ cm}^2 \times 0.02 \text{ cm}$) was used as the test electrode. The disk was mounted on a Teflon holder and was kept in contact with a Ni current collector. Current-potential curves were potentiostatically measured, where the electrode potential was stepwise changed at first from the reversible potential to anodic (discharging) ones and then changed to cathodic (charging) potentials. These experiments were carried out in a dry Ar atmosphere at room temperature (18 - 20°C). The electrolytic conductivity of the solution and the relative permittivity and the viscosity of the solvent were measured by usual methods (8) at 30°C .

Results and Discussion

In the previous work (7), it was proved that the Li cycle efficiency in mixed DOL-THF (1:1 vol)/ LiBF_4 was initially lower than that in THF/ LiBF_4 , but that the efficiency variation with cycle number in the mixed solution was rather small. The efficiency in DOL/ LiBF_4 was much lower than that in THF/ LiBF_4 or DOL-THF/ LiBF_4 . Figure 1 shows the variation of the efficiencies in DOL-THF/ LiBF_4 (1M) for different i_p ($= i_s$), where Q_p was kept constant at 0.2 C/cm^2 . Average efficiency during the first ten cycles decreased with decreasing the current densities. This was probably related to the film formation on deposited Li in the solution containing THF (10, 11). The lower i_p and i_s were, the longer the deposited Li contacted with the solution, as Q_p was kept constant. This would lead to the result that the Li deposited under low i_p is not effectively utilized owing to the inert film on Li. Conversely, in fact, decreasing Q_p tended to increase the efficiency, under the conditions of constant i_p and i_s . The efficiency at 4 mA/cm^2 was initially the highest, but it decreased gradually with increasing the cycle. When the plating is made at such high current density, the polarization of the electrode becomes high ($\sim 0.5 \text{ V}$), and then some side reaction (e.g. cathodic reduction of the solvents) would occur during the charge (plating) at the Li electrode. This results in the efficiency loss with repeating the cycle.

The efficiency variation with LiBF_4 concentration in the DOL-THF solution is shown in Fig. 2. The electrolytic conductivity of the solution increased with an increase in LiBF_4 concentration (8), and the overvoltage at the Li elec-

trode decreased with LiBF₄ concentration at constant current density. In spite of these conditions, the cycle efficiency tended to decrease with an increase in LiBF₄ concentration. The efficiency in 0.5M LiBF₄ was relatively high during the initial cycles, but it decreased with repeating the cycle, probably owing to high overvoltage in such a low LiBF₄ concentration solution. However, the low efficiencies in the high concentration solutions were possibly caused by degradation of the electrolytic solution. Viscosity of the solutions containing high concentration of LiBF₄ increased after the cycling experiments. DOL is polymerized by Lewis acid catalysts (12). Since the salt, LiBF₄, usually contains a small amount of the Lewis acid, BF₃, as an impurity, the polymerization would take place at high LiBF₄ concentration, even in the mixed DOL-THF solution. These results suggested that the maximum cycling efficiency in the DOL-based electrolytes would be gained only under the restricted conditions and it would be at most 70%. The cycling characteristics in the DOL-THF system might be improved by minor modifications of the solvents, such as the substitution of THF for 2Me-THF.

Introduction of alkyl groups to DOL at the 2 position generally reduces the rate of polymerization (13). Thus, the modification of DOL was examined in the present work. Table I shows the electrolytic conductivity of the LiBF₄ solutions. The conductivity of the mixed DOL-THF/LiBF₄ was higher than that of each parent solution, DOL/LiBF₄ or

Table I. Electrolytic conductivity (κ) of the LiBF₄ solutions at 30°C

Solvent	Concentration of LiBF ₄ (M)	$\kappa \times 10^3$ (S cm ⁻¹)

DOL-THF(1:1)	1.0	2.33
	3.0	6.06
2Me-DOL-THF(1:1)	1.0	1.32
2,2Me ₂ -DOL-THF(1:1)	1.0	0.96

Table II. Relative permittivity (ϵ_r) and viscosity (η) of the solvents at 30°C

Solvent	ϵ_r	$\eta \times 10^3$ (kg ⁻¹ s ⁻¹)
THF	7.51	0.45
DOL	6.74	0.57
2Me-DOL(1:1)	4.39	0.54
2,2Me ₂ -DOL(1:1)	3.35	0.62

THF/LiBF₄ (8). However, the solutions consisting of DOL derivatives, 2Me-DOL-THF/LiBF₄ and 2,2Me₂-DOL-THF/LiBF₄, had rather lower conductance. This decrease in the conductivity with the substitution of DOL for 2Me-DOL or 2,2Me₂-DOL is probably due to changes in the relative permittivity and the viscosity of the solvent, which are listed in Table II. High viscosity or low permittivity of the solvent generally leads to low conductance of the electrolytic solutions (14, 15). This is also the case for the present mixed systems.

Figure 3 shows the current-potential relations at the Li electrode in the mixed ether solutions. Overvoltages at given current densities (so-called polarization) in DOL-THF were lower than those in DOL or in THF (7). In 2Me-DOL-THF and 2,2Me₂-DOL-THF, however, relatively high overvoltages were observed. The Li electrode reactions in those solutions are mostly controlled by mass transfer process, if the potential is somewhat far from the reversible potential. As the current densities were dependent on solution stirring, the process was mainly controlled by Li⁺ ion diffusion in the solution (7). The results shown in Fig. 3 suggest that the diffusion rates in 2Me-DOL-THF and 2,2Me₂-DOL-THF are lower than that in DOL-THF. This is consistent with the result of the solution conductivity shown in Table I, because diffusion rate of ion is related to electrolytic con-

Fig. 3. Current-potential curves of the Li electrode in 1M LiBF₄ solutions. ∇ : DOL. \circ : THF. \bullet : DOL-THF. \blacktriangle : 2Me-DOL-THF. \blacklozenge : 2,2Me₂-DOL-THF.

Fig. 4. Variation of efficiency with cycle number in 1M LiBF₄ solutions, $Q_D = 0.2$ C/cm², $i_p = i_s = 2$ mA/cm². ●: DOL-THF. ▲: 2Me-DOL-THF. ◆: 2,2Me₂-DOL-THF.

ductivity through ionic mobility. Consequently, a lowering of the solution conductivity by introducing 2Me- or 2,2Me₂-DOL causes not only an increase in the voltage loss in the electrolytic solution during the charge-discharge cycles, but also an increase in the overvoltage for the electrode reaction itself.

The Li cycle efficiencies in 2Me-DOL-THF and 2,2-Me₂-DOL-THF were shown in Fig. 4, compared with that in DOL-THF. Substitution of DOL to 2Me-DOL reduced the efficiency, and the discharge capacity in 2,2-Me₂-DOL-THF was practically null. The reason for this efficiency reduction was not clear, but the following interpretations might be possible. As the overvoltage for the Li electrode reaction is considerably higher in 2Me-DOL-THF and 2,2Me₂-DOL-THF, some side reactions such as electrochemical decomposition of the solvents are more likely to occur during the cycle. However, methyl substituents at the 2-position of DOL contributed to depressing polymerization, but enhanced the reactivity of DOL with metallic Li. These two effects would result from stabilization of ring-opened products of DOL with methyl substituents (13). The detail of the ring-opened products was not clear, but some examples for the reactions would be presented as shown Scheme I, where Eq. [2] is analogous to that of THF (11). Both the high overvoltage for the electrode reaction and the high reactivity of the solvents with Li would reduce the Li cycle efficiency in the solutions consisting of the modified DOL. That is, the effect of methyl group introduction to DOL was a negative one for the cycling characteristics of the Li electrode, in spite of the depression of DOL polymerization in the LiBF₄ solutions.

In conclusion, however, these results suggest a possibility that high performance electrolytes can be developed by appropriate modification of common solvents.

Scheme I

Electrolytic Corrosion of Gold and the Formation of $\text{Au}_2(\text{SO}_4)_3$ in Concentrated Sulfuric Acid

Frank E. Senffle and Donald B. Wright¹

U.S. Geological Survey, Reston, Virginia 22092

Because metallic gold is relatively stable in concentrated and dilute sulfuric acid, the formation of $\text{Au}_2(\text{SO}_4)_3$ is not simply a matter of dissolution of the metal in the acid. Jirsa and Jelinck (1) prepared auric sulfate by first preparing $\text{Au}(\text{OH})_3$ by anodic oxidation of gold in dilute H_2SO_4 (0.1N) and subsequently dissolving the $\text{Au}(\text{OH})_3$ in hot concentrated H_2SO_4 to form $\text{Au}_2(\text{SO}_4)_3$. From the information in the literature, it appears that $\text{Au}_2(\text{SO}_4)_3$ is stable only in concentrated H_2SO_4 ; no isolation of a solid of this composition has been reported (2).

Although anodic oxidation of gold in dilute sulfuric acid (3, 4) has been studied, there are very few similar investigations for concentrated H_2SO_4 . Spiller (5), many years ago, reported what appears to be the formation of $\text{Au}_2(\text{SO}_4)_3$ by electrolysis of gold in concentrated H_2SO_4 . Although his work concerning the corrosion of gold has been amply verified (6), the equations describing the mechanism of formation of auric sulfate have not been well established. We have examined the direct anodic oxidation of gold in concentrated H_2SO_4 to more fully understand the chemical reactions. $\text{Au}_2(\text{SO}_4)_3$ is unstable and cannot be isolated for chemical analysis, but our experiments are consistent with the formation of $\text{Au}_2(\text{SO}_4)_3$ in concentrated H_2SO_4 , in which it is stable. Equations describing chemical reactions which are compatible with the experimental data are presented.

Concentrated H_2SO_4 (96-98%, AR grade) with a density of 1.84 was used for all the experiments, except where specifically mentioned otherwise. The electrolysis was carried out with two gold wire electrodes (99.99% pure, 1.3 mm diam) either (i) in a U-tube partially filled with glass beads to separate the anolyte and catholyte or (ii) in a beaker fitted with inverted burettes over the electrodes to collect the gases evolved. Each electrode was soldered to an insulated copper wire and, with the exception of about 2.5 cm of exposed gold wire, the electrode was encased in paraffin so that electrolysis took place only along the approximately 2.5 cm exposed section. Most of the experiments were run either at constant voltage or at constant current. A potential of about 15V and a current density close to 0.35 A/dm² was used for most of the experiments. A few experiments were run at voltages as low as 4V and as high as 21V.

In all the experiments, the results were about the same. About a minute after initiating electrolysis, we observed a yellow color about the anode, indicating the dissolution of gold. Although the anode showed a significant loss of weight during the electrolysis, the fact that no change in weight of the cathode was observed even after 10-15h of electrolysis indicated that no gold was plated out during electrolysis. After several minutes of electrolysis, a cloud of very fine white powder, subsequently analyzed as elemental sulfur, was observed at the cathode. When the yellow anolyte is allowed to mix with the catholyte containing the elemental sulfur, a black precipitate, presumably a form of gold sulfide, is immediately precipitated. Gas chromatographic analysis of the evolved electrode gases showed only hydrogen at the cathode and oxygen at the anode. However, the gas evolved at the anode initially had a distinct odor of ozone, and was undoubtedly the precursor of the oxygen formed. It is worthy of note that at ambient temperatures Hoffman (7) also observed ozone at the platinum anode and S at the cathode in an electrolysis cell using a concentrated H_2SO_4 electro-

lyte. We found no significant (< 10 ppm) SO_2 at either electrode.

More than ten electrolysis experiments were made using concentrated H_2SO_4 as an electrolyte to measure the hydrogen-to-oxygen volume ratio. In each experiment, about 6-12 measurements of the gas volume of each burette were made successively, the current being turned off between each measurement so that bubbles of gas in the solution had time to rise in the burettes. It should be noted that incremental changes in volume rather than total change in volume over the time of the experiment was measured. In these experiments, the initial ratio of the volume of hydrogen to oxygen was close to 3, but gradually dropped on successive readings to a final value of 2. At first, this was thought to be experimental error, but by using different burettes, checking for leaks, etc., we concluded that the decrease in the ratio was real. The curve in Fig. 1 is typical for these experiments. The general pattern of change in the ratio of hydrogen to oxygen volumes evolved is as follows: During stage A, an initial ratio of about 3 decreased very slowly for the first 2 min of electrolysis. The ratio gradually dropped to and remained about 2.5 for about 10 min (stage B), and then dropped to 2 (stage C), where it remained throughout the balance of the run.

Because the electric potentials used are well above the threshold for any electrode reaction, and because essentially the same results were obtained in constant-potential experiments at different potentials, one must conclude that the change in gas volume ratio with time of electrolysis is not potential-related. However, it is reasonable to assume that the observed results are related to a change in chemistry with time of electrolysis. After exploring the various possible chemical reactions, only one set of reactions was found to give results compatible with the observations.

In the concentrated sulfuric acid prior to electrolysis, autoprotolysis produces the major ions H_3SO_4^+ and HSO_4^- , and a lesser ionic concentration of H_3O^+ and HS_2O_7^- (about 20-10% of the ionization, respectively) (8). As gold is relatively inert in concentrated H_2SO_4 , it is reasonable to assume that during electrolysis the cause of the dissolution of gold is the highly reactive free radicals formed by the discharge of the negative ions in the concentrated sulfuric acid.

The anode reactions are given by Eq. [1]-[4]

O_3 is the only gas formed at the anode, as was inferred from the experiments.

The three hydrogen ions from reaction [1] protonate the undissociated H_2SO_4 molecules in the acid to form three H_3SO_4^+ ions (Eq. [2]). These ions together with three H_3SO_4^+ ions initially in equilibrium with the three HSO_4^- ions in Eq. [1] acquire electrons at the cathode to form hydrogen. Thus, at the cathode, the following reaction takes place

¹Permanent address: Howard University, Washington, DC 20059.

Fig. 1. Ratio of the incremental change in gas volume at the cathode to the gas volume change at the anode as a function of time of electrolysis.

In addition, the three H_3O^+ ions, initially in equilibrium with the three HSO_2^+ ions shown in Eq. [3], are also neutralized at the cathode

and yields 1.5 molecular volume of hydrogen. The total yield of hydrogen at the cathode from Eq. [5] and [6] is thus 4.5 mol, the required amount of hydrogen to give the initial hydrogen-to-oxygen ratio of 3 that was observed experimentally (stage A, Fig. 1).

To maintain a conservation of charge, an additional reaction takes place at the cathode. The HSO_2^+ ions formed at the anode (Eq. [3]) migrate to the cathode, gain one electron, and for a short time exist as free radicals. Thus

At the cathode surface, atomic hydrogen is also being formed (Eq. [5] and [6]), and is available to react with the HSO_2^\cdot formed at the same site. Thus

The consumption of the 3H° radicals thus reduces the hydrogen output from 4.5 to 3 mol, and the hydrogen-to-oxygen ratio decreases to 2. At the same time, elemental sulfur is formed. On initiation of electrolysis the reactions [1]-[6] take place immediately because H_3SO_4^+ and H_3O^+ ions exist throughout the bulk of the electrolyte. Thus, the hydrogen-to-oxygen gas volume ratio is initially about 3 (stage A). However, the HSO_2^+ ions form at the anode surface and must migrate to the cathode. As the HSO_2^+ ions begin to arrive at the cathode, the rate of hydrogen production decreases because of reaction [8], causing the hydrogen-to-oxygen ratio to decrease to a value of 2. If the gas volumes could be measured without interrupting the current, the transition of the ratio from 3 to 2 would undoubtedly be monotonically decreasing. During stage B in Fig. 1, the essentially flat section of the curve probably reflects the current shut-off periods during which the

volume measurements were made. Because of the bubbles clinging to the sides of the burette, a current shut-off period was necessary to obtain good volume measurements.

The above reactions take place only in concentrated H_2SO_4 . To determine the degree of concentration required, a series of experiments was made with increasingly diluted H_2SO_4 . It was found that the same electrode reactions took place until the concentration of H_2SO_4 was reduced to 16.3N. At this concentration, a dark brown precipitate was observed at the anode which was probably auric oxide, as observed by Jeffery (9), or $\text{Au}(\text{OH})_3$, as reported by Jirsa and Jelinck (1) in dilute sulfuric acid. The dark brown precipitate persisted for all dilute sulfuric acid electrolytes with concentrations between 16.3 and 6.3N. Below 6.3N, both gold electrodes were inert, and electrolysis was essentially that of water.

The above experiments and electrode reactions help to explain the formation of S at the cathode, and of $\text{Au}_2(\text{SO}_4)_3$ and O_3 at the anode. One can write equations to yield other gold compounds or ion complexes, but, invariably, one or another of the experimental results is left unexplained. For example, one can assume that monovalent rather than trivalent gold is dissolved during electrolysis, but it is easily shown that the hydrogen-to-oxygen ratio obtained is not that which is observed experimentally. While the above model uniquely fits the experimental data, it should be retained as an hypothesis.

Additional work must be done to prove all the steps. We tentatively conclude that trivalent gold formed by electrolytic corrosion in the concentrated sulfuric acid is in the form of $\text{Au}_2(\text{SO}_4)_3$.

Acknowledgments

The authors are grateful to their colleagues, Dr. Frederick Simon for his helpful comments and to Robert Johnson for x-ray fluorescence analysis of the sulfur formed during the electrolysis. Donald Wright also thanks Dr. J. Morris of Howard University for making it possible for him to take part in the research program at the U.S. Geological Survey.

On Depositing Conductors from Solution with a Laser

A. Auerbach

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

The integration of lasers into a variety of technologies is presently occurring. In no area is this more apparent than microelectronic processing (1, 2). Among the features making this possible is the ability of the laser to function as a

highly localized photon and/or heat source, and the fact that it can be used in a hands-off manner to effect processing. To date, most work has involved gaseous systems; this is because they offer the least interference to the laser radiation.

Fig. 1. Silver conductor reduced from solution onto alumina substrate. Thin portion was written using 100 mW. Thicker region was written using 500 mW. Scan rate was 300 $\mu\text{m/s}$. Laser radiation was focused through 10 \times objective.

A variety of metals have been deposited from the gas phase. Deutsch *et al.* (3) used a UV laser to deposit silicon nitride (Si_3N_4) from gaseous reactants. Refractory metals such as iron, chromium, and tungsten have also been deposited (4, 5). Recently, Solanki *et al.* deposited aluminum oxide and aluminum thin films from gaseous reactants using a UV laser (6).

Liquid systems have also been investigated. von Gutfeld *et al.* (7) used an argon-ion laser to provide localized heating to rapidly electroplate gold onto a nickel-plated beryllium

substrate without adversely affecting the quality of the deposit. The gold electroplate was crack-free, dense, and had excellent adhesion to the substrate material. Karlicek *et al.* (8) used a pulsed dye laser to electrolessly plate gold or platinum from an aqueous solution of chloroplatinic or chloroauric acid. The focused laser output heats the substrate material to promote reaction between the substrate and dissolved metal salt.

In this communication, we describe an alternative system which has been used to electrolessly deposit continuous silver conductors from solution onto an aluminum substrate. A laser is used to provide local heating of the substrate. The heat promotes a novel redox reaction between the solvent and dissolved salt to deposit silver. Since the redox reaction occurs at a moderate temperature ($< 250^\circ\text{C}$), a relatively low laser power is required to deposit silver on the alumina substrate. Substrates having higher thermal conductivities require higher laser powers so that an adequate average temperature is maintained during the scan.

The solution is formulated by dissolving 50% by weight silver nitrate (Metron, Incorporated) into N-methyl pyrrolidone (Aldrich). The salt is dissolved with mild heat and stirring. The resulting solution is colorless since the loose complex formed between the silver ion and amide group does not absorb in the visible.¹ This is significant because it is desirable that the laser energy be absorbed by the substrate and not the solution.

The apparatus consists of a quartz cell with liquid input and exit ports. The substrate is mounted in the cell with its surface 2 mm from the window. The output from an argon-ion laser is focused, through a 10 \times objective, onto the sub-

¹ A charge transfer complex to the silver ion results when the amide group contains an electron-rich side chain (e.g., N-vinyl pyrrolidone). The solution is then colored, since the charge transfer complex absorbs in the visible.

Fig. 2. 10K magnification SEM of conductor region. X-ray analysis also shown.

strate. The work area is simultaneously viewed by a video camera and displayed. The cell is translated relative to the laser using a programmable X-Y translator stage (Anorad, Incorporated).

Figure 1 shows one such silver conductor deposited onto an alumina substrate from the above solution. The wider conductor section was written using a laser power of 500 mW and translation speed of 300 $\mu\text{m/s}$. The thinner section was written using only 100 mW of power. The measured resistance of a 0.5 cm length of thicker conductor was $\sim 5\Omega$. This is close to the calculated value for pure silver of comparable dimensions (75 $\mu\text{m} \times 0.1 \mu\text{m} \times 0.5 \text{cm}$). Figure 2 shows an SEM plate at 10,000 \times of the conductor region. The silver grains (about 1000 \AA across) are obvious. Similar grain structure was previously observed for laser-assisted reduction of silver ions in a polymer matrix (9). We suspect, therefore, that the silver is incorporated in a matrix of oxidized solvent. In agreement with this, the conductivity of the silver deposit decreases with exposure to ambient atmosphere and humidity. Also shown in the figure is the x-ray spectrum of a grain showing the predominant silver peak and the background aluminum peak resulting from the substrate. Although various translation speeds and laser powers were investigated, lowest resistance values were achieved using speeds between 200-600 $\mu\text{m/s}$ and output power between 0.1 and 1W.

The advantage of this method for depositing metals is that the materials used require no special handling and are not toxic. Also, since the metal deposits in the immediate vicinity at the localized heat, little waste occurs. Since a very high density of silver ions is available in the reduction volume, conductors are formed in a single, relatively fast ($\sim 500 \mu\text{m/s}$) scan of the focused laser beam.

An important consideration is careful choice of the solvent. The solvent must be a good electron donor, but have a high boiling point. This is so that reduction can be accomplished without solvent boiling. We have found that amide

bearing solvents (e.g., N-methylpyrrolidone, N-vinylpyrrolidone, N-N-dimethyl formamide, etc.) work well.

In summary, we have demonstrated one system which was used to write silver conductors directly from solution. In the future, we will investigate gold and copper forming systems. Such systems are possible since both copper and gold ions contained in a polymer matrix have been reduced with a laser (10).

Determination of Electrocatalytic Activity of Nickel Whisker Electrodes

J. D. Hansen,* G. L. Cahen, Jr.,* and G. E. Stoner*

Applied Electrochemistry Laboratory, Department of Materials Science, University of Virginia, Charlottesville, Virginia 22901

An investigation of the effects of extremely small grained nickel electrodes on the rate of electrochemical hydrogen production was conducted. More specifically, the comparative evaluations of the electrocatalytic properties of conventional nickel 200 plate electrodes and nickel whisker electrodes for hydrogen evolution in alkaline solutions were performed. This work was stimulated by previous research performed at the University of Virginia which indicated an improvement in the energy efficiency of the hydrogen evolution reaction at porous nickel whisker electrodes as compared to nickel 200 screens on an apparent area basis (1, 2). However, it was not determined whether the energy gained by the use of sintered nickel whisker electrodes was due to their extremely high surface area or to some truly innate electrocatalytic property of the metal's composition and microstructure. The surface morphology of these whiskers is complex and is the result of their production by the chemical vapor deposition of nickel tetracarbonyl gas, $\text{Ni}(\text{CO})_4$. To separate the effects of this more complex surface condition from microstructural considerations such as grain boundaries, other types of defects, and possible impurity associated phases, it was necessary to expose the internal metal of these whiskers and use it as an elec-

trode. Thus, the fundamental question of specific electrocatalytic behavior of nickel whisker electrodes, independent of their high surface area, was the principal objective of this investigation, and no further attempt to identify effects caused by the naturally occurring whisker surface other than that previously identified (2) was made. As a result, standard quantitative comparative tests for electrocatalysis needed to be developed, and some basic questions concerning what determines an electrocatalyst were considered.

Scanning electron microscopy of nickel whisker electrodes reveals their high porosity (~ 85 volume percent) and their high surface to volume ratio (50,000 cm^2/cm^3). These characteristics created a very high surface area electrode which allows increased electrochemical reaction rate and, consequently, increased energy efficiency. In addition to their high surface area, the nickel whisker electrodes have a unique metallurgical microstructure which could result in some interesting electrocatalytic properties. The grain size of these whiskers was typically 200-400 \AA . Thus, each whisker was composed of many small grains creating a large grain boundary area. Enhanced electrocatalysis could have resulted from nucleation sites provided by the grain boundaries or possibly from the increased energy associated with these grain boundaries.

Linear regression calculations: fit (0-1) = 0.9990; Tafel slope = 132 mV/decade; exchange current density = 1.1×10^{-6} A/cm².

Electrocatalytic Activity of Nickel 200

Electrocatalytic activity should be determined on a true electrochemically active surface area basis so that current densities will be accurately known. Therefore, a comparison of the electrocatalytic activity between different electrodes requires a reproducible and consistent method of measuring effective surface area. Such a method, using low amplitude cyclic voltammetry, was carried out for this electrocatalytic comparison between nickel 200 and nickel whiskers (3). There was no problem in finding a nonfaradaic potential region for both the nickel 200 and the nickel whisker material. This provided both a confidence and reproducibility in the area calculations.

With the active electrochemical surface area of an electrode being known to an acceptable level of reproducibility by cyclic voltammetry, the electrocatalytic activity was determined by the generation of a Tafel plot. The Tafel slope and the exchange current density were the parameters used in determining electrocatalysis. Tafel plots obtained for nickel 200, determined galvanostatically from lower to higher values of current density, were quite reproducible. With proper IR (potential caused by the solution resistance) compensation, these plots were linear over five decades of current density as calculated by linear regression. A typical Tafel plot with its experimental data is shown in Fig. 1 and Table I, respectively. Table II shows that a series of Tafel experiments run on nickel 200 electrodes yielded an average Tafel slope of 135 mV/decade and an average exchange current density of 1.2×10^{-6} A/cm². These values of Tafel slope and i_0 agree favorably with those reported by Appleby *et al.* (4), who performed similar experiments and with data obtained from current industrial electrolyzers used by Teledyne Energy Systems (Baltimore, Maryland) (5).

Tafel experiments were conducted in an airtight Teflon beaker cell. Teflon was used because of its high resistivity to chemical degradation. The top of the cell provided three openings for the working, counter, and

reference electrodes. Nickel 200 plates embedded in epoxy and polished to a planar mirror finish were used as counterelectrodes as well as working electrodes in these Tafel experiments. The reference electrode was a standard calomel electrode with a minor adaptation which was necessary for IR compensation. The electrodes were supported by Teflon dowels, which extended through the openings and kept the electrode geometry relatively constant. The working electrode was approximately 3 cm from the reference electrode and 4 cm from the counterelectrode. Two additional openings were also provided for the nitrogen purge gas. All openings and fittings were sealed with O-rings. The cell was cylindrical shaped with a diameter of 7.5 cm and a height of 8 cm.

Experiments were performed at room temperature (23°C), which never varied more than a few degrees. The Teflon cell was purged prior to experiments with nitrogen gas for about 15 min to remove any dissolved gases in the electrolyte which could react at the electrodes. Purging continued throughout the experiments at a moderate rate. Reactive species were also removed by a thorough cleaning procedure, which consisted of washing the cell and electrodes in a soap solution and then rinsing with acetone, ethanol, distilled water, and electrolyte successively. The electrolyte was obtained from the stock utilized by Teledyne in their industrial electrolytic cells. It was a 25 weight percent potassium hydroxide (KOH) solution with a pH of 14.8.

Electrocatalytic Activity of Nickel Whiskers

Once surface area could be reproducibly measured and the electrocatalytic activity of conventional nickel 200 was determined with reasonable precision, a comparison with polycrystalline nickel whiskers was made. To eliminate gas masking problems and the high surface area of the porous nickel whisker electrodes, the whiskers were embedded in an inert epoxy resin. The epoxy resin filled the pores of the whisker electrode and enabled the electrode to be polished to a smooth planar surface. This allowed the nickel whisker electrode to be compared to a planar nickel 200 electrode for electrocatalytic activity on a true surface area basis, as determined by cyclic voltammetric surface area analysis. This also enabled a determination of electrocatalytic behavior based on metallurgical parameters such as microstructure and phase composi-

tion. If such an innate property of the material caused increased electrochemical activity, it would now be identified and noted as an effect in addition to that normally attributed solely to the high surface area associated with these sintered whisker electrodes.

To embed the whiskers, both sintered and nonsintered assemblies, the atmosphere within the pores was removed, which allowed the epoxy to enter. The whiskers were placed on a copper current collector in a Teflon mold and held rigidly in place by a magnet. This assembly was then placed within a vacuum system. After the system was evacuated, a valve to an epoxy reservoir was opened, permitting epoxy to flow into the mold and embed the whiskers. The epoxy was outgassed in the vacuum for a short time and then cured in an oven at 80°C until completely hard. A slow curing, low viscosity epoxy consisting of Dow 331 resin, Jeffamine D-230 hardener, and Texaco accelerator 399 was used. Once cured, a Teflon-insulated wire was attached to the current collector, thereby providing electrical connection to the whiskers and making a usable electrode. The surface of the whisker electrode when polished consists of many small metal islands surrounded by an epoxy matrix.

These nickel whisker electrodes of approximately 1 cm^2 true surface area were evaluated for electrocatalytic activity under identical experimental conditions as the conventional nickel 200 specimens. A typical Tafel plot for nickel whiskers is shown in Fig. 2. The Tafel experiments resulted in an average exchange current density of $8.2 \times 10^{-7}\text{ A/cm}^2$, with an average Tafel slope of 133 mV/decade , as seen in Table III. Therefore, no significant difference in electrocatalytic activity between the two types of nickel was observed. Annealed nickel 200, which has considerably larger grains and less strain energy than non-heat-treated nickel 200, also exhibited essentially the same electrocatalytic properties as those already mentioned. It should be noted that none of the test electrodes were run for extended periods of time, and therefore, time effects were not observed nor studied.

Conclusions

From these evaluations of the electrocatalytic activity of extremely different types of microstructure, it must be concluded that the added energy of increased grain boundary area and/or any other microstructural oddity present in these whiskers does little to enhance their hydrogen evolving capabilities in KOH. However, current-voltage improvements in alkaline electrolysis using nickel electrodes are noticeably realized by increases in

electrode surface areas (1, 2). One possible consideration would have been to break up the whiskers prior to sintering into an electrode. Because the internal material of these whiskers does not show improved performance over the naturally occurring whisker surface, electrodes can be fabricated from the whiskers in their as-formed condition. Thus, they can be produced as small or as large as the condition of use might dictate. Since only a fraction of the surface area of porous electrodes is active under gas evolution, owing to gas masking conditions, efforts should be directed towards maximizing electrode flooding and active surface area. This could possibly be done by orienting the individual whiskers into some optimum configuration and/or by taking advantage of the porosity of whisker mat electrodes by using flow-through techniques.

Although the above conclusion is a negative result in this particular case, it should not be extended to imply that microstructure has no effect on electrocatalytic activity in other electrochemical systems. Under different conditions, microstructure may have a pronounced effect on electrochemical reaction rate. This is because electrocatalysis can be influenced by the solution, the specific electrochemical reaction, and the type of electrode material. Thus, it is possible nickel whiskers may have additionally enhanced electrocatalytic activity for hydrogen evolution over nickel 200 in solutions other than potassium hydroxide or for the oxygen evolution reaction in potassium hydroxide solutions.

Finally, the data in Tables II and III and in Fig. 1 and 2 show linearity for five decades of current, indicating a well-behaved activation-controlled reaction whose kinetics are well represented by these measurements. The linearity of these plots lends support to the argument that there is only one Tafel slope for hydrogen evolution on nickel 200 in KOH, as opposed to two slopes, resulting from a change in reaction mechanism at high values of current density.

Ellipsometric Study of the Etch-Stop Mechanism in Heavily Doped Silicon

E. D. Palik, V. M. Bermudez, and O. J. Glebocki

Naval Research Laboratory, Washington, DC 20375

ABSTRACT

The etch-stop phenomenon which occurs in both p- and n-Si when the doping density exceeds 10^{19} cm^{-3} has been studied *in situ* with ellipsometry. Biasing the samples both anodically and cathodically from open-circuit potential causes layers to grow which can then be observed to etch back when the applied potential is released. We are lead to the conclusion that p-Si etch stops because of spontaneous passivation which produces a thin oxide-like layer, while n-Si shows a tendency to etch stop, probably owing to formation of a prepassive layer.

Aqueous solutions of KOH (1, 2) and ethylenediamine pyrocatechol (3) are widely used as orientation-dependent etches of Si, the etch rate of {100} surface being 1-2 orders of magnitude faster than that of the {111} surface. The etch rates are generally independent of free-carrier type and concentration (4, 5) up to 10^{19} cm^{-3} . Above this density, the etch rates on both surfaces are observed to slow down drastically (1-3 orders of magnitude) for both boron (p) and phosphorus (n) dopants, although the stopped etch rate is still angstroms per minute. This etch stop is used in the fabrication of various device configurations (6).

The mechanism for etching of boron-doped Si (B:Si) in pyrocatechol etchant (7) has been described as an oxidation-reduction process in which oxidation produces electrons in the Si surface (100Å layer) which, in turn, are used in the reduction process at the surface. When the hole doping density passes 10^{19} cm^{-3} , the electrons recombine with holes instead, thus stopping the reduction step. The etch-rate ratio (ERR) for this model varies as: $\text{ERR} \propto [1 + (p/p_c)^2]^{-4}$, where p is the doping density and $p_c = 5.5 \times 10^{19} \text{ cm}^{-3}$ is a fitting parameter related to recombination-theory parameters at high doping levels in the range 10^{19} - 10^{20} cm^{-3} . This model is not applicable to n-type Si. Another mechanism (5) suggests that B:Si and phosphorus-doped Si (P:Si) can spontaneously passivate in aqueous KOH to form a thin, protecting oxide layer. It is suggested that the tendency to grow an oxide is encouraged by the strain in the Si surface due to the high dopant density, and a borate or phosphate glass is formed.

We have made *in situ* ellipsometric studies of the formation and dissolution of surface layers as a function of applied potential bias (both cathodic and anodic) for boron- and phosphorus-doped silicon both below and above 10^{19} cm^{-3} . These studies indicate that at open-circuit potential (OCP) B:Si above 10^{19} cm^{-3} has a layer on the surface suggestive of the connective or transition layer between crystalline Si (c-Si) and amorphous SiO_2 (a-SiO₂). P:Si above 10^{19} cm^{-3} has a different layer on the surface. Similar layers are observed on lightly doped Si when the applied potential is made anodic (connective-layer formation) and cathodic (cathodic-layer formation), respectively. Consequently, we have attempted to understand the etch-stop layer formation in terms of band bending (or equivalently, a shift in OCP) and the numbers of holes or electrons needed at the surface to induce the appropriate chemical reaction to dominate, thus producing the anodic connective layer or the cathodic layer.

Experimental Approach

A spectroscopic polarization-modulation ellipsometer (8) has been adapted to measure ψ and Δ for a Si sample suspended in 2M KOH in a BK-7 glass (angle of incidence: 60.2°) or fused quartz (54.6°) hollow prism. The samples were approximately $1 \times 4 \times 0.03 \text{ cm}^3$ obtained by cleaving standard Si wafers polished on one side. Samples were immersed $\sim 2 \text{ cm}$ into the etchant. Leads were made with InGa eutectic and a pressure contact. Potential was measured with respect to a standard calomel reference electrode (SCE). Measurements were made at three wavelengths 800, 435.8, and 319 nm. Ambient temperature was $\sim 20^\circ\text{C}$. A microcomputer read and printed the pertinent parameters, such as applied potential V ; current I , photomultiplier high voltage (proportional to $\log R$, where R is the sample reflectance), and ellipsometric parameters ψ and Δ . Further details concerning the optical system will be given elsewhere (13).

We have modeled the surface layers (11) in terms of physical and chemical mixtures (9) of SiO_2 , anticipating that a connective layer will consist of such a material. A multilayer model is used to simulate gradation of optical constants across the interface.

Results

Lightly doped B:Si and P:Si.—Palik *et al.* (5) and Faust and Palik (10) measured the open-circuit potential and passivation potential (PP) for a large number of Si samples of different doping densities. Below 10^{19} cm^{-3} the OCP was nearly constant. They observed that above 10^{19} cm^{-3} the OCP for p-type samples tended to shift in the anodic direction by 0.2-0.6V, while the OCP for n-type samples shifted in the cathodic direction by about 0.1V. They also noted that the PP tended to approach the OCP at high doping levels for both n- and p-type Si, this separation being $\sim 0.5\text{V}$ below and nearing $\sim 0.1\text{V}$ above 10^{19} cm^{-3} . Certain samples were erratic, sometimes showing a peak in current just prior to passivation and sometimes not showing a peak. The data suggested that perhaps there is a prepassive layer which forms at a potential slightly cathodic of PP and forces the etch to stop when heavy doping shifts PP toward OCP.

Some of our results for light doping have been reported (11-13) along with a model to explain them. They are summarized in Fig. 1a, for p {111} Si with $1.8 \times 10^{15} \text{ cm}^{-3}$, for anodic and cathodic directions starting at OCP (solid dot). These are composite curves taken from different runs.

1985

Fig. 1. (a): Changes in ψ , Δ , and I starting at the solid circle at OCP ($-1.2V$) as a function of applied potential V anodic and cathodic for p {111} Si boron doped with $1.8 \times 10^{15} \text{ cm}^{-3}$. The sweep rate is different for anodic and cathodic directions. Angle of incidence $\theta = 54.6^\circ$. (b): Once a thin anodic-oxide layer has grown to near point e, the applied potential is released and the changes in ψ , Δ , I , and OCPV are followed as a function of time.

Generally, n {111} Si gave similar results. Without going into the detail of the modeling, we can assign the various features of the curves. The current I shows a peak and a shoulder in the anodic direction for the nominal {111} plane. The first peak is due to passivation of the edges and back of the sample with their exposed fast etching {100}, {110}, etc., surfaces. Coating these surfaces with glycol thylate or arranging a cell in which only the wafer surface contacts the liquid removes this first peak. The shoulder is the true {111} passivation peak.

The sample is etching at the solid dot at a rate of $\sim 35 \text{ \AA/min}$. As etching progresses at OCP, there is a slight roughening of the surface, which over several hours results in decreases of several tenths of a degree in ψ and Δ . In contrast to the case for GaAs (14), there is no indication of a prepassive layer forming before PP (decrease in Δ , increase in ψ) as the applied potential is slowly swept anodic.

We model the surface at OCP as an equilibrium etching layer of 4 \AA of $\text{SiO}_{0.2}$ (essentially disordered Si). At point b, another layer begins to form and etching stops. We model the region b-c as the sudden appearance of a rudimentary connective layer modeled as $\text{SiO}_{0.4}$ which undergoes change (gradation) to point d with a- SiO_2 also growing on top. At point d the connective layer stabilizes and a- SiO_2 grows on top of the connective layer from point d to e. The experiment and fitting were done for three wavelengths, although we show experimental results only for $\lambda = 435.8 \text{ nm}$.

In the cathodic direction (starting at OCP) no changes in ψ and Δ occur for about a tenth of a volt; then a layer starts growing at point b' with both ψ and Δ decreasing. We term this a "slush" layer because it is assumed that the layer is composed of insoluble silicates, as discussed below (13). It has growth and etchback features suggesting that n and k vary as the layer grows or etches (where $\tilde{n} = n - ik$ is the complex index of refraction). Interestingly, this layer continues to grow when the potential sweep is halted at a cathodic bias at point c', even for days, al-

though slowing down. The layer takes on a tan-gray color. When the potential is released to OCP conditions, this slush layer disappears slowly over several hours with the ellipsometric parameters returning very nearly to their original OCP values, but not totally along the same path in ψ - Δ space as was followed during growth. A slight anodic potential speeds up this process. Some roughening of the surface occurs as indicated by the final values of ψ , Δ , and R . We have used an SiO_x model to account for this layer (12) by assuming an equilibrium etching layer of 4 \AA of $\text{SiO}_{0.2}$ and then allowing this layer to grow at point b' getting thicker and in the process changing to $\text{SiO}_{0.7}$. This amounts to a substantial decrease in the initial large values of n and k for $\text{SiO}_{0.2}$.

As has been observed by Glembocki *et al.* (15), the etch rate is bias dependent. For p-Si, the rate drops very little in the cathodic direction, while, for n-Si, the rate decreases drastically at a few tenths of a volt cathodic. This has been qualitatively explained in terms of an abundance of electrons in the surface accumulation layer for n-Si, which favors electrolysis rather than etching. Without going into details, we note only that experimentally the etching "stops" for cathodic potential for n-Si and continues for p-Si. In both cases, some slush layer grows; however, it grows much more rapidly on the n-Si surface. Presumably, the decrease in etch rate is due, in part, to incomplete etching with accumulation of incomplete silicates which stick to the surface forming the slush layer. The p-Si continues etching at only a slightly reduced rate, producing H_2 and mostly complete silicates in the form (16) of soluble $\text{SiO}_2(\text{OH})_2^-$, while only a little incomplete etching occurs, giving rise to a more slowly growing slush layer.

When a thin oxide is established at a potential $< 5V$ as at point e' and then the applied potential is released, the layer begins to etch back at a slow rate of $\sim 0.3 \text{ \AA/min}$, as shown in Fig. 1b. Very characteristic of all samples $< 10^{19} \text{ cm}^{-3}$ are small, rapid dips in ψ , Δ , V (and R) when the connective layer is reached at point b. This effect has been modeled previously (11) as the SiO_x connective layer becoming more dielectric-like (O/Si ratio increasing), so that its optical constants decrease drastically, and then dissolving prior to the onset of etching of c-Si. In any event, these features (b \rightarrow d) are the signature for the onset of Si etching. Oxides grown at less than 5V, we term "soft"; those grown at higher potentials are referred to as "hard" because of the similarity in etch-back behavior to that of device-quality thermal oxides.

For {111} surfaces (10, 11) etch back of soft anodic oxides produces small dips in ψ and Δ [~ 0.3 and $\sim 2^\circ$ with full width at half maximum (FWHM) values of 2-4 min, respectively] and small dip in R , but etch back of hard anodic oxides produces large dips in ψ and Δ ($\sim 5^\circ$ and $\sim 15^\circ$ with FWHM values of 6-15 min, respectively) and a large dip in R . The connective-layer model (11) explains the soft-oxide etch-back effects, while we are presently trying to develop a transient-roughness model to explain the hard-oxide effect. For the fast etching (lightly doped) {100} surface, etch back of a soft anodic oxide produces a large dip in ψ and Δ ($\sim 5^\circ$ and $\sim 15^\circ$ with FWHM values of 2-4 min, respectively) and a return of ψ and Δ nearly to their initial values; a large, steady decrease in R occurs. Then, ψ and Δ decrease, while R continues to decrease, indicating rapid roughening of the surface. Etch back of a hard anodic oxide produces large decreases in ψ and Δ ($\sim 10^\circ$ and $\sim 35^\circ$) which do not recover much along with a steady decrease in R . This is a permanent roughening of this fast etching surface (13). The roughening effects no doubt dominate the small connective-layer effects shown in Fig. 1b.

Heavily doped B:Si and P:Si.—For a p {100} Si sample with $2 \times 10^{20} \text{ cm}^{-3}$, the composite results are shown in Fig. 2a. The sample is HF cleaned first, washed in deionized water, and then allowed to remain in 2M KOH for several minutes before an anodic potential is applied (at the solid dot). No peak in passivation current is seen, as

Fig. 2.(a): Changes in ψ , Δ , and I starting at the solid circle at OCP ($-0.7V$) as a function of applied potential V anodic and cathodic for p {100} Si boron doped with $2 \times 10^{20} \text{ cm}^{-3}$. The sweep rate is different for anodic and cathodic directions. Angle of incidence $\theta = 54.6^\circ$. (b): Once a thin anodic-oxide layer has grown, the applied potential is released and the changes in ψ , Δ , I , and OCPV are followed as a function of time. No dips in ψ , Δ , or V occur even for another 3h beyond the right edge of the graph, in contrast to results in Fig. 1(b).

though an oxide layer were already on the surface and merely thickened as an anodic potential was applied. It has previously been shown that a very thin oxide layer is sufficient to cause the disappearance of the passivation peak (5).

In the cathodic direction starting again (at the solid dot), very interesting dips in ψ and Δ occur, after which both ψ and Δ decrease in a manner similar to Fig. 1a, suggesting growth of a slush layer. The small dips in ψ and Δ in Fig. 2a for cathodic potential appear to be muted versions of what would be seen at OCP after etch back for the lightly doped p {100} surface, *i.e.*, large dips in ψ and Δ occurring over 2-4 min. The concurrent growth of slush layer also tends to skew the line shape. This suggests that cathodic potential allows the further etch back of the connective layer and then the start of etching of c-Si. Most of the results of Fig. 2 were also obtained for a {111} B:Si sample with $2.4 \times 10^{20} \text{ cm}^{-3}$. In the cathodic direction, however, there is little or no dip in ψ and Δ observed since these features are obscured by the larger effects of rapid slush layer growth.

After a definite anodic oxide has been grown and the applied potential released, the results of Fig. 2b are obtained. ψ and Δ decrease and increase, respectively, in a manner typical of an SiO_2 film getting thinner. Then, no dips in ψ and Δ are observed even after several hours. OCP stabilizes at $-0.7V$. We conclude that the surface has spontaneously grown a connective layer (or maintains a portion of the one anodically grown), so that the c-Si surface is never directly reached by the etchant.

To check this possibility in more detail, we prepared a p-Si {111} wafer of free-carrier density $N = 1.6 \times 10^{15} \text{ cm}^{-3}$ half implanted with $5 \times 10^{15} \text{ cm}^{-3}$ boron at 100 keV and then annealed at 1000°C for 1h. The peak free-carrier density was estimated to be $\sim 1 \times 10^{20} \text{ cm}^{-3}$, based on an implantation depth of $\sim 0.5 \mu\text{m}$ and a four-point probe measurement of resistivity $\rho = 0.00010 \Omega \text{ cm}$. Also, no H_2 bubbles were observed on the surface, indicating that the etch stop was in effect. After stripping of any oxides which may have formed, the sample was arranged with a smooth vertical motion of about 2 cm so that the top (T) of the sample (light doping) could be measured ellipsometrically; then the sample could be raised enough to illuminate the bottom (B) (heavy doping). The uncertainty in ψ and Δ was $\pm 0.1^\circ$ owing to the mechanical motion of the sample plane.

The differences in the ψ and Δ parameters for the T and B samples at OCP should be due to an additional layer on the B sample, a spontaneously grown connective layer. This difference was measured three times by anodizing both the T and B samples to 0 V and following the etch back of sample T at point d in Fig. 1b and then moving to sample B. The change from T at point d to B was made quickly, before many etching bubbles formed on the T surface. The scattering effect of macroscopic bubbles is to lower ψ and Δ slightly. The average experimental changes in ψ and Δ are given in Table I. We also measured $\delta\psi$ and $\delta\Delta$ when both surfaces had anodic oxides grown to 0 V. The average experimental changes in ψ and Δ are also given in Table I.

To fit these two sets of $\delta\psi$ and $\delta\Delta$, we have modeled the etching T surface as c-Si covered with 4\AA of $\text{SiO}_{0.2}$ equilibrium etching layer and the B surface as c-Si covered with 7\AA of $\text{SiO}_{0.4}$ connective layer. The equilibrium etching layer is included for self-consistency as it improves other modeling of the initial anodization process and the growth of the cathodic slush layer (12, 13). The anodized T and B surfaces are modeled as c-Si under 7\AA of $\text{SiO}_{0.4}$ connective layer under 10\AA of SiO_2 (identical oxides on both surface). For the T surface, we used the pure-Si optical constants $n = 4.88$ and $k = 0.14$ at 435.8 nm (18). For the B surface, we assumed the optical constants $n = 4.79$ (1.8% smaller) and $k = 0.16$ (14% larger) to fit the data. Such changes (n smaller, k larger) have been observed for heavily doped B:Si (19) and As:Si (20, 21). We assumed that both halves, T and B, are microscopically smooth and isotropic and that sample B is uniformly implanted to a depth greater than the penetration depth of light at 435.8 nm ($\sim 0.2 \mu\text{m}$).

The calculated changes in ψ and Δ from T to B upon etch back are given in Table I along with the calculated changes in ψ and Δ from T and B for identical oxides. We give differences because the absolute values of ψ and Δ [which have not been corrected for systematic errors in the ellipsometer (8)] are accurate only to few tenths of a degree, whereas changes in ψ and Δ can be measured with high precision ($\sim 0.01^\circ$) at a fixed wavelength. Considering the mechanical motion involved and the assumption of equal oxides on the T and B surfaces, the reasonable agreement suggests that there is a connective layer on the B etch-stopped surface compared to the etching T surface. The calculated $\delta\psi$ and $\delta\Delta$ are more sensitive to the substrate optical constants than to the exact values of x and thickness. However omission of any layer in the model can change the signs of $\delta\psi$ and $\delta\Delta$ or their magnitudes by a factor of two.

The results for lightly doped P:Si are similar to those for lightly doped B:Si except that, in the dark, owing to lack of holes, no additional oxide grows between points d and e in Fig. 1a. The results for an n {111} Si sample with $5 \times 10^{20} \text{ cm}^{-3}$ are shown in Fig. 3. In this case, we first start with the sample having a soft anodic oxide. Upon release of the applied potential, classical etch back of the layer begins. The usual dips in ψ and Δ for an n {111} surface occur, but then there is immediately rapid growth of what appears to be a slush layer (still at OCP = $-1.3V$). This slush layer grows indefinitely (we observed its growth for 6h without signs of termination and little change in OCP). Recall that we have previously identified the rapid slush layer growth on cathodically etch-stopped, lightly doped n-Si with the decrease in etch rate. During subsequent anodization, the optical effects of the growth of the

Fig. 3. Once a thin anodic-oxide layer has grown on n {111} Si phosphorous doped with $5 \times 10^{20} \text{ cm}^{-3}$, the applied potential is released and the changes in ψ , Δ , I , and OCP V are followed. When a steady-state OCP = -1.3 V is reached, a potential is applied which causes current to flow and passivation to occur (peak in I at the PP). The slush layer begins to disappear and masks formation of the connective layer and SiO_2 layer. Ultimately, the slush layer disappears and growing oxide layer can be seen (not shown). Angle of incidence $\theta = 54.6^\circ$.

connective layer on heavily doped P:Si are obscured by the dissolution of the slush layer. However, a PP is clearly seen with $\text{PP-OCP} < 0.1 \text{ V}$. Preliminary experiments with As:Si {111} with $7 \times 10^{19} \text{ cm}^{-3}$ gave results similar to Fig. 3.

Discussion

We will now proceed to a discussion and interpretation of the experimental results given above. The essential finding may be summarized as follows. Using ellipsometry, in conjunction with electrochemical measurements, we have detected a layer on the surface of etch-stopped (heavily B-doped) p-type Si at OCP which is similar to that observed on lightly doped material under anodic bias (for which the etch rate is drastically reduced). Likewise, for etch-stopped (heavily P-doped) n-type Si at OCP, we have observed a layer similar to that formed on lightly doped samples under cathodic bias (for which the etch rate is also greatly diminished). The implication is that the processes which occur for lightly doped Si at anodic or cathodic bias occur spontaneously at OCP for heavily doped material. What follows is a discussion of this idea in terms of both electrode potentials and energy levels at the Si/electrolyte interface. A detailed microscopic description of the relationship between changes in ψ and Δ and those in the surface films is deferred until a

later publication (13). For the present, the ellipsometric results are used simply as a basis for the above analogy between heavily doped Si at OCP and lightly doped Si under bias.

Electrode-potential considerations.—The applied potential divides between the Si space-charge layer and the liquid Helmholtz layer (electrode potential), the latter determining the chemical (or electrochemical) reactions that take place at the semiconductor surface. The nature of the semiconductor bands at the surface—depleted, accumulated, or pinned—will play a critical role in the effect that the applied bias has on the electrode potential. This, in turn, can have a profound influence on how H_2O and OH^- interact with Si-Si bonds. In fact, we have suggested that etching is the sequential attack of Si bonds by H_2O and then OH^- (11, 15).

For lightly doped n-Si at OCP, the conduction band is in electron accumulation and for p-Si the valence band is depleted of holes. In the case of n-Si, variations in the applied bias around OCP and especially cathodic will have a significant effect on the electrode potential and, therefore, on the chemical reactions which can occur. However, for p-Si changes in applied voltage, at least cathodically, do not significantly change the electrode potential.

It has been suggested that the rate-determining steps (RDS) for both etching and connective-layer growth are chemical (15). However, the nature of the RDS was shown to be a function of electrode potential. For example, at the passivation peaks of I-V curves the oxidation of n- or p-Si (connective-layer growth) dominates over the dissolution of the oxidized species and etching stops. With p-Si, further anodic shifts increase the hole concentration at the surface and induce thick oxide growth. However, the n-Si becomes depleted and further applied bias has little effect on the electrode potential or surface charge and no further oxide grows. We therefore observe that an anodic potential creates an anodic etch stop, as evidenced by the observation of the connective layer.

An analogous situation holds for n-Si under cathodic bias. As mentioned, the n-Si exhibits metallic behavior at the surface, owing to an accumulation of electrons at OCP. A cathodic bias changes the electrode potential in such a manner as to change the nature of the RDS. Current begins to flow, implying that the bias has changed the energetically favored reaction at the surface from etching, accompanied by hydrogen evolution and (possible) oxidation of OH^- ions to electrolysis of water accompanied by hydrogen evolution and production of current carrying OH^- ions. This can also be thought of in terms of energy levels, as discussed in the next section.

The effect of cathodic bias on p-Si is straightforward, since the surface is already depleted (maybe pinned). Increasing the applied potential cathodically has virtually no effect on the electrode potential, and, consequently, the current saturates and etching is affected very little.

Heavy doping of n- and p-Si (indicated as n^+ and p^+) can also induce metallic-like surface conditions. In the case of the p^+ -Si, a large number of holes at the surface causes spontaneous passivation and is accompanied by an anodic shift of the OCP. The OCP is now determined not by etching reactions (involving the conduction band) but by oxidation processes (involving the valence band). However, cathodic bias (which will change the electrode potential) begins to shift the surface reactions toward more balance between the cathodic and anodic reactions, and the oxide can be etched back. From these considerations, one might expect a resumption of etching at slight cathodic bias, as Fig. 2a suggests.

The case of the n^+ -Si etch stop is somewhat more difficult to understand. The analogy with the cathodic etch stop for lightly doped Si is attractive, since in each case the surface is metallic-like. But it is hard to imagine electrolysis dominating etching at OCP with no net current flow. We suggest another mechanism. We will make a note of important experimental observations: (i) the passivation potential for heavily doped n-Si shifts cathodically about 0.5 V and approaches the OCP, while OCP

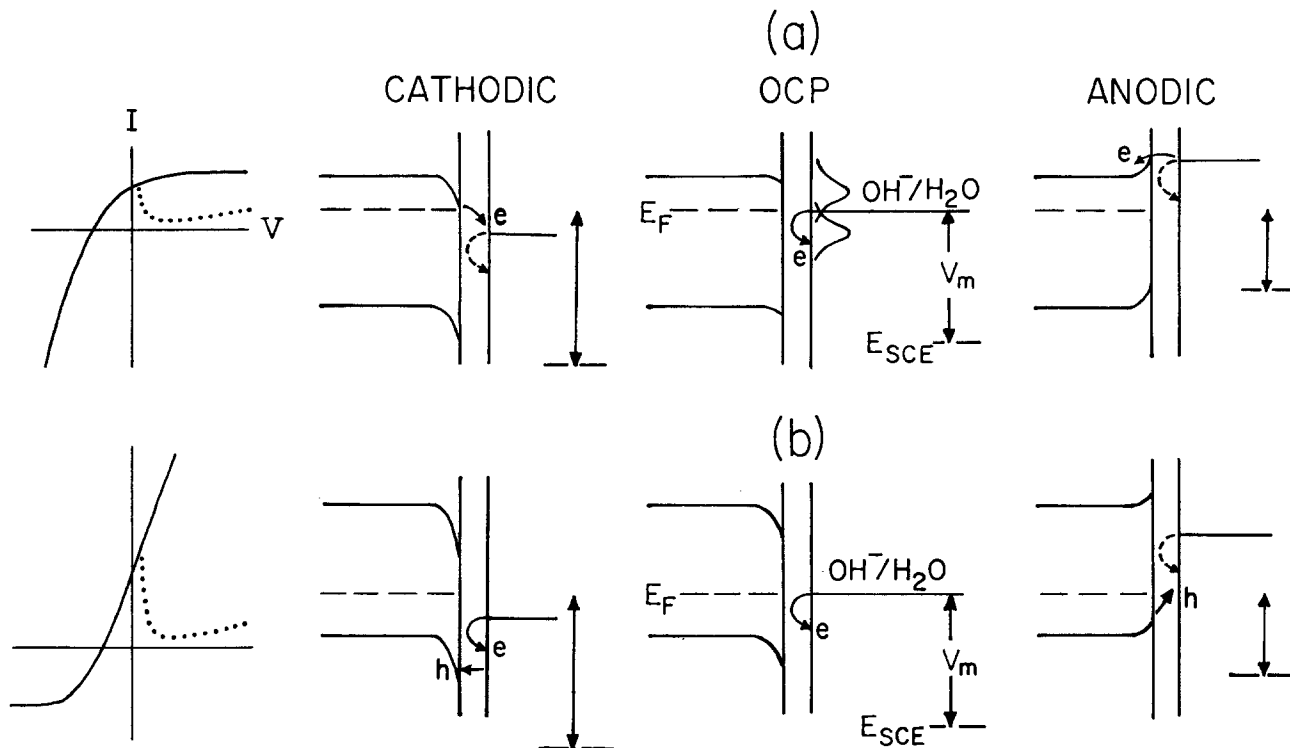

Fig. 4. (a): Schematic diagram of band bending and redox couple as a function of applied potential anodic and cathodic for n-Si. Fermi levels of bulk Si and SCE are indicated by dashed lines. The left inset shows large forward-bias current and reverse-bias saturation current with the onset of passivation (dotted line) masking saturation. (b): Schematic diagram of band bending and redox couple as a function of applied potentials anodic and cathodic for p-Si. The left inset shows reverse-bias saturation current and large forward-bias current with the onset of passivation (dotted line) masking current runaway.

shifts only 0.1V compared to lightly doped Si; (ii) Glembocki *et al.* (15) found that the etch rates for lightly doped n-Si were substantially reduced between the OCP and PP well before the PP was reached. In Ref. (15), the etch stop between OCP and PP was explained by a shift in the RDS toward connective-layer growth. For potentials between the PP and OCP, there were competitive processes, the oxidation of Si and the dissolution of the oxidized species, as well as dissolution of the crystalline substrate. In this case, as long as some oxidation occurred, the etching would be reduced and some thin layer of prepassive oxide would form only to be etched off and then regrown. In fact, the more rapid the oxidation, the lower the etch rate, until finally the connective layer was established. This suggests that at some narrow range of cathodic bias there might be a resumption of etching before the usual n-Si cathodic etch stop takes over. In the next section, we will consider the role of the band edge in this process.

Energy-level consideration.—We now give a complementary discussion of etching and etch stop based on an energy level approach. Such a band-energy-level picture can be useful, although the details are necessarily sketchy. These ideas are illustrated in Fig. 4 and 5 in terms of the Si conduction and valence bands, the redox couple level of $\text{OH}^-/\text{H}_2\text{O}$ and the Fermi levels. In Fig. 4, we assume a redox couple $\text{OH}^-/\text{H}_2\text{O}$ supplies the species for etching, electrolysis, and oxidation. We illustrate this reaction region as a thin layer between c-Si and the electrolyte. This can be the region where the surface states and the decomposition states (23) involved in the reactions are located, where initial layers begin to grow or where the Helmholtz layer forms. The $\text{OH}^-/\text{H}_2\text{O}$ couple with its Fermi level is shown at OCP, the lower lobe being the filled electron states due to OH^- and the upper lobe being the empty electron states to be associated with H_2O . This population distribution is omitted in other panels of Fig. 4. We do not include the decomposition states of $\text{SiO}_2(\text{OH})_2^-$ and SiO_2 or the surface states, since we do not know their locations or distributions in such a variety of complicated reactions (24). The SCE Fermi level is also

indicated, since all measured potentials V_m are between the Si bulk Fermi level and the SCE. The positions of the various levels are only approximately to scale, the $\text{OH}^-/\text{H}_2\text{O}$ couple being 1.1V above the SCE (24). The horizontal dimensions are not to scale. We assume that an applied potential moves the liquid levels in unison with the SCE level. Note, that in Fig. 4 we have chosen to keep the bulk Si bands constant from panel to panel rather than the SCE Fermi level.

At OCP (-1.2V), we show the bands bent down, since it has been determined that for n-Si flatband occurs near

Fig. 5. (a): Schematic diagram of band bending and redox couple for lightly and heavily doped n-Si suggesting how OCP shifts cathodic. (b): Schematic diagram of band bending and redox couple for lightly and heavily doped p-Si suggesting how OCP shifts anodic.

-1.0V, while for p-Si it occurs near -0.2V (22). The etching reaction transfers an electron from the OH⁻ into the Si surface bond (or the conduction band at the surface) and then to the etch products (no net current flow), as the semicircular arrow indicates. This sequence of charge transfer must be maintained in order for etching to continue.

If the charge transfer sequence is broken, one expects the etching to stop. This may be accomplished in n-Si through a cathodic bias (15) when strong accumulation of electrons occurs in the conduction band. Then, electrons can flow from the Si electrode to solution via the OH⁻/H₂O couple. Water, which would normally participate in etching, is electrolyzed to produce H₂ and current carrying OH⁻ through the reaction $\text{Si} + 2\text{H}_2\text{O} + 2e^- \rightarrow \text{Si} + \text{H}_2 + 2\text{OH}^-$. This cathodic current is shown schematically in the I-V curve at the left side of Fig. 4a. Also, OH⁻ ions cannot easily discharge electrons into the accumulated conduction band, owing to the relative positions of the redox Fermi level and the conduction-band edge at the surface. Both mechanisms would decrease the etch rate, as the dashed semicircular arrow indicates.

Anodic potential applied to n-Si raises the OH⁻/H₂O level with respect to the conduction band, causing electron current to flow into the depleted conduction band of Si, presumably with some etching continuing. Eventually, the few thermal holes can fall into the filled redox state, causing some oxide to grow, stopping the etching, and drastically reducing the nearly saturated current at passivation. This is shown as a dotted line in the I-V curve. We observe that only the thin connective layer can be grown in the dark.

An etch stop with similarities to both the cathodic etch stop and the anodic etch stop (connective layer) occurs for n⁺ doping (Fig. 5). As the doping density is raised, the semiconductor Fermi level rises above the OH⁻/H₂O couple initially; then, as the Fermi levels equilibrate, electrons flow from Si to liquid. We note that the upward Fermi-energy shift of the semiconductor might produce a slight cathodic increase in the OCP as is observed (OCP = -1.3V). The space-charge region is shown narrow with a slight upward band bending. As Fig. 3 shows, while etching has stopped (slowed down drastically), a slush layer continues to grow. The appearance of this layer signals that, while water continues to attack Si-Si bonds, subsequent OH⁻ attack has been inhibited, so that mostly incomplete, nonsoluble silicates are formed which stick to the surface.

At equilibrium, no current flows (Fig. 5a). It is now somewhat difficult to understand the etch stop. We can only suggest two possibilities: (i) if there is a large upward band bending (not shown), this would form a barrier to electron transfer from OH⁻ to the conduction band, thus interrupting the etching charge transfer process, just as in the cathodic panel of Fig. 4a electrons are stopped from moving from the redox level to the conduction band; (ii) since the PP has shifted very close to OCP, oxide attempting to form consumes OH⁻, thus slowing the etch rate. This prepassive layer undergoes etch back and growth (perhaps as a monolayer). We have not clearly seen its presence by ellipsometry, since the slush layer dominates, and we have not seen it in lightly doped Si. Note, however, that as soon as an anodic potential is applied, the surface passivates within <0.1V in spite of the slush layer, implying that OH⁻ can penetrate it. We are tempted to compare the right panel of Fig. 5a with the right panel of Fig. 4a as regards transfer of electrons from OH⁻ to the conduction band, not to produce net current, but to form the prepassive connective layer. The few thermal holes available would be needed to start the oxidation of Si and keep the net current zero.

For lightly doped p-Si the Fermi level is much lower than the OH⁻/H₂O level before contact. A large band bending is induced when the semiconductor is brought into contact with the electrolyte at OCP (see Fig. 4b), since the OH⁻/H₂O couple discharges electrons into the

semiconductor surface to equilibrate the Fermi levels. The etching charge transfer process continues, however.

Cathodic bias drives the p-Si into depletion (Fig. 4b), and, therefore, the energy separation between the conduction band and the OH⁻/H₂O couple becomes almost constant and the current saturates. The little current that flows is shown schematically in the I-V curves and is due to a small number of holes in the H₂O redox states flowing into the valence band during electrolysis. The etching charge-transfer sequence is not interrupted since electrons from redox tail states can still reach the conduction band so etching continues.

With the application of an anodic potential (Fig. 4b), hole current initially flows from p-Si to the filled electron states of the OH⁻/H₂O couple. This increase in current is shown in the I-V curve of Fig. 4b. With further anodic bias, initial oxide (connective-layer) growth is induced. This stops the etch and produces a drastic drop in current, as the dotted portion of the I-V curve shows. A thick oxide can be grown since there are plenty of holes available.

Heavy doping of a p-Si sample at OCP to produce a p⁺-Si sample moves the bulk Fermi level toward the valence band (see Fig. 5b). These holes move to the electron-filled redox couple state, lowering its Fermi level as equilibrium is achieved. The OCP shifts in the anodic direction (OCP = -0.7V), a potential which favors initial growth of the connective layer, and etching stops. Conversely, note that one could argue that the etching charge transfer sequence is interrupted because the electron-filled redox states are too far below the conduction band. However, the ellipsometric observations of connective layer rule this out as the primary etch-stop mechanism.

Summary

Ellipsometry has been used to "tag" optically the events that occur during anodization and etching and, thus, to permit correlation among the various processes. The microscopic model relating changes in the different interfaces to observed variation in ψ and Δ is beyond the scope of the present work and will be presented elsewhere (13). Specifically, we have shown that etching through the connective layer on a lightly doped substrate is signaled by the appearance of dips (negative peaks) in ψ and Δ . The absence of such dips for a heavily doped B:Si substrate indicates that the connective layer is never penetrated (or else spontaneously regenerated). The persistence of the connective layer and the drop in etch rate are both related to the shift in OCP. Similarly, cathodic bias of a lightly doped n-type sample leads to rapid slush layer growth related to a decrease in etch rate (cathodic etch stop). For heavily doped P:Si, we observed the optical signature of rapid slush layer growth immediately upon etching through the connective layer at OCP. This is taken as an indication that what happens on the surface of lightly doped, cathodically etch-stopped n-Si may also happen spontaneously at (the shifted) OCP for heavily doped P:Si; alternately, a prepassive connective layer may begin to form with subsequent slow down of etch rate. Heavily doped As:Si behaves similarly. We assume that other dopants, such as Sb (n) and Al (p) would also etch stop if the doping density could be raised toward 10^{20} cm⁻³. Of special interest is the fact that the connective layer on p⁺-Si can be removed by slight cathodic bias so that the sample may start etching again. Also, there is the possibility of cathodically biasing n⁺-Si and encouraging etching. We have not yet measured the stopped and unstopped etch rates.

We assume that since orientation-dependent etching and the etch stop are seen for both aqueous KOH and ethylenediamine pyrocatechol, the present results would also be observed in the pyrocatechol etchant. Thus, the etch-stop mechanism of Raley *et al.* (7) for p⁺-Si is probably not valid; rather, p⁺-Si probably spontaneously passivates.

Acknowledgments

We thank H. B. Dietrich of NRL for the boron implantation and J. R. Ehrstein of the National Bureau of Standards for several heavily doped Si samples. We have had many fruitful discussions of possible etching and stopping mechanisms with J. W. Faust, Jr., of the University of South Carolina, and D. L. Kendall, of Instituto Nacional de Astrofisica, Optica y Electronica, Puebla, Mexico. O.J.C. is a NRC-NRS Research Associate.

Deposition and Reflow of Phosphosilicate Glass

R. A. Bowling and G. B. Larrabee

Texas Instruments Incorporated, Materials Science Laboratory, Dallas, Texas 75265

ABSTRACT

The chemical vapor deposition (CVD) and reflow of phosphosilicate glass (PSG) have been reviewed. The CVD reaction from silane and phosphine has been simulated by SOLGAS thermochemical calculations. This equilibrium calculation method predicts stoichiometric conversion of silane and phosphine. In comparison to experimental determinations, the calculations underestimate the glass phosphorus content by about 1-3 weight percent. In addition, recent observations that the reflow of PSG is greatly enhanced by the presence of a steam ambient during heating have been examined. A possible mechanism of this reflow enhancement has been discussed. Experimental evidence, which support this mechanism, by electron microprobe, FTIR, and SIMS studies of PSG films, are presented.

Phosphosilicate glass (PSG) is widely used throughout the semiconductor industry in the fabrication of bipolar and metal oxide semiconductor (MOS) devices. Many of the properties of PSG make it well suited for use as a solid-to-solid diffusion source, as a mask against other dopant diffusion, as a gettering agent for mobile alkali ions, as an interlayer dielectric and insulation for multilevel interconnections, or a passivation layer. The ability of PSG to stabilize devices against mobile ions such as sodium has been well known for over a decade (1-5). As an interlevel layer, the addition of phosphorus pentoxide to silica glass to form PSG significantly reduces the temperature needed to reflow the glass to provide smooth steps for metallization interconnection. Higher phosphorus contents give lower reflow temperatures, but high phosphorus concentrations can induce metal corrosion by reaction of phosphorus pentoxide with water to form phosphoric acid. This is particularly important in the production of low cost plastic-encapsulated devices as compared to the more expensive water-protected ceramic packages. Devices packaged in ceramic are sealed against water so that much higher phosphorus levels are tolera-

ble. This water-induced corrosion possibility can have a dramatically adverse effect on the long-term reliability of plastic-packaged devices, particularly since the rate of corrosion and thus the time to failure are dependent upon the temperature and humidity conditions of use for the device. As a passivation layer, thermally grown silicon dioxide has a limited thickness range over which it can be used because of thermal expansion mismatch with the substrate and high internal stresses which induce cracking. Alternatively, PSG is more dense and thus provides more contaminant protection. Its reduced intrinsic stress improves the layer's resistance to cracking (6-8). As the level of device integration increases, there is an increasing need for lower process temperatures of reflow in order to reduce undesired lateral diffusions. Therefore, it is imperative to control the phosphorus content of the PSG and the reflow conditions so that the optimum reflow is achieved at the lowest possible temperature, yet maintain phosphorus levels that do not induce metal corrosion. Understanding the processes of PSG formation and reflow is, then, of great importance in making decisions about present process control and process improvements

and about future plans to meet the needs of more highly integrated devices. This understanding could also play a significant role in the possible development of new glasses required for future device processing.

The phase diagram for the silicon dioxide-phosphorus pentoxide system is well characterized (9, 10). Since PSG is a glass and not a crystalline solid, it has no phase diagram, but some general implications may be taken from the phase diagram of the silicon dioxide-phosphorus pentoxide system. It can be seen from the phase diagram that a mixture of silicon dioxide and phosphorus pentoxide with a composition to the left of the eutectic which is cooled from liquid to solid will be composed of crystals of silicon dioxide as quartz in a solid of eutectic composition. This solid is water insoluble (11) and is inert to water attack, so that interaction with water will not occur to produce phosphoric acid. Metallization should not corrode in the presence of moisture when deposited on such a solid. Conversely, a mixture with composition to the right of the eutectic should form a material composed of crystals of $2\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ in the solid eutectic composition. While the solid matrix is not water soluble, the crystals of $2\text{SiO}_2 \cdot \text{P}_2\text{O}_5$ are readily soluble. If the phase diagram were correct for PSG, glasses formed from compositions greater than about 0.2 mole fraction of phosphorus pentoxide or equivalently about 15.7 weight percent (w/o) phosphorus will contain water soluble crystals and metallization will corrode in the presence of moisture. It is not correct, and thus the maximum allowable amount of phosphorus before encountering metallization corrosion problems may be significantly less than 15.7 w/o. Particularly in a production situation, the maximum advisable phosphorus content is probably on the order of 10-12 w/o.

Another introductory topic which should be considered because of its relevance to phosphoric acid-induced metal corrosion and to the PSG reflow mechanism is the thermochemistry of phosphoric acid (H_3PO_4) and phosphorus pentoxide (P_4O_{10}). Phosphoric acid is the product of hydration of phosphorus pentoxide. Phosphoric acid undergoes a partial loss of water at 213°C and complete dehydration above ~320°C. The dehydration reaction can be written as follows

Thus, phosphoric acid is only stable at fairly low temperatures. Also, phosphorus pentoxide begins to sublime at about 300°C and is completely gaseous above approximately 600°C. The significance of this property will become apparent in the discussion section.

Presently, the most commonly used method for PSG deposition is chemical vapor deposition (CVD). The reaction of silane and phosphine with excess oxygen to form a PSG of silicon dioxide and phosphorus pentoxide is typically used. This reaction at 300°-500°C can be written as

Phosphorus pentoxide is correctly written as P_4O_{10} , but, in many cases, is referred to as P_2O_5 . They are most often used interchangeably to mean the same compound. Mass spectrometric evidence by Kern *et al.* (12, 13) showed that both hydrogen and water vapor are present as reaction products in the exhaust of a PSG deposition reactor. Excess hydrogen is present because phosphine is used as a mixture of phosphine, hydrogen, and argon. One major concern, with water vapor being present as a reaction product, is that water might become incorporated into the glass or that water will react with the phosphosilicate glass to form phosphoric acid. However, the instability of phosphoric acid above 320°C specifically excludes the possibility of acid formation during high temperature deposition. Infrared spectroscopic results by Kern *et al.* (12, 13) suggest that, even with the addition of excess amounts of water vapor into the reactant gas flow, there

is no evidence of incorporation of water into the glass during chemical vapor deposition. Their data further suggest, however, that water vapor is actually helpful to the deposition reaction, since they found empirically that it reduces the intrinsic stress of the deposited film. High phosphorus content glasses are a problem in the presence of moisture only at temperatures lower than about 320°C. This, however, does not preclude water incorporation into the glass at room temperature and thus does not rule out corrosion under normal device operation conditions. However, water should not pose any problems during deposition or reflow.

The technical literature contains several studies of the conditions of PSG chemical vapor deposition and the dependence of the glass deposition rate and phosphorus content upon various experimental parameters, including the reactant gas flow rates, substrate temperature, and several others (12-16). From a comparison of the experimental results of Kern *et al.* (12, 13) and Shibata *et al.* (14, 15), the PSG always contains more phosphorus than is predicted from stoichiometric conversion of silane and phosphine because the conversion of silane to silicon dioxide is generally believed to be inhibited by surface kinetics during co-oxidation with phosphine. This deviation from stoichiometry appears never to be more than about 2-4 w/o phosphorus. In most cases, it is on the order of 1-2 w/o phosphorus.

Phosphosilicate glass, as it is chemically vapor deposited, does not have a density as high as possible for the film. The film, however, can be annealed at temperatures ranging from about 450° to 800°C for periods of time ranging from 15 min to over 10h to produce densification of the film to a desired level (17). In other instances, the densification is achieved simultaneously with the higher temperature (950°-1050°C) reflow process which is designed to give a surface with smooth gradual steps on which to put metallization interconnections. A larger amount of phosphorus in the glass allows reflow at lower temperatures, but, as stated earlier, there is a limit to the amount of phosphorus before one encounters the probability of interaction with water to form phosphoric acid and the consequential corrosion of the metallization. One approach has been to deposit a PSG with a moderate level of phosphorus and then carry out the reflow while introducing POCl_3 gas into the reflow chamber. This introduces additional phosphorus into the outer layer of the PSG, allowing it to be reflowed more completely. The reflow is then followed by an anneal to remove the excess phosphorus, which was added for the reflow. This procedure of reflow with high surface phosphorus and then the removal of this excess phosphorus works because of the high vapor pressure of phosphorus pentoxide, as explained above, which can volatilize from the surface of the PSG, owing to the open porous structure of the glass.

Recently, it has also been observed that reflow is also greatly enhanced by the presence of a steam ambient during the reflow process, and that reflow is increased to a lesser extent by an oxygen ambient gas. These results are supported by several experimental reports in the chemical literature. Nauman and Boyd (18) found that the flow of PSG in wet nitrogen is greater than for dry nitrogen. Armstrong and Tolliver's SEM investigation (19) of PSG reflow showed the greatest flow for steam, and the least flow for dry nitrogen. Also, recently, Razouk and Lie (20) found that the high pressure-induced flowtime of PSG is reduced the most for a pyrogenic steam ambient. Steam-enhanced reflow of PSG may then be an important alternative for avoiding the use of high temperatures and high phosphorus contents to achieve the desired surface reflow.

Experimental

In an attempt to model the PSG system so that predictions of glass phosphorus content could be made, the reaction was simulated using a thermochemical calculation program called SOLGAS. It is a computer program for

the calculation of equilibrium compositions based upon minimization of the free energy of the system being considered. The method has been described in some detail by Eriksson (21). Calculations were performed for temperatures ranging from 300° to 450°C, for SiH_4/PH_3 molar ratios from 1 to 50, and for $\text{O}_2/(\text{PH}_3 + \text{SiH}_4)$ molar ratios of 1 to 50.

All thermodynamic heats of formation used by the program were taken from the JANAF thermochemical tables (22), except for PSG, which was estimated from the values of silicon dioxide and phosphorus pentoxide. The results of these calculations are discussed in the section on results.

To evaluate the effects of water vapor on the reflow of PSG film produced by the CVD reaction of silane and phosphine with oxygen at 430°C, films were studied using Fourier transform infrared spectroscopy (FTIR), secondary ion mass spectrometry (SIMS), electron microprobe analysis, and wet chemical colorimetric analysis.

For the purpose of these studies, silicon wafers with the deposited films of PSG in the 7-12 w/o phosphorus range were broken into four parts. One part was left unannealed for comparison as the as-deposited film. The other three parts were annealed one in each of the following gas ambients: dry nitrogen, dry oxygen, and steam. The steam was flowed into the annealing furnace using nitrogen and all anneals were carried out at 950°C for 15 min. The FTIR analyses were carried out on an IBM IR98-14 FTIR instrument. SIMS measurements were made on an ARL ion microprobe basing the quantitative results on phosphorus standards generated from neutron activation analysis. The electron microprobe results were obtained on a JEOL JSM-35 scanning electron microscope with Kevex x-ray detector. Its results were also based on the same neutron activation generated phosphorus standards. The wet chemical colorimetric determinations of phosphorus were based on weighed and dissolved phosphorus salt standards.

Results and Discussions

All SOLGAS calculations indicate a complete stoichiometric conversion of phosphine and silane to PSG. That is, thermodynamically, all the reactant silane and phosphine go to make a glass with the same silane to phosphine molar ratio as for the reactant gas mixture. This was true as long as there was excess oxygen, *i.e.*, sufficient oxygen to convert all silane to silicon dioxide and to convert all the phosphine to phosphorus pentoxide. The other predicted products of the deposition reaction were hydrogen and water vapor, consistent with the experimental findings of Kern *et al.* (12, 13). The stoichiometric conversion predicted by SOLGAS, though possibly a good first approximation of the reaction, does not take into account two important factors. First, CVD is not in an equilibrium situation as assumed by the SOLGAS program; second, SOLGAS bases its results upon thermodynamic consideration only, and does not include other factors, such as kinetic effects.

Enhanced reflow of PSG by the addition of steam as an ambient gas, although it greatly enhances the PSG reflow, should not be used as a process before considering its effects on the other aspects of semiconductor devices. Whether or not reflow in the presence of steam causes water to be trapped in the glass is of extreme importance to the long-term reliability of a semiconductor device. Recent FTIR results in this laboratory on samples which had been annealed in steam have shown no evidence of trapped water. In support of this finding, it is known that a temperature of about 400°C facilitates the removal of OH^- groups and condensed water molecules from a silica surface (23).

Many people in the semiconductor industry talk about the concept of steam leaching of phosphorus from the glass by phosphoric acid formation. They have noted that when the glass is reflowed in the presence of steam the final film has a lower phosphorus concentration than the

as-deposited film, and they are familiar with the reaction of phosphorus pentoxide and water to form phosphoric acid and the consequential metal corrosion that occurs at low temperatures. The two facts have been incorrectly pieced together to indicate that the water reacts with the phosphorus to facilitate its removal. What has not been considered is that the water may interact with the glass structure to allow the phosphorus pentoxide to escape from the sample because of its high vapor pressure. Another supporting fact is that phosphoric acid is not stable at these high temperatures. To further examine this phosphorus loss during annealing, a discussion of the interaction of water with silica glass structures is required. This is given below.

It is a very common practice for a ceramicist to add steam to any glass to reflow it at a lower temperature or reflow it more quickly at a given temperature (23, 24). Vitreous silica glass has a very high viscosity. The silica glass Si-O bonds are very strong, and the major cation (Si^{4+}) core has a rigid screening demand which requires four-fold coordination. Its network of O^{2-} ions in only two-fold coordination represents a very open, porous structure. The anion-to-major network forming cation ratio is by far the most important factor which determines the screening of the cation and the need of the cation to share anions, that is, to "polymerize" and form a glass. The addition of O^{2-} ions introduced by oxides such as phosphorus pentoxide or sodium oxide improves the screening of the major cation and decreases the need to polymerize, therefore lowering the viscosity of the glass. This is the reason that PSG, which contains phosphorus pentoxide in silica, has a much lower viscosity than pure silica and can consequently be reflowed at a much lower temperature than pure silica glass. Silica is also very sensitive to defects which cause any asymmetry, again because of the cation screening demand; a reduction in viscosity can also occur by this mechanism. Vitreous silica glass can contain OH^- groups or electron pairs in the place of O^{2-} ions. This fact is very important in explaining the reduction of viscosity by addition of water vapor or oxygen during reflow. The viscosity of silica can be reduced by an order of magnitude by the introduction of water because it participates in the structure of the glass as OH^- ions, displacing some of the bridging oxygen bonds, and thus increasing the number of anions. This not only increases the screening of the major cation, but also introduces an asymmetry, both of which act to reduce the glass viscosity. Oxygen can produce more limited viscosity reduction by accepting an electron transfer and participating in the structure as an electron pair substitution for an O^{2-} ion (24). By similarity, since PSG is primarily a silica glass with a relatively small percentage of added phosphorus pentoxide, water and oxygen are expected to produce similar viscosity reduction in PSG.

The reflow enhancement of steam by its participating in the glass structure as OH^- ions would give the necessary structural changes to bring about the observed loss of phosphorus during annealing in steam. This phenomenon of loss is much more than can be explained by surface volatilization alone. The glass changes to a less viscous substance which has a more open porous structure, thus allowing more phosphorus pentoxide to evaporate. Balk and Eldridge (1) first proposed this type of mechanism in 1969. The mechanism is also supported by a recent study of the densification and water absorption of PSG films chemical vapor deposited at 640°C using phosphine, tetraethyl orthosilicate, and oxygen (25). The following experimental observations were made by the present authors in an attempt to investigate the feasibility of this mechanism.

In Fig. 1 are shown the FTIR spectrum of an as-deposited PSG film and the spectra of the same film annealed in steam, oxygen, and nitrogen gas ambients. In the FTIR spectrum of PSG annealed in steam, the energy and shape of the Si-O stretch band most closely resembles the same band of the as-deposited PSG, thus indicating a structure which is more open and less dense as is

Fig. 1. FTIR spectra of PSG film annealed in different gas ambients

characteristic of the as-deposited film. However, the same band in the spectrum of PSG annealed in nitrogen is shifted to an energy much closer to the corresponding band of quartz, a much more closed densely packed structure. Oxygen shows an effect intermediate between the other two. Further information on FTIR studies of PSG films can be found in Ref. (26). Confirmation of the loss of phosphorus during annealing, the amount of which depends on the ambient and its effect on the structure, is shown in Fig. 2 and in Table I. Figure 2 shows the SIMS profiles of phosphorus in a PSG sample, pieces of which have been annealed separately in steam, nitrogen, and oxygen. The steam-annealed sample has significantly less phosphorus than the other two. Table I indicates the phosphorus contents obtained for similar samples *vs.* the as-deposited PSG from electron microprobe and wet chemical complexation colorimetric analysis. Both methods indicate the highest phosphorus content for the as-deposited film and the lowest for the steam-annealed samples. Nitrogen is closest to the as-deposited film in phosphorus content, and oxygen is intermediate, indicative of its more limited reduction of the glass viscosity. There is a large discrepancy between the

Fig. 2. SIMS profiles of phosphorus in PSG sample annealed in different gas ambients.

Table I. Annealed PSG phosphorus content as a function of gas ambient

Reflow gas ambient	Average PSG phosphorus content (w/o P) Electron microprobe	Wet chemical analysis
As-deposited PSG	7.6	11.4
Dry nitrogen	7.4	9.9
Dry oxygen	7.1	9.6
Steam	6.8	7.6

absolute magnitudes of the values obtained by the two techniques first because the analyses were performed on different samples which were only deposited under similar conditions and because of the use of different standards for the techniques as described in the experimental section. The ordering of phosphorus content which is the same for both is the more important observation. This combination of FTIR results showing most dense films for nitrogen anneal, and other results showing least remaining phosphorus for steam reflow, supports the mechanism described above but does not specifically exclude all other explanations.

In light of all these results, the addition of steam to reflow PSG films is feasible and poses no water-related problems to the device reliability during reflow. Addition of steam to enhance the reflow may then be a viable and safe procedure of PSG processing for semiconductor device manufacture (27).

Summary

The useful properties of PSG as applied to use as a semiconductor oxide layer have been discussed along with the problems that it can induce if not closely controlled. The simulation of the CVD reaction from silane and phosphine by SOLGAS thermochemical calculations was shown to predict stoichiometric conversion, this prediction always being about 1-3 w/o phosphorus less than actual experimental observations. The differences arise because CVD is not an equilibrium situation, as assumed by SOLGAS, and because SOLGAS neglects kinetic factors influencing the reaction. It was shown that PSG reflow enhancement by steam has been well documented by several authors. A mechanism for this reflow enhancement involving the participation of water in the glass structure as OH⁻ ions is described, and supporting evidence has been given.

Bias-Dependent Etching of Silicon in Aqueous KOH

Orest J. Glembocki and Robert E. Stahlbush

Naval Research Laboratory, Washington, DC 20375

Micha Tomkiewicz*

Physics Department, Brooklyn College of CUNY, Brooklyn, New York 11210

ABSTRACT

The current-voltage characteristics and the bias dependence of the etch rates of <100>- and <111>-oriented n- and p-type low doped Si samples in aqueous KOH have been studied. We find that voltages cathodic of the open-circuit potential have little effect on the p-type etch rates, while the n-type etching is stopped. Anodic of the open-circuit potential, both carrier types stop etching, owing to passivation of the surface. These results are used to characterize the rate-determining steps of the chemical or electrochemical reactions which take place at the semiconductor surface at various biases. A mechanism is proposed in which the rate-determining step shifts between among chemical, electrochemical, or diffusion limited. Also, a mechanism involving susceptibility to nucleophilic attack is proposed to explain the vastly different etching rates of <100> and <110> vs. <111> faces.

The etching of silicon in aqueous KOH is of both technological and fundamental interest. Its technological promise stems from two properties. First, the etching rate of the <111> face can be several orders of magnitude less than that of the <110>, <100>, and any other fast etching plane (1). Second, heavy phosphorous or boron doping ($>10^{19}$ cm⁻³) inhibits the etching (2). As a result of these phenomena, it is possible to fabricate microstructures using KOH etching in conjunction with standard semiconductor processing techniques. For example, V-grooves, pyramids, and high-aspect-ratio structures of micron dimensions are routinely constructed. For more information about these types of applications, the reader is referred to the work of Kendall (3) and Angell *et al.* (4).

The fundamental interest in the etch-stop and orientation-dependent etching (ODE) of Si in KOH, as well as certain other basic solutions, dates back many years. Various studies such as current-voltage (1, 2, 5, 6), capacitance (6, 7), pH dependence of the etch rates (3, 8-11), illumination effects (6, 10), etc., have been performed. It is interesting to note that despite the volume of work on the problem, the mechanism of the corrosion processes that take place is still not understood. This state of events is not particularly surprising in view of our incomplete knowledge of the mechanism of corrosion reactions in simpler systems such as metals, in which passivation competes with corrosion. It is our objective, in this paper, to shed additional light on some of the most basic mechanistic questions concerning the etching of Si. In doing so, we hope to present a coherent picture of the current status of the field.

The most important question to consider is whether the rate-determining steps in the etching reactions are chemi-

cal or electrochemical in nature. The distinction between the two rests on the participation of free carriers in any rate-determining step (RDS). If the RDS is chemical, one might expect a simultaneous oxidation-reduction of the Si bond through a reaction sequence such as

followed by

The question marks in reactions [1] and [2] indicate the unknown nature of the catalysts (if any) that participate. In basic solutions, for example, OH⁻ is a good candidate to play this role. The question marks also imply that reactions [1] and [2] are not elementary steps, but are, rather, stoichiometric manifestations of an overall process which must be considered before any attempt at the understanding of the elementary steps can be contemplated. Equations [1] and [2] do not predict the final form of the etch by-products, as this will be greatly influenced by the pH of the solution. Therefore, the species leaving the surface could be different from those in solution.

If, however, the reaction is electrochemical in nature, then the most useful presentation on a level commensurate with Eq. [1] and [2] is given in terms of a short-circuit electrochemical cell. For a corrosion reaction to be represented as a short-circuit, energy producing cell, the potential difference across the interface should be between the equilibrium potential of the reduction reaction of the electrode and the equilibrium potential of the oxidation reaction of the electrode. Note that this implies that both reactions occur at the open-circuit potential (12). Electrochemical reactions can be complicated by the fact that

*Electrochemical Society Active Member.

the process can take place by short circuiting, physically separated reaction sites on the electrode or through the Wagner-Traud mechanism which does not require that the reaction sites be distinct in space and time; they can occur randomly over the surface of the electrode (12). Since our cell is energy producing, the presence of corrosion pits ("noise" in the etch profiles: see the experimental section) suggests some spatial separation in the oxidation and reduction sites. When an insoluble oxide forms at potentials anodic of the corrosion potential, as in the present case, the rate-determining step will change (for these biases) from being determined by the interfacial kinetics to diffusion through the passivating film.

The most useful tool to distinguish between the two mechanisms is to monitor the etch rate as a function of the electrode potential. For an electrochemical RDS, the etch rate should be proportional to the concentration of free carriers at the surface, which varies exponentially with the potential drop across the space-charge layer. If the mechanism is chemical, then the only dependence on the electric field across the interface is expected if the ionic diffusion across the passivating film is electric-field assisted. Even this simple criterion should be treated with caution. In the case of Fermi-level pinning, the concentration of free carriers will be unaffected by the electrode potential, and an electrochemical mechanism may behave like a chemical one.

In this paper, we present a study of the bias dependence of the etch rates of n- and p-type, lightly doped Si samples of $\langle 111 \rangle$ and $\langle 100 \rangle$ orientations. Hereafter, the notation n(111), etc., will be used in referring to n-type samples of $\langle 111 \rangle$ orientation, etc. We will compare the etch rates to linear-sweep voltammograms (I-V curves), taken under identical conditions. Waggener and Dalton (13) had previously studied the bias dependence of the etch rates for voltages anodic of the open-circuit potential (OCP), but did not consider potentials cathodic of the OCP, and thus their data are not adequate for our purposes. In the discussion section, we will utilize the rich harvest of prior experimental work, together with our own data and try to reach some conclusions as to the relative importance of the chemical and electrochemical mechanisms in the orientation-dependent etching of Si in KOH.

Experimental

The samples used in our experiments were commercial 2 in. diam wafers obtained from General Diode, Incorporated. The resistivities were typically 9-10 Ω -cm, and the orientation was within $\pm 1^\circ$ of the $\langle 111 \rangle$ or $\langle 100 \rangle$ planes. No special surface treatments were used. Two closely spaced contacts were made by first scratching the surface and then rubbing In-Ga amalgam into the damaged area. The two spots were subsequently tested on an I-V curve tracer. Finally, pressure contact was made to a copper wire.

In Fig. 1, we show a schematic representation of the experimental apparatus which was used for both the I-V measurements and the etching work. A PAR 173 potentiostat was used to bias the sample with respect to a standard calomel electrode (SCE). The sample cell was a beaker filled with KOH and was raised and lowered with respect to the electrodes with a scissor jack. Before etching, the wafers were masked with thermal oxide 0.6 μ m thick. Portions of the oxide were removed through standard lithographic techniques, leaving a grid pattern composed of squares of oxide, 0.8 mm on a side, separated by 0.4 mm wide streets and avenues of clean Si. The wafer was then cleaved into strips 3.6 mm wide. Figure 2 shows a schematic representation of a typical strip and the expected etch grooves. A negative oxide pattern was also tried, with no observable differences in the results.

The strip was submerged in 2M KOH at 20°C with the contact above solution. After removing the native oxide (signaled by bubbling and OCP stabilization), the KOH level was lowered by approximately 1 cm, and the sample was etched at the OCP. Typically, the level was lowered

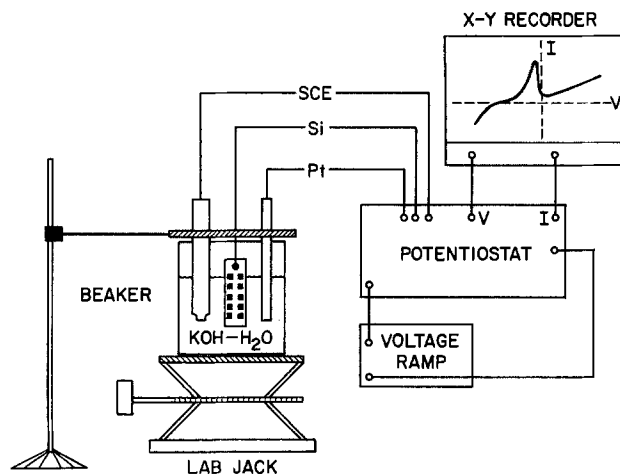

Fig. 1. The experimental arrangement for measuring current-voltage (I-V) characteristics and bias-dependent etch rates. The lab jack is used to lower the liquid level with respect to the sample. The voltage ramp is used only to obtain the I-V curve. All voltages are with respect to a standard calomel electrode (SCE).

several times and each time the sample was etched at a different bias. The etch times were 20 min for the fast etching $\langle 100 \rangle$ plane and 60 min for the $\langle 111 \rangle$ face. Key points as well as several random ones were rechecked using only three measurements per sample, i.e., native-oxide removal, OCP, and one bias.

The etch steps were measured by removing the oxide mask with HF and running a Dektak mechanical stylus down the length of the strip. This technique has a resolution of a few percent. In Fig. 3, we display a typical result from a stylus measurement (Dektak trace), which shows two nearly flat regions separated by a transition section of variable depth. The transition section is caused by etching due to a small amount of liquid creeping up the strip. The "noise" in the etched grooves is a result of nonuniform etching and was substantially reduced by stirring.

Results

In addition to the bias-dependent etch rates, we have also measured the current-voltage (I-V) characteristics of our samples. From these curves, we are able to determine

Fig. 2. A schematic representation of the oxide pattern used to protect portions of the sample during etching. The dashed line shows the direction of travel of the Dektak needle. To the right is a cross-sectional view of the expected etch grooves.

Fig. 3. A typical Dektak scan for an n(100) sample at the open-circuit potential (V_{oc}), which in the text is called the OCP. The trace is taken from left to right and corresponds to motion from the top of the sample toward the bottom. The unetched regions are $760 \mu\text{m}$ on a side.

both the open-circuit potential (OCP) and the passivation potential (PP). This information allows us to choose a range of voltages in which the sample has no oxide on the surface and is under etching conditions. Displayed in Fig. 4 and 5 are the linear-sweep voltammograms (taken at 0.02 V/min) for both n- and p-type Si samples of $\langle 100 \rangle$ and $\langle 111 \rangle$ orientations. The areas of all of the samples were approximately 1 cm^2 . There are two voltage regions of importance to us, and they are separated by the passivation potential. Just cathodic of the PP, the sample etches, while just anodic an oxide grows. For oxide-free surfaces, the OCP is always at more negative voltages than the PP.

The I-V curves of the $\langle 111 \rangle$ oriented samples show two peaks for both n- and p-type materials. Faust and Palik (1) have suggested that the more cathodic (left) peak is due to the passivation of the exposed edges, which correspond to $\langle 100 \rangle$ and $\langle 110 \rangle$ faces. Consequently, the true I-V curve of the $\langle 111 \rangle$ surface should be similar in shape to that of the $\langle 100 \rangle$ curves shown in Fig. 4. The major difference between the two orientations is the fact that the current densities at the passivation peak are almost an order of magnitude smaller on the $\langle 111 \rangle$ surface than on the $\langle 100 \rangle$ surface.

Another parameter which is very important in electrochemical reactions at semiconductor electrodes is the

Fig. 4. The room-temperature (I-V curves) voltammograms for n-type (solid line) and p-type (dashed line) samples of $\langle 100 \rangle$ orientation, denoted by n(100) and p(100), respectively. Here PP(n) and PP(p) refer to the passivation potentials of the n- and p-type samples, respectively, while V_{fb} is the flatband potential. The areas of the samples were similar and approximately equal to 1 cm^2 .

Fig. 5. The room-temperature (I-V curves) voltammograms for n-type (solid line) and p-type (dashed line) samples of $\langle 111 \rangle$ orientation. The notation for the passivation and flatband potentials is the same as in Fig. 4. The areas of the samples were similar and approximately equal to 1 cm^2 . The more negative peaks in both curves are spurious and caused by the passivation of exposed edges, which may have $\langle 110 \rangle$ or $\langle 100 \rangle$ orientations.

flatband potential. With previously unpublished electrolyte electroreflectance (14) and capacitance (15) measurements, the flatband potentials have been determined for Si in $2M \text{ KOH}$ and are $V_{FB} = -1.0V$ and $V_{FB} = -0.2V$ for n- and p-type samples, respectively. From these numbers, we find that the p-type sample was in depletion (hole) during both etching and oxide growth. However, since there is evidence for Fermi-level pinning in p-type Si, its value of flatband is somewhat questionable (16). For the n-type sample, the situation is different and the data clearly show that flatband occurs between the OCP and the passivation potential. Therefore, the n-type sample is in electron accumulation during etching and in depletion at oxide producing potentials.

A closer examination of the figure reveals that the OCP as well as the PP are not the same for n- and p-type Si; the values for the p-type samples are somewhat more cathodic than for the n-type. This information will be used in our discussion of the bias dependence of etching.

In Fig. 6, we display our results for the etch rates of n(111), n(100), p(111), and p(100) Si over the range of -2.0 to $-0.5V$. The measurements were taken at room temperature, and the resistivities of all of the samples were similar. Each point represents an average of several measurements, with a spread of $\pm 20\%$. The first thing to note is the fact that our OCP results for the $\langle 111 \rangle$ face (both carrier types) agree with the etch rates previously measured by weight loss (1), whereas our p(100) and n(100) values are somewhat larger. This may be attributable to the fact that the wafers used in the weight-loss experiments had roughened back surfaces, which probably exposed many $\langle 111 \rangle$ facets, having reduced etch rates. Under these conditions, the measured etch rate would be an average of the etch rates of the front and back faces. Since in our case, etch depths were measured, no such problem was encountered.

We also note that the etch rates for the $\langle 111 \rangle$ surface are about an order of magnitude smaller than for the $\langle 100 \rangle$ face. For "perfectly" oriented samples, Kendall (17) has shown that this factor is 400 and that the etching in misoriented materials is due to ledges formed by the intersection of the $\langle 111 \rangle$ surface with a faster etching plane, such as the $\langle 110 \rangle$ or $\langle 100 \rangle$ faces. Since the n(100) and p(100) etch rates are similar at the OCP, the factor of 3 difference between the n(111) and p(111) etch rates in the data of Faust and Palik (1) as well as this work may be a manifestation of the misorientation effect rather than a carrier-type effect.

Fig. 6. The bias dependence of the etch rates for (a) p(100) and n(100), and (b) p(111) and n(111) low-doped Si. The data have an experimental spread of approximately $\pm 20\%$. The open-circuit (OCP) and passivation (PP) potentials are marked. Note that the OCP is the same for the n(111) and p(111) samples. Also shown are the approximate potential ranges in which the samples (of both orientations) are in accumulation and depletion modes. Even though we have depicted the p-type samples as in depletion, the experimental evidence strongly supports Fermi-level pinning at these biases.

Next, we see that all of the samples stopped etching at anodic biases, owing to passivation of the surface. The etch rates are finite near the passivation potential for all samples except n(111), because, even though oxidation begins to occur, etching of the substrate and newly formed oxide continues. For these biases, our results are similar to those of Waggener and Dalton (13).

At cathodic potentials, however, we see a substantial difference in the n- and p-type etch rates. The p-type samples continue to etch at a rate close to that of the OCP value, whereas the n-type Si exhibits etch-stop. We also note that for the n(100) sample there is an increase in etching for voltages between the OCP and the cathodic etch-stop bias. Furthermore, a point is seemingly out of place. However, this point and its immediate neighbors were checked several times and found to be reproducible, suggesting the possibility of structure in the curve in this voltage range. Since we currently have no reason to expect structure, we have chosen to draw two curves, which fit the data.

We also notice that not only is the etch rate for the $\langle 111 \rangle$ face much smaller than for the $\langle 100 \rangle$ plane, but that under bias the ratio of the $\langle 111 \rangle$ etch rate to the $\langle 100 \rangle$ etch rate is not a constant and, in particular for the p-type samples, it can be decreased by an order of magnitude. This fact presents us with the possibility of utilizing a bias to control the orientation-dependent effect. The fact that even low doped n-type samples stopped etching under cathodic bias suggests that p-n junctions could be used to make thin ($< 3 \mu\text{m}$) Si membranes of fairly low carrier density. This would be accomplished by a diffusion or implantation of donor atoms into one side of a

p-type wafer. The etching would then be performed at a bias (cathodic or anodic) which exhibits n-type etch stop. A similar idea was suggested by Waggener (18) for the case of anodic potentials at which the n-type material passivates and the p-type does not. But, to our knowledge, the cathodic etch-stop has not been previously observed. In the next section, we will attempt to understand the origins of the observed bias dependence of the etch rates.

Discussion

Chemical mechanism.—The most compelling argument in favor of a chemical mechanism for etching of Si in KOH is based on the results observed by Price (8) and by Palik *et al.* (2) that the etching is independent of carrier density, for both n- and p-type Si, up to a concentration of about $N \approx 10^{19} \text{ cm}^{-3}$. For $N > 10^{19} \text{ cm}^{-3}$, there is a dramatic decrease in the etch rate, i.e., the etch-stop mechanism. For fixed flatband and electrode potentials, the electric field, and free-carrier density at the surface depend upon the doping level (linear with $N^{1/2}$ for conditions within the Mott-Schottky approximation) (18). Therefore, one expects a strong variation of the concentration of free carriers at the surface with the doping level. Here again, if the Fermi level is pinned to surface states (even for the low doped materials), the conclusions that one draws from these experiments might have to be modified. As stated in the previous section, there is strong evidence for Fermi-level pinning in p-type Si in 2M KOH, and care must be taken in dealing with these data.

Since for n-type materials the OCP is slightly negative of the flatband potential, the system will be in an accumulation mode at the OCP. Glembocki and Palik (14) have observed in their electroreflectance work evidence for the onset of Fermi-level pinning (in n-type samples) for biases cathodic of -2V , but not in the range of voltages of interest to us. Thus, one is hard pressed to find a mechanism that will depend on the free-carrier density at the surface and yet be insensitive to five orders of magnitude variation in doping level for both n- and p-type materials. Another strong argument in favor of a chemical mechanism which is independent of free carriers is the observation that under open-circuit conditions there is very little difference between the etch rates of n- and p-type samples of the same orientation (1-3). These results point to a chemical RDS under open-circuit conditions.

Electrochemical mechanism.—In Fig. 6, we show the experimental etch rates for both orientations and carrier types over a broad potential range. At the OCP, where the etching is close to its maximum, the difference in the etch rates is small (at most a factor of 3 for the misoriented samples). But this difference increases substantially as one goes anodic and cathodic of the OCP.

This result might be addressed in relation to the differences found in the linear-sweep voltammograms (I-V curve) taken under identical conditions and shown in Fig. 4 and 5 for the $\langle 100 \rangle$ and $\langle 111 \rangle$ faces. It is seen here, confirming prior observations, that the current densities at the PP are almost the same for the n- and p-type samples. However, aside from this, very little else is identical. The passivation and rest (OCP) potentials are different for n- and p-type samples of a given orientation and cathodic to the PP, the current of the p-type material saturates (or passivates), while for the n-type the cathodic current (hydrogen evolution) grows. All of this seems to suggest that free carriers play a dominant role in these reactions. In the next section, we will try to relate the facts mentioned above to the nature of the RDS.

Characterization of the rate-determining steps.—Here, we will concentrate on the ramifications of our experimental results to the question of whether the RDS involves free carriers or is chemical in nature. As stated above, the evidence is strongly in favor of a chemical RDS at the open-circuit potential. However, all of our data indicate that this may not be the case at other applied voltages. The voltammogram itself is an electro-

chemical experiment which measures the flow of free carriers in some parts of the electrochemical cell. Since the contributions of ionic mobilities within the semiconductor are negligible, the similar current densities at the passivation peaks of the n- and p-samples (for both orientations) strongly support the contention that at least at these potentials the RDS is chemical. Faust and Palik (1) also found that the peak currents are independent of carrier density. Furthermore, Palik and Bermudez (20) have observed a thin connective layer ($\sim 7\text{-}10\text{\AA}$ thick) between the substrate and oxide on both n- and p-type samples. The transition region is oxygen deficient and can be characterized as $\text{Si}_{1-y}(\text{SiO}_2)_y$, with $y \approx 0.1$. The fact that the connective layer is the same for both carrier types favors a chemical RDS for its formation. This is in contrast to the growth (at more positive voltages) of an anodic oxide (SiO_2), which requires the presence of holes.

A chemical mechanism, similar to Eq. [1] and [2], for the oxidation of the first Si—Si bond, followed by faster electrochemical processes to oxidize subsequent bonds (of the same atom), offers a qualitative explanation for the similar current densities of the different carrier-type samples at the PP. Here, both the first and subsequent bonds lie below the oxidized (or hydrated) surface. It should be noted that the chemical reaction is the RDS for the connective layer growth (as well as the current production). This type of mechanism is similar to one proposed for the oxidation of GaAs in the presence of bromine (21).

The growth of the oxide comes as a result of a competition between the oxidation of Si at the interface and the dissolution of the oxidized products. If the dissolution of the oxidized species is faster than their formation, significant hydrogen evolution should take place. At potentials anodic to the PP, the electrochemical hydrogen-evolution will be quenched and the equilibrium will shift to the formation of the oxide. Here, the RDS will change from being determined by the charge-transfer reactions at the Si interface to being controlled by diffusion across the oxide (1). In the following discussion, we describe the various reactions as applied to the n- and p-type samples.

p-Type silicon.—We will first consider p-type materials, for which the majority carriers are holes. Anodic to the PP, the surface is in depletion and enough holes are available to oxidize the Si through an electrochemical mechanism such as

where v and c denote valence and conduction bands, respectively. This reaction involves current doubling (21, 22) and is similar to one proposed by Turner for Ge (23, 24) in F^- solutions. In our case, the oxide dissolution is much slower than its formation and a film grows. An oxide (SiO_2) can be formed by removing water from the final products in Eq. [3]. The electrons, which are injected into the conduction band, will either recombine with the majority carriers at the surface or reduce the electrolyte producing hydrogen. At potentials in which such a mechanism can take place, the diffusion of the electrolyte through the oxide will be the RDS.

If, after oxide growth, we go cathodic and approach the PP, the surface starts to be strongly depleted of holes and the chemical mechanism takes over. Dissolution of the oxidized species will compete with their synthesis. If the new applied potential is anodic of the PP, only a portion of the oxide will be removed, whereas for biases cathodic of the PP all of the oxide etches. Cathodic of the OCP, the current saturates, and the etch rate remains constant and near its OCP value. The be-

havior of the current can be understood from a band model of the semiconductor/electrolyte interface (22). In our case, depletion conditions will result in current saturation. Since in depletion, few free carriers are present, the position of the bandedges with respect to any redox couple in the liquid is independent of the applied voltage, and, therefore, any electrochemical reactions which may occur at the solid surface should be independent of bias. For p-type samples, the equilibrium between electrochemical hydrogen evolution due to the electrolysis of water (current-producing) and the chemical one resulting from Si etching will be independent of the applied bias. The large cathodic voltage range over which the current saturates and the etch rate is nearly constant probably results from Fermi-level pinning.

n-Type silicon.—The flatband potential of the n-type sample occurs at a voltage slightly cathodic of the PP. At the PP, the chemical oxidation process is the RDS and a connective layer is formed. In this sample, however, there is a lack of holes and reaction [3] cannot readily proceed. Consequently, even at large anodic biases (which result in thick films on the p-type material), no appreciable oxide is grown. This is consistent with ellipsometric measurements, which indicate that intense illumination is required to produce any substantial amount of oxide on an n-type sample (1).

Cathodic to the PP, the semiconductor is in accumulation and majority carriers become available at the surface for reducing the solvent. At the OCP, the etching reactions, accompanied by H_2 evolution, will dominate. However, more negative of the OCP, hydrogen evolution will proceed not through the hydrolysis of Si—Si bonds (etching) but rather through the reduction of the solvent (electrolysis). Etching will stop, and the hydrogen evolution will follow the conventional electric-field-mediated activation mechanism which is dominant on most metals and n-type semiconductors in an accumulation mode.

Illumination effects.—The nature of the RDS can also be probed by the introduction of free carriers. Even though the etching of Si under illumination has been studied by several workers, a clear picture of the effects of light on the OCP etch rates has not been developed. The weight-loss measurements of Repinskii and Pershkova (10) in NaOH showed that under illumination, the n-type Si etch rates were reduced, whereas Izidinov *et al.* (6) found that light had no effect on the hydrogen evolution of n-Si in KOH. We have performed preliminary weight-loss measurements which indicate that under illumination the n-type etch rates are decreased, while the p-type etching is unaffected. These results, along with those of the hydrogen-evolution experiments of Izidinov *et al.* (6), suggest that the introduction of free carriers has a different effect on the two carrier types. For the n-type material, the RDS seems to shift toward the electrochemical hydrogen-evolution reaction, while in the case of the p-type sample a large anodic shift in the OCP suggests the possibility that the Fermi level is unpinned without any change in etching. The reason for this phenomenon is not known. In general, the effects of light on the etching of Si are not understood and require further investigation.

Orientation dependence.—The orientation dependence of the OCP etch rates is the focus of the technological interest in this system. From Fig. 4, 5, and 6, one can see that qualitatively the $\langle 100 \rangle$ and $\langle 111 \rangle$ faces behave similarly as a function of the electrode potential. The mechanistic arguments that were explored in the previous section will apply equally to both orientations (or any other orientation). The only obvious difference that can be observed is in the magnitudes of the etch rates and current densities involved. Since our samples were probably misoriented by approximately 1° , the differences shown here may not reflect the actual differences between the $\langle 100 \rangle$ and $\langle 111 \rangle$ surfaces. Kendall (17) has

shown that the etch rate of a misoriented $\langle 111 \rangle$ sample is that of ledges formed from the intersection of the $\langle 111 \rangle$ plane and $\langle 100 \rangle$ or any other fast etching face.

Kendall also noted that the oxidation rates go in reverse order to the etch rates (3). He suggested that since the $\langle 111 \rangle$ plane oxidizes more rapidly, it is immediately covered with an oxide layer that slows further etching. Such a protective prepassive layer was reported to be observed on GaAs (25). However, the more recent ellipsometric results of Palik and Bermudez (20) found no such layer on Si. Epova *et al.* (9) proposed that the selectivity correlates with heat of adsorption of water, which according to Meyer and Moributo (26) is smaller for the $\langle 100 \rangle$ surface than for the $\langle 111 \rangle$ face. According to them the reaction requires simultaneous adsorption of OH^- and H_2O , in agreement with Eq. [1] and [2]. They showed that propyl alcohol, which can reduce the number of available adsorption sites for water, decreases the pre-exponential factor in the expression for the etch rate by as much as three orders of magnitude. This correlation can account for the observations and is fully consistent with the mechanism proposed in the previous section.

Price (8) has tried to correlate the etch rates to the bond densities on the two surfaces. However, these differ by no more than a factor of 2. A related argument that was advanced by Ligenza (27) to account for the orientation dependence of oxidation rate of Si by steam, is that bonds which are parallel to the surface are easier to oxidize than bonds at an angle with surface. On this basis, it was postulated that the activation energies for this reaction (oxidation) should increase in the following order: $\Delta E_{100} > \Delta E_{111} > \Delta E_{311} > \Delta E_{110}$.

Let us now introduce some "chemical" arguments into this picture and try to correlate them with the mechanistic considerations that we have previously discussed. The etch rate of a given surface can be written as (14)

$$R(s) = R_0(s)e^{-\Delta E_s/kT} \quad [3]$$

where s denotes the surface orientation and can be 111, 100, etc. Here R_0 is a pre-exponential factor which may depend upon s , the free-carrier density, etc., ΔE_s is the activation energy of the chemical reaction, and T is the temperature.

If we neglect relaxation of the surface then on the average, the termination of the lattice for the $\langle 100 \rangle$ face can be represented as

and for the $\langle 111 \rangle$ surface as

where we have assumed that all of the dangling bonds are fully oxidized. Based on the electronegativity of the hydroxyl group, we expect the surface OH species to behave as an electron withdrawing group, making the Si susceptible to nucleophilic attack by OH^- (28). This effect should be stronger in the case of the $\langle 100 \rangle$ surface, which has two OH groups per surface atom. The difference in the susceptibility to nucleophilic attack would manifest itself through the activation energy and would have an exponential effect on the ratio of the etch rates of the $\langle 100 \rangle$ and $\langle 111 \rangle$ faces. It is interesting to note that the etch rates increase with the concentration of the base to a maximum near $4M$ and then slowly decrease. This effect may be related to the relative concentrations of water and OH^- .

The activation energies of the $\langle 100 \rangle$ and $\langle 111 \rangle$ faces have been measured, and little difference between the two was found (8, 29). This result is not surprising, because the samples were of commercial grade and probably oriented only to $\pm 1^\circ$. Based on Kendall's work, we conclude that the measured activation energy for the $\langle 111 \rangle$ surface was actually representative of the ledges, rather than the true $\langle 111 \rangle$ face.

The $\langle 110 \rangle$ face is somewhat more complex than the $\langle 100 \rangle$ and $\langle 111 \rangle$ surfaces (3). Each surface atom has one back bond to the lattice and one oxidized bond. The remaining two bonds are in the plane of the surface and connect adjacent surface atoms. This situation is different from that of the other faces, on which neighboring surface atoms do not share common bonds. We postulate that even though there is only one oxidized surface bond per atom, the OH group on its neighbor will also contribute to electron withdrawing from the common Si-Si bond. Therefore, the activation energy of the $\langle 110 \rangle$ face should be comparable to that of the $\langle 100 \rangle$ surface, and the difference in etch rates between the two attributable to the pre-exponential factor.

Until now, we have neglected the role of the pre-exponential factor, which is characteristic of the entropy of the reaction and is related to the crystal orientation. Since the etch rates depend linearly upon this parameter, it is difficult to imagine that it alone could account for a factor 400 in the etch rates. However, owing to the difference in bond orientations on any two faces, one does expect it to contribute. As mentioned above, its effect may be important in the difference in the etch rates of the $\langle 100 \rangle$ and $\langle 110 \rangle$ faces.

From the above discussion, we see that it is vital to accurately determine the relative contributions to the etch rates of R_0 and ΔE_s . The activation energy of the $\langle 111 \rangle$ surface must be measured on a perfectly oriented material. This might be accomplished through a technique similar to the one used by Kendall to obtain the true $\langle 111 \rangle$ etch rates.

Conclusions

We have presented experimental results for the bias-dependent etch rates and the current-voltage behavior of n- and p-type Si of $\langle 111 \rangle$ and $\langle 100 \rangle$ orientations. The data show that at voltages cathodic of the OCP, the n-type materials stops etching, while the p-type etch rate is unaffected. In order to account for these observations as well as the results of the considerable amount of prior work, we proposed a mechanism which involves an RDS that shifts between a chemical mechanism, an electrochemical mechanism which involves free carriers, and one limited by the diffusion of electrolyte through the oxide layer. At the OCP, the RDS participates in the chemical cleavage of the first Si-Si bond and is accompanied by hydrogen evolution. Anodic to the PP, the hydrogen-evolution reaction is quenched, and the forming oxide layer limits diffusion of the electrolyte. Cathodic to OCP, and RDS remains the same for the p-type material, while for the n-type material the reaction shifts to an electrochemical hydrogen-evolution reaction, resulting from the presence of majority carriers (electrons) at the surface.

We also proposed a mechanism which can account for the orientation dependence of the etch rates and is consistent with the overall scheme. The mechanism involves the difference in reactivity to nucleophilic attack of a Si sample which has two oxidized surface bonds (the $\langle 100 \rangle$ surface) compared with one that has only one oxidized bond ($\langle 111 \rangle$ face). This mechanism also accounts for the relative etch rate of the more complicated $\langle 110 \rangle$ face.

Owing to the complexity of the system, we have not concentrated upon the details of the reaction, but rather have developed an overview from which more detailed questions can be more systematically asked. In particular, we have attempted to clarify under which conditions the experimental results indicate participation by free-charge carriers and under which conditions spontaneous chemical reaction accounts for the rate-determining step.

Comparison of Thin Thermal SiO₂ Grown Using HCl and 1,1,1 Trichloroethane (TCA)

Richard G. Cosway and Schyi-yi (C.-E.) Wu

Motorola, Incorporated, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

ABSTRACT

HCl and 1,1,1 trichloroethane (TCA) were used as chlorine sources for the growth of thin ($\leq 150\text{\AA}$) oxides. The resultant oxides were compared for ϕ_{ms} , breakdown voltage (both ac and dc), tertiary breakdown fractions, C-V shifts, and leakage current. The total C-V shift at flatband was more than twice as large for the TCA oxides as for the HCl oxides though ϕ_{ms} , the average breakdown voltage, tertiary breakdown fractions, and leakage current were comparable for the two chlorine sources. The breakdown and C-V shift distributions were tighter for the HCl oxides.

Several chlorine sources (HCl, Cl₂, 1,1,2 trichloroethene (TCE), 1,1,1 trichloroethane (TCA), and dichloroethane) can be used during oxidation to enhance the oxide growth rate, reduce defects, and improve the passivating ability of the resultant oxide. The role of chlorine in silicon oxidation was reviewed in more detail by Monkowski (1, 2). HCl has been widely used while TCA is emerging as an alternate chlorine source.

At room temperature, HCl is a gas and so is plumbed into a furnace in the same manner as the other gases except that special attention must be paid to ensure that the HCl stays as dry as possible. When dry, HCl is noncorrosive, but it can readily absorb water and become very corrosive even to stainless-steel fittings. Therefore, all fittings for HCl use must be kept tight to keep any air and its moisture from entering the lines.

TCA is a volatile liquid at room temperature with a boiling point of 74.1°C (3). At room temperature, TCA has a high enough vapor pressure to be carried to the tube in

significant amounts by a carrier gas passing through a bubbler containing the liquid. An inert gas (N₂ or Ar) must be used as the carrier because O₂ used as a carrier can cause the mixture to burn or explode (4).

TCA can be dangerous at elevated temperature even with small amounts of oxygen present, since it can react to form phosgene (COCl₂), an extremely poisonous gas (5). An excess of oxygen must be maintained to assure no phosgene formation in the lines or the tube. For this reason, as soon as possible after the TCA leaves the bubbler in an inert stream, it is mixed with a great excess of oxygen before it starts heating up near the tube entrance.

When in an oxygen excess at temperatures > 300°C, TCA reacts initially according to the reaction

These primary reaction products can then further react, depending on temperature, to compounds such as Cl_2 , H_2O , and, to a lesser extent, CO .

In this paper, the oxides grown using these two chlorine sources are compared for ϕ_{ms} , dielectric breakdown voltage, tertiary breakdown fraction, C-V stability, and current leakage.

Experimental

The wafers used were 75 mm Czochralski-grown of $\langle 100 \rangle$ orientation. All were phosphorus doped to 8.0-12.0 $\Omega\text{-cm}$ except for the p-type samples used in the ϕ_{ms} study. Those were boron doped to 14.0-22.0 $\Omega\text{-cm}$. All wafers were given a standard piranha clean immediately prior to being run.

The 160 mm id quartz tube and boat used for all oxidations were cleaned prior to every run at 1000°C for 1h, with either 10% HCl/90% N_2 for HCl oxidations or TCA to yield after pyrolysis 9.2, 6.1, 76.4, and 8.3% HCl, CO_2 , O_2 , and N_2 , respectively, for TCA oxidation.

The furnace that was used for all oxidations was equipped with a microprocessor which controlled the rate of the boat pusher/puller, the temperature of the tube, ramp temperature, and gases.

The wafers were pushed into the oxidation tube at low temperature, to prevent thermal stress-induced damage, and then ramped to 900°C in N_2 containing a small amount of oxygen to grow a thin layer of SiO_2 to protect the wafer surface from being thermally etched. Oxidation at 900°C consisted of a 20 min dry O_2 cycle followed by 22 min of O_2 + 3 volume percent (v/o) HCl equivalence. Thick enough oxide was grown in the 20 min dry O_2 oxidation to insure no surface etching by HCl in the subsequent oxidation cycle. The 3 v/o HCl equivalence is 3 v/o HCl or the amount of TCA necessary to yield, after pyrolysis, the same HCl flow rate. The concentration of HCl during a TCA oxidation was actually somewhat less than 3 v/o because the CO_2 and carrier gas present increased the total flow. A 60 min 900°C N_2 anneal followed the oxidation.

Following the oxidation, 4000Å of aluminum was deposited (dc magnetron) on the front of the wafers using a mask that gave circular dots with nominal areas of $7.5 \times 10^{-3} \text{ cm}^2$. The back oxide was then RF sputter etched for 3 min and 1000Å of Al was deposited all over to provide good back contact. Following this, the wafers were annealed at 450°C in forming gas (5 v/o H_2 /95 v/o N_2) for 30 min. This forming gas anneal gave the best C-V stability upon bias-temperature stressing among all conditions investigated (350°-550°C for 30 min and 450°C for 10-60 min).

Oxide thicknesses were measured using an automated spectrophotometer after the metal had been deposited and annealed.

C-V measurements were made on a computerized C-V plotter with the first trace being taken after unbiased (shorted) heating of the sample to 200°C, holding it there for 1 min, and then cooling it back to 25°C. The second trace was taken after biasing the sample at 3 MV/cm oxide while it was heated to 200°C, held at 200°C for 1 min, and cooled back to 25°C. The third trace was taken after biasing the sample at -3 MV/cm of oxide while it was heated to 200°C, held at 200°C for 1 min, and then cooled back to 25°C. The only flatband voltage shifts reported are the total shifts, i.e., the shift between the leftmost and rightmost trace at flatband.

Dielectric breakdown measurements were taken using a curve tracer with the collector output connected to a probe on the top of the aluminum dots. The base output was connected to the vacuum chuck holding the wafer. AC and dc breakdowns were taken in the same manner, with the collector voltage ramped manually (at about 5 V/s in accumulation mode), the only difference being the waveform used. In the case of the ac breakdown, it was a full-rectified (60 Hz) sine wave. As noted in the text, breakdowns are destructive or defined at $26 \mu\text{A cm}^{-2}$. The latter value corresponds to about 10 MV cm^{-1} , below which the breakdown field is independent of ramp rate (6).

Note that the spread in destructive breakdown voltage is partly due to variation in voltage ramp rate (6). In addition, ac destructive breakdown voltage is about 2V higher than the dc destructive breakdown. This is explained below.

Two charging processes can occur upon application of high enough field: (i) charging of pre-existent traps and (ii) creation of traps and trapped electrons. Charging may enhance local internal field. When a certain local internal field is exceeded, numerous Si-O bonds have been broken and the oxide breaks down (6). The charging processes continue uninterrupted in dc measurements since applied voltage continues to rise. But, the charging processes are constantly interrupted in ac measurements because the applied voltage oscillates up and down. That is, the average rate of charging is lower in ac measurements than in dc measurements at the same ramp rate. Thus, higher applied ac voltage is required to cause oxide breakdown than applied dc voltage.

Leakage current measurements were taken using a power supply/amplifier and a picoammeter connected to a shielded probe.

Results and Discussion

ϕ_{ms} and total oxide charge.—An oxide related parameter that is of particular importance to device characteristics is ϕ_{ms} , i.e., the metal-semiconductor work function difference. Previous investigations (7) have shown that ϕ_{ms} is process related and so, for an accurate value, it must be determined for each set of process conditions. One way to determine ϕ_{ms} from oxide C-V data is from the equation (8)

$$V_{\text{FB}} = \phi_{\text{ms}} - \frac{Q t_{\text{ox}}}{\epsilon_0} \quad [2]$$

By plotting V_{FB} (the voltage corresponding to the flatband capacitance of the initial unbiased trace) as a function of t_{ox} (the oxide thickness), a straight line should be obtained with a slope of $-Q/\epsilon_0$ (total charge divided by oxide permittivity) and an intercept at ϕ_{ms} .

Oxides were grown in both HCl and TCA and on both n- and p-type substrates in thicknesses of 100-300Å. The resultant V_{FB} 's are plotted as a function of t_{ox} in Fig. 1. The data follows a straight line well with each ambient and substrate. For each substrate type, little or no difference is seen between HCl and TCA oxides. The "total charge" is about $1 \times 10^{11} \text{ cm}^{-2}$ on n-type substrates and $5 \times 10^{10} \text{ cm}^{-2}$ on p-type substrates.

ϕ_{ms} is shown to be about +0.1V for the n-type and about -0.7V for the p-type substrate. Compare this with -0.3

Fig. 1. V_{FB} as a function of t_{ox} for TCA and HCl oxides

and $-0.9V$, respectively, for thick oxides given in the literature (8).

Also implicit in Fig. 1 is a comparison of the rate of oxidation in HCl vs. TCA. Adjacent points, that is each circle with the corresponding triangle for HCl and TCA oxidations, respectively, were oxidized for the same time. It can be seen that, in all cases, TCA runs result in 5-10% thinner oxides than the comparable HCl runs. This is likely due to the lower concentration of O₂ and HCl in the TCA runs.

C-V stability.—For each kind of oxide, a total of 12 capacitors (6 wafers \times 2 capacitors/wafer) were measured for total flatband voltage shift. HCl oxide gave less shift than TCA oxide (14 ± 12 vs. 37 ± 20 mV) at the 90% confidence level. There was no apparent difference in the skewedness of the plots for the two chlorine sources, so no qualitative or quantitative statement about D_{it} differences can be made.

Current conduction.—The conduction of both HCl and TCA oxides followed the Fowler-Nordheim tunneling mechanism (9) in the high field regime, as evidenced by the linear relationship between $\log(J/E^2)$ vs. $1/E$. Leakage is <1 nA cm⁻² for voltages up to 7.5V for both kinds of oxides. The above conduction measurements were taken in dc mode at 1/2V increments with a 1 Vs⁻¹ ramp rate and a 4s delay between attaining the desired voltage and taking the reading.

Dielectric breakdown.—DC breakdown voltage (defined at $26 \mu A$ cm⁻²) histograms are shown in Fig. 2 for HCl oxide and Fig. 3 for TCA oxide. Each histogram was obtained from three oxidation runs (six wafers from one run and two wafers each of the other two runs). Ten capacitors per wafer were measured. The yields (those capacitors that failed at the highest voltage peak) were 85%, 85%, and 95% (14.5V) for HCl oxide and 90%, 100%, and 75% (14.0) for TCA oxide. Thus, the average yield by this definition is the same for both types of oxides (88.3%), but HCl oxide showed tighter distribution below the highest breakdown voltage peak.

CO₂ effect.—Since the amount of CO₂ generated during the pyrolysis of TCA is comparable to the amount of HCl formed, an investigation was undertaken to see what effect the presence of CO₂ had on the resultant oxides. Also, to give an idea of the process latitude with respect to CO₂, extreme amounts were used, even though when using TCA this concentration is fixed. The same flow sequence used for 150Å HCl oxides was used; however, the O₂/HCl cycle gas flows were changed. The HCl flow remained the same but the rest of the flow was made up of various combinations of CO₂ and O₂ (Table I). The CO₂ flow was about 2% in the standard TCA oxidation. Note that, as the CO₂ concentration increased, the HCl/O₂ ratio

Fig. 2. Breakdown voltage (dc, $26 \mu A/cm^2$) histogram for 150Å HCl oxide.

Fig. 3. Breakdown voltage (dc, $26 \mu A/cm^2$) histogram for 150Å TCA oxide.

increased and the O₂ concentration decreased. The last set of flow conditions means an ambient of only CO₂ and HCl and no O₂. In this case, the oxide is produced in dry O₂ and then "annealed" in a mixture of CO₂ and HCl before the N₂ anneal.

Oxide thickness is shown to monotonically decrease with increasing CO₂ concentration. This is due to the corresponding decrease in O₂ concentration. Previous experiments showed oxidation by CO₂ at 900°C for 1h to be insignificant.

No significant effect on tertiary breakdowns ($<1V$) is seen, at least up to a CO₂ concentration of 72.75%. (Note that no tertiary breakdowns were measured for 100Å oxide.) The higher fraction of tertiary breakdowns (10%) for the 90Å oxide could be due to thinner oxide rather than a CO₂ effect, since 100Å HCl oxide sometimes showed $>10\%$ tertiary breakdowns.

DC breakdown field (destructive) and the spread are not degraded by CO₂ in the concentration range studied. The same Fowler-Nordheim I-V characteristics were observed for CO₂ concentrations $\leq 48.5\%$. At 72.75%, the I-V characteristics deviate only slightly from those for lower CO₂ concentration. At 97%, I-V characteristics showed obvious departure from those for lower concentrations and a more gradual increase in current with voltage. This could be due to the thickness or HCl effect, since no O₂ is present at this CO₂ concentration and etching of the silicon and/or the SiO₂ by HCl is possible. Nevertheless, it appears possible to produce oxides as thin as 100Å with only a few low field breakdowns.

Total flatband C-V shift is seen to be small for all concentrations investigated. Even though the data show some scatter, because of the small magnitudes, all results are considered equivalent.

From this study then, it can be concluded that CO₂ present during oxidation using TCA produces insign-

Table II. Lag time effect on ac breakdown field of 150Å HCl and TCA oxides (MV/cm)

Premetal lag time	Postanneal lag time	1 day	1 week	2 weeks	1 month	2 months	3 months
		1 day	HCl TCA	14.0 11.9	13.7 14.0	14.3 15.3	14.6 14.0
1 week	HCl TCA	13.5 12.8	14.6 13.0	14.1 13.7	14.0 10.8	13.8 12.6	12.7 13.1
2 weeks	HCl TCA	15.3 13.5	— —	14.7 13.0	— —	14.3 13.8	14.0 13.5
1 month	HCl TCA	14.1 14.0	13.2 12.5	14.3 14.1	— —	14.3 13.6	15.4 14.3
2 months	HCl TCA	14.1 14.7	14.8 15.0	14.3 14.4	14.4 15.7	14.6 13.9	13.7 14.5
3 months	HCl TCA	14.4 15.9	— —	— —	15.3 15.9	15.2 16.0	14.2 13.8

nificant effects on tertiary breakdowns ($< 1V$), dc breakdown field (destructive), total flatband C-V shift, and oxide thickness.

Process lag times.—One concern, especially for thin oxides, is that the oxides may degrade upon storage. To examine this effect we chose two long lag times and ran a matrix with each lag time ranging from 1 day to 3 months. These two lag times were the premetalization lag time between oxidation and metal deposition and the postanneal lag time between metal anneal and breakdown measurement (ac destructive). Four wafers were prepared for each of the six metallization lag times, and five capacitors were measured on each wafer to arrive at an average breakdown field for each point in the premetalization and postanneal lag time matrix.

Results for both HCl and TCA oxides are shown in Table II, where it is apparent that storing has no effect on breakdown voltage in the chosen time span.

In this experiment, a total of 598 capacitors on 24 wafers for each kind of oxide were measured. The fraction of tertiary breakdowns ($< 1V$) is only 0.5% in each case. The means and standard deviations are 21.2 and 3.8V for the HCl oxide and 20.9 and 4.5V for the TCA oxide. T- and F-tests with a 95% confidence level show that the average ac breakdown voltages (destructive) can be considered

equal, but the HCl distribution is tighter than the TCA distribution.

Conclusions

Electrical characteristics of 150Å HCl and TCA oxides are summarized in Table III. Both HCl and TCA yield acceptable 150Å oxides with few tertiary breakdowns (0.5% $< 1V$), average breakdown strength of 14 MV/cm (ac, destructive), and low leakage current. However, HCl oxides have less C-V shift and a tighter breakdown distribution. The CO₂ present during TCA pyrolysis has been shown to have no significant effect on tertiary breakdowns ($< 1V$), average breakdown field and spread, and C-V shift.

Acknowledgments

The authors wish to thank Ginger Stapleton for providing all of our metal deposition, Dan McGuire for performing the I-V measurements, Craig Thornton for his valuable assistance in the design of the TCA transport system, and Glenn Shirley for helpful discussions.

Thermal and Physical Properties and Etching Characteristics of PI Films

Atsushi Endo and Toshio Yada

Mitsubishi Electric Corporation, Materials and Electronic Devices, 1-1, Tsukaguchi Honmachi 8 Chome, Amagasaki, Hyogo 661, Japan

ABSTRACT

The thermal properties of spin-coated polyimide films and their etching characteristics are evaluated. The physical properties of polyimide films are presented, such as density, softening temperature, thickness, and wet etching characteristics which change with curing temperature. Wet etching characteristics, such as the etch rate and the pattern profile, are influenced not only by the imidization, but also by the molecular state of aggregation. When the crystallinity is chosen as the physical parameter, the wet etching characteristics closely correspond to the crystallinity. Desirable patterns of polyimide films can be obtained when the crystallinity is about 10%.

Polyimide (PI) films are finding wide acceptance in electronics industry as an interlayer dielectric material and for passivation and other applications. PI films provide excellent step coverage and can be coated in very thin layers. PI films remain pinhole and crack free, so they have excellent quality and good controllable metallic ion content. PI films can be precisely etched both by wet processes with organic amines and by dry processes with an O₂ plasma.

The published studies have discussed the patterning techniques, the application methods to devices, and the electric properties of PI films (1-4). There have only been a few reports published on the effect of the heat-treatment on the molecular structure and on the etching characteristics such as etch rate and pattern profile.

The purpose of this paper is to report the experimental results of the thermal and physical properties, the molecular structures, and the etching characteristics of PI films.

Experiments

Polyimide film.—SP 510 (Toray Industries, Japan) was used as a polyimide resin. The main solvent of PI materials was DMAc(N,N-dimethylacetamide). A prepolymer solution of 15.9% and 12 poise viscosity was spin coated onto silicon wafers and thermally cured for 1h in a N₂ atmosphere at various temperatures. The film thickness was typically 3 μm.

Etching.—The masks employed were negative photoresists, such as OMR83 (Tokyo Ohka Kogyo, Japan), which were spun onto the cured PI films and photoetched by the conventional technique (1-2). Wet etching was carried out 25°C with hydrazine hydrate containing 80% ethylene diamine. Dry etching was carried out in a parallel-plate plasma etcher. Pure dry oxygen was used as the etching gas.

Evaluation of the PI film properties.—The chemical structure and the imidization of the sample films were investigated by IR absorption spectra. The mass thermal analyses were carried out for characterizing the thermal properties, and chromium-polyimide-chromium structures were prepared on silicon wafers for measuring the dielectric properties. The various mixtures of ortho-xylene and carbon tetrachloride were prepared to obtain the film density. Samples were cut to 2 × 2 mm and then placed in the mixture. The measurement was carried out at 25°C with the pycnometer. The crystallinity of the films was calculated from the results of the density measurements (5)

$$X = \frac{d_c(d - d_a)}{d(d_c - d_a)} \quad [1]$$

Where X is the crystallinity of the films, d_c is the density of the crystalline phase 1.58 (6), d_a is the density of the amorphous phase 1.39 (7), and d is the density of the sample films. The softening temperature was determined

from the thermomechanical analysis in a N₂ atmosphere. The weight of the probe was 7.0g, and the thickness of the sample films was about 7 μm. The surface of the sample films was scratched to measure the film thickness with a surface roughness analyzer.

Results

IR spectral analysis.—PI materials used in this work were formed by imidization of polypyromellitic acid (PAA) as shown in Fig. 1. The IR spectra of the sample films are recorded to evaluate the change of the chemical structure with additional heating. Figure 2 shows the IR spectra of the films cured at 100°C (broken line) and 300°C (solid line) for 1h. The former film shows the absorption bands at 1650, 1540, and 1320 cm⁻¹ belonging to the amino groups (—NH—CO—). The latter film does not show these absorption bands, but does show the characteristic bands at 1785, 1375, and 723 cm⁻¹ corresponding to the imide groups (>N—CO—). However, two films show the unchanged absorption bands at 1495 and 880 cm⁻¹ for the phenyl groups (C₆H₅—). When the peak height of the absorption bands which changes with heating temperature is traced, the change of the chemical structure of the films can be known. Figure 3 shows the change of the chemical structure of the films with additional heating. The absorption bands for the phenyl groups are used for normalizing the characteristic absorption bands. The absorption ratio and the relative imidization were calculated from the absorption ratio change with additional heating. From the analysis of the IR spectra shown in Fig. 3, it is known that the sample films cured below 250°C show the

Fig. 3. Imidization of PI films obtained from the IR analysis. PI films were cured for 1h.

change of the chemical structure, and that those films cured above 250°C show no further detectable change in the IR spectra with additional heating.

Mass thermal analysis.—The sample film cured at 80°C for 1h generated H₂O and DMAc with additional heating. The peak heights of the fragments (H₂O: *m/e* = 18, DMAc:

Fig. 4. Plots of the fragment peak height of H₂O (*m/e* = 18) and DMAc (*m/e* = 44) with additional heating.

Table I. Crystallinity and etch rate of PI films cured for 1h

	Temperature of heat-treatment (°C)					
	150	200	250	300	350	400
Crystallinity (%)	(0)	6.65	11.7	17.2	17.6	22.7
Wet etch rate ^a (μm/min)	10.0	2.0	0.65	0.35	0.22	0.20
Dry etch rate ^b (μm/min)	0.76	0.65	0.60	0.59	0.59	0.59

^a Etchant is hydrazine hydrate containing 80% ethylene diamine, and temperature is 25°C.

^b Oxygen flow rate is 20 sccm, power density is 0.49 W/cm², and pressure is 0.16 torr.

m/e = 44) were traced with the temperature. Figure 4 shows the plots of the fragment peak height of H₂O and DMAc. The generation of H₂O continues till 250°C, and that of DMAc continues till 180°C. Other gasses cannot be detected and traced above this temperature.

Dry etch rate and dielectric properties.—The dry etch rate varies with the cure temperature and shows the constant value about 0.59 μm/min above 300°C (Table I) (O₂ flow rate is 20 sccm, the power density is 0.49 W/cm², and the pressure is 0.16 torr). The etch rate shows little dependence on the O₂ flow rate and the power density. Figure 5 shows the dielectric properties such as the dielectric constant ε' and the dielectric loss factor tan δ. The dielectric properties vary with the cure temperature as well as the dry etch rate and reach a constant value (ε' is about 3.3, and tan δ is about 0.003). The PI films used in this work exhibit excellent electrical characteristics of an insulator.

These experimental results show that it is necessary to cure the film above 300°C in order to obtain a stable film. When the sample film is stabilized, the dry etch rate and the dielectric properties show a constant value. The reasons why the chemical structure in the IR spectra shows no further detectable change above 250°C and the dry etch rate and the dielectric properties show constant value above 300°C are not yet clear from these experiments.

Physical properties.—Figures 6 and 7 show the physical properties of PI films such as the density, the softening temperature, and the thickness. It is shown that the physical properties vary with the cure temperature even when the temperature is above 250°C. For example, the softening temperature depends on the cure temperature and shows almost the sample temperature as the cure temperature. The film thickness decreases with additional heating, and these results show no dependence on the initial thickness for the sample films. Figure 8 shows the visible absorption spectra of PI films. The films become colored upon additional heating. It is predicted that PI films prepared in this work undergo other reactions at a high

Fig. 5. Dielectric properties of PI films

Fig. 6. Density and softening temperature vs. heat-treatment temperature. PI films were cured for 1h.

temperature because the imidizing reaction cannot describe clearly this result.

X-ray diffraction analysis.—Figure 9 shows the x-ray diffraction patterns of the sample films. There are differences in the diffraction patterns among the sample films cured at various temperatures. As the cure temperature increases, the diffraction peak becomes narrower and a new peak appears. The diffraction pattern of the sample films with the higher cure temperature becomes similar to that of du Pont Kapton film, which has been identified as crystalline material by the x-ray measurement method (8-9). The crystallinity of the sample films is calculated by Eq. [1] and is listed in Table I. The crystallinity increases with additional heating and goes up to about 23%.

Fig. 7. Relation between the film thickness and the heat-treatment temperature. PI films were cured for 1h.

Fig. 8. Visible absorption spectra of PI films cured at various temperatures and cured for 1h.

Wet etching characteristics.—Wet etching characteristics such as the etch rate and the pattern profile are influenced by the cure temperature. The etch rate of the sample films varies from 0.2 to 10.0 μm/min, as shown in Table I, and the pattern profile of the sample films is changed with the cure temperature, as shown in Fig. 10.

Fig. 9. X-ray diffraction patterns of PI films cured for 1h

Discussion

IR spectral analysis indicates that, when the cure temperature is below 250°C, the physical properties of the sample films correspond to the change of the primary chemical structure of the materials, but that, when the cure temperature is above 250°C, the physical properties of the sample films do not depend on the change of primary chemical structure of the materials. The x-ray diffraction analysis shows that the films prepared for this work have the crystalline phase during the cure process. So, the reason why the physical properties of the sample films cured above 250°C change as the cure temperature increases is predicted by the change of the molecular state of aggregation, especially the production of higher-ordered region in the sample films. From the result of the x-ray diffraction analysis, it is shown that the change of

physical properties of the sample films cured above 250°C is consistent with the degree of the molecular state of aggregation. The physical properties of the sample films change with the crystallinity. However, the relationship between the wet etching characteristics and the chemical structure was evaluated for PI films. Figure 11 shows the relationship between the etch rate and the degree of imidization obtained from the IR analysis and the crystallinity obtained from the film density. The imidization reaches the saturated value of 1.0 when the crystallinity varies from 0% to 23%. The etch rate does not saturate and varies from 0.2 to 2.0 $\mu\text{m}/\text{min}$. It is clear from these results that the etch rate depends not only on the degree of imidization but also on the crystallinity. The pattern profile is influenced by the molecular state of aggregation and the desirable pattern can be obtained when the cure temperature is 250°C. The crystallinity of the sample film cured at 250°C is about 10%.

Conclusions

The thermal properties and the etching characteristics have been evaluated for spin-coated polyimide films. Experimental results show that in order to obtain a stable PI film, it must be cured above 300°C. When a stable film is formed, the dry etch rate and the dielectric properties have a constant value.

The physical properties of PI films, such as density, softening temperature, thickness, and wet etching characteristics, are proportional to the cure temperature. Wet etching characteristics, such as the etch rate and the pattern profile, are influenced not only by the imidization, but also by the molecular state of aggregation. When the crystallinity is chosen as the physical parameter, the wet etching characteristics closely correspond to the crystallinity. Desirable patterns of polyimide films can be obtained when the crystallinity is about 10%.

In-Source Al-0.5%Cu Metallization for CMOS Devices

R. A. Levy,* L. C. Parrillo, L. J. Lecheler, R. V. Knoell

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

This study examines the use of radiation-free RF induction-source evaporated (In-Source[®]) Al-0.5%Cu as a viable metallization scheme for CMOS devices. The fact that it is radiation free offers ways of optimizing the thermal cycle so as to achieve desirable device and electromigration characteristics. Wafers fabricated with 3.5 μm design rules have shown no threshold shifts or changes in the transistor gain at sintering temperatures up to 450°C, in either H₂ or N₂, for both N- and P-channel devices, confirming the absence of deposition-induced fixed interface charges. Wafers processed with 2.5 μm design rules have exhibited low and well-behaved values of contact resistance to N⁺ and P⁺ diffusions, at sintering temperatures in the range 300°-400°C in either H₂ or N₂, with no evidence of junction penetration. Electromigration measurements, gathered over a wide range of processing conditions, have yielded values of median time to failure (MTF) that were observed to improve with narrower linewidths, higher sintering temperatures, and in the presence of a plasma SiN passivation coating. In typical device operation conditions of 80°C and $1 \times 10^5 \text{A/cm}^2$, the extrapolated MTF value of $3.6 \times 10^7 \text{h}$, for 3.0 μm wide In-Source Al-0.5%Cu lines is found to exceed the value of $\sim 2 \times 10^6 \text{h}$ reported for E-Gun Al-0.5%Cu.

Aluminum and aluminum-silicon-copper alloy films are widely used for metallizing devices in IC processing. The silicon is generally introduced in concentrations of up to ~ 2 atom percent (a/o) to minimize the Al-Si interdiffusion at contact areas (1), while copper is added at concentrations of up to ~ 4 a/o to enhance the electromigration resistance of the metal (2, 3). The industry standard for aluminum deposition has, by far, been electron-beam evaporation (E-Gun[®]), although more recently high rate sputtering techniques have become more prominent. The major justification for using E-Gun aluminum has been its superior electromigration characteristics (4), while one of the major drawbacks in fine-line CMOS processing is the high temperature sintering required to anneal out radiation damage effects.

In this study, we examine the use of radiation-free RF induction-source evaporated (In-Source[®]) Al-0.5%Cu as a viable metallization technology for CMOS devices. Our primary thrust for investigating the use of In-Source Al-0.5%Cu was based on the premise that this deposition process induces no radiation damage. That in turn, affords ways of optimizing the thermal cycle so as to achieve low junction leakage currents as well as good contact resistance to both P⁺ and N⁺ areas. Historically, the selection of 0.5%Cu dates back to the period where the aluminum was patterned by wet chemical etching and the additional Cu was observed to improve linewidth uniformity. With the advent of dry etching techniques, this concentration level was observed not to adversely affect pattern definition and was consequently maintained for traditional reasons. Silicon was purposely excluded as an alloying element in the binary Al-0.5%Cu system in order to eliminate supersaturated precipitates of Al-doped Si at contact areas and minimize the contact resistance to the N⁺ source/drain regions. The results of this work will establish the viability of In-Source Al as a metallization technology by examining its effect on CMOS device performance and by evaluating its electromigration characteristics.

CMOS Device Performance

The effect of In-Source Al-0.5%Cu on device performance was evaluated by automatically probing the IGFET and contact resistance testers present across device wafers fabricated in accordance with the 3.5 and 2.5 μm Twin-Tub CMOS process (5, 6). Wafers processed with the 3.5 μm design rules (5) were targeted for investigation of the transistor characteristics because the thicker gate oxide used ($\sim 600\text{\AA}$) enhanced the sensitivity of the MOS structure to changes in the density of fixed interface charges. Wafers processed with the 2.5 μm design rules (with TaSi₂) were selected for examination of contact resistance and leakage currents due to junction spiking. All

device wafers were metallized with In-Source Al-0.5%Cu deposited at $\sim 220^\circ\text{C}$, patterned using single-level resist, dry etched, and sintered isochronally for 30 min in either a H₂ or N₂ ambient at temperatures of 200°, 300°, 350°, 400°, or 450°C. Results pertinent to device performance will now be considered.

Transistor characteristics.—The threshold voltage, V_T , and beta, β , were determined as a function of sintering temperature and ambient gas from probing various $75 \times 75 \mu\text{m}$ transistors. Both parameters were calculated from measurements of drain current, I_D , vs. gate voltage, V_G , at a constant drain voltage ($V_D = 0.1\text{V}$) using the relationship.

$$I_D = \beta(V_G - V_T)V_D \quad [1]$$

The test structure consisted of $\sim 6500\text{\AA}$ phosphorus-doped (PBr₃) polysilicon gate with a sheet resistance of $\sim 10 \Omega/\square$, a $\sim 0.060 \mu\text{m}$ thermally grown gate oxide, and a $\sim 1 \mu\text{m}$ In-Source Al-0.5%Cu metallization. The N⁺ and P⁺ source/drain areas were formed by ion implantation of P and B with subsequent diffusion during the phosphosilicate glass (P-glass) flow and reflow cycles yielding sheet resistance values of ~ 28 and $\sim 100 \Omega/\square$, respectively. In Fig. 1, the average values of threshold voltage and beta are plotted as a function of temperature for N- and P-channel devices sintered in H₂. For the N-channel devices, V_T is observed to exhibit, for the as-deposited Al films, a value of $0.89 \pm 0.02\text{V}$, which remains stable with sintering temperatures up to 450°C. A similar temperature-independent behavior is observed for the threshold voltage of the P-channel devices, which maintain through the various thermal cycles the as-deposited value of $-0.87 \pm 0.04\text{V}$. This lack of variation in the value of V_T with sintering temperature is a direct indication of the absence of radiation damage in the In-Source deposition process. If fixed interface charges were generated during deposition, they would be expected to anneal out with higher sintering temperatures, causing observable shifts in the threshold voltage of both N- and P-channel devices. The values of β_{\square} (i.e., the gain for transistors with $75 \times 75 \mu\text{m}$ square geometries) for both types of devices remain, as shown in Fig. 1, temperature independent but differ in magnitude by a factor of ~ 3 , reflecting the difference in the mobility of electrons and holes. Examination of devices sintered in N₂ were seen to exhibit similar transistor parameters as well as a similar temperature-dependent behavior to those sintered in H₂.

Contact resistance.—The contact resistance of aluminum to N⁺ and P⁺ source/drain areas was measured from testers present on device wafers processed in accordance with the 2.5 μm Twin-Tub CMOS process (6). The test pattern, shown in Fig. 2A, is comprised of three sections, where windows in the P-glass are opened to make contact to the gate material and to the N⁺ or P⁺ diffusions. These

Fig. 1. Average values of threshold voltage and beta per square as a function of sintering temperature for both N- and P-channel square devices. Sintering time was 30 min; sintering ambient was H_2 .

were formed by ion implantation of P and B and a subsequent drive-in to yield sheet resistance values of ~ 30 and $\sim 115 \Omega/\square$, respectively, and junction depths of $\sim 0.9 \mu m$. Provisions are also provided on this tester to contact the N- and P-tub for leakage current measurements between source/drain regions and tubs. An expanded photograph of the active region is shown in Fig. 2B. It is designed to cover an area of $(190 \times 5 \mu m)$, ending within the center of $(20 \times 20 \mu m)$ pads on each side, and to include four variable size contact windows defined on the mask with dimensions of $(2 \times 2 \mu m)$, $(2.5 \times 2.5 \mu m)$, $(3 \times 3 \mu m)$ and $(4 \times 4 \mu m)$. The measurement is conducted by passing a current between two adjoining contact windows of different sizes and measuring the voltage drop between a common window site and another adjoining contact window of a different size. This measurement is based on a four-point probe technique with the contact resistance calculated from the ratio of the voltage drop at the "contact end" (i.e., the common window site) to that of the input current

Fig. 3. Plot of Al/N⁺ contact resistance as a function of reciprocal area for as-deposited Al-0.5%Cu and Al-0.5%Cu sintered at 300°, 350°, and 400°C for 30 min in H_2 .

set in this case at 0.5 mA. In Fig. 3, the Al/N⁺ contact resistance is plotted as a function of reciprocal area for the as-deposited Al-0.5%Cu and after sintering at 300°, 350°, and 400°C in H_2 . The contact area was assumed not to be that specified by mask dimensions but was measured for each contact size directly from scanning electron micrographs. The Al/N⁺ contact resistance is seen, over the investigated range of contact sizes and sintering temperatures to scale linearly with reciprocal area. The contact resistivity, ρ_c , calculated from the slope of these linear curves, is observed to decrease significantly with higher sintering temperatures. For the as-deposited Al-0.5%Cu condition, $\rho_c = 4.5 \times 10^{-6} \Omega\text{-cm}^2$; for progressively higher sintering temperatures, the value of ρ_c decreases from $1.6 \times 10^{-6} \Omega\text{-cm}^2$ at 300°C to $0.83 \times 10^{-6} \Omega\text{-cm}^2$ at 350°C and

Fig. 2. (A) Optical photograph of contact resistance tester. (B) SEM micrograph of active region on contact resistance tester.

Fig. 4. SEM replicas of nominal ($2 \times 2 \mu\text{m}$) windows to Si on the contact resistance tester after sintering for 30 min in N_2 at temperatures of (A) 300°C , (B) 350°C , (C) 400°C , and (D) 450°C .

$0.64 \times 10^{-6} \Omega\text{-cm}^2$ at 400°C . We postulate that this variation in the Al/N^+ contact resistance is directly related to the degree of interdiffusion occurring through the native oxide at the Al-Si interface. In the presence of an imperfect native oxide, the interdiffusion, which is a thermally activated process, has been reported to proceed through pinholes in the oxide, causing, in the case of (100) silicon, preferential spiking along $\langle 111 \rangle$ crystallographic planes (7). The extent of the interdiffusion, as determined by the density and size of those spikes, provides an "effective" area, by which Al contacts N^+ silicon. In order to investigate the spike formation mechanism as a function of sintering temperature and contact area, polyimide replicas of the silicon surface were prepared and examined with the aid of a scanning electron microscope (SEM). Figure 4 represents a series of SEM replicas of the nominal ($2 \times 2 \mu\text{m}$) window on the contact resistance tester at progressively higher sintering temperatures. At 300°C (Fig. 4A), the spikes are observed to be sparsely concentrated at the conduit to the largest Al supply *i.e.*, at the periphery of the contact window, and to extend in height up to $\sim 0.20 \mu\text{m}$. At a sintering temperature of 350°C (Fig. 4B), spikes retain their individuality but grow significantly in size reaching, in some cases, peaks of $\sim 0.75 \mu\text{m}$. At 400°C (Fig. 4C), coalescence among spikes yield an almost continuous ring with little unreacted space and with a dimensional height of as much as $\sim 0.80 \mu\text{m}$. At 450°C (Fig. 4D), results of the interdiffusion achieve the extreme case in which a single pyramidal pit is now formed extending beyond the original contact area and exhibiting an apex at a height of $\sim 2 \mu\text{m}$. At the sintering temperature of 400°C , the extent of interdiffusion is revealed in Fig. 5 for the four available contact sizes. For a specific thermal cycle and given window geometry, a given amount of Si will be transported into the Al to satisfy the solubility limit. The smaller the cross-sectional area of that contact window,

the deeper will be the loss of Si required to achieve this transported volume. For the 450°C sinter, the Al/N^+ contact resistance, as seen in Fig. 6, ceases to scale with reciprocal area. That is believed to be due to the influence of lateral diffusion which, as shown in the series of micrographs of Fig. 7, is now causing uptake of silicon for aluminum from beyond the original contact boundaries. That has the effect of minimizing differences in the "effective" contact area of the various windows, which is in turn reflected in the lack of variation of the Al/N^+ contact resistance. As observed in the case of the transistor parameters, the values and temperature dependent behavior

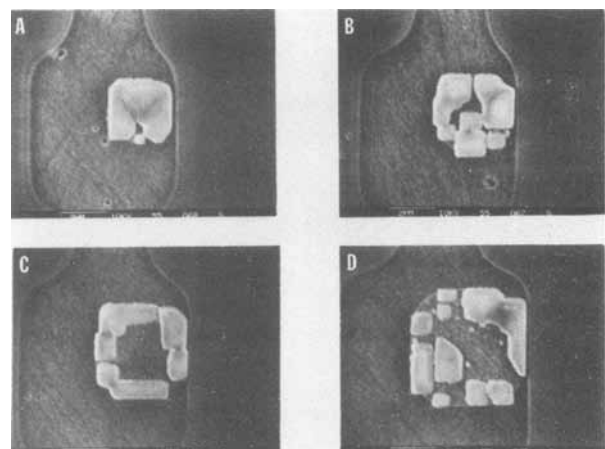

Fig. 5. Top view of SEM replicas of windows to Si on contact resistance tester after a $400^\circ\text{C}/30\text{min}/\text{N}_2$ sinter. Contact dimensions as defined on the mask were (A) $2 \times 2 \mu\text{m}$, (B) $2.5 \times 2.5 \mu\text{m}$, (C) $3 \times 3 \mu\text{m}$, and (D) $4 \times 4 \mu\text{m}$.

Fig. 6. Plot of Al/N⁺ contact resistance as a function of reciprocal area for In-Source Al-0.5%Cu sintered at 450°C/30min/H₂.

of Al/N⁺ contact resistivity for devices sintered in N₂ are similar to those sintered in H₂. At 200°C, the contact resis-

tivity is $3.5 \times 10^{-6} \Omega\text{-cm}^2$; at progressively higher sintering temperatures, the value of ρ_c decreases from $1.5 \times 10^{-6} \Omega\text{-cm}^2$ at 300°C to $0.77 \times 10^{-6} \Omega\text{-cm}^2$ at 350°C and $0.58 \times 10^{-6} \Omega\text{-cm}^2$ at 400°C.

The dependence of the Al/P⁺ contact resistance on contact dimensions and sintering temperature is revealed in Fig. 8. Values of contact resistance plotted against reciprocal area are observed to fall, generally, regardless of the sintering temperature, on a single line with a slope yielding a contact resistivity of $0.66 \times 10^{-6} \Omega\text{-cm}^2$. This temperature independent behavior of ρ_c suggests that the mechanism by which the Al/P⁺ contact is established is different than that for the Al/N⁺ contact and is based primarily on barrier height considerations. The barrier height for p-type silicon (8) is ~ 0.4 eV, a value significantly lower than that of ~ 0.7 eV reported for n-type silicon (8). The increase in the data scatter with decreasing contact dimensions reflects, in this case, secondary effects caused by the extent of the Al-Si interdiffusion.

Leakage current.—The contact resistance tester used to generate the results discussed in the previous section had also provisions for automatic determination of leakage current at five sites across the wafer. As a test of junction penetration due to Al-Si interdiffusion, the N⁺/P Tub leakage current was measured at a reverse bias of 1V on devices processed in accordance with the 2.5 μm Twin-Tub CMOS process (6) and sintered in H₂ or N₂ at 200°, 300°, 350°, 400°, and 450°C. Regardless of the sintering ambient, the leakage current is observed to exhibit a value of $\sim 10^{-10}$ A (low current limit of automatic test equipment) for the as-deposited Al-0.5%Cu condition. That value is observed to remain independent of sintering temperature up to 400°C. This falls within the range of temperatures in which the maximum observable spike height (Fig. 4C) was ~ 0.80 μm. However, that is still shallower than the

Fig. 7. Top view of SEM replicas of windows to Si on contact resistance tester after a 450°C/30min/N₂ sinter. Contact dimensions as defined on mask were (A) $2 \times 2 \mu\text{m}$, (B) $2.5 \times 2.5 \mu\text{m}$, (C) $3 \times 3 \mu\text{m}$, and (D) $4 \times 4 \mu\text{m}$.

Fig. 8. Plot of Al/P contact resistance as a function of reciprocal area for as-deposited In-Source Al-0.5%Cu and Al-0.5%Cu sintered at 300°, 350°, and 400°C.

$\sim 0.9 \mu\text{m}$ N^+ junction depth characteristic of those devices and is therefore consistent with the present data. At the 450°C sintering temperature, the leakage current is observed to increase significantly with values as high as $\sim 10^{-6}\text{A}$, pointing to serious junction penetration. This is consistent, specifically, with the SEM replica of Fig. 4D which had shown a pyramidal pit, $\sim 2 \mu\text{m}$ high, for the smallest contact geometry. It is important to note that the present contact resistance tester represents a worst-case evaluation of the effect of junction spiking because the contact windows considered are small and are strapped individually by wide ($\sim 25 \mu\text{m}$) metal runners. Typically in device patterns, several contact windows share a common narrow ($\sim 5 \mu\text{m}$) metal strap, easing considerably the spiking situation.

Having evaluated the effect of In-Source Al-0.5%Cu on device properties, we wish now to focus on its electromigration characteristics.

Electromigration Characteristics

Electromigration is a major concern as a failure mode associated with the use of Al or Al alloys in VLSI devices (9-11). It is defined as the transport of matter caused by the passage of an electric current and is the result of momentum exchange between conduction electrons and diffusing metal atoms. Nonvanishing divergences of this atomic (or vacancy) flux, generated by structural inhomogeneities or temperature gradients, can lead to open-circuit failures because of depletion of matter.

The temperature and current density dependence of electromigration is generally expressed by the relationship (12)

$$\text{MTF} = \text{CJ}^{-n} \exp(Q/kT) \quad [2]$$

where MTF is the median time to failure, C a constant, J the current density, n the current density exponent, Q the activation energy, k Boltzmann's constant, and T the absolute temperature. For Al conductors the reported values of Q and n lie in the ranges of 0.3-1.2 eV and 1-7, respectively (13). The median time to failure has been observed to improve with increases in grain size, with decreases in grain size distribution, and with a higher degree of (111) texture in the Al film (4). Henceforth,

optimization of these parameters becomes a prerequisite in the present electromigration investigation of In-Source Al-0.5%Cu. Using transmission electron microscopy (TEM), horizontal cross-sectional micrographs depicting the grain size and grain size distribution were examined for In-Source Al-0.5%Cu deposited over a wide range of temperatures (135°-300°C) and rates (10-140 Å/s). A sample representation of this data is shown in Fig. 9. At a given background pressure of $\sim 2 \times 10^{-6}$ torr and a deposition temperature of $\sim 135^\circ\text{C}$, the grain size is seen to increase from an average value of $\sim 0.3 \mu\text{m}$ for Al films deposited at $\sim 30 \text{ Å/s}$ (Fig. 9A) to $\sim 0.7 \mu\text{m}$ for Al film deposited at $\sim 140 \text{ Å/s}$ (Fig. 9B); for a higher deposition temperature of $\sim 245^\circ\text{C}$, the grain size increases from $\sim 0.6 \mu\text{m}$ for Al films deposited at $\sim 30 \text{ Å/s}$ (Fig. 9C) to $\sim 1.3 \mu\text{m}$ for Al films deposited at $\sim 140 \text{ Å/s}$ (Fig. 9D). The distribution of grain sizes, characterized by the calculated standard deviation, was found typically to be of the order of $\pm 10\%$. The observed increase in grain size with higher deposition temperature and higher deposition rate provides, henceforth, the guideline necessary to optimize the deposition parameters and produce films with desirable electromigration characteristics.

The electromigration test structure used in the present investigation consisted of five meander patterns on a chip, each 1 cm long and all with nearly identical linewidths. An array of 116 chips was laid out for 75 mm size wafers so as to provide a wide selection of meanders with defined widths of 2, 2.5, 3, 4, and 5 μm . The combination of lines and spaces were designed on the meander pattern to add up, in all cases, to 15 μm . After separation, the chips were eutectically bonded, using Au-P preforms, onto 40-pin dual-in-line ceramic packages. In order to eliminate the possibility of Al-Au interdiffusion on the test pattern, Al-1% Mg wires, 25 μm thick, were wedge bonded ultrasonically at room temperature to aluminum pads on the chip side and gold pads on the package side. The electromigration tests were conducted typically on 24 packages heated in atmospheric ambient in an oven capable of providing temperatures up to 300°C and controlled within $\pm 1^\circ\text{C}$. Constant current sources were designed to power up to 96 meanders with adjustable outputs of 10-250 mA and a stability better than $\pm 1\%$. Chart recorders were used to monitor the voltage drop across summing resistors and to mark the failure time. One meander on each of the chips was dedicated to monitor the temperature through the testing period. The procedure consisted of passing a low current of typically 250 μA through that monitor meander at room temperature and measuring the voltage drop across it. The furnace was then brought up to test temperature and the procedure repeated. From the recorded change in temperature and voltage drop, the temperature dependent coefficient of resistivity, α , was calculated. One of the other four test meanders is then powered and from the known value of α , and from the change in voltage drop caused by the additional Joule heating, the average temperature of the monitor meander was established. A comparison between the temperature as measured on the monitor meander to that as measured directly on the other four test meanders using the above procedure revealed, within the considered range of current densities, insignificant differences. The test temperature referred to during the course of the present investigation represents the overall (i.e., ambient + Joule contribution) average of the experimental cell.

The In-Source Al-0.5%Cu films, typically 1 μm thick, were all deposited at $\sim 300^\circ\text{C}$ on thermally oxidized Si substrates. They were patterned using tri- or single-level resist and defined using reactive ion etching. The cross-sectional area, A, was calculated from the product of the average thickness and linewidth of the patterned Al lines which were measured using a Dektak stylus and a Nanospec interferometer, respectively.

The data were fitted to a log-normal distribution using a computer program which derived values of median time to failure and proceeded to produce a graphical display of the results. The dependence of median time to failure on

Fig. 9. TEM horizontal cross-sectional micrographs illustrating grain size and grain size distribution for In-Source Al-0.5%Cu films deposited at a temperature and rate of (A) 135°C, ~ 30 Å/s, (B) 135°C, 140 Å/s, (C) 245°C, ~ 30 Å/s, and (D) 245°C, ~ 140 Å/s.

sintering temperature, plasma SiN capping, linewidth, and current density acceleration will now be considered.

Effect of sintering temperature.—In order to investigate the effect of sintering temperature on the median time to failure, In-Source Al-0.5%Cu films were evaporated on thermally oxidized Si wafers under optimized conditions for deposition temperature ($\sim 300^\circ\text{C}$) and deposition rate (~ 140 Å/s). The films were then sintered for 30 min in H_2 at either 300° or 450°C . Meander lines with a 3.0 μm linewidth were selected for testing. For samples sintered at $300^\circ\text{C}/30$ min/ H_2 , the electromigration measurements were carried out at test temperatures of 209° and 264°C and at a current density of 2.1×10^6 A/cm 2 . The samples sintered at $450^\circ\text{C}/30$ min/ H_2 were tested, under accelerated conditions, at temperatures set at 232° , 258° , 289° , and 304°C and a current density set at 1.62×10^6 A/cm 2 . In Fig. 10, values of the median time to failure, normalized with the use of Eq. [2] and a value of $n = 2$ to $J = 1 \times 10^5$ A/cm 2 , are plotted on an exponential scale as a function of reciprocal temperature for the samples sintered at 300° and 450°C . A comparison between these two curves indicate, in the case of the higher sintering temperature, a factor of ~ 3 improvement in lifetime as well as an enhanced value of the activation energy (0.84 vs. 0.73 eV). These observations reflect the differences in the microstructure of the Al-0.5%Cu films. TEM cross-sectional micrographs, taken at a pad area on the electromigration tester, are seen to exhibit an average grain size of 2.9 μm for samples sintered at 450°C (Fig. 11C) as compared to 1.8 μm for samples sintered at 300°C (Fig. 11A). An increase in the ratio of grain size to strip width, as in the case of the higher sintering temperature, has been reported (14) to enhance the lifetime because of possible formation of single-crystal grains, across parts of the meander, blocking the mass transport. The larger grains are also expected (9) to

cause a reduction in the number of grain boundaries, with their associated low energy diffusion paths, accounting for the observed increase in activation energy. SEM examination of electromigration-induced defects reveals, as shown in the series of micrographs of Fig. 12, the presence of voids, cracks, and hillocks randomly distributed along the length of the stressed meanders. The depleted areas assumed a variety of sizes and shapes with the fatal openings generally observed to cross the meander width in a direction perpendicular to current flow. Evidence for the accumulation of materials was found in the vicinity of large voids or cracks always in the direction of positive bias (electron flow). Using the measured values of Q and the conventional value of $n = 2$, the median times to failure extrapolated to 80°C and 1×10^5 A/cm 2 were determined to be equal to 3.7×10^6 h and 3.6×10^7 h for samples sintered at 300° and 450°C , respectively. The value of 3.6×10^7 h is more than an order of magnitude higher than that of 12×10^6 h reported for E-Gun Al-0.5%Cu deposited and sintered under similar conditions (4). That demonstrates that In-Source Al-0.5%Cu processed under optimum conditions can, indeed, provide excellent resistance to electromigration failure.

Effect of plasma SiN capping.—In the final stages of IC processing, a scratch-resistant plasma SiN passivation coating is generally deposited to protect devices from mechanical damage. In order to investigate the effect of plasma SiN capping on median time to failure, one of the patterned wafers metallized with In-Source Al-0.5%Cu deposited at 300°C , at a rate of 140 Å/s, was sintered at 300°C for 30 min in H_2 and then capped with a 1.4 μm plasma SiN coating. The plasma SiN cap was deposited at 330°C for 105 min in a plasma-assisted CVD reactor known to produce tensile films. The wafer was patterned and plasma etched in a barrel reactor to expose the aluminum

Fig. 10. Plot of normalized median time to failure as a function of reciprocal temperature for In-Source Al-0.5%Cu deposited at 300°C, at a rate of $\sim 140 \text{ \AA/s}$ and sintered under different conditions.

pads for wire bonding. Groups of typically 24 meanders with a $3.0 \mu\text{m}$ linewidth were tested, under accelerated conditions, at temperatures of 205°, 231°, 263°, and 283°C and at a current density of $1.82 \times 10^6 \text{ A/cm}^2$. A plot of normalized median time to failure vs. reciprocal temperature is shown in Fig. 10 for samples sintered at 300°C with plasma SiN caps and for those with no caps sintered isochronally at 300° and 450°C. It is evident from a comparison of the data that the presence of the passivation coating enhances the median time to failure by almost an order of magnitude, when compared to uncoated samples sintered at 450°C, and by a factor ~ 22 when compared to uncoated samples sintered at 300°C. SEM examination of the stressed meanders revealed significant reduction in the occurrence of macroscopic voids and in the degree of material accumulation below the plasma SiN layer. This is an indication that the electrotransport rate has, indeed, been slowed down, presumably by a consequence of reduced vacancy density. Vacancies are generally generated by inward diffusion from the surface or through formation of Schottky defects. In both cases, as reported by Learn and Shepherd (15), the addition of a strongly bonded impervious coating can reduce vacancy generation and movement. From the slope of the MTF vs. $1/T$ curve a value of $Q = 0.68 \text{ eV}$ was calculated for the samples capped with plasma SiN. This value for the activation energy is quite comparable to that of 0.73 eV, for samples similarly sintered at 300°C/30min/ H_2 but with no plasma SiN. Examination of TEM micrographs of samples with (Fig. 11B) and without (Fig. 11A) plasma SiN also reveal quite comparable dimensions in grain size, establishing the fact that the thermal cycle associated with the present plasma SiN deposition process has an insignificant effect on both grain growth and activation energy. Using the value of $Q = 0.68 \text{ eV}$ and the conventional value of $n = 2$, the extrapolated median time to failure (80°C , $1 \times 10^5 \text{ A/cm}^2$) for In-Source Al-0.5%Cu sintered at 300°C with plasma SiN was calculated to be

Fig. 11. TEM horizontal cross-sectional micrographs illustrating grain size and grain size distribution of In-Source Al-0.5%Cu deposited at 300°C at a rate of $\sim 140 \text{ \AA/s}$ and sintered at (A) 300°C/30 min/ H_2 , (B) 300°C/30 min/ H_2 with additional $1.4 \mu\text{m}$ plasma SiN cap, and (C) 450°C/30 min/ H_2 .

equal to $5.0 \times 10^7 \text{ h}$. The closing of the gap between the extrapolated MTF values of samples with the additional plasma SiN cap and those sintered at 300° and 450°C with no plasma SiN is a result of differences in the activation energy which owing to the exponential dependence, strongly affect the extrapolation procedure.

In order to evaluate the effect of lower deposition rates on the electromigration characteristics, In-Source Al-0.5%Cu was evaporated at $\sim 300^\circ\text{C}$, at a rate of $\sim 63 \text{ \AA/s}$ onto thermally oxidized Si monitors. Following patterning with single-level resist and a 300°C/30min/ H_2 sintering cycle, a $1 \mu\text{m}$ thick plasma SiN cap was deposited at 330°C for 145 min in a plasma-assisted CVD reactor known to produce compressive films. Packaged testers with $2.0 \mu\text{m}$ lines were selected for the present study. The testing proceeded at temperatures of 194°, 221°, 250°, and 274°C and at a current density of $1.9 \times 10^6 \text{ A/cm}^2$. From the slope of a plot of normalized median time to failure as a function of reciprocal temperature, an activation energy of $Q = 0.68 \text{ eV}$ was calculated. This value is identical to that calculated for In-Source Al-0.5%Cu at the higher rate of 140 \AA/s pointing to heat-treatment, i.e., sintering and plasma SiN deposition as the determining factor in the establishment of the final microstructure. Using the value of $Q = 0.68$ and the conventional value of $n = 2$, the

Fig. 12. SEM micrographs showing electromigration-induced defects such as voids, cracks, and hillocks for samples with In-Source Al-0.5% Cu deposited at 300°C at ~ 140 Å/s and sintered at 450°C/30min/ H_2 .

extrapolated median time to failure (80°C, 1×10^5 A/cm²) was calculated to be equal to 2.7×10^7 h. With the exception of using a thicker plasma SiN cap (1.4 vs. 1.0 μ m), a repeat of these measurements on lines with the identical 2.0 μ m linewidth patterned from samples deposited under identical conditions (300°C, ~ 63 Å/s) and also sintered at 300°C for 30 min in H_2 , yielded an extrapolated median time to failure (80°C, 1×10^5 A/cm²) equal to 3.5×10^8 h. The difference in these values of MTF is believed to be directly related to the plasma SiN cap thickness and not, as to be discussed in the following paragraphs, to the induced stress. With the thinner films, there is the distinct possibility of encountering a higher density of pinholes or microcracks which would form the source of vacancies and Schottky defects necessary to enhance the electrotransport mechanism. Similar results on the effect of a passivation coating on median time to failure have recently been reported by Lloyd and Smith (16) who observed that E-Gun Al-4%Cu stripes covered with 1.5 μ m of glass lasted as much as 18 times longer than those which were not covered. Furthermore, an increase in passivation film thickness from 1.5 to 4.0 and 8 μ m was reported to monotonically enhance the lifetime of the underlying thin film conductors from 636 to 909 and 1083h, respectively. Electromigration-induced compressive stresses were believed to be responsible for these observations.

A comparison of samples with similar linewidth (~ 3.0 μ m) deposited at different rates (~ 63 vs. ~ 140 Å/s) but otherwise identical in terms of deposition temperature (~ 300 °C), sintering cycle (300°C/30min/ H_2), and plasma SiN thickness (1.4 μ m) revealed, as shown in Fig. 13, similar values of median time to failure (4.5×10^7 vs. 5.0×10^7 h). That provides additional correlation and support for the reproducibility of our results. It is, however, interesting to note that in the case of Al films deposited at ~ 63 Å/s the plasma SiN process used was known to produce compressive films ($\sim -10^{10}$ dyne/cm²); in the case

Fig. 13. Plot of extrapolated median time to failure (80°C, 1×10^5 A/cm²) as a function of linewidth for In-Source Al-0.5%Cu deposited at 300°C, at a rate of ~ 63 Å/s, sintered at 300°C/30min/ H_2 , and capped with 1.4 μ m plasma SiN.

of Al films deposited at ~ 140 Å/s, the plasma SiN process used was different and known to produce tensile films ($\sim +10^9$ dyne/cm²). Thus, the noted similarity in the electromigration results over such extreme stress conditions tends to undermine the role of stress in accounting for the lifetime enhancement observed in the presence of a passivation coating.

Effect of linewidth.—In order to determine the dependence of median time to failure on linewidth, films metallized with In-Source Al-0.5%Cu (300°C, ~ 63 Å/s), sintered at 300°C for 30 min in H_2 , and capped with 1.4 μ m plasma SiN (330°C, 145 min) were tested. The linewidth was varied to cover a range in values extending from 1.6 to 4.0 μ m. The electromigration measurements were carried out for all samples at test temperatures around 275°C and at a current density of 2.0×10^5 A/cm². Using values for $Q = 0.68$ eV and $n = 2$, the extrapolated median time to failure (80°C, 1×10^5 A/cm²) is plotted as a function of linewidth in Fig. 13. The results point to an exponential increase with narrower linewidth with values ranging from 1.1×10^7 h at 4.0 μ m to 3.9×10^8 h at 1.6 μ m. As previously discussed, a narrowing of linewidth enhances the likelihood that the meander cross section will be blocked at some points by single-crystal grains. That develops a configuration consisting of polycrystalline segments blocked at both ends by a single-crystal grain. Since electromigration is known to proceed primarily through grain boundary diffusion, mass transport from the cathode to anode end within a polycrystalline segment is expected to develop concentration gradients and compressive stresses at these ends which can create a reverse mass flow to that produced by electromigration. At progressively narrower linewidths the display of single-crystal grains across the stripe ought to become more prominent favoring, in the extreme case, formation of the "bamboo structure" (4). This model, first proposed by Blech (17), appears to be consistent with our experimental observations.

Effect of current density acceleration.—There is considerable disagreement over the value of the current density exponent, n in the J^{-n} dependence. Values of n in the published literature (18) range from 1 to 7. Early work predicted that n was a constant, with a value of 1 for failures at structural sites (19) and a value of 3 where temperature gradients were dominant (20). The work of Venables and Lye (21) and also of Sigsbee (22) has predicted that n is a function of current density and varies from a value of 1 at current densities below 1×10^5 A/cm² to greater than 3 at current densities exceeding 2×10^6 A/cm². The results of Blair *et al.* (23) yielded a value of $n = 5$ for current densities between 1×10^6 and 2×10^6 A/cm². In order to determine the value of n within our range of testing conditions, electromigration measurements were carried out at different current densities for the In-Source Al samples deposited at ~ 140 Å/s as well as those deposited at ~ 63 Å/s. A log-log plot of current density vs. normalized median time to failure is shown in Fig. 14 for the $3.0 \mu\text{m}$ wide In-Source Al-0.5%Cu samples deposited at a rate of 140 Å/s and sintered at 300° and 450°C . From the slope of these curves values of n equal to 3.2 and 3.8 were calculated, in the range of $\sim 5 \times 10^5$ to $\sim 2 \times 10^6$ A/cm², for samples sintered at 300° and 450°C , respectively. A similar plot is shown in Fig. 15 for In-Source Al-0.5%Cu samples with 3.2 and $4.0 \mu\text{m}$ linewidths deposited at a rate of ~ 63 Å/s, sintered at 300°C for 30 min in H_2 , and capped with a $1.4 \mu\text{m}$ film of plasma SiN. The results reveal over the investigated range of current densities ($1 \times 10^6 - 2 \times 10^6$ A/cm²) a value of n , also, close to 4.0 for both linewidths precluding the influence of sintering or plasma SiN addition. This calculated value of n is significantly higher than that of $n = 2$ used, throughout the present investigation, to extrapolate the median time to failure, showing the extrapolation procedures in this study to be quite conservative.

Effect of thermal annealing.—The possibility that the electromigration samples underwent thermal annealing during accelerated testing was addressed by searching for changes in the failure distribution, the failure mechanism, the temperature dependent behavior of MTF, and the metal structure. A likely occurrence for such an effect would expectedly be in the case of samples stressed at temperatures relatively high compared to the sintering temperature, and for long periods of time. Sim (18) has observed for as-deposited E-Gun Al samples, with an average grain size of $2 \mu\text{m}$, a change in failure distribution for meanders tested at 220°C between 100 and 5000h at current densities in the range of 2×10^4 A/cm², which was attributed to thermal annealing. Furthermore, these samples showed evidence of very local failure indicating that some potential failure sites (*i.e.*, dislocations) had

Fig. 14. Log-log plot of current density vs. normalized median time to failure for In-Source Al-0.5%Cu deposited at 300°C , at a rate of ~ 140 Å/s and sintered under different conditions.

Fig. 15. Log-log plot of current density vs. normalized median time to failure for In-Source Al-0.5%Cu, of various linewidths, deposited at 300°C , at a rate of ~ 63 Å/s, sintered at $300^\circ\text{C}/30\text{min}/\text{H}_2$, and capped with $1.4 \mu\text{m}$ plasma SiN.

been annealed out. However, no obvious physical change in the metal structure, such as a change in grain size, could be found. The author remarks that other contributing factors, such as a redistribution of impurities in the aluminum, could have also accounted for those observations. Examination of our results on sintered In-Source Al-0.5%Cu revealed over the range of testing conditions, a unique failure distribution in all cases and, as shown, for instance, in Fig. 12, a random occurrence of voids along the meander length. Reproducibility measurements on sintered samples ($300^\circ\text{C}/30\text{min}/\text{H}_2$), with no passivation coating, stressed at 215°C after a prior 47h thermal exposure yielded a comparable value of median time to failure (13.40 ± 0.97 vs. $13.44 \pm 0.63\text{h}$) to that of the earlier test. In the course of determining the activation energy, a well-behaved linear fit of MTF to $1/T$ has been exhibited with no evidence of anomalous deviations in lifetime. Measurements of grain size before and after accelerated testing, on samples with no passivation coating, revealed no detectable differences. All these observations are consistent with the absence of significant thermal annealing effects in the course of present testing procedures.

Conclusions

Our results have established that In-Source Al-0.5%Cu is a viable metallization technology compatible with fine-line CMOS processing. The fact that it is radiation free has offered ways of optimizing the thermal cycle so as to achieve desirable device and electromigration characteristics. CMOS device wafers fabricated in accordance with the $3.5 \mu\text{m}$ Twin-Tub CMOS process have shown no threshold shifts or changes in the transistor grain at sintering temperatures up to 450°C , in either H_2 or N_2 , for both N- and P-channel devices, confirming the absence of deposition-induced fixed interface charges. CMOS device wafers fabricated in accordance with the $2.5 \mu\text{m}$ Twin-Tub CMOS process have exhibited low and well-behaved values of contact resistance to N^+ and P^+ diffusions, at sintering temperatures in the range of $300^\circ-400^\circ\text{C}$, in either H_2 or N_2 , with no evidence of junction penetration. Electromigration measurements, gathered over a wide range of processing conditions, have yielded values of median time to failure which were observed to improve with narrower linewidths, higher sintering temperatures, and in the presence of a plasma SiN passivation coating. In typical device operation conditions of 80°C and 1×10^5 A/cm², the calculated lifetime of $\sim 10^6\text{h}$ for the $2.5 \mu\text{m}$ wide passivated In-Source Al-0.5%Cu lines epitomizes the superior reliability of this metallization process.

Approximating Spun-On, Thin Film Planarization Properties on Complex Topography

L. K. White

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

A method for characterizing and estimating spun-on, thin film planarization properties is proposed. The spun-on film is considered to be a low pass frequency filter. Two adjustable parameters are used to weight the frequencies to experimental planarization data for isolated line features. Using these parameters, the planarization properties on more complex topographies having a nominal unity of step height can be accurately estimated. One fitting parameter, α , gives an indication of the planarization (flow) properties of the spun-on solution. The other fitting parameter, P_{\min} , represents the minimum period (maximum frequency) with a weighting factor equal to one. Planarization properties of two distinctly different spun-on solutions are simulated on complex topography to verify the approximation procedure. The stencil pattern used to obtain the experimental planarization data for isolated line features can also be used to obtain an unambiguous determination of the planarization properties independent of step height and the spun-on film thickness.

Detailed descriptions of the spun-on planarization properties of thin films are becoming increasingly important for integrated circuit processing. Resist dimensional control issues on topographical features are strongly influenced by resist thickness changes (1, 2). Dual-etch-back techniques for the planarization of passivation and isolation layers (3-5) also depend on the spun-on, thin film planarization properties. Our previous work (6, 7) and the work of others (5, 8-11) have provided insights into the planarization phenomena that occurs for spun-on films. All of these workers point out the complexity of these phenomena. One of the most complex aspects is the effect that the surrounding topography has on planarization. Changes in the position and size of topographical features can change the polymer film thickness on adjacent features. In this work, a method of characterizing and estimating the magnitude of these effects is proposed. Film shrinkage, thermal flow of films, and radial flow anomalies over different topography orientations can further complicate this situation. This work confines itself to situations where these effects do not play a prominent role.

To calculate polymer planarization properties from first principles is a difficult rheological problem. Poly-

mer solution viscous-elastic properties during the turbulent spun-on planarization process are not completely understood. Film deformations are frequently the same order of magnitude as the film thickness. Deformations of this magnitude do not follow the analytical procedures frequently used to model relatively small deformations. On complex topography even with a well-defined approach, the problem becomes exceedingly complex. In light of these considerations, we have chosen a semi-empirical approach to simulate spun-on film planarization properties. The spun-on film is considered to be a low-pass frequency filter for the topography. The data from isolated line features are fitted to a mathematical model with two adjustable parameters. These parameters can then be used to approximate the spun-on planarization properties for any complex topography having a unification of step heights.

Experimental

Substrates for the planarization characterization studies were prepared by growing thermal oxide on 3 in. silicon wafers to a thickness equivalent to the desired step height. The thermal oxide was patterned with positive resist and an anisotropic plasma etching procedure. These

topographical features were then coated with a LPCVD polysilicon film 0.5 μm thick. The patterned substrates contain isolated line features of various widths and lengths in excess of 500 μm . Typically, isolated line features with widths of 40, 30, 20, 15, 10, 5, 3, 2, 1.5, and 1.0 μm were used. The spacing between the isolated line features was 100 μm . Linewidths were determined with a flar eyepiece and step heights measured with a Tencor Alpha-Step Profilometer.

Two different spun-on solutions are analyzed here: OFPR 800 (30 Hz) positive resist and KTI polymethylmethacrylate, PMMA, at 9% solids. These two solutions were selected because of their substantially different planarization properties and their resistance to thermal flow during cures to harden the films for profilometric analysis. A static dispense, maximum acceleration to a spin speed of 6000 rpm and a spin time of 30s were used to coat the substrates. The OFPR 800 coating was cured at 110°C and the PMMA coating at 140°C. Thicknesses of the spun-on coating were measured with an instrument similar to a Rudolph Thin-Film Thickness Monitor at a refractive index setting of 1.60 on bare silicon substrates. Spun-on, thin film planarization properties were also determined with the Tencor Alpha-Step Profilometer operating at a 15 mg tracking force. A stylus radius of 3 μm was used to minimize the effects of the stylus tracking on the recorded profilometer trace. The accuracy of this step-height determination is nominally $\pm 100\text{\AA}$ on the 10 kÅ scale. All the profilometer traces were taken on grating and isolated lines that had the ends of the features oriented toward the wafer center.

Calculation Procedure

A number of investigators (5-11) have observed the strong dependence feature size (dimension) has on planarization phenomena. Figure 1 shows this dependence on the isolated line features for two different polymer films. The initial step heights were all 0.5 μm and both spun-on film thicknesses were nominally 0.9 μm . At feature sizes greater than 20 μm , the PMMA coating reduces the step height (planarizes better) than the OFPR coating. Below the 20 μm feature size, the OFPR coating shows significantly better planarization properties. Over a wide range of feature sizes, there is a linear correlation between the logarithm of the feature size and the step-height reduction. This type of planarization property dependence on feature size suggested to us that the periods or frequency components of the topography may contribute to the observed planarization phenomena.

If the topography can be described by a piecewise continuous function, the same topography can be described with a series of sine and cosine functions (12): for example, when a one dimensional function, $T(y)$, is represented by an even number of and a sequence of evenly spaced

points, N . Then $T(y)$ can be expressed as

$$T(y) = \sum_{n=0}^j a_n \cos \frac{2\pi ny}{N} + b_n \sin \frac{2\pi ny}{N}$$

where $j = N/2$. The cosine and sine coefficients, a_n and b_n , can be obtained from the fast Fourier transform (13) of $T(y)$.

When a spun-on coating is applied to the topography, $T(y)$, a deformed or smoothed topography results, $T_s(y)$. An approximation of the smoothed topography is obtained by weighting the a_n and b_n coefficients. Thus

$$T_s(y) \approx \sum_{n=0}^j a_n w_n \cos \frac{2\pi ny}{N} + b_n w_n \sin \frac{2\pi ny}{N}$$

where $1.0 > w_n > 0.0$ and $w_{n+1} \geq w_n$.

Several weighting schemes are possible, but Fig. 1 suggests a form that has worked reasonably well for us. The w_n 's are selected below a certain minimum period, as shown in Fig. 2, and are proportional to the logarithm of the period associated with the corresponding cosine and sine coefficient. The change in w_n with respect to the logarithm of the period is specified by the adjustable parameters, P_{\min} and a . P_{\min} is the minimum period with a w_n equal to one. a is the slope of the w_n curve or the change in the w_n value divided by the change in the logarithm of the period. This weighting procedure dampens high frequency or small period components on the surface topography. It results in approximating planarization properties as function of feature size, smooths sharp corners, and broadens the bottom of steps. Although the curves in Fig. 1 suggest the form of the weighting factors, the factors themselves cannot be obtained directly from Fig. 1. Isolated square-wave features are themselves an ensemble of sine and cosine functions. Nonetheless, a frequency weighting scheme can be obtained from a series of isolated square-wave features with various dimensions. Generally, the P_{\min} value is approximately 3-4 times the feature size denoted by the intercept of the planarization curve with original step height. The a parameter is usually 1.0-1.5 times the slope of planarization curve where the Y-axis units are expressed as the fraction of the original step height. The values of the adjustable parameters to fit the experimental data in Fig. 1 are 165 μm and 0.60 for the OFPR 800 coating and 300 μm and 0.28 for the PMMA coating. Figure 3 shows simulated computer traces of the OFPR 800 and HPR 204 materials on isolated line features ranging from 40-5 μm wide. Table I shows the comparison between the experimental and simulated step heights.

The selection of the proper interval between points and the number of points, N , are important to obtain the best simulation results. N should span a range at least twice the P_{\min} distance. The interval between points depends on

Fig. 1. Planarization properties of OFPR 800 and PMMA on 0.5 μm step heights.

Fig. 2. Period weighting schematic for spun-on, thin film simulations

Fig. 3. Simulated planarization properties for isolated line features. Original step height is 0.5 μm. Top: PMMA 0.87 μm thick. Middle: OFPR 800 0.93 μm thick. Bottom: no coating.

the feature size dimension that needs to be simulated. Generally, the interval between points should be one-tenth that of the minimum feature size. For small deformations, (i. e., little planarization), this requirement can be relaxed to some degree. Our simulations typically span a distance of 1260 μm and use a 1 μm interval between points. The filtering of the high frequency components produces ripple effects in the simulated planarization curves. These effects are usually much smaller than the experimental error. Smoothing routines for the high frequency ripple can be used, if further refinements are required. The simulations presented here are set up for a minimum feature size of 10 μm.

Figure 1 shows that the step-height vs. logarithm of feature size curve is no longer linear in the small feature size range. Weighting the sine and cosine coefficients according to logarithm of the period over the 10-40 μm feature size range does produce simulated planarization curves that exhibit a similar nonlinear behavior at small feature sizes. The simulated nonlinear behavior in the small feature size range resembles that shown in the PMMA experimental curve of Fig. 1. In general, the simulated curves at small feature sizes predict a step height that is slightly lower than that observed experimentally. If a spun-on coating does not show this characteristic nonlinear behavior at small feature sizes, errors in simulated planarization properties are possible. These high frequency components not only influence small feature sizes, but also the wall profiles on relatively large feature sizes. More sophisticated frequency weighting procedures may be required to simulate the planarization properties of small feature sizes accurately. Thus far, we are pleased with the simulation results at the top and bottom of steps for large feature sizes (> 10 μm).

These weighting factors only apply to a specific spun-on coating thickness and step height. Figure 4 shows how the planarization properties change with the step height and the spun-on film thickness. Note that all the curves

Fig. 4. Planarization properties of PMMA for different film thicknesses and step heights.

follow the same slope over the 5-40 μm feature size range. The intercept with the original step height and the behavior in the high frequency (small period) region changes. For an increased spun-on thickness, the intercept with original step height becomes larger, and for an increased step height the same intercept becomes smaller. Our frequency weighting parameters, α and P_{min} show the same behavior. Evidently, our α fitting parameter represents a characteristic planarization property of a specific spun-on polymer solution. P_{min} changes with film thickness and the step-height variations. Since P_{min} represents the first frequency component of the topography that is changed by the spun-on film, an estimation of the range of the feature-feature interaction is also implied. If this frequency weighting scheme is correct, the P_{min} values suggest that thicker spun-on coatings influence planarization properties over a wider range, while taller step heights appear to reduce the range of feature-feature interactions.

Simulation Results

After obtaining the frequency weighting parameters for the two spun-on coatings, planarization properties were simulated for other topographies. Figure 5 shows experimental profilometer traces for the two spun-on films on 10 × 10 μm gratings. A schematic of the relevant step

Fig. 5. Experimental profilometer traces for OFPR 800 and PMMA on 10 × 10 μm line-space gratings.

heights is also displayed. The grating is assumed to run infinitely to the right and flat expanse infinitely to the left. Planarization data obtained for an isolated $10\ \mu\text{m}$ feature cannot be used to predict the step height, A, at the edge 10×10 grating or the step heights within the $10 \times 10\ \mu\text{m}$ grating, B, C, and D. Simulated planarization curves are shown in Fig. 6, and a comparison of measured and simulated step heights in Table II.

The simulated step heights match the experimental step heights for both coatings. Even shapes of the simulated traces resemble those of the experimental traces. We have simulated the planarization properties of these polymer films on more complex topography with good success. The step heights were predicted accurately, and the general shapes of the computed traces were consistent with the experimental profilometer traces.

Limitations of Approximation Techniques

This approximation technique does not address some important aspects of spun-on, thin film planarization phenomena. Many topographies of interest do not exhibit a uniform step height. However, for some of these cases, this technique can give reasonable results. We have shown experimentally that the wall profile does not affect measured planarization properties at the top and bottom of steps (7). Narrow shelves at the edge of larger steps and tapered-wall features should not introduce major errors. The most difficult cases are those involving small features on top of the larger ones. Here, the prevailing step height should be used in the approximation procedure, although significant errors may be introduced in the vicinity of the smaller feature.

Planarization properties are not necessarily constant with respect to feature position relative to the center of the wafer. Different spun-on, planarization properties have been reported for PMMA-coated E-beam alignment marks (14). We have detected changes in the measured step height as a function of orientation with respect to the wafer center for several polymer films. These effects also produce asymmetries in the step profile for large feature sizes and higher step heights. Orientation effects become less prominent at the smaller features sizes. This simulation technique does not correct for these deviations, owing to radial flow anomalies during spinning. Care should be taken that the isolated line data are oriented so that the end of the lines are oriented toward the substrate center.

Shrinkage during the cures of the spun-on film increases the measured step heights. Films that shrink considerably (*i. e.*, greater than 20% of original thickness) and topography configurations that show the more reduced step heights are expected to show the most significant

Fig. 6. Simulated planarization properties for $10 \times 10\ \mu\text{m}$ line-space gratings. Original step height is $0.5\ \mu\text{m}$. Top: PMMA ($0.87\ \mu\text{m}$ thick). Middle: OFPR 800 ($0.93\ \mu\text{m}$ thick). Bottom: No coating.

D	0.08	0.083	0.14	0.137

discrepancies. Thermal flow of the film, however, tends to reduce the measured step heights.

The simulated and experimental results have thus far only considered single-dimensional feature sizes (*i. e.*, finite width and infinite length). On most device surfaces, both the width and length of a feature influence the planarization properties. For example, the data for isolated $10\ \mu\text{m}$ line features here only represent maximum possible step height for that feature size on a device structure. Features with lengths less than the range of feature-feature interaction can produce reduced step heights (*i. e.*, a more planar, less conformal coating). We believe that the same planarization frequency weighting (filtering) parameters for the single-dimensional feature sizes can be applied to features that have both finite width and length.

Concluding Remarks

In spite of the apparent limitations of this technique, the spun-on planarization properties of spun-on films can be estimated with reasonable accuracy under some conditions that are encountered in device processing. The experimentally determined fitting parameters appear to represent meaningful physical constants related to the nature of the spun-on, thin film planarization phenomena. It involves expressing the topographical features in frequency domain (*i. e.*, a Fourier transform) and weighting the frequency components to simulate the smoothed topographical features. Two adjustable parameters are used to fit experimental planarization data for isolated line features. The α fitting parameter gives an unambiguous indication of the planarization properties of the spun-on solution. The P_{\min} parameter represents the minimum period that does not require a weighting factor.

Although the frequency weighting procedure lacks theoretical and mathematical rigor, reasonable results have been obtained using a fairly simple low pass frequency filtering scheme. Conceivably, more accurate and justifiable filtering schemes may be devised in the future. These results show that useful approximation procedures are possible by treating topographical features in the frequency domain. To verify this approximation procedure, the planarization properties of two distinctly different spun-on solutions, OFPR 800 (30 Hz) and KTI 496K PMMA (9% solids) have been simulated on complex topography.

Investigation of Melt Carry-Over during Liquid Phase Epitaxy

I. Growth of Indium Phosphide

R. B. Wilson,¹ P. Besomi,^{*2} and R. J. Nelson¹

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Melt carry-over characteristics as a function of melt height, wafer clearance, push speed, and wafer surface morphology during the liquid phase epitaxy growth of InP are described. It is found that a "critical clearance" exists, below which carry-over is minimized and nearly independent of clearance. For single layers of InP doped with zinc and grown on planar [100] oriented substrates, this critical clearance is about 75 μm . It is shown that deviations from nonplanarity of the substrate influence carry-over in this subcritical regime. A theory is developed to explain this behavior in terms of a flow model which is dependent upon the melt pressure head and surface tension effects. A new boat design is proposed to reduce melt carry-over effects.

Liquid phase epitaxy (LPE) has played an important role in the development of optoelectronic devices fabricated from III-V semiconductor materials (1). Although it has successfully competed with other growth technologies such as molecular beam epitaxy, vapor phase epitaxy, and metal-organic chemical vapor deposition, the LPE technique suffers from several disadvantages inherent in using the liquid phase. Because of the high density, viscosity, and surface tension of the liquid metal melts used for growth, hydrodynamic and surface effects can strongly modify local growth conditions, resulting in inhomogeneous growth over the surface of the wafer. One example of these effects is melt carry-over or dragover, which occurs when the substrate is moved from one growth melt to another. Because some clearance must be maintained between the bottom of the graphite melt holder and the top of the substrate to prevent scratching, indium can be trapped in this clearance volume above the wafer. As the wafer is moved underneath the next growth melt, this trapped solution can locally alter the composition of the melt, resulting in inhomogeneous and/or nonreproducible growth characteristics (2). This is particularly true in the case of double heterostructure (DH) growth, where very thin (0.2 μm), uniform active layers must be grown to achieve high yields of low threshold laser devices (3). For this reason, a detailed understanding of the carry-over phenomena is desirable, particularly with respect to how carry-over can be influenced by accessible growth variables such as clearance and push speed.

In Part I of this work (this paper), we have studied melt carry-over during LPE growth of InP as a function of wafer clearance, push speed, melt height, and wafer surface morphology under otherwise identical growth conditions. This has led to an improved understanding of the factors which govern the carryover phenomena and indicates that a region of critical clearance exists below which carry-over is minimized and nearly independent of clearance. In addition, it is shown that surface morphology can strongly influence carry-over in this critical regime. In Part II of this study (the following paper) (4), the practical implications of melt carry-over is reported for growth of InGaAsP double heterostructure wafers.

Experimental

An automated LPE growth system was used for these experiments. The temperature cycle, as well as the gas flows, were computer controlled in order to improve run-to-run repeatability as compared to manual LPE systems (5). Moreover, the push mechanism used to translate the InP substrate from melt was also computer controlled to a time accuracy of 50 ms. Single layers of InP doped with zinc ($p \sim 10^{18}/\text{cm}^3$) were grown on [100] InP substrates at 580°C using step cooling at a supersaturation of 6°C. The growth melt was prepared from InP and metallic indium weighed to an accuracy of $\pm 5 \mu\text{g}$. The substrates were 1.27 cm length \times 1.52 cm width \times 0.25 mm thickness. After measuring the substrate thickness to $\pm 3 \mu\text{m}$, graphite shims of known thickness were used to obtain the desired clearance for the growth run. The substrates were degreased in successive chloroform, acetone, and methanol rinses prior to a 10 min etch in 10:1:1 (H_2SO_4 : H_2O_2 : H_2O). This latter etch removes about 0.4 μm of surface from the wafer and leaves a flat, smooth, reproducible surface for growth. After the growth run, the used indium melt was weighed to $\pm 5 \mu\text{g}$ to determine the weight loss of the melt. The maximum weight loss of a melt due to P evaporation was determined to be less than 0.05 mg. The weight loss due to the thickness of the grown layer was 0.6-0.8 mg in all cases.

Theory

Flow model.—In order to understand the results presented in this paper, we first develop a model for melt carry-over based on the expected fluid flow characteristics. Shown in Fig. 1 is a schematic drawing of the graphite boat, growth melt, and substrate in an arbitrary position of the slider during the push from one melt to the next. We examine the flow of liquid melt from the melt bin into the narrow channel above the substrate and below the graphite boat bins block. This problem is similar to the flow of the melt out of the channel as the substrate is moved away from the melt. This channel has a height equal to the clearance (c) above the substrate and is typically 0.5-5 mil. The width of the channel is approximately equal to the width of the substrate (W), and the channel length, X_0 , is determined by the wall thickness between adjacent melts. The substrate length (L) is usually larger than the wall thickness, X_0 .

Fig. 1. Schematic diagram of indium carry-over in a typical graphite boat.

For a rectangular channel of this sort, the velocity distribution in the y direction is given by well-known expressions (6) for Couette flow between two parallel plates in which one is moving with speed S

$$V = \frac{1}{2\rho\nu} \frac{\partial P}{\partial X} (y^2 - cy) + \frac{Sy}{c} \quad [1]$$

In this expression, ρ and ν are the density and kinematic viscosity of the melt. By integrating this expression with respect to y and dividing it by c , an equation for the average fluid velocity into the channel is obtained (6)

$$\langle v \rangle = \left(-\frac{\partial P}{\partial X} \right) \frac{c^2}{12\rho\nu} + \frac{S}{2} \quad [2]$$

It should be pointed out that these expressions are steady-state expressions which are valid after a period of time on the order of $t \geq c^2/\nu$, which for the conditions of these experiments is $\sim 10^{-2}$ s. Since the duration of the push is 0.1s, this is considered to be an acceptable approximation. However, these expressions assume laminar flow conditions and do not take account of the possible discontinuous motion of the slider, which is driven by a stepper motor. Thus at high slider velocities, turbulence effects are expected to modify the $S/2$ dependence in Eq. [2]. Likewise, at low slider velocities, the $S/2$ term will not properly take account of the stepwise motion of the slider. In addition to these expected problems with the $S/2$ term, it has been found that inclusion of this term in the flow model theory results in expressions for melt carry-over which disagree significantly with experimental results. We therefore anticipate our experimental results in the remaining theoretical development and disregard the $S/2$ term for the reason mentioned above. Further experimental investigation may be required to ascertain why the $S/2$ term in Eq. [2] may be neglected without negative consequences on the validity of this model.

The quantity $(-\partial P/\partial X)$ in Eq. [2] is the pressure gradient across the melt flowing into the clearance channel shown in Fig. 1. Because the push speeds we consider here are much less than the velocity of sound and the melt fluid is considered to be incompressible, this gradient can be rewritten as

$$\left(\frac{\partial P}{\partial X} \right) = \frac{\Delta P}{X_1} \quad [3]$$

where ΔP is the pressure applied to the fluid at the mouth of the clearance channel, and X_1 is the distance from the mouth of the channel to the moving meniscus of the fluid in the channel. In the next two sections, we consider the origin of the pressure ΔP which drives fluid into the clearance channel.

Melt pressure head.—One contribution to the pressure which drives melt carry-over is gravitational force on the melt. At the base of the melt, this pressure is given by the weight of the melt divided by the wafer area

$$P_g = \frac{\rho L W h g}{L W} = \rho g h \quad [4]$$

where L is the length of the wafer, g is the gravitational constant, and h is the melt height. Because the top surface of the melt is curved due to surface tension, h is defined such that

$$h = \frac{\text{melt weight}}{L W \rho} \quad [5]$$

In these expressions, the melt density can be assumed to be very nearly equal to that of pure indium. At 580°C, the density is calculated by extrapolation of known data (7) to be 6.69 g/cm. This gravitational contribution to the melt carry-over driving pressure ΔP , then, is approximately equal to 3×10^3 dyn/cm² for a 6g melt. From Eq. [4] and [5], this pressure should vary linearly with melt height and melt weight.

Surface tension effects.—An additional contribution to ΔP comes from surface tension effects inside the clearance channel. The well-known principles of capillarity (8) arise because of a capillary pressure, P_c , which is most generally expressed for a rectangular channel by the equation (8)

$$P_c = \frac{2\gamma \cos \Theta}{r} \quad [6]$$

where r is the radius of curvature of the meniscus, Θ is the contact angle, and γ is the fluid surface tension. Pressure is defined such that a positive pressure causes fluid to flow into the channel. It is clear from this equation that the wetting properties of the materials forming the walls of the rectangular channel will strongly influence the magnitude of the capillary pressure P_c because of the dependence on contact angle.

In the case where the surfaces are not wetted by the melt, e.g., having two parallel graphite walls, $\Theta \approx 180^\circ$ and P_c is large and negative. In this case, the capillary pressure tends to force fluid out of the clearance channel unless the gravitational pressure P_g is greater. Using a value of $\gamma = 630$ dyn/cm (9) and $\Theta = 180$, the capillary pressure P_c is calculated to be approximately -1.3×10^5 dyn/cm for a 4 mil clearance. The absolute magnitude of this value is considerably larger than the value of P_g estimated in the previous section.

A second case occurs if both surfaces are wetted by the melt where $\Theta \approx 0$. In this situation, P_c is large and positive, and melt will be drawn into the clearance channel much in the same way that water is drawn into a glass capillary tube. This situation is partially realized in LPE growth when a sapphire bins block is used. It has been found (11) that the amount of melt carry-over is larger for sapphire boats than for equivalent graphite boats of similar clearance in the LPE growth of AlGaAs.

The third case is the more usual one in LPE growth in graphite boats where one surface is nonwetting (upper graphite bins block surface) and one is wetting (substrate). In this case, the meniscus curvature is not well-defined, and the resultant capillary pressure can be calculated only in certain symmetrical cases (11). However, it is intuitively clear that the resulting capillary pressure should be intermediate between the former two cases and be significantly smaller than the previously calculated value, and it should easily compare to the pressure which arises from gravitational effects, P_g . Furthermore, because the surface tension and contact angle are expected (12) to be strongly influenced by the composition of the melt and grown layer, P_c should be composition dependent.

In accordance with the foregoing discussion, we can write the pressure which drives melt carry-over, ΔP , as a sum of two terms

$$\Delta P = P_g + P_c = \rho g h + P_c \quad [7]$$

It is next asserted that the mass of melt carry-over is proportional to the total volume of melt which flows into the channel during the time elapsed for the push. This is given by the time integral

$$M_{\text{carry-over}} = \rho c W \int_0^{L/S} \langle v \rangle dt \quad [8]$$

where t_0 is equal to L/S . Combining Eq. [2]-[4], [7], and [8], we arrive at the expression

$$M_{\text{carry-over}} = \rho c W \int_0^{L/S} \left[\frac{c^2}{12\rho\nu} \frac{(\rho gh + P_c)}{X_t} \right] dt \quad [9]$$

Because the parameter X_t varies during the push, we replace this variable with an average value, X_{eff} , which remains as an adjustable constant to be determined by experiment. Integration with respect to time then yields the expression

$$M_{\text{carry-over}} = \frac{c^3 W}{12\nu X_{\text{eff}}} (\rho gh + P_c) \frac{L}{S} \quad [10]$$

In the next section, we experimentally establish the magnitudes of $\Delta P = \rho gh + P_c$ and of P_c by measuring the functional dependence of melt carry-over on melt height. This data, in conjunction with melt carry-over *vs.* clearance data, allows comparison with the theoretical model just developed.

Results and Discussion

Shown in Fig. 2 is a plot of experimentally obtained melt carry-over data *vs.* melt height as defined by Eq. [5]. These data were obtained using a constant clearance of $102 \pm 8 \mu\text{m}$ and a push speed of 12.7 cm/s. The linear behavior of these data strongly support the assertion that the experimental conditions are such that Eq. [10] of the theoretical model is applicable. Using known indium viscosity data (13), the slope obtained from a least squares fit to the data yields a value of $X_{\text{eff}} = 0.60 \text{ cm}$. This value is reasonable because the spacing between growth bins is 0.76 cm. From the y -intercept, P_c is calculated to be $-1.4 \times 10^3 \text{ dyn/cm}^2$, again in good agreement with the expectations previously discussed. The negative value of P_c indicates that the meniscus effects tend to keep melt out of the clearance space. This effect, however, is overcome by pressure head effects for melt heights greater than $\sim 0.25 \text{ cm}$. It is important to point out that the dependence of melt carry-over on melt height strongly suggests that confined melts (14) should significantly reduce melt carry-over, provided that a pressure head is not maintained on the confined melt by weights or other configurations such as a baffled solution holder. It is therefore desirable that boat configurations which minimize melt

Fig. 2. Plot of melt carry-over *vs.* melt height. The solid line is a least squares fit to the experimental data, with slope of 146 mg/cm and y -intercept of -33.8 mg .

pressure head and, hence, carry-over be utilized in the LPE growth of InGaAsP.

In a second set of experiments, melt carry-over was measured as a function of clearance for a constant melt height of 0.47 cm (6g melt). These data are shown in Fig. 3, along with the theoretical prediction (solid curve) using the parameters just derived. Although the calculated curve is consistently too high by about 20%, the agreement is seen to be fair and could be improved using somewhat different values of the adjustable parameters X_{eff} and P_c . Of great practical importance is the predicted and experimentally observed minimization of melt carry-over for clearance values less than $\sim 75 \mu\text{m}$.

In order to further verify the cubic dependence of melt carry-over on clearance, the data of Fig. 3 was replotted on a log-log scale, shown in Fig. 4. The solid line is a least squares fit to the data and yields an exponent of 3.8. If the fit is performed setting the exponent to 3 and allowing only the pre-exponential factor to vary, the dashed curve is obtained. Although the scatter of the experimental points does not allow a clear determination of the exponent, the agreement with the theoretical model is fair. Furthermore, the value of P_c determined from the pre-exponential factor corresponding to the dashed line was calculated to be $-1.2 \times 10^3 \text{ dyn/cm}^2$, in reasonable agreement with the previous determination from melt height data.

Until now, the theoretical model and results presented have been for planar substrates such as those used for LPE growth of double heterostructure wafers. However, another important application of LPE is the regrowth step used in fabrication of buried heterostructure lasers (3). In this case, the substrate has nonplanar etched features (mesas) present on the substrate which can influence melt carry-over. Shown in Fig. 3 is a plot of melt carry-over *vs.* clearance data for $6 \mu\text{m}$ -high etched mesa substrates (triangles) compared to the previously presented planar substrate results. In addition, points corresponding to single epilayers which exhibited meniscus lines are also presented (squares). These data suggest that surface morphology can significantly increase the melt carry-over in the clearance region below $\sim 75 \mu\text{m}$. In terms of the theoretical model, this can be attributed to the effects of surface tension and surface wetting. Because

Fig. 3. Plot of melt carry-over *vs.* clearance for a single Zn-doped InP layer on planar and nonplanar [100] InP substrates. The solid line is the relationship predicted from Eq. 10 for planar substrates. The typical error bar on the clearance was $\pm 3 \mu\text{m}$ for these experiments.

Fig. 4. Log-log plot of melt carry-over vs. clearance. Solid line is a least squares fit to the data allowing the exponent and pre-exponential factor to vary. The dashed line is a least squares fit with the exponent fixed at 3.0. The typical error bar on the clearance for these experiments was $\pm 3 \mu\text{m}$.

nonplanar surface features will in general enhance the surface wetting, $|P_c|$ will be reduced, resulting in more carry-over. This can also be interpreted as "edge-effects," where etched surface features act as excess edges on the surface of the wafer. It can also be expected that other perturbations of surface morphology, such as roughness created during meltback, might significantly enhance melt carry-over (2).

Because Eq. [10] predicts a variation in melt carry-over with push speed S , the influence of this parameter was also investigated experimentally, and the results for planar wafers are shown in Fig. 5 for a constant melt height of 0.47 cm and clearance of $51 \mu\text{m}$. A least squares fit to

Fig. 5. Log-log plot of carry-over vs. push speed

Fig. 6. Plot of relative decrease in carry-over left on the substrate vs. successive empty bin number for three different growth runs.

these data gives an exponent of -0.31 . Although this value is substantially different than the value of -1.0 predicted by Eq. [10], the trend of decreasing carry-over with increasing push speed is qualitatively in agreement. This discrepancy may be due to wafer edge effects, or possibly to dynamic surface wetting effects (13). In any case, the push duration time, determined by L/S , is an important variable in carry-over phenomena and should be taken into consideration when wafer area is "scaled up."

Another phenomenon, which we describe as a wipe-off effect, was noticed during the course of these experiments. It was found that for a given amount of melt carry-over left on the wafer after leaving the melt, this material was wiped off the surface as the wafer was pushed through empty melt bins at the push velocity. After the run, small quantities of residual wiped-off melt were found in these empty bins. These quantities were collected for each empty bin following the growth melt bin and were weighed. It was found that the amount left in each well decreased for successive empty bins away from the grown melt. These data are plotted in Fig. 6. The explanation for this wipe-off effect is that as the wafer leaves the growth melt, the carried-over melt, no longer constrained by the clearance space, collects into approximately hemispherical balls because of surface tension effects. As the wafer continues through the empty bin, these balls are sheared off at the opposing bin wall. This process is then repeated in successive empty bins. This suggests an effective melt carry-over removal scheme, which would be to have a series of slots on the underside of the graphite boat adjacent to the wafer, as shown in Fig. 7. Provided that the spacing and width of these slots

Fig. 7. Schematic diagram of proposed graphite boat designed to reduce melt carry-over.

is large enough to allow relaxation of the melt carry-over into balls, these slots will trap the residual melt and remove it from the wafer surface.

Conclusions

It has been shown that melt carry-over phenomena can be successfully modeled by a fluid flow mechanism which is driven predominantly by a pressure head originating from the growth melt. The degree of melt carry-over can be influenced by melt height, clearance, melt composition, push speed, and surface morphology. Because small values of melt height result in reduced carry-over, it is concluded that confined melts that do not maintain any additional pressure head should be effective in controlling carry-over. In addition, narrow clearances, fast push speeds, and smooth surface morphologies also result in reduced carry-over. Finally, a boat design has been proposed which should reduce carry-over effects via a geometrical shearing effect.

Investigation of Melt Carry-Over during Liquid Phase Epitaxy

II. Growth of Indium Gallium Arsenic Phosphide Double Heterostructure Material Lattice-Matched to Indium Phosphide

P. Besomi,^{*2} R. B. Wilson,¹ and R. J. Nelson¹

ABSTRACT

The effects of indium melt carry-over were investigated during liquid phase epitaxy (LPE) growth of InGaAsP double heterostructure (DH) material lattice-matched to InP substrates. Compositional and thickness variations associated with melt carry-over were studied as a function of the clearance between the substrate and the graphite boat. Moreover, x-ray lattice-constant measurements, as well as photoluminescence spectrum analysis, showed that meltback of the substrate prior to growth may lead to enhanced indium melt carry-over. Finally, broad area lasers were fabricated, and it was shown that enhanced indium melt carry-over led to nonlasing devices. A study of secondary ion mass spectroscopy (SIMS) profiles for the major constituents of DH material showed that indium melt carry-over adversely affects interface abruptness and subsequent device performance.

A major problem encountered in liquid phase epitaxy (LPE) is the carrying of melt solution from one growth well to the next, induced by the movement of the substrate. This carry-over phenomenon can affect important material parameters such as epitaxial layer thickness, lattice mismatch, and layer composition. These effects are especially deleterious in the case of LPE growth of InGaAsP double heterostructure (DH) material closely lattice-matched to InP substrates, because binary InP melt carried over into adjacent quaternary or ternary solutions can modify such critically melt-composition-sensitive solutions. If not corrected, melt carry-over can potentially reduce LPE yield because of the reduced available wafer area having the desired material characteristics.

In Part I of this study (1), melt carry-over was investigated for the LPE growth of InP layers grown on InP substrates. For this binary material, a theoretical model was developed which adequately describes experimental data. The most significant feature of our model is its prediction of melt carry-over as a function of melt height,

melt composition, push speed, and clearance. In particular, melt carry-over is a cubic function of clearance, giving rise to a drastic increase in carry-over for clearances greater than $\sim 75 \mu\text{m}$. By utilizing this dependence on clearance, it is possible to vary melt carry-over in a well-defined manner and systematically investigate the influence of melt carry-over on critical DH material characteristics such as layer thickness, composition, and lattice mismatch. The purpose of this work is therefore to evaluate effects of clearance control upon DH material and device characteristics during LPE growth. It is shown that increasing clearance and, hence, increasing melt carry-over lead to variations in active layer wavelength, lattice mismatch, and increased broad-area threshold current densities, all of which have a negative effect on devices fabricated from this type of DH material. In addition, it will be shown that interface properties and dopant profiles are also adversely affected. Finally, practical solutions for reducing or eliminating melt carry-over will be discussed.

Experimental

In the experiments reported here, the LPE growth was carried out in a palladium-diffused hydrogen ambient. A multiwell graphite boat (see Fig. 1) held the various

Fig. 1. Schematic of an LPE boat assembly. 1) indium melt well; 2) InP substrate; 3) graphite chambers; 4) graphite slider; 5) Sn-In-P solution.

growth solutions, and a graphite slider transported the InP substrate from one growth melt to the next. A combination of boat assembly clamping by recessed walls and graphite plugs, in addition to a tight machining tolerance, lead to no more than $\pm 25 \mu\text{m}$ clearance variation between the graphite slider and the graphite boat. This corresponded to an improvement of the boat design, compared to the design discussed in another work (2).

In order to eliminate the decomposition of the InP substrate before growth due to phosphorus evaporation, a graphite chamber (see Fig. 1) external to the LPE boat assembly and containing a Sn-In-P solution was used (3). The near-equilibrium LPE growth method developed by Nelson (4) was used: undoped InP, GaAs, and InAs pieces were weighed and were added to 99.9999% pure indium melts baked for at least 14h at 720°C in hydrogen. At the end of the typical growth procedure, the wafer was pushed under the end part of the graphite block until the boat was cooled to 300°C to limit thermal degradation of the epitaxial layers and then was pushed out of the boat.

The substrates used were sulfur-doped [100] InP having a dislocation etch-pit density less than 10^3 cm^{-2} . They were etched in a solution of $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2:\text{H}_2\text{O}$ (10:1:1 concentration) and thoroughly rinsed in deionized water prior to growth. The typical structures consisted of either a Sn-doped InP buffer layer ($3\text{--}4 \mu\text{m}$ thick, $n \sim 2 \times 10^{18} \text{ cm}^{-3}$) and an unintentionally doped InGaAsP layer ($E_g = 0.95 \text{ eV}$, $0.5 \mu\text{m}$ thick, $n \sim 5 \times 10^{16} \text{ cm}^{-3}$) or of a p-InP buffer layer ($2.5 \mu\text{m}$ thick, $p \sim 1 \times 10^{17} \text{ cm}^{-3}$) and a p^+ top-layer InGaAs ($E_g = 0.75 \text{ eV}$, $0.5 \mu\text{m}$ thick, $p \geq 3 \times 10^{19} \text{ cm}^{-3}$). The various layer thicknesses were determined using a scanning electron microscope (SEM), and the doping levels reported here were calculated from the atomic fraction of the dopants in the growth solutions (5), as well as from Hall measurements.

The photoluminescence (PL) measurements were performed using a CW YAG laser or an Argon laser for excitation and using a grating monochromator to resolve the PL spectrum (6). The mismatch of the epitaxial layers was determined by x-ray diffraction measurements of the wafer curvature, with $\bar{g} = \langle 511 \rangle$ or $\langle 422 \rangle$ as the operating reflection. Secondary ion mass spectroscopy (SIMS) analysis was performed to determine the interface profile of the major constituents and to detect the possibility of dopant diffusion (7).

Results and Discussion

The most obvious effect related to melt carry-over is certainly the presence of an indium-rich alloy, usually at the trailing edge of the wafer, after the run is completed. Shown in Fig. 2 is a plot of indium melt carry-over, as determined by the weight increase of the wafers after growth, vs. clearance. These results were corrected for the grown layers' weight contribution. The push speed used was approximately 5 cm/s , similar to the one used in Part I for the study on InP (1). The observed nonlinear increase in melt carry-over is similar to that previously described in Part I for InP (1). However, the ternary $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ alloy exhibits a slightly stronger dependence on clearance than the $1.3 \mu\text{m}$ wavelength InGaAsP alloy,

Fig. 2. Plot of the amount of indium melt carry-over vs. the clearance between the substrate and the graphite boat, for ternary (using meltback prior to growth) and quaternary (without meltback) epitaxial layers. The labeled point corresponds to ternary growth without a meltback.

as evidenced by the increased indium melt remaining on the wafer (dotted line in Fig. 2). Such composition dependence of melt carry-over is consistent with the model developed in Part I (1).

Another phenomenon which may affect melt carry-over is surface roughness. In fact, improper melt composition due to melt carry-over may also lead to surface roughness and thus enhance the melt carry-over itself. A common manifestation of excessive melt carry-over is the presence on the wafer of cross hatching dislocation patterns (8). Eliminating surface roughness is therefore an important consideration in LPE reproducibility. It has been observed that melt carry-over is reduced in the case of the ternary growth when meltback of the substrate prior to growth of the first layer is avoided (see Fig. 2). These results further demonstrate the advantages of eliminating substrate thermal degradation prior to growth and, thus, the meltback usually associated with improper substrate protection schemes (3). Along with the drastic increase in melt carry-over for large clearances, our study suggests that clearances of $50 \mu\text{m}$ or less should be used and that the commonly used meltback technique should be avoided.

Another effect related to melt carry-over is the control of epitaxial layer thickness. Layer thickness results are listed in Table I for a series of consecutive LPE runs in which clearance increased from 30 to $160 \mu\text{m}$. The thickness of the binary InP layers does not significantly vary. Such results are also compared in Table II with expected changes of melt supersaturation. Since the amount of phosphorus carried over to the next melt does not significantly modify the supersaturation of the following binary melt composition, no effect on layer thickness should be expected. Moreover, in the case of the $1.3 \mu\text{m}$ wavelength quaternary alloy, the thickness variation is not significant, although the melt supersaturation increases a few centigrade degrees because of InP melt carry-over (see Table II). Only for very large changes in melt composition will the layer thickness increase.

The effects of melt carry-over are more dramatic for the ternary layers. In the case of ternary growth it was observed that the trailing area of the wafers were covered by

Table I. Epitaxial layer thickness for increasing substrate clearance

Clearance (μm)	InP layer (μm)	InGaAsP layer (μm)	InGaAs layer (μm)	"Postgrowth" InGaAs layer (μm)
30	1.2	0.5	1.3	None
100	1.3	0.5	2.4	1.6
160	1.2	0.5	3.0	2.7

Table II. Change in LPE melts supersaturation for increasing substrate clearance

Melt	Indium mole fraction (%)	Phosphorus mole fraction (%)	Arsenic mole fraction (%)	Gallium mole fraction (%)
Binary InP melt, without melt carry-over	0.993906	0.006094	0.0	0.0
Binary InP melt with 60 mg InGaAsP melt carry-over	0.993198	0.006236	0.000486	0.000080

a second epitaxial layer much thicker than the original layer present on the whole wafer. This feature can again be explained by the presence of an indium melt thinly spread over the wafer during the cooling down phase, from which a "postgrowth" layer up to 3 μm thick grows after the scheduled run is over (9). By pushing the wafer out of the graphite boat, using a long graphite slider, immediately after completion of the growth, it was noted that the postgrowth ternary layer was eliminated, although In-rich droplets remained on the trailing edge of the wafer. Finally, similar questions may arise for the effects of melt carry-over from the 1.3 μm wavelength quaternary alloy into the InP binary melt. Table II indicates that the change of InP binary melt composition due to melt carry-over of 60 mg of InGaAsP melt has a negligible effect on melt composition. Only the phosphorus content increases, by almost 5%, corresponding to an increase of 0.2°C in the supersaturation of the melt.

These various layers were also characterized by photoluminescence. As shown in Fig. 3, the composition of 1.3 μm quaternary layers is not sensitive to the change of melt composition because of the indium melt carry-over (less than 1% change in the bandgap for a 160 μm clearance related to less than 3×10^{-4} change in arsenic mole fraction of the melt). However, the InGaAs ternary layers exhibit two features. First, the photoluminescence wavelength decreases from 1.665 to 1.623 μm , indicating a slow change in the alloy composition containing an increasingly large amount of phosphorus. Second, the postgrowth ternary layer grown over the original ternary layer during the cool-down phase has a much longer wavelength, 1.698-1.703 μm . This indicates that it is an InAs-rich ternary layer which grows during cool-down, because the bandgap of InAs is only 0.35 eV (9) smaller than the one of GaAs.

Figure 4 shows the plots of the lattice mismatch $\Delta a/a$ determined by x-ray diffractometric measurements for the quaternary and ternary layers. It is noted that the lattice mismatch remains small for the quaternary layer, even when the indium melt carry-over is large. However,

Fig. 3. Plot of the photoluminescence spectrum shift vs. substrate clearance for ternary and quaternary epitaxial layers.

Fig. 4. Plot of the lattice mismatch $\Delta a/a$ vs. substrate clearance for ternary and quaternary epitaxial layers.

for a clearance larger than 50 μm , the mismatch $\Delta a/a$ is more than -5×10^{-4} , an upper limit for device applications (10). For the ternary layers, the mismatch of the original ternary layer increases to very large values (nearly $\sim 10^{-2}$, from Fig. 4) because of the addition of phosphorus to the melt, as pointed out earlier. Moreover, the trailing edge postgrowth layer is heavily mismatched by up to $+4.2 \times 10^{-2}$ with a lattice larger than the one of InP. This result again suggests that the postgrowth layer is InAs-rich, because the lattice of the InGaAs ternary increases when the alloy tends towards the InAs composition.

Finally, this study of the effects of indium melt carry-over during LPE growth was completed by analyzing its consequences on InP/InGaAsP DH lasers. The typical laser structure was described earlier (11), and the clearance used during DH growth was varied between 20 and 160 μm . The broad-area laser thresholds reported in Table III for devices with identical active layer thicknesses of 0.2 μm also indicate that large clearance should be avoided. The influence of melt carry-over on the active layer properties was further investigated in order to ascertain the sensitivity of the electrical properties of DH lasers on growth procedure, possible constituent segregation, or dopant diffusion. In Fig. 5a, the SIMS profile of phosphorus and arsenic shows a marked decrease in the interface abruptness of sample F1664, which did not lase and was grown with a wipe-off clearance of 160 μm , as compared to sample F1669 (1.3 kA/cm² threshold), grown with a wipe-off clearance of 25 μm . Similar results were obtained in Fig. 5b for gallium. Moreover, it is seen from Fig. 5b that zinc diffusion into the quaternary active layer from the p-InP cladding layer was more pronounced in the case of sample F1664. The enhanced zinc diffusion observed here for the sample grown with the 160 μm clearance is probably the result of a high concentration of interface defects in this poorly lattice-matched layer.

Table III. Broad-area threshold current density for increasing substrate clearance

Sample	Broad-area lasers threshold (kA/cm ²)	Clearance (μm)
F1662	2.0	50
F1663	1.8	50
F1664	Did not lase	160
F1667	1.5	20
F1668	1.4	25
F1669	1.3	25

Fig. 5. SIMS profile of: a, top) phosphorus and arsenic; b, bottom) gallium and zinc dopant at the interface of InGaAsP/n-InP DH material. The dashed lines represent the interface widths as determined from these data.

Conclusions

It has been shown that indium melt carry-over during LPE growth of InP/InGaAsP DH material is enhanced by large clearances between the substrate and the graphite boat. Not only is the available wafer area reduced in size because of remaining indium melt, but layer thicknesses, compositions, and lattice mismatches are also adversely affected by melt carry-over. The results of this study therefore indicate that (i) indium melt carry-over usually increases as substrate clearance increases and as melt-back is used, and (ii) increased indium melt carry-over has a deleterious effect on InP/InGaAsP DH material lasing properties because important materials characteristics (such as lattice match, interface abruptness, and doping level) deteriorate.

This study suggests that the use of an improved boat design ensures that good control of clearance between substrates and graphite block can be maintained during LPE growth and that melt carry-over can be eliminated. And finally, the broad area threshold of DH lasers increases because melt carry-over leads to mismatched layers, less abrupt interfaces, and enhanced zinc diffusion into the active layer.

Mechanism of Dry Etching of Silicon Dioxide

A Case of Direct Reactive Ion Etching

Ch. Steinbrüchel, H. W. Lehmann,* and K. Frick

Laboratories RCA Limited, CH-8048 Zürich, Switzerland

ABSTRACT

Reactive sputter etching of SiO₂ with CHF₃-O₂ plasmas has been investigated in a parallel-plate reactor by combining etch-rate measurements with concurrent determination of ion densities (using a Langmuir probe) and the composition of neutral plasma species (using a mass spectrometer), and by examining etched profiles in the SEM. The importance of geometrical variables, such as plate separation and plate area, and the electrical parameters appropriate for characterizing the discharge are discussed. Etch rates are found to follow the ion density and to be fairly independent of the plasma chemistry under most experimental conditions. Moreover, a comparison of reactive sputter etching and reactive ion beam etching of SiO₂ with CHF₃ and CF₄ shows that etch yields per incoming ion are essentially independent of the flux of neutral radicals to the substrate. This strongly suggests as the dominant etch mechanism for SiO₂ direct reactive ion etching, where ions themselves are the main reactants in the etch reaction. Measured etch yields are consistent with this picture. However, the plasma chemistry has a decisive influence on the etch rate of Si, and thus on the etch selectivity of SiO₂ with respect to Si, and also on the exact shape of profiles etched into SiO₂.

One of the many steps in the production of large-scale integrated devices involves delineating fine patterns in thin films of various materials by plasma processing. In silicon-based technology, two of the main materials of interest are Si, as the active medium, and SiO₂, as a compatible insulator. Thus, in order to control the manufacturing process properly one needs to address two key issues: how to etch profiles with a desired shape into the two materials, and how to etch them selectively with respect to each other.

As regards etching of SiO₂, we showed in our early investigations, using SEM micrographs, that it is quite possible to etch well-defined square wave profiles with submicron dimensions (1, 2). In another publication, it was demonstrated that the directionality of the incoming ions plays a crucial role in defining the actual etch profiles (3). In addition, etch rates were shown to be enhanced significantly by ion impact (4, 5, 30). Heinecke (6) and Ephrath (7) pointed out that maximum selectivity for SiO₂ with respect to Si could be obtained in fluorine-deficient plasmas. But it was also realized that, whenever the C/F ratio increased beyond a certain critical point (the polymer point), deposition of polymers occurred on chamber walls and even on SiO₂ surfaces (8). Thus one must work in a relatively limited regime in terms of gas composition and pressure in order to obtain maximum selectivity and a minimum of polymer deposition.

A large number of publications has appeared since, describing etch processes with a variety of gases (CHF₃, CF₄ + H₂, C₃F₈, etc.), reactors, and processing conditions. Whereas in general the reported etch rates are similar, the exact gas composition at which polymerization occurs, the selectivity, and the shape of etched profiles often differ slightly from paper to paper. In addition, a variety of contamination effects has been observed. Thus, although dry etching of SiO₂ is used in almost all IC manufacturing lines, its fundamentals are still rather poorly understood. This is quite in contrast to dry etching of Si, for which numerous studies have revealed many details about the relevant etch mechanisms [see e.g., Ref. (9, 10)].

It is the purpose of this paper to elucidate the mechanisms giving rise to anisotropic etching of SiO₂. To this end, we have investigated the relationships between reactor geometry, gas composition, and ion densities and energies in CHF₃-O₂ plasmas and how they affect etch rates, anisotropy, and selectivity. Our investigation is based on etch rate measurements with concurrent mass spectrometry, Langmuir probe measurements (to determine ion densities), and scanning electron microscopy of etched profiles.

Experimental Arrangement

The reactor used in this study is essentially the same as described before (11) but with a few modifications (Fig.

1). The vacuum chamber is made of stainless steel, 42 cm diam, and 24 cm height. The RF-driven copper cathode is of 20 cm diam and, except where noted otherwise, is covered with an SiO₂ plate. A copper tape around the vertical edge of the SiO₂ plate provides sufficient electrical contact between the plasma and the cathode to make possible reliable measurements of the RF-induced dc bias voltage. Opposite to the cathode, a movable grounded Al plate of equal diameter is mounted so that the reactor configuration can be changed continuously between a symmetrical parallel-plate and a so-called reactive-sputter-etch geometry (with the top plate removed). A differentially pumped mass spectrometer (UTI 100C) is connected to the side of the chamber. The background pressure in the mass spectrometer is about 1×10^{-7} torr (1.3×10^{-5} Pa), and during etching a pressure ratio of about 10^3 can be maintained between the plasma chamber and the mass spectrometer. Data acquisition is computer controlled and allows the rapid recording of either entire mass spectra or only selected mass peaks of neutral plasma species (12). With the movable Langmuir probe the dc current to the probe *vs.* the applied voltage is measured as a function of the probe position within the plasma. From such measurements spatially resolved ion densities and electron temperatures can be inferred, as described before (13). Etch rates are determined interferometrically *in situ*, using a He-Ne laser.

Results

With the results described below, we wish to address four issues important for the etching of SiO₂ in CHF₃, the goal being a better understanding of the factors determining etch rate, anisotropy, and selectivity. First, we study the effect of changing the reactor geometry, especially the separation of the parallel plates, on the discharge characteristics. We then examine etch rates in pure CHF₃ and CHF₃-O₂ mixtures, specifically in relationship to plasma ion densities and to changes in the composition of neutral plasma species. Finally, we show that on this basis one can understand slight variations in the shape of etched profiles and, in particular, the conditions for perfect anisotropic etching.

Geometrical effects.—It is generally recognized that the geometry of a reactor affects a discharge sustained therein, and thus the etching by that discharge, in rather unpredictable ways. We have investigated systematically one aspect of this problem, *i.e.*, the effect of the plate separation in a reactive sputter etch system with parallel-plate geometry (Fig. 1). Figure 2 shows the RF power P dissipated (really the forward power read on the RF power supply, with the system tuned well) as a function of the peak-to-peak voltage V_{RF} at various plate separations, while gas pressure and flow rate are being held constant. Clearly, P is always proportional to V_{RF} , but the

proportionality factor depends on the plate separation. Thus it is not obvious whether P or V_{RF} is the relevant parameter in establishing equivalent plasma conditions. We have found that in general etch rates R_e (and ion densities N_i) correlate better with P than with V_{RF} if the plate separation is varied. The same applies if the cathode material is changed. However, for a mistuned system it is V_{RF} which determines R_e (and N_i) rather than P or the difference between forward and reflected power.

Figures 3 and 4 show the spatial variation of the ion density N_i and the electron temperature T_e between the plates, along a line perpendicular to the plates in the center of the plasma. (We assume, in accord with mass spectrometric results, that the major ion in a CHF₃ plasma is CHF₂⁺). N_i is very small near the cathode, but rises rapidly through the dark space to a maximum, then decreases gradually up to the counterelectrode. At 20 mtorr, for plate separations smaller than about 5 cm the maximum of N_i is reduced and shifted towards the cathode, whereas for plate separations larger than about 5 cm the region of maximum N_i is unaffected by the plate separation. We also note that varying the power P changes the magnitude of N_i , but not the shape of its spatial distribution. In the horizontal direction, at 2 cm within the plate edge N_i is reduced by 25% as compared to its value in the center of the plasma.

Etch rates and ion densities.—First, we point out that at constant RF power and constant pressure of CHF₃ the

Fig. 2. RF power vs. peak-to-peak RF voltage for different plate separations. CHF₃ at 20 mtorr (flow rate = 30 sccm).

Fig. 3. Ion density vs. probe position in the center of a CHF₃ plasma for three different plate separations. $p = 20$ mtorr (flow rate = 30 sccm), RF power = 60W. Hatched symbols at the right end of the curves denote position of the upper plate.

etch rate of SiO₂ does not depend significantly on the plate separation as long as the plates are far enough apart to allow for a fully developed dark space (cf. Fig. 3). Hence, the results of this and the following sections were all obtained with the top plate removed.

Figure 5 shows etch rates R_e of SiO₂ vs. total pressure p in different CHF₃-O₂ mixtures. Here, the RF power and the flow rate of CHF₃ have been held constant. (At constant power V_{RF} decreases with increasing p). At low p , R_e increases with increasing p up to a maximum. The pressure at which R_e reaches its maximum is the higher the larger the O₂ content. The maximum value of R_e becomes smaller with larger O₂ content.

The ion density N_i in the plasma also varies with p , as shown for pure CHF₃ in Fig. 6. The maximum in N_i occurs closer to the cathode at higher p , which indicates a decreasing width of the dark space with increasing p (Fig. 6). The reason for this is, of course, the smaller mean free path for plasma collisions at higher p . The main point to note here is that the maximum value of N_i , $N_{i,max}$, follows closely R_e as a function of p (Fig. 7). For a CHF₃-O₂ mixture, $N_{i,max}$ and R_e also show qualitatively similar behavior vs. p , although the correspondence is not quite as good as with pure CHF₃ (Fig. 7).

Plasma chemistry.—In order to correlate the above results with changes in the composition of neutral plasma species, we tried two different methods of sampling the

Fig. 4. Electron temperature vs. probe position. Same conditions as in Fig. 3. Hatched symbols at the right end of the curves denote position of the upper plate.

Fig. 5. Etch rate of SiO_2 vs. total pressure with three different CHF_3 - O_2 mixtures. CHF_3 flow rate = 30 sccm, RF power = 75W.

plasma: spatially resolved (in a direction perpendicular to the cathode) through a thin flexible tube, or spatially averaged through an orifice (Fig. 1), into the differentially pumped mass spectrometer chamber. However, in sampling with the tube we were unable to detect any spatial variations in the plasma composition of neutrals that would have paralleled those seen for the ions. Thus, the following remarks will refer to sampling through the orifice.

Figure 8 illustrates the behavior of some representative plasma species observed upon adding O_2 to a constant partial pressure of CHF_3 , at constant RF power. First we note that SiF_3^+ , as the main peak deriving from the reaction product SiF_4 , is easily detectable. With increasing O_2 content, both SiF_3^+ and the etch rate (cf. Fig. 5) decrease similarly, species arising from the parent molecule also decrease, whereas larger polymeric species are strongly suppressed. At the same time, oxygen bearing species increase continuously. A point of interest here is that the oxygen introduced into the plasma by etching the SiO_2 cathode with pure CHF_3 is equivalent, in our system, to the effect of adding about 1 sccm of O_2 in the gas phase. If the cathode material is Al, then no increase in the O bearing peaks results from turning on the plasma with pure CHF_3 , and the qualitative behavior of the various species upon addition of O_2 is the same as in Fig. 8.

Results for pure CHF_3 as a function of pressure (RF power constant) are given in Fig. 9, where differences in peak heights between the plasma-on and the plasma-off

Fig. 7. Etch rate and maximum ion density vs. total pressure for CHF_3 and CHF_3 -10% O_2 plasmas. RF power = 60W.

Fig. 8. Mass spectral data for neutral plasma species, ionized in the mass spectrometer, with O_2 added to CHF_3 . 10 units on the ordinate correspond to the full scale ion currents given in brackets. CO_2^+ (on the 2E-7 scale) and CO_3^+ (on the 5E-7 scale) show behavior identical to that of COF^+ . Larger polymers decrease more rapidly than C_2F_4^+ upon addition of O_2 . Partial pressure of CHF_3 is 20 mtorr. RF power = 75W.

condition are plotted. The dissociation of CHF_3 is clearly visible, amounting to 10% at 10 mtorr, and becomes somewhat more efficient as the pressure increases. Again, the SiF_3^+ peak height follows the same behavior as the etch rate R_e (cf. Fig. 5). So do the intensities of the CO^+ , CO_2^+ , COF^+ (or SiF^+), and COF_2^+ (or SiF_2^+) peaks. Beyond the point of maximum R_e (25 mtorr, cf. Fig. 5), a rapid increase of polymeric species (e.g., C_2F_4^+ , C_2HF_4^+ , etc.) is observed.

In CHF_3 - O_2 mixtures, generally similar results are obtained vs. total pressure, with the provision that etching proceeds to higher pressures as indicated by the SiF_3^+ peak (cf. Fig. 5), and that much larger amounts of such species as CO^+ , COF^+ , etc., are seen, presumably because of gas phase reactions between O atoms and CHF_3 -derived radicals (14) (see also Fig. 8).

With the etch rate of SiO_2 quite independent of minor variations in the plasma composition, the selectivity in etching SiO_2 over Si turns out to be largely a function of the Si etch rate. This is very sensitive to even minute amounts of O or Cl containing gaseous impurities, whether they are introduced directly with the etching gas or liberated by the plasma from the reactor walls or the

Fig. 9. Mass spectrum peak height differences between plasma-on and plasma-off condition vs. CHF_3 pressure. 10 units on the ordinate correspond to the full scale ion currents given in brackets. CO_2^+ (on the 2E-8 scale) shows behavior identical to that of COF^+ . RF power = 75W.

cathode. Such impurities invariably cause a significant increase in the etch rate of Si and thus a reduction in the selectivity.

Etched profiles.—In Fig. 10, we show a few profiles etched into SiO_2 under different conditions. The mask was a square wave grating of $3\ \mu\text{m}$ periodicity exposed and developed in a layer of HPR 206 photoresist about $1\ \mu\text{m}$ thick. In all experiments, the flow rate of CHF_3 was 30 sccm and the RF power was 65W, this being the maximum power still assuring the integrity of the photoresist in our reactor.

If one relates the etching conditions of Fig. 10a-10e to the results described above, it is apparent that careful control of the plasma chemistry is required for perfect anisotropic etching. This can be achieved either at low pressure in pure CHF_3 (Fig. 10a) or at much higher pressure with the addition of O_2 (Fig. 10b). However, O_2 in excess of the optimum at a given pressure leads to a slightly overetched profile (Fig. 10d). Conditions favoring polymerization give rise to nonvertical sidewalls, which are produced by the growth of a thin polymeric film extending from the top of the photoresist to the bottom of the etched trough (Fig. 10c and 10e). Everything else being the same, polymerization is enhanced at higher pressure (Fig. 10c) or by an oxygen consuming cathode (Fig. 10e), and also at lower flow rate or at lower RF power.

Discussion

We now wish to discuss our results, putting them in context with previous work, by focusing attention on two main themes: the truly important parameters and proper characterization of an etching discharge, and the physical and chemical mechanisms determining etch rates and etch anisotropy.

Plasma discharge parameters.—In reviewing the literature on dry etching, one is struck by the large number of processes (*i.e.*, combinations of reactor configuration, etch gas, and discharge operating conditions) in existence to etch any one of several materials of interest. The present work, together with previous results (13), allows us to give a fairly comprehensive description of the relevant discharge parameters for the etching of SiO_2 with CHF_3 and CF_4 . As variables, we have examined in detail plate separation (including the case of reactive sputter etching [RSE] with only one, RF-driven plate and the reactor chamber as counterelectrode) material of the RF-driven plate (or cathode), and, previously, size of the cathode (13)

Fig. 10. SEM micrographs of profiles etched into SiO_2 under different conditions. Photoresist still present. RF power = 65W. (a): 15 mtorr CHF_3 . (b): 60 mtorr CHF_3 -4% O_2 . (c): 30 mtorr CHF_3 . in a given reactor. We wish to characterize the conditions producing comparable etch discharges, as reflected by the etch rate R_e .

If at constant gas pressure the plate separation is varied, we find that R_e changes in accordance with the RF power P , and not with the peak-to-peak voltage V_{RF} or the induced dc bias voltage at the cathode, V_{dc} (see also Fig. 2). This agrees with behavior found for a rather different process: etching Si with SF_6 (15). If one changes the material covering the cathode from SiO_2 to Al or graphite, everything else being the same, again P correlates best with R_e , rather than V_{RF} or V_{dc} . (But note that the cathode material has a noticeable effect on the discharge chemistry.) However, if in the RSE mode the cathode size is changed, then it is V_{RF} which best parallels R_e rather than the power P , or the power density (*i.e.*, P divided by the cathode area), or V_{dc} [cf. Ref. (29)]. [In etching Si with SF_6 , V_{dc} was said to correlate best with R_e , but V_{RF} was not looked at (15)]. The same also holds if, with fixed geometry, the RF power is not properly matched to the reactor.

We emphasize that if one considers major changes in the reactor configuration, then none of the above externally accessible electrical variables are useful in a comparison with the parallel-plate geometry. Thus, for example, in a flexible diode reactor (16) it is not true, in general (17), that the state of the discharge as indicated by the ion density is independent of the division of power between the two driven electrodes as long as the total power is constant (16). Also, with a "hollow cathode" (18), V_{RF} is vastly different from that with a single cathode of the same size at a given power, so that it is not obvious why one should compare the two situations at constant V_{RF} .

Taking into account the different reactor configurations as described, we arrive at the remarkable conclusion that the operating conditions for a given etch rate R_e of SiO_2 all have one feature in common: the same ion density at the edge of the dark space. (We define this edge, somewhat loosely, as the point of maximum ion density

in a direction normal to the cathode; see Fig. 3.) The correlation between R_e and $N_{i,max}$ is excellent if at a fixed pressure the cathode size (13) or the plate separation are changed, or if with fixed geometry the pressure is changed (Fig. 7). The correlation between R_e and $N_{i,max}$ also holds with minor changes in plasma chemistry [e.g., addition of small amounts of O_2 or H_2 to CF_4 (13)] but breaks down with major changes in plasma chemistry (e.g. addition of O_2 to CHF_3 for p beyond the polymer point; see Fig. 7). This intimate connection between R_e and $N_{i,max}$ is of great significance for the etch mechanism, as we will show below.

Etch mechanisms.—Having recognized the important role of the ions, we now wish to elucidate the contribution of neutral species to the etching of SiO_2 . Our goal is to identify the main reactants and products and the processes relating them. In doing mass spectrometry of plasma species, we are aware of potential pitfalls, such as complications due to wall reactions, memory effects, etc. Still, we believe that our experimental setup, with excellent background pressure in the differentially pumped mass spectrometer chamber, allows us to monitor without difficulty stable neutral plasma species.

In order to identify such species, we rely on their characteristic cracking patterns as produced by electron impact in the mass spectrometer ionizer. We note, in agreement with Ref. (19), that for SiF_4 the major peak is SiF_3^+ at $M/e = 85$ and that the next most important peak, SiF^+ at $M/e = 47$, is down by almost two orders of magnitude. Two other potential etch products are COF_2 and SiF_2 , which, unfortunately, have the same mass. However, the cracking patterns of the two species are quite different. For COF_2 , the ratio of peak heights at $M/e = 66$ (COF_2^+), 47 (COF^+), 44 (CO_2^+), and 28 (CO^+) is roughly 1:2:2:1, whereas for SiF_2 the ratio of peak heights at $M/e = 66$ (SiF_2^+) and 47 (SiF^+) is about 2:1 [cf. also Ref. (8, 19)].

With these facts in mind, we conclude, from Fig. 9, that SiF_4 is the main Si bearing product in the etching of SiO_2 by a CHF_3 plasma. Indeed, the SiF_3^+ peak parallels nicely R_e vs. pressure p and also $N_{i,max}$ vs. p (cf. Fig. 5 and 7). At the same time, we observe substantial amounts of CO , CO_2 , and COF_2 as etch products, all showing the same behavior vs. p as does SiF_4 , with CO apparently the main O bearing product. Furthermore, O_2 is only present in the background in small amounts and is not produced by the etch reaction. Thus, our results are in agreement with those of Winters (19), who used XeF_2 as etchant and bombardment by Ar^+ or CF_3^+ ions, as far as the production of SiF_4 is concerned, but we observe far larger amounts of O bearing products and no O_2 . Comparing CHF_3^+ , CF_3^+ , and CF_2^+ peaks vs. p (Fig. 9) we note that beyond the polymer point their relative intensities do not correspond to those of the cracking pattern of CHF_3 anymore. At about 20 mtorr, a new source of CF_3^+ and CF_2^+ begins to appear, for which the most logical candidate is polymeric species resputtered from the SiO_2 surface. At much higher p , when etching of SiO_2 has virtually ceased, the additional production of CF_3^+ just about compensates for the reduction of CF_3^+ from the dissociation of CHF_3 in the discharge.

In CHF_3 - O_2 mixtures, qualitatively similar results are obtained vs. p . SiF_4 is again a major product and follows R_e vs. p . However, the production of CO , CO_2 , and COF_2 is greatly enhanced, probably because of efficient oxidation of polymeric species as well as CHF_3 in the gas phase (cf. also Fig. 8). Upon adding O_2 to a constant partial pressure of CHF_3 (Fig. 8), the correspondence between SiF_4 (i.e., SiF_3^+) and R_e is not quite as close, in that R_e decreases somewhat faster than SiF_3^+ with increasing O_2 .

So far, we have pointed out the parallel behavior of the etch rate R_e , the production of SiF_4 , and the ion density $N_{i,max}$ at not too large p (i.e., $p \approx 20$ mtorr), and also the rapidly increasing deposition of polymeric material on the substrate above the point of maximum R_e . Since we cannot detect neutral radicals, we cannot investigate directly potential neutral reactants although we can rule out

HF as one of them (3). The role of the radicals is clarified, however, if one compares etch yields per ion in reactive sputter etching (RSE) with those in reactive ion beam etching (RIBE), as shown in Table I. The etch yields in RSE were estimated as described before (13), based on the measured ion densities $N_{i,max}$ at the dark space edge. Most surprisingly, at a fixed ion energy, the etch yields turn out to be quite independent of the flux of radicals to the substrate, with the ratio of the radical flux to the ion flux varying over about four orders of magnitude.

All our results point to the conclusion that in the etching of SiO_2 by CHF_3 or CF_4 plasmas, ions are the main reactants. The following reactions, among others, can be visualized as being involved [the first one was suggested also by Harper *et al.* (20)], with the respective etch yields Y in atoms per ion (e.g., in reaction [1], three SiO_2 units are removed by four CF_3^+ ions, so that $Y = 3 \times 3/4$)

The figures for these etch yields should be interpreted as maximum yields possible which may only be attained by sufficiently energetic ions. The yields depend on the F/C ratio in the reactant ion (cf. reactions [1], [5], and [6]) and on the extent to which available F atoms are used to volatilize Si rather than O (cf. reactions [1] and [2] or [3] and [4]). Of course, reactions producing SiF_2 rather than SiF_4 have a higher etch yield (cf. reactions [1] and [3]). Furthermore, the production of SiF_2 seems to be tied to the production of O_2 (cf. reactions [3] and [4]). We note that the idea of ions as reactants is consistent with the picture advanced earlier (26) that energetic molecular ions dissociate completely upon impact on the substrate, thus creating highly reactive atoms.

Since several or all of these reactions may occur simultaneously, the measured etch yields (Table I) are in good agreement with those predicted. For example, for CF_3^+ at

Table I. Etch yields (at./ion) for SiO_2

Ion	E_i (keV)	j_{ion} (mA/cm ²)	Mode	Y (at./ion)	$\frac{f_{ion}}{f_{radical}}$	Ref.

		0.8		1.0		(25)

E_i is the ion energy, j_{ion} the ion current density at the substrate, and $f_{ion}/f_{radical}$ the ratio of particle fluxes at the substrate.

With a reactive gas in the RIBE mode, the beam contains a mixture of ions, the one given in the table being the main ion except for the work of Ref. (23) and (25), where the main ion was more likely CF_2^+ (22, 26). The plasma potential in RSE turns out to be about 30V, regardless of the plate separation or the plasma pressure, so that to a good approximation E_i in RSE is equal to the induced dc bias voltage V_{dc} .

500 eV on SiO₂, the physical sputtering yield is estimated as 0.7 at./ion (26), so that the part of the total yield due to reactions [1]-[6] is 2.3 at./ion. Table I also indicates that etch yields saturate at high ion energies, as is expected from reactions [1]-[6]. At low ion energies, yields are considerably smaller but still independent of the neutral flux. This may be rationalized as arising from the lower dissociation probability of the impinging ions. Moreover, relative yields predicted for different ions CF_r⁺ compare favorably with those deduced by Mayer and Barker (22), who used an ion beam of well-characterized composition.

Let us add, however, that there is also evidence showing the non-negligible contribution of neutrals (radicals) to the etching of SiO₂. The composition of products depends on the nature of the neutrals present (compare this work with Ref. (19), where the neutrals were F atoms from XeF₂). Also, the measured etch yields for 500 eV ions may be slightly higher than predicted on the basis of reactions [1]-[6], in light of the fact that high yield reactions such as [3] and [4], leading to SiF₂ as a product, are evidently less probable than those leading to SiF₄, the main product [cf. Ref. (19)]. In addition, changes in the ion beam composition in RIBE cannot account for the entire change in the etch rate *vs.* pressure (22). It is clear, though, that, in the case of SiO₂, the nature of the ions is much more important, and the flux of radicals much less important, than in the case of Si. This conclusion receives additional support from the fact that loading effects are much smaller for SiO₂ than for Si (4).

Anisotropic etching.—We argued above that the overall ion-enhanced etch rate of SiO₂ is to a large extent due to direct etching by reactive ions, in competition at higher pressure with deposition (and resputtering) of polymeric species. The former mechanism leads naturally to anisotropic etching because the etch rate is only appreciable on surfaces exposed to ion bombardment. However, the shape of etched profiles also depends in a subtle way on the latter, surface inhibiting mechanism (9).

In order to achieve clean profiles with vertical sidewalls, one must operate somewhat below the polymer point, *i.e.*, somewhat below the point of maximum etch rate (cf. Fig. 5 and 10). At the polymer point, growth of a thin polymeric film has set in already on vertical surfaces, becoming more pronounced at higher pressure (Fig. 10c). This results in profiles with nonvertical sidewalls. Addition of O₂ in the gas phase counteracts the polymerizing tendency of the plasma (Fig. 10b and 10d), but O₂ in excess of the optimum attacks the photoresist and, thus, also leads to nonvertical sidewalls. In addition, excess O₂ degrades the selectivity with respect to Si.

Thus it is the plasma chemistry which determines the conditions for optimal anisotropic etching, and minor changes in that chemistry may have a major effect on the shape of the etched profiles. Given the large number of parameters affecting the plasma chemistry, such as gas composition, pressure, flow rate, cathode material, RF power applied, etc., it is not surprising that one can obtain acceptable results with a variety of combinations of these parameters. Proven processes for SiO₂ have been based on CHF₃ (1, 2), CF₄-H₂ (7), C₂F₈ (6), and CHF₃-H₂ (27) plasmas. We have been able to etch good profiles even with a C₂F₄-O₂ mixture, although with pure C₂F₄ there is no etching, only deposition, under any conditions.

Let us keep in mind that the plasma chemistry has a decisive influence not only on the etch anisotropy, but also on the etch selectivity of SiO₂ with respect to Si (see the "Plasma chemistry" section). In general, one may expect the conditions for maximum selectivity to yield slightly nonvertical sidewalls in SiO₂. Conversely, the best profile shape may only be obtainable at less than maximum selectivity. Thus, in a practical situation an optimal trade-off between the two requirements will have to be achieved.

Conclusion

Winters *et al.* (10) have discussed ion-enhanced etching in terms of three possible mechanisms. One is called

chemically enhanced physical sputtering, in which the role of the ions is to remove physically reaction products which are loosely held on the substrate surface. In the second mechanism, ion bombardment is visualized as creating a damaged surface with sites particularly suitable for reaction. The third mechanism, favored by Winters *et al.* (10), is called chemical sputtering and assumes that ion bombardment provides the energy required for certain exothermic reactions to occur in the near-surface region of the substrate which lead to products desorbing into the gas phase.

We contend that the dominant mechanism in the etching of SiO₂ is a fourth one, for which we propose the name "direct reactive ion etching." By this, we mean that energetic reactive ions serve as the main reactants in the overall etching reaction. Or, in other words, ions themselves do most of the etching, rather than radicals (9). This conclusion is based on the finding that etch yields per ion are largely independent of the flux of radicals to the substrate in a wide variety of situations. Only under rather polymerizing conditions do the radicals affect the etch yield significantly, by way of forming a polymeric layer on the substrate. However, small changes in the plasma chemistry of neutral species have large effects on the etch anisotropy and selectivity.

Of course, ion-enhanced etching in general may involve all four of these mechanisms contributing simultaneously to the overall etch rate. Indeed, etching of Si in a fluorine-based plasma appears to be due largely to chemical sputtering (10) and chemically enhanced physical sputtering (28), whereas the dominant mechanism in etching Si with a chlorine-based plasma is still to be determined.

The term "reactive ion etching" is often used to describe the general situation of ion-enhanced etching whereby the substrate is etched at low pressure on the RF-driven cathode and thus is exposed to ion bombardment (4, 7, 16). We propose, in light of our results, that the term "reactive ion etching" be reserved for the particular etch mechanism in which ions themselves react, and that the more general mode of etching mentioned above be referred to as "reactive sputter etching," *i.e.*, etching involving ion bombardment in a reactive environment.

Beryllium Ion-Implanted Junctions in GaAs with Submicron Lateral Diffusion

P. M. Campbell and B. J. Baliga

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12345

ABSTRACT

Beryllium ion implants in GaAs annealed at 900°C for 30 min with a Si₃N₄ encapsulant have been shown to form p-n junctions with lateral diffusion between 0.5 and 1.0 μm, junction depth of 0.7 μm, and implant activation rate of ~ 100%. SiO₂ and phosphosilicate glass encapsulants yield similar values of lateral diffusion, junction depth, and activation rate, but are shown to induce near-surface degradation effects manifested by a reduced carrier concentration within 1.0 μm of the surface in unimplanted annealed material and to produce anomalously high breakdown voltages and high leakage currents in Be-implanted junctions.

One of the critical requirements for GaAs device technology is a reliable technique for the fabrication of high quality micron-size planar p-n junctions. For example, such junctions are required for the gate region of JFET's in high speed GaAs integrated circuits. Planar junctions have previously been fabricated using sealed-tube diffusions with both vapor and solid sources (1, 2). Although lateral diffusions equal to the depth were achieved in the sealed-tube process, these studies indicated that lateral diffusion of 100 times the vertical depth can be observed if the diffusion conditions are not carefully controlled. The fabrication of diffused JFET's with tolerable lateral diffusion using a metal-organic Zn source has been reported (3), but for integrated circuit fabrication, it would be preferable to use ion implantation followed by an open tube annealing cycle in order to obtain greater control and uniformity, as well as simplified processing. However, surface degradation during the high temperature annealing required to activate the implant remains a serious problem, requiring either an encapsulant or an arsenic overpressure to prevent dissociation of the GaAs. A comprehensive review of ion implantation techniques in GaAs is given in Ref. (4). It has been demonstrated that p-n junctions can be fabricated in GaAs with beryllium ion implantation (5). However, the lateral diffusion during high temperature annealing was measured by junction staining, which may not reveal surface diffusion between implant islands, which, for example, has been detected in Zn-diffused GaAsP using high sensitivity SEM techniques (6).

We have investigated the comparative suitability of silicon dioxide, phosphosilicate glass, and plasma-deposited silicon nitride as encapsulants for high temperature (900°C) annealing of Be implants in GaAs. These Be implants were performed in high purity ($n = 2.5 \times 10^{15}/\text{cm}^3$) liquid-phase epitaxial GaAs, which served as a sensitive medium for the detection of surface lateral diffusion and other degradation effects induced by high temperature annealing.

Sample Preparation

The bare GaAs samples were first cleaned in boiling solvents, then soaked in hot H₂O to form a thin oxide film which was then removed in hot HCl. The wafers were then coated front and back with a thin film of either SiO₂, phosphosilicate glass (PSG), or Si₃N₄.

The SiO₂ films were formed by the reaction of silane and oxygen at atmospheric pressure and a temperature of 400°C. The phosphosilicate glass films were deposited under the same conditions, but with the addition of flowing phosphine, yielding films with 8% phosphorous by weight. The rate of deposition for the SiO₂ and PSG films was 300 Å/min, with a thickness of 4000Å used for each film, as measured by ellipsometry. The refractive index of the SiO₂ and PSG films was 1.45.

The Si₃N₄ films were formed by the plasma-enhanced reaction of both silane and ammonia in an argon ambient at a pressure of 0.6 torr and a temperature of 450°C. The rate of deposition for this process was 150 Å/min. All Si₃N₄ layers were 900Å thick and had a refractive index between 1.95 and 1.98.

Following deposition, a pattern of closely spaced implant windows was opened in each film, using standard photolithographic techniques, with a thick (2 μm) layer of positive photoresist, which also served as a selective mask during the implantation. The opened implant windows varied in separation from 1 μm upwards in steps of 1 μm.

Next, Be ions of energy 100 keV and fluence $5 \times 10^{13}/\text{cm}^2$ were implanted in the open windows (Fig. 1). The wafers were then stripped of the remaining photoresist and coated with a second identical layer of either SiO₂ (4000Å), PSG (4000Å), or Si₃N₄ (900Å). Following this, the wafers were annealed in flowing nitrogen gas at a temperature of 900°C for 30 min. Finally, contact windows were opened to each implant island. If desired, a lift-off metallization was then deposited to improve the ohmic nature of the contacts.

Lateral Diffusion Measurement Technique

The lateral diffusion of the implanted and annealed Be was measured electrically by detecting the punch-through of the lateral diffusion between adjacent implant islands, which is clearly observable because the I-V characteristic of two P⁺ islands joined by diffusion (Fig. 2, top) will be ohmic, while that of two P⁺ islands separated by a thin N region (Fig. 2, bottom) will be rectifying. Since the implant islands varied in separation from 1 μm upward in steps of 1 μm, the lateral diffusion can be measured to within half the smallest distance, or 0.5 μm. This electrical measurement of lateral diffusion is of direct relevance to device and circuit fabrication because it measures directly the electrical isola-

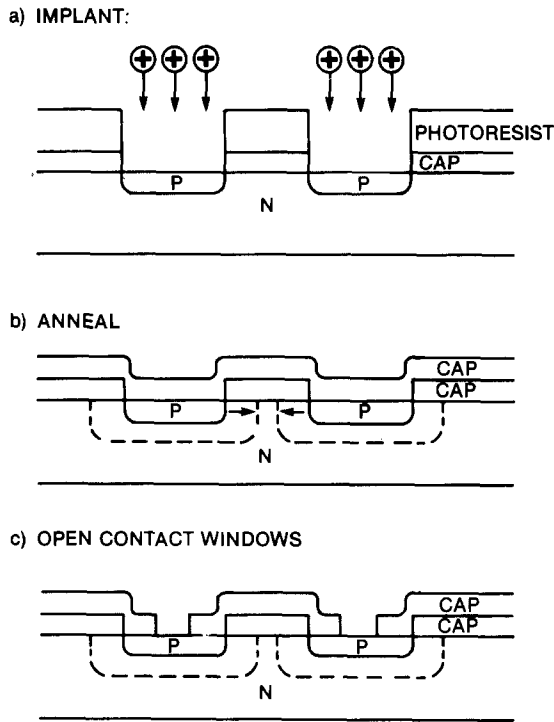

Fig. 1. Processing steps for lateral diffusion measurement

tion of the implanted regions, unlike the commonly used angle lapping/staining technique which may not, for example, detect the formation of thin diffused conductive surface channels under the encapsulant. This technique has the additional advantage of being compatible with nondestructive on-chip testing during processing, whereas the staining method in Ref. (5) and the SEM technique in Ref. (6) each require cleaving of the sample.

Lateral Diffusion Results

The lateral diffusion of the implanted Be after a 30 min anneal at 900°C was measured to be between 0.5 and 1.0 μm for each of the three encapsulants Si₃N₄, SiO₂, and PSG. This measurement technique is demonstrated in Fig. 3 for the case of Si₃N₄; a rectifying characteristic between two implant windows separated by 2 μm is shown, indicating a lateral diffusion of less than half the window separation, or 1.0 μm. A 1 μm window separation gives an ohmic charac-

Fig. 2. Two P⁺ implant islands joined by diffusion (top) yield ohmic I-V characteristics, while two islands separated by N region (bottom) yield rectifying I-V characteristics.

Fig. 3. I-V characteristic of two implant islands separated by 2 μm is rectifying, indicating a lateral diffusion of less than half the separation, or 1 μm.

teristic, indicating a lateral diffusion of at least 0.5 μm. In the rectifying case, no current flows until the two depletion regions touch; this occurs in Fig. 3 at a bias of 4V, and the characteristic is symmetric, as expected. The depletion width of each junction varies as $W = [2\epsilon(\psi - V)/qN]^{1/2}$, where ϵ is the permittivity, ψ = built-in potential of the junction, V = external bias across the junction, q = electronic charge, and N = doping of the base material. Hence, for greater window separation, a greater bias voltage is required for the depletion region of the reverse-biased junction to penetrate the additional distance and reach that of the forward-biased junction, causing the onset of conduction. Figure 4 shows a graph of this punch-through voltage as a function of implant window separation, with ohmic characteristics plotted as having a zero punch-through voltage. The data points with nonzero punch-through voltage in Fig. 4 follow a roughly parabolic form, as expected from the depletion width equation, and could in principle be used to solve the equation for a precise value of the lateral diffusion if N were accurately known. This is not simple in the case of GaAs because there exist near-surface compensation effects resulting from the high-temperature anneal which can affect the value of N , as shown in a later section.

Fig. 4. Punch-through voltage vs. implant window separation for implant islands annealed with Si₃N₄ encapsulant.

Fig. 5. Leakage current vs. reverse bias for implanted junction diode annealed with Si_3N_4 encapsulant.

Electrical Characterization

There exist significant differences in the electrical characteristics of diodes annealed with different encapsulants. Circular junction diodes (diameter = $250\ \mu\text{m}$), fabricated as above on $n = 2.5 \times 10^{15}/\text{cm}^3$ LPE GaAs and annealed at 900°C for 30 min using Si_3N_4 as the encapsulant, exhibit leakage currents as low as the 10^{-9}A range for reverse bias as high as 200V (Fig. 5), whereas those fabricated with SiO_2 or PSG caps show leakage currents in the 10^{-6}A range. In addition, the diodes annealed with a Si_3N_4 cap undergo avalanche breakdown at a reverse bias of $\sim 200\text{V}$, as predicted by Sze and Gibbons (7) for GaAs with $n = 2.5 \times 10^{15}/\text{cm}^3$. However, identical diodes annealed with SiO_2 or PSG as the encapsulant show anomalously high breakdown voltages of up to 450V. This suggests the existence of a near-surface compensation mechanism associated with the SiO_2 and PSG encapsulants, but not with the Si_3N_4 .

Annealing Damage Study

In order to investigate the effect of high temperature annealing with the various encapsulants on the near-surface carrier concentration independently of any ion implantation effects, adjacent pieces from the center of a single unimplanted wafer of boat-grown silicon-doped ($n = 1.4 \times 10^{18}/\text{cm}^3$) bulk GaAs were coated with either SiO_2 , PSG, or Si_3N_4 as above and annealed at 900°C for 30 min. The films were then removed with HF, and each sample was measured with a Polaron Semiconductor Profile Plotter (8), which performs a series of differential capacitance-voltage measurements in sequence with a series of photochemical step-etches and generates a plot of carrier concentration as a function of depth. Figure 6 shows the postanneal carrier profiles of the samples capped with SiO_2 , PSG, and Si_3N_4 , as well as a profile of unannealed material. In comparison with the unannealed material, which, as expected, has a flat profile, the SiO_2 -capped material shows a marked decrease in the carrier concentration within $1\ \mu\text{m}$ of the surface. The PSG-capped material shows a similar decrease that is almost as severe as the SiO_2 case, while the damage in the Si_3N_4 -capped material is confined to a region closer to the surface than in the other two cases. This postanneal decrease in the carrier concentration could account for the anomalously high breakdown voltages achieved with implanted junctions in material annealed with SiO_2 and PSG caps, provided the junction depth is shallower than the depth of the compensation. As will be seen in the next section, the junction depths are shallower than the damage with SiO_2 and PSG caps, but not shallower than that with Si_3N_4 . This compensation may be due to the out-diffusion of Ga and/or As through the films, creating vacancies which could be electrically active or serve as sites for the migration of active impurities. Such near-surface degradation

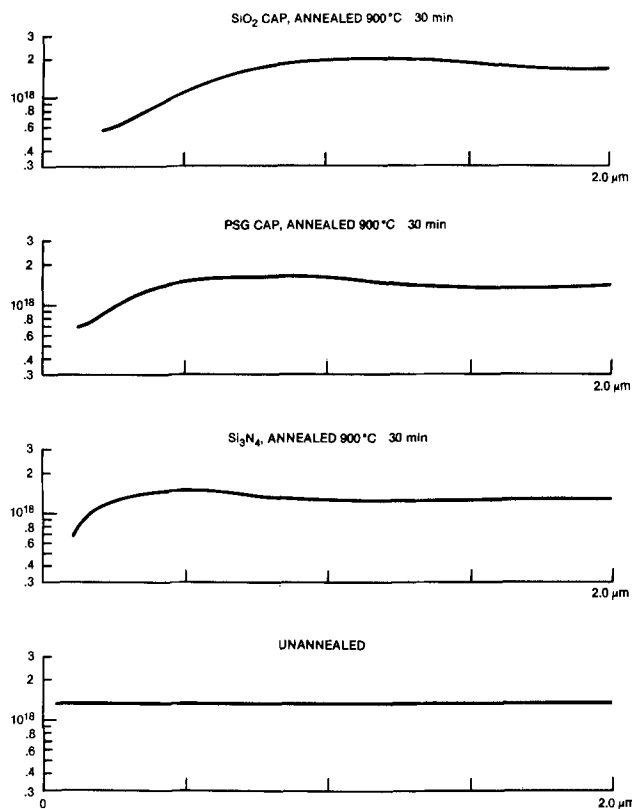

Fig. 6. Carrier concentration depth profiles of unimplanted boat-grown silicon-doped ($n = 1.4 \times 10^{18}/\text{cm}^3$) bulk GaAs annealed at 900°C for 30 min with: a) SiO_2 cap; b) PSG cap; c) Si_3N_4 cap; and d) unannealed material.

could also be responsible for the higher leakage currents observed with SiO_2 and PSG and may be related to the thermal conversion effects observed in the high temperature annealing of semi-insulating GaAs (9).

Implanted Junction Depth Profiles

In order to measure the depth profiles of the implanted junctions, unpatterned LPE GaAs was implanted with Be ($100\ \text{keV}$, $5 \times 10^{13}/\text{cm}^2$), capped with either SiO_2 , PSG, or Si_3N_4 as above, and annealed for 30 min at 900°C to duplicate the conditions of the lateral diffusion experiment. After removing the encapsulant, each sample was analyzed with the Polaron Profiler. The results are shown in Fig. 7.

The SiO_2 -capped sample (Fig. 7a) shows a peak carrier concentration of $2 \times 10^{18}/\text{cm}^3$ at a depth of $0.1\ \mu\text{m}$, with the CV characteristic indicating p-type material. The concentration decreases to a plateau value of $\sim 1.5 \times 10^{18}/\text{cm}^3$ in the range of 0.3 to $0.5\ \mu\text{m}$, then drops rapidly, with the junction occurring at a depth of $0.7\ \mu\text{m}$, as shown in Fig. 7a and also determined from a plot of the electrical phase of the capacitance-voltage data recorded automatically by the Polaron Profiler as a function of depth. The total integrated carrier density gives an implant activation rate of $\sim 100\%$.

The PSG-capped sample (Fig. 7b) shows a similar profile, but the peak value is only $1.3 \times 10^{18}/\text{cm}^3$ and the plateau is $\sim 7.5 \times 10^{17}/\text{cm}^3$. This profile yields an activation rate of $\sim 80\%$. The junction depth is $0.8\ \mu\text{m}$.

Figure 7c gives the profile of a PSG-capped sample annealed at 900°C for 60 min. This longer anneal raises the peak value to $2.5 \times 10^{18}/\text{cm}^3$ and the plateau value to $\sim 1.2 \times 10^{18}/\text{cm}^3$. This increases the activation rate to $\sim 100\%$, but does not change the junction depth.

Figure 7d shows the profile of the Si_3N_4 -capped sample annealed at 900°C for 30 min. In contrast to the three preceding cases, there is no near-surface peak. The carrier concentration has a constant value of $1.7 \times 10^{18}/\text{cm}^3$ to a depth of $0.2\ \mu\text{m}$, decreases slowly to $1.4 \times 10^{18}/\text{cm}^3$ at $0.4\ \mu\text{m}$, and then begins to drop more rapidly, with the junction occurring at a depth of $0.7\ \mu\text{m}$. The implant activation rate is $\sim 100\%$.

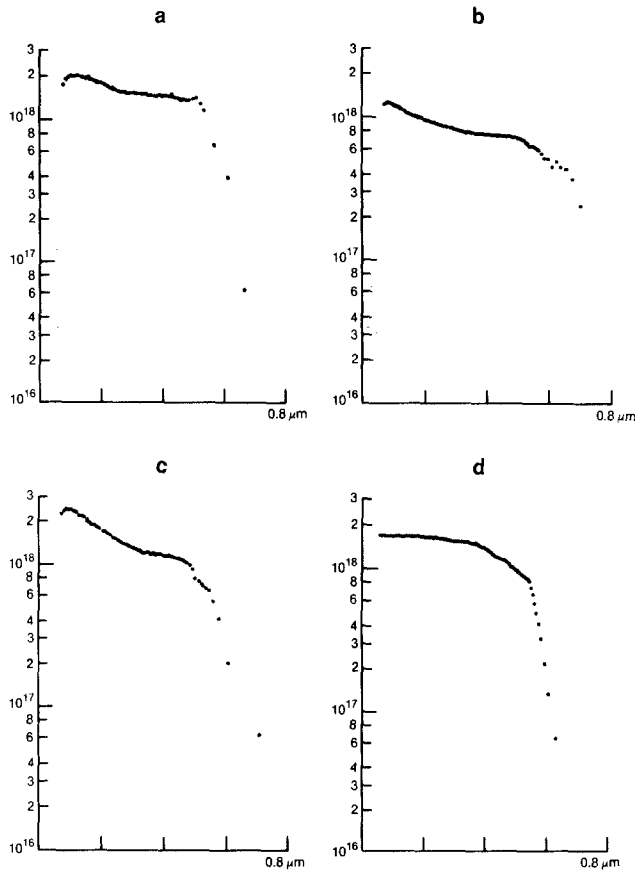

Fig. 7. Carrier concentration depth profile of implanted junction annealed at: a) 900°C for 30 min with SiO₂ cap; b) 900°C for 30 min with PSG cap; c) 900°C for 60 min with PSG cap; and d) 900°C for 30 min with Si₃N₄ cap.

The distinguishing characteristic of the Si₃N₄-capped profile is the lack of the near-surface peak evident in the SiO₂ and PSG cases. This peak occurs too near the surface (0.1 μm) to be a remnant of the preanneal implant profile because the LSS theory gives a projected range of 0.32 μm for 100 keV Be in GaAs. One possible explanation is that the near surface degradation shown to occur in both SiO₂ and PSG serves to getter the implanted Be. Because electrically active Be atoms would have preferentially occupied Ga sites, this suggests that the near-surface degradation may be the result of Ga vacancies created during the anneal. An-

other possibility is that the thermal damage of Fig. 6, acting as an acceptor in compensating n-type material, would in p-type material increase rather than decrease the carrier concentration. If this is the case, then the implant activation rates given above may be overestimated because some of the measured hole density may arise from these damage-induced acceptors, rather than from the implanted Be atoms.

Conclusion

Beryllium ion implants in GaAs annealed at 900°C for 30 min using either SiO₂, phosphosilicate glass (PSG), or Si₃N₄ encapsulants have been shown to form p-n junctions with lateral diffusion between 0.5 and 1.0 μm, junction depths of 0.7 (SiO₂ and Si₃N₄) to 0.8 μm (PSG), and implant activation rates of 80 (PSG) to 100% (SiO₂ and Si₃N₄). However, SiO₂ and PSG encapsulants induce more severe near-surface degradation effects manifested by a reduction carrier concentration within 1 μm of the surface in unimplanted annealed GaAs, and they induce anomalously high breakdown voltages and higher leakage currents in Be-implanted p-n junctions, as compared with similar material annealed with a Si₃N₄ encapsulant.

ABSTRACT

An optical method using the diffraction of a lamellar grating is described for continuously measuring the etching of a substrate through a masking layer. The finite selectivity of the process is accounted for. Automation and real-time measurement are possible. Some theoretical situations are analyzed, and the method is applied for the experimental plasma etching of silicon through a thermally grown silicon dioxide layer.

Dry etching plays an important role in the manufacture of semiconductor devices requiring high resolution lithography. Many times, not only the end point detection for the process is desirable but also the measurement of the depth of incompletely etched areas is desirable. This is the case with etching silicon substrates for isolation purposes, when the etched depth should be carefully controlled in real time if a precise control of thickness is required.

Kleinknecht and Meier (1) first proposed monitoring the plasma etching of dielectric films by measuring the diffraction of a lamellar grating adequately lithographed somewhere on the sample.

Recently, Sternheim and van Gelder (2) used an interferometric system for monitoring the etching of a patterned silicon substrate. A laser beam is diffracted by the pattern being etched onto the substrate, and the zero-order diffracted intensity is monitored. Its principal advantage is the fact that it uses the etched pattern itself for control purposes.

Mendes *et al.* (3-6) further developed a method using lamellar gratings for thickness measurement and etching monitoring which permits one to measure the point-by-point evolution of the depth of the layer being etched. In this paper, we shall profit from the previous developments, extending the method to monitor the etching of the substrate, and accounting for the selectivity of the process with respect to the mask layer. We illustrate its advantages in continuously measuring the evolution of the etched depth of a silicon substrate masked with silicon dioxide.

Description of the Method

The optical modulation of a lamellar grating recorded in the full depth of a layer may be used to monitor the etch rate of the layer by measuring the first-to-zero diffraction intensity orders ratio I_1/I_0 (4, 5). If a substrate is etched through a lamellar grating masking layer, the etched depth h may also be determined by measuring the I_1/I_0 ratio of the grating being formed in the process, as shown in Fig. 1. The I_1/I_0 ratio may be written as

$$I_1/I_0 = \frac{|r_a - r_b|^2 (a/d)^2 \sin^2 c^2(a/d)}{|r_b + (r_a - r_b) a/d|^2} \quad [1]$$

with $\sin c(x) \equiv \sin \pi x / (\pi x)$ and r_a and r_b being the complex amplitude reflectivities on bars and grooves of the grating, respectively. For normal laser beam incidence, it should be written (7)

$$\left. \begin{aligned} r_a &= \frac{r_1 + r_2 e^{i2\beta}}{1 + r_1 r_2 e^{i2\beta}} \\ r_b &= r_3 e^{i2\gamma} \end{aligned} \right\} \quad [2]$$

with

$$2\beta \equiv 4\pi T n_1 / \lambda$$

$$2\gamma \equiv 4\pi(T + h)n_0 / \lambda$$

and

$$\left. \begin{aligned} r_1 &= (n_0 - n_1)/(n_0 + n_1) \\ r_2 &= (n_1 - n_2)/(n_1 + n_2) \\ r_3 &= (n_0 - n_2)/(n_0 + n_2) \end{aligned} \right\} \quad [3]$$

where T is the thickness of the masking layer and h represents the etched depth of the substrate. In our experiment, we shall choose $a/d = 0.5$ for which value the I_1/I_0 ratio is less sensitive to a/d variations (4). In this case, Eq. [1] simplifies to

$$I_1/I_0 = \frac{|r_a - r_b|^2 \sin^2 c^2(a/d)}{|r_a + r_b|^2} \quad [4]$$

Substituting Eq. [2] into Eq. [4], we get the following terms contained in the latter equation

$$\left. \begin{aligned} \cos 2\beta &= \cos(4\pi T n_1 / \lambda) \\ \cos 2\gamma &= \cos([4\pi n_0 / \lambda]T + [4\pi n_0 / \lambda]h) \\ \cos(2\beta - 2\gamma) &= \cos(4\pi T[n_1 - n_0] / \lambda - [4\pi n_0 / \lambda]h) \end{aligned} \right\} \quad [5]$$

If we assume the plasma etching to be infinitely selective (which means that the film thickness T remains constant throughout the process), the I_1/I_0 ratio should be periodic in h with a spatial period $H = \lambda/(2n_0)$. It means that two successive extrema appearing in the I_1/I_0 measured ratio represent a variation in the substrate etched depth (h) of $\lambda/(4n_0)$. In this way, the measurement should be carried out in exactly the same way as for the reflectivity method (8) for thin transparent films. The layer of air lim-

Fig. 1. A stage of the etching of a lamellar grating into a substrate. The substrate has been etched a depth h and a thin mask film of thickness T remains on the top of the structure. The period of the grating is d and the bar and groove sizes are a and b , respectively. The complex indexes of refraction of the mask and substrate are n_1 and n_2 , respectively.

Fig. 2. Computed first-to-zero diffraction intensity orders ratio (I_1/I_0) as a function of the etched silicon depth (h) for two different thicknesses of SiO_2 film ($T = \lambda/(2n_1)$ and $T = \lambda/(4n_1)$), n_1 being the SiO_2 refractive index for the test wavelength $\lambda = 6328\text{Å}$. We assume the process to be infinitely selective, which means that T remains constant. Note that period of both curves is $\lambda/2$, but the amplitudes are widely different. We assumed $n_0 = 1$ (air).

Fig. 4. Computed I_1/I_0 as a function of the etched Si depth (h) for a SiO_2 masking film with an initial film thickness $T_0 = 4000\text{Å}$, assuming infinite selectivity (continuous line) and a selectivity $S = 3$ (dashed line). The former example shows a periodic function (period of $\lambda/2$); the latter one is not apparently periodic and shows only relative extrema. $n_0 = 1$ in both cases.

ited by the upper and lower surfaces of the patterned structures plays the role of the transparent film in the reflectivity method. This is basically the method described by Sternheim, with the difference that we measure I_1/I_0 instead of I_0 , and use an auxiliary lamellar grating instead of the patterned structure itself.

The method we are proposing in this paper, however, presents two important advantages upon the Kleinknecht and Sternheim methods. First, during the etching process, we compare the measured temporal variation of the I_1/I_0 ratio with the computed I_1/I_0 vs. h curve, which permits describing the temporal evolution of h . In this way, we are continuously measuring the substrate etched depth so that we are not limited to monitoring thicknesses in intervals of quarter wavelength as with the methods referred to above. Second, infinitely selective processes are an idealized situation, and rather low selectivities are encountered in actual etching processes. This finite selectivity may be accounted for in Eq. [1]-[4].

These improvements arise from the fact that the well-defined grating structure that is used lends itself to accu-

rate description by the mathematical model represented by Eq. [1]-[4].

Temporal evolution of h for infinite selectivity processes.—This matter was already described in a recent paper concerning the real-time measurement of the etching of thin film samples (5). The approach here is similar, except that, in this case, the film thickness T is constant and the substrate etched depth h is the variable in Eq. [4]. As pointed out above, the I_1/I_0 curve is periodic in h with period $\lambda/(2n_0)$ and $\lambda/(4n_0)$ between successive extrema (3), no matter whether the mask is metallic or dielectric. It should be noted that the film thickness T affects the sensitivity of the method: the period remains unchanged, but the amplitude of the I_1/I_0 oscillations is very dependent on the parameter T . Figures 2 and 3 illustrate this effect for a SiO_2 mask [$n_1 = 1.46$ (9)] on a Si substrate [$n_2 = 3.85 + i0.02$ (9)] for a wavelength of 6328Å , showing that T may be adequately chosen for optimizing the sensitivity of the I_1/I_0 variations.

Fig. 3. Plotting of the amplitude of the I_1/I_0 vs. h curve as a function of the SiO_2 mask film thickness T (assuming $n_0 = 1$), showing that $T = \lambda/(4n_1) \sim 1100\text{Å}$ corresponds to the minimum. This curve is periodic in T , with period $\lambda/2n_1$.

Fig. 5. This figure shows the same case as in Fig. 4, except that there is a 4000Å Al film on the Si instead of the SiO_2 film. Note that both curves corresponding to $S = \infty$ and $S = 3$ are periodic, but only the former has a period of $\lambda/2$. The dashed line ($S = 3$) has a period of $3\lambda/4$ as computed from Eq. [9].

Temporal evolution of h for finite selectivity processes.—A finite selectivity process means that T is somewhat modified from its initial value (T_0) as h increases from its initial zero value, so that

$$T = T_0 - \frac{h}{S} \quad [6]$$

where S should be defined as the selectivity of the process. The higher this value is, the more selective the process is.

Substituting Eq. [6] into Eq. [4] and assuming the sample in air ($n_0 = 1$), the terms in Eq. [5] turn into

$$\left. \begin{aligned} \cos 2\beta &= \cos(4\pi n_1 T_0/\lambda - 4\pi n_1 h/(S\lambda)) \\ \cos 2\gamma &= \cos(4\pi T_0/\lambda + 4\pi(1 - 1/S)h/\lambda) \\ \cos(2\beta - 2\gamma) &= \cos(4\pi T_0(n_1 - 1)/\lambda + 4\pi(1 - (n_1 - 1)/S)h/\lambda) \end{aligned} \right\} [7]$$

Through Eq. [7], it may be realized that all three cosine terms have different periods in h , which are

$$S \frac{\lambda}{2n_1}, S \frac{\lambda}{2(S - 1)}, \text{ and } \frac{2\lambda}{2(S - n_1 + 1)}$$

respectively.

If the selectivity S is finite, all three cosinoidal terms should have different periods so that the I_1/I_0 curve may not even be periodic. It may have relative extrema but in general they are not uniformly spaced from $\lambda/4$.

Figure 4 shows the computed I_1/I_0 vs. h for the case of a SiO_2 mask on a Si substrate having an initial thickness $T_0 = 4000\text{\AA}$, corresponding to a finite selectivity ($S = 3$) and to infinite selectivity for comparative purposes.

If a metallic mask is used instead of the SiO_2 , the three cosinusoidal terms in Eq. [5] turn into just one

$$\cos 2\gamma = \cos \left[\frac{4\pi T_0}{\lambda} + \frac{4\pi h}{\lambda} (1 - 1/S) \right] \quad [8]$$

which is periodic in h even considering a finite selectivity S , being the period H no longer $\lambda/2$ but

$$H = \frac{\lambda}{2(1 - 1/S)} \quad [9]$$

In Fig. 5, we have plotted the computed curves corresponding to an aluminum mask ($T_0 = 4000\text{\AA}$) on a Si substrate showing a period of $\lambda/2$ for infinite selectivity, and a period of $3\lambda/4$ (Eq. [9]) for finite selectivity ($S = 3$).

Note that for practical situations, the influence of the finite selectivity of the process cannot be neglected.

Experimental Setup and Results

The sample was a 2 in. silicon wafer in which a thin SiO_2 film was thermally grown. A lamellar grating with a period of $100\ \mu\text{m}$ and $a/d = 0.5$ was photolithographed in

Fig. 6. Simplified schema of the plasma etching chamber and associated diffraction measurement setup.

Fig. 7. The experimentally measured first and zero diffraction intensity orders as a function of the etching time for a lamellar grating being etched on a Si wafer through a thin SiO_2 mask, in air.

the SiO_2 film. The plasma etching of the silicon was carried out through the SiO_2 mask in a home-made planar reaction chamber of 8 in. diam with 20 mm distance between the electrodes. The reacting gas was CCl_4 . The plasma was excited by a 60W, 13.56 MHz RF generator. The pressure in the chamber was kept constant at 0.1 torr. A 1 mW commercial He-Ne laser ($\lambda = 6328\text{\AA}$) was directed near normal incidence onto the grating and the first and zero diffraction orders on reflection were measured and recorded with two photovoltaic silicon detectors D_1 and D_2 , as seen in the schematic setup in Fig. 6.

During the plasma etching process, the I_1 and I_0 orders were recorded as a function of the etching time (Fig. 7) in a Hewlett-Packard dual channel strip-chart recorder. From the above recorded data, we obtain the I_1/I_0 ratio evolution as a function of time, as seen in Fig. 8a. Note that the plot is not periodic (neither the amplitude nor the interval between successive extrema is constant), showing that the selectivity is not infinite and that it must be accounted for.

In Fig. 8b, we show the computed I_1/I_0 vs. h curve which best fits the experimental data in Fig. 8a. For doing that, a value for S was found that provided the best matching with the successive experimental I_1/I_0 vs. time extrema. For the present experiment, a slightly variable selectivity averaging $S = 30$ was found to suit the best, which value agrees in order of magnitude with previous independent tests performed on similar samples. Comparing the experimental and the fitted curve, a correlation between h and the etching time is obtained; it is plotted in Fig. 8c, which slope provides the evolution of the etching rate. For the present process it appears to be quite constant at $300\ \text{\AA}/\text{min}$.

Two pictures obtained with an interference microscope are shown in Fig. 9, where the shape and modulation of the sample grating may be appreciated before and after completion of the etching process.

Conclusions

The method we describe in this paper allows the continuous measurement of the etching depth, thus resulting in a very fine control over each individual sample. It is especially suited for small depths because it does not depend upon the presence of any singular point, such as the extrema in the reflectivity curve.

Furthermore, this method accounts for the presence of finite selectivities for the etching process and can even be used to calculate it if it is not known in advance with enough precision.

The method requires the etching of a lamellar grating, somewhere on the sample, to be carried out during the process that is being monitored.

Fig. 8. The experimental data in Fig. 7 is rearranged in order to plot the I_1/I_0 ratio (a, top). A computed I_1/I_0 vs. h curve was plotted (b, middle) which best fits the experimental data. This fitting leads to a value of $S \approx 30$. Comparing the experimental and computed curves, the etched Si depth (h) vs. etching time is plotted in (c, bottom) which slope indicates etching rate of $\approx 300 \text{ \AA}/\text{min}$.

Some optical parameters of the sample must be known in order to provide the data required by the mathematical model of the lamellar grating (Eq. [2]-[3]).

Automation and real-time measurement are possible, depending upon the degree of complexity of the experimental situation and availability of computational resources.

Fig. 9. Interferential microscope pictures showing the sample (a, top) before the plasma etching of Si and (b, bottom) after the plasma etching of Si and with the masking layer removed. $\lambda = 6000 \text{ \AA}$ is the average illumination on wavelength.

Dopant Activation and Redistribution in As⁺-Implanted Polycrystalline Si by Rapid Thermal Processing

R. A. Powell and R. Chow

Varian Associates, Incorporated, Corporate Solid State Laboratory, Palo Alto, California 94303

ABSTRACT

Dopant activation and redistribution in ⁷⁵As⁺-implanted (100 keV, 1×10^{15} - 1×10^{16} cm⁻²) polysilicon films following rapid thermal processing (RTP) are reported. For the annealing conditions used (10-30s exposure to a 1150°C graphite heater), significant arsenic redistribution was observed, unlike the case of comparably implanted and annealed single-crystal silicon. For uncapped films, surface loss of arsenic during RTP resulted in high sheet resistance; however, a thin oxide cap (600Å) prevented this arsenic loss. Sheet resistance comparable to furnace-annealed samples ($\sim 30 \Omega/\square$ for 1×10^{16} cm⁻² dose films) could then be obtained in ~ 15 s. The shape of carrier concentration and total dopant depth profiles following RTP was found to be dependent on both implant dose and time of annealing. These results can be qualitatively understood using recently proposed models for arsenic diffusion in furnace-annealed polysilicon films.

Doped polysilicon is employed for a variety of purposes in the fabrication of microelectronic devices, including interconnect lines and gate electrodes in MOS integrated circuits, emitters in bipolar transistors, and high-value load resistors in static random access memory circuits (1). For the latter two applications, the required doping can be accomplished with precise control by use of ion implantation (2, 3). For the fabrication of polycide structures (silicide/n⁺-polysilicon), it may also be advantageous to use ion implantation, since the high conductivity of the silicide allows reduced doping levels to be used in the underlying polysilicon (4). Following implantation, polysilicon films are in general subjected to a variety of high temperature cycles, and the effect of dopant redistribution must be considered. For example, unwanted lateral diffusion of arsenic in implanted-polysilicon load resistors can reduce resistor length and alter circuit electrical characteristics (3).

Over the last several years, rapid thermal processing (RTP) has been developed as an alternative to conventional furnace annealing, whereby high temperature steps are carried out in times so short that minimal dopant redistribution occurs (5). Particularly attractive is RTP performed in an isothermal mode, whereby the whole wafer volume is uniformly heated to temperature $\geq 800^\circ\text{C}$ in times on the order of 1-10s. Isothermal RTP has been successfully used to activate dopants and anneal out implant damage in single-crystal Si (6, 7) and, more recently, to rapidly sinter silicides (8-9) and Ti-polycides (10).

In actual device fabrication, such applications of RTP are likely to affect polysilicon layers as well. For example, when isothermal RTP is used to remove implant damage from the self-aligned source/drain regions of a MOSFET, the adjacent polysilicon gate will also be subjected to the same rapid high temperature anneal. For this reason, it is important to understand the effect of RTP on ion-implanted polysilicon. In cases where annealing of polysilicon is desired, e.g., for the activation of implanted species or for dopant drive-in into an underlying single-crystal substrate (11), it may be possible to precisely control dopant redistribution profiles by a proper choice of rapid annealing conditions.

In this paper, we report the effect of isothermal RTP on ⁷⁵As⁺-implanted polysilicon films, with particular attention to dopant activation and redistribution.

Experimental

Polysilicon films of thickness $0.41 \pm 0.10 \mu\text{m}$ were deposited by low pressure CVD onto oxidized Si substrates. Substrates were Czochralski-grown, 100 mm diam, n-type Si (100) wafers on which 800Å of thermal oxide was grown. The oxide was used to simulate a polysilicon gate MOS structure and served to isolate the polysilicon overlayer for subsequent sheet resistance measurements. Samples were implanted with either 1×10^{15} cm⁻² or 1×10^{16} cm⁻² As⁺ at 100 keV, which is a shallow implant with

respect to the polysilicon film thickness [experimentally measured range and standard deviation are $R_p = 500\text{Å}$ and $\Delta R = 235\text{Å}$, respectively (12)]. To investigate the effectiveness of a surface barrier in preventing arsenic outdiffusion, one-half of each wafer was capped with about 600Å of SiO₂, deposited by plasma-enhanced CVD. The low temperature (<200°C) of the plasma-deposition step prevented activation or diffusion of the implanted arsenic prior to rapid annealing.

All annealed samples were subsequently characterized by four-point probe measurement of sheet resistance. Selected samples were analyzed by secondary ion mass spectrometry (SIMS) to determine arsenic concentration depth profiles¹ and by spreading resistance probe measurements to determine electrically active dopant profiles.²

RTP was carried out using an automated, serial process rapid thermal processing system (Varian Model IA-200) (13). This same equipment has been used to successfully anneal and activate As⁺-implanted single-crystal Si with minimal dopant redistribution (7, 14-16). Wafers are exposed in vacuum of $\sim 2 \times 10^{-6}$ torr to the blackbody radiation of a resistively heated planar graphite heater which is continuously on during the annealing process. The time which a Mo shutter, located between heater and sample, is open determines exposure time and can be regulated to ± 0.15 s. Past experience with RTP of As⁺-implanted single-crystal Si (14-16) guided the choice of annealing conditions used in the present study of polysilicon; viz., heater temperature was set at 1150°-1300°C in 50°C intervals and exposure times ranged from 5 to 25s in 5s intervals. From measurements of the wafer's central area with a focused IR pyrometer, sample temperature was estimated to be $>900^\circ\text{C}$ after 10s and within $\sim 10^\circ\text{C}$ of the heater set-point temperature after 25s. Figure 1 plots the measured wafer temperature as a function of exposure time to the graphite heater (1150°-1300°C). As used in this paper, the terms "annealing temperature" and "annealing time" refer to heater temperature and total exposure time to the heater, respectively.

Results

Four-point probe data from As⁺-implanted polysilicon films annealed without an oxide cap is presented in Fig. 2. Sheet resistance, R_s , is plotted vs. exposure time for implant doses of 1×10^{15} cm⁻² and 1×10^{16} cm⁻² and heater temperatures of 1150°-1300°C. For comparison, data obtained by Wilson *et al.* on As⁺-implanted (100 keV, 1×10^{15} cm⁻²) single-crystal Si annealed in an identical RTP system is also shown (14). Arsenic doses in excess of 1×10^{15} cm⁻² are sufficient to amorphize the polysilicon surface region and increase its reflectivity. Films exposed to the

¹SIMS performed at Charles Evans & Associates, San Mateo, California.

²Spreading resistance probe measurements performed at Solcon Laboratories, Sunnyvale, California.

Fig. 1. Time-temperature profile of a Si (100) wafer exposed to a graphite heater for 30s with heater temperatures as shown. After 30s, the heater is shuttered off and the wafer cools by radiation.

heater for 5s or less maintained this higher reflectivity over their complete surface area. For exposures between 5 and 10s, incomplete annealing, as evidenced by gross

nonuniformity of both surface reflectivity and sheet resistance, was observed.

For exposures above 10s, the sheet resistance increases rapidly with time of RTP, this increase being more pronounced at higher annealing temperatures. For example, at 1300°C, depending on implant dose, R_s increases by 3-4 orders of magnitude as exposure time increases from 10-25s. The lowest values of R_s , obtained following 1150°C, 10s exposure, were ~ 220 and $\sim 1000 \Omega/\square$ for $1 \times 10^{16} \text{ cm}^{-2}$ and $1 \times 10^{15} \text{ cm}^{-2}$ As⁺ dose, respectively. By contrast, comparably implanted (100-keV, As⁺, $1 \times 10^{15} \text{ cm}^{-2}$) and annealed single-crystal Si has a sheet resistance which is 10-100 times lower than that of polysilicon (Fig. 2) and which is relatively insensitive to exposure time. For the single crystal, R_s reaches a minimum value of $\sim 90 \Omega/\square$ after 15s exposure at 1150°C and then increases to $\sim 110 \Omega/\square$ after 25s. Wilson *et al.* attribute this increase to loss of implanted arsenic from the uncapped single-crystal Si surface (14) and, for these RTP conditions, calculate an arsenic diffusivity of $\sim 9 \times 10^{-13} \text{ cm}^2/\text{s}$. It is well known that the diffusion coefficient of As in polysilicon is enhanced due to grain boundary diffusion and can be much greater than in single-crystal Si: 10^2 - 10^3 times greater at temperatures $\sim 1150^\circ\text{C}$ (2, 12, 17). Assuming this enhancement holds under RTP conditions as well, one expects effects observed in single-crystal Si and attributed to dopant outdiffusion to be far more pronounced in the case of polysilicon. This is seen to be the case in Fig. 2 for the $1 \times 10^{15} \text{ cm}^{-2}$ dose implants annealed at 1150°C. As exposure time varies from 15-25s, sheet resistance of the single crystal increases by about 20%, while that of the polysilicon film increases by more than an order of magnitude.

In the case of ³¹P⁺-implanted polysilicon ($1 \times 10^{16} \text{ cm}^{-2}$, 40-80 keV), surface loss of dopants during RTP has also contributed to high values of sheet resistance (18). Dopant depth profiles to be presented later support the conclusion that significant arsenic migration is occurring in our polysilicon films under RTP conditions which, in single-crystal Si, give rise to negligible redistribution.

One way of avoiding arsenic outdiffusion during furnace annealing of polysilicon is to employ an oxidizing ambient (2, 12) or Si₃N₄ cap (12). In the case of isothermal RTP, thin oxide capping layers ($\sim 500\text{\AA}$) have successfully prevented arsenic loss from single-crystal samples (14, 15), while thick capping layers ($\sim 3000\text{\AA}$) of phosphosilicate glass have prevented phosphorus outdiffusion (18). In Fig. 3, we present our results for polysilicon samples capped with a thin oxide. The implantation and the rapid annealing conditions are the same as in Fig. 2; the 600Å of plasma-deposited oxide was wet chemically stripped in BHF prior to sheet resistance measurement.

Comparison in Fig. 3 with data of Wilson *et al.* (15) show that the sheet resistance of identically implanted and rapidly annealed (1200°C) single and polycrystalline silicon samples exhibit qualitatively the same behavior, but values of R_s for the single-crystal case are several times lower. For example, after a 25s 1200°C anneal, R_s for implanted single-crystal Si ($1 \times 10^{16} \text{ cm}^{-2}$ dose) is $\approx 11 \Omega/\square$, while the corresponding value of polysilicon is $\approx 35 \Omega/\square$. This difference is more pronounced at $1 \times 10^{15} \text{ cm}^{-2}$ dose where values of $R_s = 80$ and $700 \Omega/\square$ are obtained for single-crystal and polysilicon, respectively.

Depth profiles of total dopant concentration (*i.e.*, both electrically active and inactive arsenic), measured by SIMS, and carrier concentration, measured by spreading resistance probe, are plotted in Fig. 4-6 for capped polysilicon films. Conditions of RTP were 1150°C and 15-25s. The atomic concentration scale is based on previous analysis of an As⁺ implant standard, while the depth scale is determined by direct profilometer measurement of the sputtered crater depth following SIMS. In the absence of direct mobility profile measurements on these films, spreading resistance data were converted to carrier concentration by using mobility values obtained by Wilson on similarly implanted and rapidly annealed LPCVD polysilicon films (18).

Fig. 2. Sheet resistance vs. exposure time to the graphite heater (1150°-1300°C) for As⁺-implanted polysilicon films. The films were uncapped and had either a $1 \times 10^{16} \text{ cm}^{-2}$ (solid line) or a $1 \times 10^{15} \text{ cm}^{-2}$ (dashed line) implant dose. Results of similarly processed single-crystal Si(100) wafers [Ref. (14)] are given for comparison (phantom line).

Fig. 3. Sheet resistance vs. exposure time to the graphite heater (1150° - 1300°C) for As^+ -implanted polysilicon films. The films were capped with 600\AA of SiO_2 prior to rapid anneal, and had either a $1 \times 10^{15} \text{ cm}^{-2}$ (solid line) or a $1 \times 10^{16} \text{ cm}^{-2}$ (dashed line) implant dose. The results of similarly processed single-crystal Si(100) wafers [Ref. (16)] are given for comparison (phantom line).

Figures 4 and 5 show data obtained from $1 \times 10^{15} \text{ cm}^{-2}$ dose implants annealed for 15 and 25s, respectively. In Fig. 4, the Gaussian as-implanted arsenic profile, taken from experimental result of Tsukamoto *et al.* (12) for 100-keV $^{75}\text{As}^+$ into polysilicon, is also shown. After 15s anneal, the atomic arsenic concentration still peaks at the range of the as-implanted profile, but at a value which is slightly less (about $1.2 \times 10^{20} \text{ cm}^{-3}$) than that before RTP (about $1.8 \times 10^{20} \text{ cm}^{-3}$). The concentration profile then gradually tails exponentially off with distance, reaching about $2 \times 10^{18} \text{ cm}^{-3}$ at the polysilicon-oxide interface, where it decreases abruptly.

By contrast, As^+ implants into single-crystal Si (100 keV, $1 \times 10^{15} \text{ cm}^{-2}$) show only slight dopant redistribution after identical rapid annealing conditions (14). Moreover, the polysilicon carrier concentration profile (dashed line) is dramatically different than the dopant profile (solid line) in that it does not exhibit a gradual tail. Instead, it decreases rapidly with depth, closely resembling the tail off of the Gaussian as-implanted profile. Comparison of carrier and dopant profiles show that at depths $\geq 0.2 \mu\text{m}$ arsenic is present in relatively high concentration ($\sim 10^{18}$ - 10^{19} cm^{-3}) but is almost completely inactive.

After 25s anneal (Fig. 5), however, the shape of carrier and atomic concentration profiles are seen to be similar. Namely, dopant redistribution is so great that relatively flat profiles are measured throughout the entire polysilicon film thickness. The sharp peak at the oxide interface is probably not arsenic pile-up, but an artifact of the SIMS technique caused by oxide charging and higher secondary ion yield from arsenic in the oxide matrix (20). Good agreement of the integrated area under the SIMS profile with the implanted dose shows that loss of arsenic from the capped films is negligible.

Fig. 4. Depth profiles of atomic dopant concentration (solid line) obtained by SIMS and carrier concentration (dashed line) determined from spreading resistance data for $1 \times 10^{15} \text{ cm}^{-2}$ dose implanted polysilicon films. The films were capped with 600\AA of SiO_2 and exposed to the heater at 1150°C for 15s. The as-implanted arsenic profile prior to RTP (dotted line) is taken from Ref. (12) for 100-keV, $1 \times 10^{15} \text{ cm}^{-2} \text{ As}^+$.

Discussion

The behavior observed in Fig. 4 and 5 can be qualitatively understood by a model for the thermal diffusion of implanted arsenic in polysilicon proposed by Swaminathan *et al.* (17). In this model, As atoms are electrically active when located within the crystalline grains, but inactive when located along the grain boundaries. In addition, arsenic diffuses much more rapidly along the grain boundaries than within the bulk of the grains (about four orders of magnitude faster). Before RTP, the implanted arsenic is mostly in the interior of the grains and is distributed within $\sim R_p + \Delta R \approx 0.1 \mu\text{m}$ of the surface. Upon rapid heating, implant damage begins to anneal out as As atoms begin to activate within the grains and to segregate out at the grain boundaries. Diffusion along the grain boundaries then rapidly transports electrically inactive arsenic deeper into the film, where it much more slowly diffuses back into the grain interiors and becomes electrically active. In light of this model, the gradual tail of the atomic concentration profile seen in Fig. 4 at depth $\geq 0.2 \mu\text{m}$ is taken to represent electrically inactive As atoms along the grain boundaries. The carrier concentration, similar in shape to the as-implanted profile, is taken to represent As atoms which have been activated but have not diffused far from their original positions within the grains. This interpretation is consistent with estimated diffusion lengths for As in single-crystal and polysilicon. Data of Swaminathan *et al.* (17) extrapolated to 1100°C gives a grain boundary diffusion coefficient of $D_1 \approx 2 \times 10^{10} \text{ cm}^2/\text{s}$. Data of Wilson *et al.* (14) give a diffusion coefficient of $D_2 \approx 9 \times 10^{-13} \text{ cm}^2/\text{s}$ for single-crystal silicon samples with implant and RTP conditions the same as the polycrystalline samples used in the present study. Assuming our wafers were close to 1100°C for $t \sim 5\text{s}$ (Fig. 1), leads to thermal diffusion of $\sqrt{2D_1 t} \sim 0.5 \mu\text{m}$ and $\sqrt{2D_2 t}$

Fig. 5. Depth profiles of dopant (solid line) and carrier (dashed line) concentration for implanted and capped polysilicon films (As⁺, 100 keV, $1 \times 10^{15} \text{ cm}^{-2}$) which were exposed to the 1150°C heater for 25s.

$\sim 0.03 \mu\text{m}$. The former length is comparable to the polysilicon film thickness, while the latter is approximately the observed broadening of the carrier profile relative to that of the as-implanted dopants. As exposure time increases to 25s and wafer temperature to $\sim 1150^\circ\text{C}$, one expects diffusion lengths within the grains to be comparable to or greater than the average grain size [$\sim 600\text{\AA}$ as determined from TEM micrographs³ of these samples] and a larger fraction of the implanted arsenic can reach the grain boundaries. In addition, As atoms which have diffused into the film have had more time to diffuse back into deeper lying grains and be activated. The net effect is that after 25s exposure (Fig. 5), the shape of electrically active and total dopant profiles are brought into closer agreement.

Data for a polysilicon film implanted at $1 \times 10^{16} \text{ cm}^{-2}$ dose and annealed for 15s are shown in Fig. 6. Unlike the $1 \times 10^{15} \text{ cm}^{-2}$ dose data in Fig. 4, the carrier and atomic concentration curves in this case have a similar, flat profile throughout the film, more like the 25s anneals shown in Fig. 5. One possible explanation for this dose-dependent behavior is that the wafer with the higher dose implant may have more quickly reached thermal equilibrium with the heater, so that the effective time for arsenic diffusion at 1150°C was longer. Measurements of wafer temperature *vs.* exposure time made with an IR pyrometer do not support this explanation. Instead, we propose that dose-dependent differences in the arsenic profiles following RTP are due to the concentration-dependent diffusivity of arsenic in single-crystal silicon which is known to increase with carrier concentration (21).

Studies by Swaminathan *et al.* (17) of concentration profiles of As⁺-implanted polysilicon after furnace annealing (750°-950°C) indicate that the grain boundary diffusion coefficient is more or less independent of arsenic concentration or polysilicon grain size (0.2-0.5 μm grains),³ TEM analysis performed by Universal Energy Systems, Dayton, Ohio.

Fig. 6. Depth profiles of dopant (solid line) and carrier concentration (dashed line) for implanted (As⁺, 100 keV, $1 \times 10^{16} \text{ cm}^{-2}$) and capped polysilicon films which were exposed to the 1150°C heater for 15s.

while the diffusion coefficient within the grains is the same as in single-crystal Si. Using the model presented earlier in connection with Fig. 4 and 5, we qualitatively explain the difference between Fig. 4 and 6 as follows. Upon rapid annealing, As atoms diffuse from the bulk to segregate at the grain boundaries. Since the diffusivity of As in Si increases with concentration, we expect a greater percentage of implanted arsenic to reach the grain boundaries of the film with the higher, $1 \times 10^{16} \text{ cm}^{-2}$, dose. This greater source of dopant is then available for diffusion deeper into the film. Since diffusion back into the grain interiors is also expected to proceed more rapidly in the higher dose case, the activation profile can more closely track the dopant profile deeper in the film.

The $1 \times 10^{16} \text{ cm}^{-2}$ dose film annealed for 25s at 1150°C produced a relatively flat concentration profile averaging about $2.5 \times 10^{20} \text{ cm}^{-3}$ throughout the 0.41 μm thick polysilicon layer (Fig. 6) and exhibited a sheet resistance (Fig. 3) of $\sim 45 \Omega/\square$ ($\sim 1.8 \times 10^{-3} \Omega\text{-cm}$). Murota and Sawai (22) have reported the dependence of resistivity for annealed polysilicon films as a function of carrier concentration. Following 1150°C furnace anneal (N₂, 30 min), films with dopant concentrations the same as in Fig. 6 had resistivity about $1.6 \times 10^{-3} \Omega\text{-cm}$, comparable to that measured in this work under RTP conditions. Recently, Josquin *et al.* (11) reported sheet resistance of furnace-annealed 100-keV, $1 \times 10^{16} \text{ cm}^{-2}$, ⁷⁵As⁺-implanted, 0.5 μm polysilicon deposited onto field oxide. Following furnace anneal (1000°C, 95 min in N₂), a value of 65 Ω/\square was obtained, which again is similar to our result of $\sim 45 \Omega/\square$ for a 1150°C rapid anneal.

Summary

In conclusion, we have measured sheet resistance, dopant profiles, and carrier concentration profiles for As⁺-implanted polysilicon films. For the RTP conditions used, both $1 \times 10^{15} \text{ cm}^{-2}$ and $1 \times 10^{16} \text{ cm}^{-2}$ dose films exhibit significant dopant redistribution and, when uncapped, surface loss of arsenic after even 15s anneal,

unlike the case of comparably implanted and annealed single-crystal Si.

By use of a thin (600Å) oxide cap, however, arsenic outdiffusion could be completely prevented and stable sheet resistance of $\sim 30 \Omega/\square$ obtained for $1 \times 10^{16} \text{ cm}^{-2}$ films (25s, 1250°C). This value of sheet resistance is comparable to that of n⁺-polysilicon films produced by furnace annealing of identical As⁺ implants. The shape of the carrier concentration and total dopant profiles following RTP are dependent both on implant dose and annealing time. The behavior of these profiles can be qualitatively understood in terms of a model whereby (i) thermal diffusion of electrically active arsenic within the polysilicon grains and electrically inactive arsenic along the grain boundaries occur with significantly different rates, and (ii) where the former process is concentration dependent and the latter is not.

As a result of the rapid redistribution of dopants, thick ($\sim 0.4 \mu\text{m}$) polysilicon films could be uniformly doped in times on the order of 15s from a relatively shallow, high dose As⁺ implant (100 keV, $1 \times 10^{16} \text{ cm}^{-2}$). Under these same RTP conditions, comparably implanted and annealed single-crystal Si shows minimal dopant redistribution. It may be possible to use this fact to advantage when fabricating NMOS devices with self-aligned gates. In this case, a single, high dose As⁺-ion-implantation step could be used to dope source and drain regions as well as the surface of the polysilicon gate (capped by a thin oxide or Si₃N₄ layer). RTP could then be used to anneal implant damage and activate implanted dopants in the single-crystal source/drain regions with minimal dopant redistribution, preserving shallow n⁺-p junction depths. In the polysilicon layer, however, this same rapid anneal would produce significant arsenic redistribution resulting in a uniformly doped, low sheet resistance gate electrode. A second possibility suggested by the present study is to use heavily implanted polysilicon as a diffusion source and RTP as a means of rapidly driving arsenic from the polysilicon surface into a much deeper, underlying, single-crystal Si substrate. Fabrication of emitters and buried collectors for npn bipolar devices, for example, could then be carried out in the doped, damage-free single-crystal regions (11).

Finally, we note that the behavior of implanted arsenic observed under RTP in this work should not be assumed to hold, *a priori*, for other implanted species. For example, recent work on RTP of ¹¹B⁺-implanted polysilicon shows that successful activation can be achieved without having to cap the film surface (23).

Electrical Characteristics of Tantalum Pentoxide-Silicon Dioxide-Silicon Structures

S. Seki, T. Unagami, and B. Tsujiyama

Ibaraki Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokai, Ibaraki 319-11, Japan

ABSTRACT

Electrical characteristics for metal-tantalum pentoxide-silicon dioxide-silicon structures are described. The interface charge density and the surface-state density are measured to determine the interface properties. By optimizing each insulator thickness, the interface charge density can be reduced to as low as $6\text{--}12 \times 10^9 \text{ cm}^{-2}$ at flatband. The surface-state density of $3\text{--}4 \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ can be obtained near the midgap by inserting a 25 nm thickness of SiO_2 . It is indicated that the interface charge density variation with each insulator thickness can be explained by the charge compensation mechanism between the positive charge at SiO_2/Si interface and the negative charge at $\text{Ta}_2\text{O}_5/\text{SiO}_2$ interface. It is found that the negative charge localized at $\text{Ta}_2\text{O}_5/\text{SiO}_2$ interface gradually decreases and that the dielectric constant for Ta_2O_5 deposited on SiO_2 monotonically increases with the underlying SiO_2 layer thickness.

In recent years, tantalum pentoxide (Ta_2O_5) film has been of interest for use as a storage capacitor in large-scale integrated-circuit memory cells (1, 2) and as a gate insulator for MOS devices (3, 4). The higher dielectric constant of Ta_2O_5 , compared with that of SiO_2 , makes it attractive as dielectric material for these devices. In our most recent paper, it was reported that a relatively good quality Ta_2O_5 gate insulator could be fabricated using RF-magnetron sputtering and that annealing in the hydrogen ambient had a great effect on removing damage produced during the sputtering process (4). Under optimum annealing conditions, the interface charge density could be reduced to as low as $-1.4 \times 10^{11} \text{ cm}^{-2}$ and the surface-state density of $1.5 \times 10^{11} \text{ cm}^{-2} \text{ eV}^{-1}$ could be obtained near the midgap. These were the lowest values in the $\text{Ta}_2\text{O}_5/\text{Si}$ interface to have been reported. However, in order to obtain high-quality MOS devices with high transconductance and low threshold voltage, it becomes increasingly important to reduce both the interface charge density and the surface-state density to much lower values.

In this work, the electrical characteristics of MTOS (metal-tantalum pentoxide-silicon dioxide-silicon) double-dielectric insulator structures have been studied. In this structure, a SiO_2 layer is inserted between the Ta_2O_5 layer and the silicon substrate in order to reduce damage induced during the Ta_2O_5 sputtering process. The interface charge density and the surface-state density are calculated from the high-frequency capacitance-voltage characteristics to investigate the interface behavior. This paper reports the results of these experiments and shows the effects of the inserted SiO_2 layer on the electrical properties of MTOS structures.

Experimental

$\text{Al}/\text{Ta}_2\text{O}_5/\text{SiO}_2/\text{Si}$ structures were used to investigate the interface behavior. All of the MTOS structures were fabricated on p-type, $\langle 100 \rangle$ -oriented, 10-20 $\Omega\text{-cm}$ silicon wafers. SiO_2 was thermally grown at 1100°C in dry oxygen atmosphere. The SiO_2 thickness was 86 nm. Immediately before being installed into the sputtering chamber, the wafer was etched by buffered HF solution to adjust the SiO_2 thickness. Sputtering was performed using an ULVAC SBH-2204 RS RF-magnetron sputtering system. Instead of the conventional oil diffusion pump, a cryogenic pump was used to eliminate oil contamination. The Ta_2O_5 target was 10 cm in diameter and 5 mm thick. The target-to-substrate distance was 5 cm. The sputtering gas consisted of mixtures of argon and oxygen (partial pressure ratio of $\text{Ar}/\text{O}_2 = 80/20$). The sputtering chamber was evacuated to less than 1×10^{-7} torr prior to sputtering and was then backfilled with the sputtering gas. The sputtering pressure was 5×10^{-3} torr. Typical deposition rate for Ta_2O_5 ranged from 2 to 6 nm/min. Aluminum dot electrodes 300 μm in diameter were electron-beam-deposited. To minimize the radiation damage, the wafers

were annealed at 450°C for 30 min in the hydrogen ambient.

After a final H_2 anneal, high-frequency capacitance-voltage characteristics were measured. In this measurement, capacitance meters (HP 4274A and HP 4275A) and a dc voltage source (HP 4140B) were automatically controlled by a microcomputer (APPLE II plus) through the General Purpose Interface Bus (GPIB). The interface charge density was calculated from the flatband voltage measured at 1 MHz, and the surface-state density distribution was obtained from the C-V characteristics measured at 1 mHz, using the Terman method (5). Frequency dispersion in the C-V characteristics was studied by varying the measurement frequencies in the range of 1 kHz to 1 MHz. These measurements were performed in the dark at room temperature.

Results and Discussion

Ta_2O_5 thickness dependence.—The interface charge density in the $\text{Al}/\text{Ta}_2\text{O}_5/\text{SiO}_2/\text{Si}$ structures has been studied for various Ta_2O_5 thicknesses. The SiO_2 thickness was adjusted to 22 nm by chemical etching, prior to the Ta_2O_5 sputtering deposition. After annealing in the hydrogen ambient, no apparent hysteresis and frequency dispersion were observed in their C-V curves.

Figure 1 shows the interface charge density variation with different Ta_2O_5 thicknesses. The interface charge density changes monotonically from positive to negative as the Ta_2O_5 thickness increases. The results shown in Fig. 1 indicate that the interface charge density can be controlled by adjusting the Ta_2O_5 thickness. This interface charge density variation can be explained by the charge compensation mechanism between the positive charge localized at the SiO_2/Si interface and the negative charge in the Ta_2O_5 layer. In our most recent paper, it was shown that the negative charge in the Ta_2O_5 layer was fully localized in the transition layer formed in the early stage of the Ta_2O_5 formation (4). Based upon this result, the negative charge in the Ta_2O_5 layer deposited on SiO_2 is assumed to be localized at the $\text{Ta}_2\text{O}_5/\text{SiO}_2$ interface. In this model, the interface charge density Q_{ss}/q can be given by

$$\begin{aligned} \frac{Q_{ss}}{q} &= \frac{1}{q} \int_0^{d_s} \frac{x}{d_{ox}} \rho_{ox}(x) dx \\ &= \frac{1}{q} \left\{ \frac{Kd_t}{d_s + Kd_t} (-Q_2) + Q_1 \right\} \quad K = \epsilon_s/\epsilon_t \quad [1] \end{aligned}$$

where d_s is the SiO_2 thickness, d_t is the Ta_2O_5 thickness, $\rho_{ox}(x)$ is the charge distribution function in the insulator, ϵ_s is the dielectric constant for SiO_2 , and ϵ_t is the dielectric constant for Ta_2O_5 . Q_1/q is the positive charge density at the SiO_2/Si interface and $-Q_2/q$ is the negative charge density at the $\text{Ta}_2\text{O}_5/\text{SiO}_2$ interface. Introducing

Fig. 1. The interface charge density variation with different Ta_2O_5 thickness. The SiO_2 thickness is adjusted to 22 nm. Calculated result of the interface charge density variation with Ta_2O_5 thickness is depicted by the solid line.

$$n = Q_2/Q_1 \quad [2]$$

Eq. [1] becomes

$$\frac{Q_{ss}}{q} = \frac{Q_1}{q} \left(1 - \frac{n}{1 + d_s/(Kd_i)} \right) \quad [3]$$

The interface charge density variations with Ta_2O_5 thickness were calculated for several sets of n and Q_1/q . Calculated results are given in Fig. 1. It is found that the best fit is obtained with $n = 4.7$ and $Q_1/q = 1.5 \times 10^{11} \text{ cm}^{-2}$.

SiO₂ thickness dependence.—Figure 2 shows the interface charge density variation with different SiO_2 thicknesses. The Ta_2O_5 thickness was kept within the range of 75–80 nm, and the SiO_2 thickness was varied within the

Fig. 2. The interface charge density variation with different SiO_2 thickness. The Ta_2O_5 thickness is kept within a range of 75–80 nm. Calculated results of the interface charge density variation with SiO_2 thickness are shown in the solid and dashed lines.

range of 10–60 nm by chemical etching. The interface charge density changes monotonically from negative to positive as the SiO_2 thickness increases. Results shown in Fig. 2 indicate that the interface charge density can be controlled by adjusting the SiO_2 thickness.

This interface charge density variation is based on the charge compensation mechanism described above. If Q_1 and Q_2 are assumed to be invariant with different SiO_2 thicknesses, the interface charge density variation can be expressed by Eq. [3] with $n = 4.7$ and $Q_1/q = 1.5 \times 10^{11} \text{ cm}^{-2}$. Calculated results based upon these values of n and Q_1/q are plotted in Fig. 2 (solid line). The experimental values do not coincide with the calculated result. This implies that the assumption mentioned above cannot be applied to the MTOS structure with different SiO_2 thicknesses, *i.e.*, charges in the insulator change with the underlying SiO_2 thickness. The positive charge localized at the SiO_2/Si interface is invariant throughout the whole SiO_2 thickness range studied. Therefore, results shown in Fig. 2 indicate that the negative charge at the $\text{Ta}_2\text{O}_5/\text{SiO}_2$ interface monotonically changes with the underlying SiO_2 thickness.

The variation of the negative charge with the underlying SiO_2 thickness is expressed by the simultaneous variation of the parameter n in Eq. [3]. Calculated results for the case that the parameter n is variable with the SiO_2 thickness are also shown in Fig. 2 (dashed line). In this case, the inversely proportional relationship between the parameter n and the SiO_2 thickness is considered as one example of variation manners of n ; the parameter n is assumed to decrease linearly from 5.5 to 0.5 as the SiO_2 thickness increases from 10 to 60 nm. The coincidence of the experimental data with calculated values is improved. Therefore, it is concluded that the negative charge at the $\text{Ta}_2\text{O}_5/\text{SiO}_2$ interface gradually decreases as the underlying SiO_2 thickness increases.

Based upon the results mentioned above, the MTOS structure with low interface charge density has been designed and fabricated. Figure 3 shows capacitance-voltage characteristics for the MTOS capacitor with the 25 nm-thick SiO_2 and the 38 nm-thick Ta_2O_5 . Measurement frequencies were varied in the range of 1 kHz to 1 MHz. As shown in Fig. 3, nearly ideal C-V curves were obtained, and no apparent hysteresis and frequency dispersion were observed. The interface charge density, calculated from the flatband voltage measured at 1 MHz, ranges from $6\text{--}12 \times 10^9 \text{ cm}^{-2}$. These are the lowest values to have been reported.

Surface-state density.—Figure 4 shows the surface-state density distributions near the valence band for $\text{Al}/\text{Ta}_2\text{O}_5/$

Fig. 3. Capacitance-voltage characteristics of the MTOS capacitor with optimum insulator thickness. The Ta_2O_5 thickness is adjusted to 38 nm; the SiO_2 thickness is adjusted to 25 nm.

Fig. 4. The surface-state density distributions near the valence band are compared for two samples with different SiO₂ thicknesses. The SiO₂ thicknesses are 10 and 25 nm, respectively.

SiO₂/Si structures. The surface-state density distributions for two samples with different SiO₂ thicknesses are compared. The SiO₂ thicknesses are 10 and 25 nm, respectively. As shown in Fig. 4, lower surface-state density has been obtained for the sample with the thicker SiO₂ layer. The surface-state density has been able to be reduced to as low as $3.4 \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ near the midgap. These are the lowest values in Al/Ta₂O₅/SiO₂/Si structure devices. Furthermore, the values obtained in this work are comparable to those for SiO₂/Si interface with an aluminum gate. Therefore, it is concluded that the SiO₂ layer, inserted between Ta₂O₅ and Si, has a great effect on the protection of the damage produced at the silicon surface during the Ta₂O₅ sputtering process.

Dielectric properties.—Dielectric properties of the Ta₂O₅ deposited on the SiO₂ layer have been studied. The dielectric constant of the Ta₂O₅ layer is calculated from the capacitance in the accumulated region of the C-V characteristics measured at 1 MHz, the Ta₂O₅ thickness, the SiO₂ thickness, the dielectric constant of SiO₂, and the electrode area. Figure 5 shows the dielectric constant variation for the Ta₂O₅ layer with changes in the underlying SiO₂ layer thickness. As shown in Fig. 5, the dielectric constant of the Ta₂O₅ layer monotonically increases as the SiO₂ layer thickness increases. The dielectric constant of Ta₂O₅ deposited on 10 nm-thick SiO₂ is 16.8, which is a smaller value than that for the bulk of Ta₂O₅. On the other hand, the dielectric constant of the Ta₂O₅ layer deposited on the 60 nm-thick SiO₂ reaches 23.8, which is very close to that for the bulk of Ta₂O₅.

It was reported in our most recent paper (4) that Ta₂O₅ deposited on single-crystalline silicon consisted of two re-

Fig. 5. The dielectric constant variation of Ta₂O₅ with the underlying SiO₂ thickness.

gions: a low dielectric-constant transition layer at the interface; and the following homogeneous layer, whose dielectric constant was close to that for the bulk of Ta₂O₅ (4). Applying this two-layer model to the Ta₂O₅ deposited on SiO₂, the dielectric constant variation shown in Fig. 5 can be explained by transition layer thickness changes: the low dielectric-constant transition layer thickness decreases as the underlying SiO₂ layer thickness increases. In this two-layer model, the negative charge is fully localized in the transition layer and it is assumed to change with the transition layer thickness variation. Under these assumptions, the dielectric constant variation with the underlying SiO₂ thickness is in coincidence with the gradual variation of the negative charge density localized at the Ta₂O₅/SiO₂ interface mentioned above.

Conclusions

Ta₂O₅ films were deposited onto thermally grown SiO₂ on the silicon substrate, using RF-magnetron sputtering. High-frequency capacitance-voltage characteristics were measured to determine the interface charge density and the surface-state density in the Al/Ta₂O₅/SiO₂/Si structures. The results indicate that the interface charge density can be controlled by adjusting the Ta₂O₅ and SiO₂ thickness. By optimizing each thickness, the interface charge density ranging from $6\text{--}12 \times 10^9 \text{ cm}^{-2}$ can be obtained. The surface-state density can be reduced to as low as $3.4 \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ near the midgap by inserting 25 nm-thick SiO₂. These are the lowest values to have been reported.

It is also indicated that the interface charge density variation with Ta₂O₅ or SiO₂ thickness can be explained by the charge compensation mechanism between the positive charge at SiO₂/Si interface and the negative charge at Ta₂O₅/SiO₂ interface. In addition, it is found that the negative charge gradually decreases as the underlying SiO₂ thickness increases. The dielectric constant of the Ta₂O₅ layer deposited on the SiO₂ layer gradually increases with the underlying SiO₂ thickness. The negative charge variation and the dielectric constant variation with the underlying SiO₂ thickness can be explained by a two-layer model. A narrow transition layer exists at the interface, where the rest of the film is homogeneous.

Surface Potential Profiling of HV Devices Using Scanning Auger Microscopy

D. M. Taylor¹, D. W. Tong, and W. R. VanDell²

General Electric Company Research & Development Center, Schenectady, New York 12345

ABSTRACT

The shift in Auger electron energies is used to measure the voltage profile on high voltage semiconductor devices. The scanning mode available on present-day Auger microscopes allows two-dimensional quantitative voltage-contrast imaging. This technique has been used to measure surface potentials on a high voltage npn transistor biased up to 1 kV. An accuracy of better than 10V and a spatial resolution of 8 μm are demonstrated.

Computer modeling is used extensively in the design of high voltage semiconductor devices. However, not many convenient techniques are available for testing the accuracy of the modeling, and often the breakdown voltage of the device is the only measurable parameter for comparison. Fine metal probes can be used for measuring the surface potential, but they have limited spatial resolution and may well be ineffective in the presence of passivation.

By measuring the energy shift of the secondary electrons, the scanning electron microscope (SEM) has been widely used as a noncontacting probe of submicron spatial resolution to measure voltages on integrated circuits (1-3). However, the low energy (5-10 eV) of the secondary electrons makes them unsuitable for probing high voltage devices where high lateral fields are present (4). For this reason, the use of Auger electrons of much higher energies was proposed over a decade ago for surface potential measurement of high voltage devices (5, 6). Surface potentials of $\pm 40\text{V}$ were successfully measured in this way. Since that time, Auger spectroscopy instrumentation has been considerably refined, and sophisticated signal processing has enhanced the capabilities of the method. Whereas the earlier instruments could only make point-by-point measurements, newer instruments provide a scanning mode so that two-dimensional potential contour images can be obtained. This work demonstrates, using a high voltage npn transistor, that surface potentials of up to 1 kV can be measured in this way.

It is known that a high energy beam penetrating an insulating film can render it locally conductive (7). This feature makes electron beam probing methods particularly suited to semiconductor devices having passivation layers, as demonstrated by the results of this work.

Experimental

The test devices used in the study were npn power transistors designed to operate up to 1 kV. Figure 1a is a schematic diagram of the cross section of the base-collector junction of such a device, and the surface of the device in this same region is shown in the SEM photograph in Fig. 1b. At the outer edge of the device and concentric with the base region are two p^+ field spreading rings. The outlines of the diffusion windows are clearly visible in the SEM image and serve as useful references for beam location. The devices were passivated with a 200 nm silicon nitride layer over a

450 nm semi-insulating polycrystalline silicon (SIPOS) layer.

All measurements were carried out in a PHI 590 SAM. Possible drift in the energies of the Auger lines, caused by charging of the insulating nitride layer, were minimized by using an accelerating voltage of 8 keV so that the beam easily penetrated through the nitride layer, thus rendering it conductive (7). During the measurements, the beam current was held constant at $\sim 1 \mu\text{A}$. The Auger spectrometer uses a lock-in amplifier (PAR Model 120) for the detection of the Auger signal. The modulation voltage of the amplifier can be varied from 1 to 20V, with the smaller values re-

Fig. 1. (a) Cross-sectional diagram of the base collector junction in the test device; (b) a SEM photograph of the same area of the device.

sulting in better voltage resolution, but poorer signal-to-noise ratio. For the results reported below, a modulation of 10V was used. Voltages for biasing the devices were provided by a Fluke Model 412B high voltage power supply.

Results

Curve (a) in Fig. 2 shows a typical Auger spectrum obtained from the test device when all terminals are grounded. In addition to the silicon and nitrogen lines expected from the Si_3N_4 passivation, lines due to carbon and oxygen contamination on the surface are also present. These extra lines do not detract from the measurement technique. Indeed, in many instances, the oxygen line can be used to advantage because of its high intensity, as will be demonstrated later. That all the lines in Fig. 2a occur at the expected energies (within $\pm 5\text{V}$) confirms that any charging effects in the nitride must be small. With the base biased to -200V , the spectrum from this same location (between the base and first p^+ ring) shifts to higher energies as shown by curve (b) in Fig. 2. A shift of 165 eV in the energy of each line indicates a local surface potential of -165V . The accuracy of the measurement can be demonstrated by following the calibration procedure described below.

Calibration.—Negative voltages of up to -1 kV are calibrated by locating the beam on the base of the device in an area close to the metallization and observing the shifts in the silicon (1620 eV) and oxygen (508 eV) lines when known voltages are applied to the base. The silicon line cannot be followed beyond -600V because of the 2300 eV upper limit of the electron energy analyzer. The oxygen line is followed over the whole voltage range.

Calibration of positive voltages is achieved by positioning the beam over the collector region, well away from any depletion edges, and using the shift in the silicon line which occurs when biasing the collector. For this part of the measurement, the base is grounded and the device is mounted on an insulating support to isolate the silicon substrate (collector) from the grounded header. Measurements above 500V are not possible because of the unexpectedly rapid reduction in signal strength as the bias increases. A similar effect sets in at much lower voltages for the oxygen line. It is believed that this loss of signal is caused by the fringing field pattern directing the Auger electrons away from the analyzer. However, in the range of -1 kV to $+500\text{V}$, excellent correlation is obtained between the applied voltage and the shift in the energy of the peaks, as demonstrated in Fig. 3.

The fringing field from the device bias also causes a deflection of the primary beam, as evidenced by a noticeable shift of the SEM image. Fringing fields far from the device surface will result in a uniform deflection of the beam over the image area. Provided the beam location is measured with respect to a known reference point on the sample surface, say, a metallization edge, a uniform deflection will not affect measurement accuracy. On the other hand, fringing fields close to the sample surface can

Fig. 2. Auger spectra from a location near the collector-base junction when (a) $V_{BC} = 0\text{ V}$ and (b) $V_{BC} = -200\text{V}$.

Fig. 3. Shifts in the energy of the silicon (X) and oxygen (O) lines for known voltages applied to the base or collector.

result in a nonuniform beam deflection and can lead to erroneous beam location. Visually, a nonuniform beam deflection will translate into an expansion or compression of the SEM image. The relative shift in beam position can be estimated by approximating a lateral field of V_b/W , where W is the width over which the bias voltage V_b is dropped. For a high voltage transistor, this corresponds to the collector-base depletion width. This lateral field acts upon the primary beam over a vertical distance of approximately W . From the vertical velocity of the primary electrons

$$v_v = \sqrt{2qV_p/m_e}$$

where V_p is the primary electron energy and m_e the electron mass, the transit time of the electrons through the lateral field zone is

$$\Delta t = W \sqrt{m_e/2qV_p}$$

In this period, the lateral displacement δ is approximately

$$\delta = qV_b \Delta t^2 / 2m_e W = V_b W / 4V_p$$

For a typical W of $100\ \mu\text{m}$ at 1 kV of bias, δ is about $2\ \mu\text{m}$, which is of the order of the spatial resolution of the beam. Thus, at the voltage levels of this work, the deflection of the primary beam is not considered significant. Indeed, while uniform image shifts can be detected in the measurements described, no significant distortion of the device image is apparent.

Resolution.—The linearity of Fig. 3 means that voltage resolution is in the range of a few volts and is determined by the accuracy of the analyzer ($\pm 1\text{V}$) and by the chosen modulation voltage. To obtain satisfactory signal strength, a modulation voltage of 10V was chosen for these experiments.

Positional information is currently being obtained from photographic records, and spatial resolution is estimated to be $\sim 8\ \mu\text{m}$. Improvements are obviously possible, but ultimately, resolution will be determined by the primary beam size. Again, there is a trade-off between signal strength and spatial resolution because a larger beam current results in a greater beam diameter.

Voltage profiles.—To determine the voltage distribution on the device, a spectrum similar to that in Fig. 2 is recorded at several locations along the surface. For example, Fig. 4 shows the energies of the silicon peak as the beam is moved from point to point along a line from the outer p^+ ring toward the edge of a device where $V_{BC} = -1\text{ kV}$ is applied. By matching the corresponding spatial positions for each spectrum to the secondary electron image taken at the same time (Fig. 4, inset), plots such as in Fig. 5 are obtained for different values of V_{BC} . These plots clearly show the isopotential bands formed by the two p^+ rings. Obviously, the voltage profiles can be better defined if more points are taken, but this is a slow process which, under certain cir-

Fig. 5. Voltage profiles along the surface of a device when $V_{BC} = -1000$ V (X), $V_{BC} = -700$ V (O), and $V_{BC} = -500$ V (●). Solid line is the computer result for $V_{BC} = -700$ V.

cumstances, can be obviated by using the scanning facility of the SAM.

Two-dimensional surface mapping.—By setting the electron analyzer to detect electrons of one energy, e.g., setting the oxygen line at 508 eV and raster scanning the beam over the surface, a two-dimensional image corresponding to the oxygen distribution over the surface can be displayed on the video monitor. If the device is not biased, the distribution is essentially uniform. If the device is biased and the analyzer energy is changed to $508 + V$ (eV), then the only oxygen Auger electrons detected will be those emitted from that part of the device at a voltage of $-V$. Therefore, the image displayed will be an isopotential contour corresponding to $-V$ volts.

Using the oxygen line and the procedure outlined above, the images of Fig. 6a-6e are obtained for the various analyzer energies indicated. In this sequence of photographs, $V_{BC} = -200$ V. By use of multiple exposures, images corresponding to several analyzer settings can be superimposed on one photograph to analyze the data.

An alternative, more rapid method used to obtain the same information is to step the analyzer energy by known amounts during a scan. This method produces an image with a stepped appearance (Fig. 7) from which the potential distribution can be obtained. There is no observable differ-

ence between the voltage profiles obtained by the raster scanning or by the point-by-point method.

Discussion

After establishing that the SAM can be used to obtain voltage profiles on the surface of high voltage devices, the technique is used to compare the measured data with data obtained from a computer simulation of the test device, as illustrated in Fig. 5. The program used solves Poisson's equation in two dimensions using a finite difference formulation and successive over-relaxation (SOR), and it self-

Fig. 7. SAM image obtained when the analyzer energy is changed in discrete steps while scanning the beam. $V_{BC} = -200$ V.

consistently calculates the potential at each point in the device (8). Although the solution shown ignores the presence of surface charges and the passivation layer, the model predicts the avalanche voltage with an accuracy of $\sim \pm 5\%$. Therefore, it is presumed that a high degree of confidence can be put in the theoretical voltage profiles. It is reassuring to obtain such good agreement between the theoretical and the measured values in Fig. 5. This agreement also indicates that for the particular sample tested, the passivation has insignificant influence on device behavior.

The Auger profiling technique has also proved particularly useful in troubleshooting devices and in evaluating the effects of various device process steps. For example, Fig. 8 shows the voltage profiles corresponding to $V_{BC} = -300V$ in devices subjected to three different process conditions. In (a), the process has resulted in a device which goes into avalanche well below the designed voltage of 1 kV. The voltage profiles reveal that the p^+ rings are not functioning correctly, their potentials differing only slightly from the base. Changing the process conditions results in a device which apparently meets the design performance, but the Auger measurement, (b), once again reveals incorrect functioning of the p^+ rings, suggesting possible early failure of the device in operation. With further modification of the process, the device functions correctly, as shown in (c).

Limitations of the technique.—The general limitation of the technique as currently used is the time required to extract the positional information from photographic records. Digital beam positioning now available in new SAM's will certainly improve the ease of making point-by-point scans.

A limitation of the raster scanning mode appears when the bias on the device exceeds $-500V$ or so, causing a rapid change in the collection efficiency of Auger electrons to occur as the beam scans the surface. Between the base and outer p^+ ring, the carbon, nitrogen, and oxygen peaks are large, but when the beam is just beyond this outer ring, the signals decrease rapidly, resulting in a loss of image. This shows up clearly in Fig. 9, in which the device is biased to $-800V$ and the carbon signal is used to measure the surface voltage. No isopotentials can be observed beyond the outer p^+ ring. Figure 9 also shows the reappearance of signals from the base and the inner p^+ ring as the analyzer energy is reduced. This is caused by an increase in the background noise in the measurement window for electron energies ≤ 150 eV.

In principle, these difficulties can be overcome by detecting the 1620 eV silicon line whose intensity remains almost unchanged over a wide range of voltage. Unfortunately, the intensity of this line is insufficient to produce good two-dimensional scans. Enhancement techniques, e.g., signal averaging, can conceivably be applied to facili-

Fig. 9. Effect of high bias voltages on the SAM image. Here the carbon line has been used and the analyzer energy changed in discrete steps during the scan. $V_{BC} = -800V$.

tate such measurements (at the expense of longer measurement time).

The beam energy of 8 keV chosen for this work is sufficient to allow energetic electrons to penetrate the SIPOS layer and cause ionization in the silicon substrate. This can conceivably change the local potentials, and to check this possibility, the measurements are repeated with a 4 keV beam which cannot penetrate the silicon. The results obtained are almost identical, except for an apparent stretching out of the distribution near the depletion edge. Repeating the experiments with zero bias on the device shows that this effect is caused by the beam-induced resistive drop across the SIPOS film. In the vicinity of the outer p^+ ring, this voltage is about $-10V$, but between the ring and the edge of the device, it increases to about $-60V$. After correcting for this effect, the 4 and 8 keV data are in agreement, showing that no adverse effects result from using the higher beam energy.

An interesting effect noticed during this work is the appearance of apparently spurious noise peaks in the Auger spectrum when the device is biased. These tend to appear in groups of three, and their energies always coincide with the voltages on the base and the two p^+ rings. For example, with $-500V$ applied to the base, the p^+ rings float at -440 and $-240V$, and the extra lines induced in the Auger spectrum are seen at 505, 435, and 250 eV. The peaks are believed to arise from the elastic reflections of primary electrons from the device to the walls of the vacuum chamber and back to the device. Because of the large area of the base and field rings, a significant background current of secondary electrons will be emitted from these areas, and their energies will be within 5 or 10 eV of the voltages on these features, thus giving the extra lines observed. Occasionally, the line being used for the voltage measurement can be swamped by these extra lines in the spectrum.

The penetration of highly energetic electrons into the silicon can conceivably disturb the local silicon surface potential. This is certainly likely if, for example, the passivation is oxide and the oxide-trapped charges determine device behavior in some way. Hence, for each application, the effect of the beam probing itself on device behavior should be carefully assessed.

Conclusions

The scanning Auger microscope has been shown to be a powerful tool for measuring the voltage distribution on the surface of a high voltage transistor. This technique has been demonstrated on an npn transistor with biases of up to 1 kV. An accuracy of 10V and a spatial resolution of $8 \mu m$ or better can be readily achieved on commercially available instruments.

The method is suitable for unpassivated devices, as well as those having thin ($\leq 2 \mu m$) passivation layers. Even

highly insulating layers present no surface charging problems if the beam energy is high enough for the beam to penetrate into the conductive silicon. The method is not suitable for devices with thick passivation.

The Dependence of Silicon Etching on an Applied DC Potential in $CF_4 + O_2$ Plasmas

H. Kawata, K. Murata, and K. Nagami

Department of Electronics, College of Engineering, University of Osaka Prefecture, Sakai, Osaka, Japan

ABSTRACT

A copper rod which is biased by a dc potential, V_s , is placed in $CF_4 + O_2$ plasmas. The etch rate of a (100) silicon wafer placed on the rod is measured as a function of V_s at various O_2 contents. At the 45% O_2 content, there are plenty of F and O atoms, and a relatively high value of V_s is necessary to enhance the etch rate. At the 10% O_2 content, the density of O atoms decreases remarkably, and the etch rate is enhanced with a low value of V_s . This difference can be interpreted by reference to the O atom adsorption on a silicon surface. The silicon etching by F atoms is enhanced effectively by incident ions with low energy, but incident ions with relatively high energy are necessary to remove adsorbed O atoms. At oxygen-free content with a silicon load on the anode, the numbers of F and O atoms are small, and the enhancement of the etch rate by incident ions is not large, even when V_s increases. This means that the physical sputtering rate is much lower than the chemical one. The etch rates on the cathode and the anode are discussed, based on these results.

Because the mobility of electrons is much higher than that of ions, an ion sheath is formed in front of any material exposed to a plasma, in order to satisfy the charge neutralization. Through this ion sheath, positive ions gain some amount of kinetic energy and hit the surface of the material (1, 2). The ion incidence with kinetic energy is very important in interpreting the etch rate, the etching selectivity, and the etching anisotropy. Recently, silicon etching has been performed with a reactive ion beam (3) and a source of F atoms (4), instead of a plasma environment, because it is almost impossible to control only a desirable plasma parameter. For the etching mechanism, a clear explanation has been made by these experiments. However, in practical use, the etching is performed under a plasma environment because both active and ionic species, which are easily formed in the plasma, seem to be necessary to obtain a satisfactory etch rate (5).

In this work, a copper rod is placed in the plasma produced by a parallel-plate-type reactor. The etch rate of silicon placed on the rod is measured by varying the dc bias voltage, V_s , which is applied between the rod and the anode. A change in V_s seems to have little effect on the plasma. The energy of incident ions on the rod must be smaller than eV_s . Our experiments are mainly performed under three conditions: with a large number of F and O atoms at the 45% O_2 content; with a small number of O atoms at the 10% O_2 content; and with a very small number of F and O atoms at the 0% O_2 content. It will be shown that the dependence of the etch rate on V_s can be characterized at each condition. Moreover, the etch rates on the cathode and on the anode are also discussed, based on the experimental results of the etch rate on the rod.

Experimental

A schematic view of the experimental apparatus is shown in Fig. 1. A copper rod is inserted between the cathode and anode electrodes in a conventional parallel-

plate-type reactor (6). The diameter of the rod is 15 mm, and one end of the rod is flattened to make it easy to set a sample. The center of the rod is set at distances of 21 and 14 mm from the cathode and the anode, respectively. The rod is cooled by cold water and is biased by applying a dc potential, V_s , between the rod and the anode. Because a large current can flow to the rod when a large area is exposed to a plasma, the plasma condition seems to change as V_s is varied. In order to suppress this effect, the copper rod is covered with a quartz tube, except at its end, where a silicon sample is mounted. The area of the rod directly exposed to the plasma is estimated to be about 6 cm². The temperature of the rod is measured by a thermocouple and found to be $10^\circ \pm 3^\circ\text{C}$. The thermocouple is set at the other end of the rod, outside the chamber, as shown in Fig. 1. The temperature of the rod inside the chamber can be different from the temperature observed outside the chamber. In order to check this difference, both temperatures are measured simultaneously with two thermocouples. The temperature of the rod end inside the chamber is $23^\circ \pm 3^\circ\text{C}$ after 10 min discharge, while the temperature

Fig. 1. The schematic view of the experimental apparatus

outside the chamber remains at 10°C. This temperature rise, however, is almost independent of discharge condition.

The flow rate of $\text{CF}_4 + \text{O}_2$ gas is maintained at 50 cm^3/min , even when the O_2 content is changed from 0% to 45%. In order to correct the optical emission intensity, Ar gas is added at a flow rate of 1 cm^3/min . The pressure is 0.3 torr, the RF power of 13.56 MHz is 100W, and the etching time is 10 min. The sample is a p-type single-crystal silicon wafer with (100) orientation. The area of the sample is 0.6–0.8 cm^2 . It is dipped into a 46% HF solution in order to remove a native oxide before mounting on the copper rod. The sample weight is measured before and after the etching; from the difference, the etch rate is obtained by dividing by both etching time and surface area. A silicon sample is also placed on the anode to check, by measuring the etch rate, the effect of V_s on the plasma.

At the center between the cathode and the anode, the optical emission intensities from F, O, and Ar atoms are measured at wavelengths of 703.7, 777.1, and 705.4 nm, respectively. An optical fiber, which is not shown in Fig. 1, is used in order to guide a light beam to a monochromator. The dc potential of the cathode is measured through a low-pass filter.

The etch rates on both the cathode and the anode are measured before the copper rod is introduced. In this case, the etch rate is measured by an interferometer by using a small silicon sample half-covered by an aluminum film. The etching time is 7 min. The CO emission intensity is also measured at 519.8 nm, as are the F, O, and Ar emission intensities.

In some experiments, additional silicon wafers are placed on either the anode or the cathode to examine the loading effect. The word "load" appearing in this paper means, unless otherwise specified, that three pieces of 2 in. Si wafer, whose total area is 60 cm^2 , are placed on the anode.

Results

The dependence of the rod current, I_s , on V_s is shown in Fig. 2. When net positive charges flow to the rod, I_s is defined to be positive. V_s is taken positive when the potential of the rod is negative relative to the anode. At $V_s = 0$ V, i.e., when the rod potential is equal to that of the anode, I_s is about -2 mA. This means that particles with negative charge, mostly electrons, dominantly flow to the rod. A floating potential, where $I_s = 0$ mA, is about 30V. Because the rod current is the sum of electron and ion currents under $V_s = 50$ V, it greatly depends on V_s . From $V_s = 50$ V to $V_s = 100$ V, I_s is almost independent of V_s . In this region, electrons are repelled completely. Only positive ions can reach the rod, and then I_s can be regarded as the ion-saturated current. When V_s increases further, I_s increases gradually in our experiments. The result is also shown in Fig. 2, when the rod end is covered by an Al foil at the 45% O_2 content. In this case, the ion-saturated current is not changed, but an increase in I_s beyond $V_s = 100$ V is larger than that without the Al foil. With increasing V_s , the length of the ion sheath increases, and I_s also increases, in spite of a constant electrode area, because of an increase in a capture area of positive ions. However, the increase in I_s at large values of V_s seems to be caused by secondary electrons emitted from the surface by incident ions, along with the effect of the ion sheath length, considering the dependence of I_s on the rod material. The energy of incident ions must be smaller than eV_s . However, the energy of incident ions will be proportional, though maybe not directly proportional, to eV_s , considering the increase in I_s .

The rod current and the Ar emission intensity are shown in Fig. 3 as a function of the O_2 content at $V_s = 100$ V. The rod current at $V_s = 100$ V is sufficiently saturated, as shown in Fig. 2. These values show a different dependence on the O_2 content. The F and O emission intensities are shown in Fig. 4 as a function of V_s . They are obtained by dividing the measured emission intensities by the Ar emission intensity (7). The data at $V_s = -25$ V, when the

Fig. 2. The rod current as a function of V_s at various O_2 contents. There are Si loads on the anode at oxygen-free O_2 content, but no Si load at other O_2 contents. The rod current is also measured when a portion of the rod is covered with an Al foil at the 45% O_2 content.

Fig. 3. The rod current, I_s , and the Ar emission intensity, I_{Ar} , as a function of the O_2 content. The solid lines show those without Si loads; the broken lines show those with Si loads on the anode.

Fig. 4. The F and O emission intensities as a function of V_s in the same condition as the one in Fig. 2. At the 45% O_2 content, only the data are shown without an Al foil. The data near $V_s = -25V$ show those when the rod current is adjusted to -5 mA, and the ones near $V_s = 25V$ show those at the floating potential.

rod current is adjusted to -5 mA, are also shown in this figure. They are normalized to unity at the 45% O_2 content and the rod current of -5 mA. The F and O emission intensities are strong at the 45% O_2 content. At the 10% O_2 content, the F emission intensity decreases to about 55% of that at 45% O_2 content, while a decrease in the O emission intensity is much faster than that in the F emission intensity. At oxygen-free content with the Si load, there are only a small number of F and O atoms. According to the changes in these emission intensities, the etching condition at each O_2 content can be characterized as follows. Because there are enough F and O atoms in the plasma at the 45% O_2 content, O atoms adsorbed on a silicon surface prevent silicon etching by F atoms (8). Because there are plenty of F atoms in the plasma, but not plenty of O atoms at the 10% O_2 content, the effect of adsorbed O atoms is small. The number of active species for silicon etching is few at oxygen-free content. All of the emission intensities are almost independent of V_s . This shows that the incident fluxes of F and O atoms are not affected by V_s .

The etch rates on the anode and on the copper rod are shown in Fig. 5 and 6, respectively. The etch rate on the anode is almost independent of V_s . This shows that the plasma is not affected largely by a change in V_s . Probably, the potential of V_s is shielded by the ion sheath formed in front of the rod. In all cases in Fig. 6, the silicon etch rate on the copper rod increases as V_s increases beyond the floating potential. At the 45% O_2 content, the etch rate increases gradually below $V_s = 200V$, but increases rapidly above $V_s = 200V$. On the other hand, at the 10% O_2 content, the etch rate increases rapidly at low V_s and goes to saturation at high V_s . At oxygen-free content with the Si load, an increase in the etch rate is not remarkable.

Fig. 5. The etch rates on the anode as a function of V_s in the same condition as the one in Fig. 4.

Figure 7 shows the etch rates on the cathode and on the anode without the rod as a function of the O_2 content. These are obtained from etched depth measurements. $100 \mu\text{g}/\text{cm}^2 \text{ min}$ in Fig. 5 and 6 corresponds to about $430 \text{ nm}/\text{min}$ in Fig. 7, assuming that the etching proceeds uniformly on the sample surface. The etch rate on the anode in this figure is somewhat different from that in Fig. 5. Probably, this is because the plasma condition is disturbed by the rod, and/or the etching uniformity is insufficient. There is an O_2 content where the etch rate is the largest. Obviously, these O_2 contents are different between the cathode and the anode.

Discussion

Optical emission intensity and rod current.—The Ar emission intensity, I_{Ar} , which is proportional to the Ar density at the excited level (9), is expressed as $k_e n_e n_{Ar}$, where k_e is the rate constant, n_e the electron density, n_{Ar} the Ar density. Because the flow rate of Ar gas is constant through our experiments, n_{Ar} is also constant. When a Maxwell distribution is assumed, I_{Ar} is directly proportional to $n_e \sqrt{T_e'} \exp(-E_i/kT_e')$ (10), where T_e' is the electron temperature and E_i is the excitation energy ($E_i = 13.5 \text{ eV}$ for the Ar emission line of 750.4 nm) (11). Because the electron temperature, T_e , which is not always equal to T_e' (as discussed later), for the bulk of electrons is much larger than the ion temperature, T_i (i.e., $T_e \gg T_i$), the ion current, I_i , is proportional to $n_i \sqrt{T_e/M_i}$, where n_i is the ion density and M_i is the ion mass (12). At $V_s = 100V$, electrons are repelled completely, and the rod current in Fig. 3 seems to be equal to I_i at each O_2 content. I_i increases monotonically as the O_2 content increases, but I_{Ar} has a maximum value at about 25% O_2 content. When the O_2 content is varied, the constituent of ions in the plasma is also changed. Coburn and Winters (13) have reported from the observation of mass spectra of positive ions that CF_3^+ is a main component with the powered electrode of

Fig. 6. The etch rates on the copper rod as a function of V_s in the same conditions as the one in Fig. 4. Some data are also shown when Si loads are placed on the anode at the 10% O_2 content.

Si, and CF_3^+ , COF^+ , and COF_2^+ are main components with the one of SiO_2 . O atoms are liberated from the SiO_2 powered electrode. From their results, CF_3^+ is a main component at oxygen-free content, but CF_3^+ , COF^+ , and COF_2^+ must be mixed when O_2 is added. Supposing that all ions are converted from CF_3^+ to COF^+ , and that n_i and T_e are not changed when O_2 is added, I_i increases by about 20%. Because an increase in I_i is more than 20%, as shown in Fig. 3, n_i and/or T_e seem to be increasing. This contradicts the fact that the Ar emission intensity decreases at the high O_2 content region. Ar atoms are excited only by electrons whose energy is greater than E_i . T_e' has to be the electron temperature for such electrons. Kushner (14) measures the electron energy distribution, $f(\epsilon)$, by the electrostatic probe method and shows that the maximum value of $f(\epsilon)$ appears in higher electron energies when the fraction of CF_4 is increased, because there are fewer inelastic processes to slow the electrons down. When inelastic collisions occur, the number of electrons with high energy decreases. Then, T_e' decreases, and T_e' is not equal to T_e (10). Considering this effect, it is possible that T_e' decreases while T_e is constant or increases and that I_{Ar} decreases while I_i increases when the O_2 content is changed. Because both I_i and I_{Ar} at oxygen-free content are smaller than those at the other O_2 contents, both the electron temperature and the plasma density seem to be small at oxygen-free content (12).

Etch rate on the copper rod.—We discuss the etch rate on the copper rod, as shown in Fig. 6, at each O_2 content.

0% O_2 content.—Because the F atom density is very low at oxygen-free content with the Si load, the etch-rate enhancement by incident ions seems to be caused mainly by the physical sputtering. This enhancement is not large, even though we take into consideration that I_s is relatively small at oxygen-free content.

10% O_2 content.—Because the O atom density is low, silicon etching by F atoms is enhanced by incident ions without effects of adsorbed O atoms. This enhancement is possible with a relatively low energy of incident ions. Some data are also shown in Fig. 6 at the 10% O_2 content with the Si load. If the etch-rate difference between $V_s = 0$ V and $V_s = 50$ V is assumed to be the etch-rate enhancement by incident ions at $V_s = 50$ V, this enhancement without the Si load is about 1.8 times as large as that with the Si load. The F emission intensity is about 2.7 times as large as that with the Si load. The two rod currents are almost equal with and without the Si load. Though the etch-rate enhancement is not directly proportional to the F emission intensity, it seems to depend strongly on the F emission intensity in our experimental condition. Tu *et al.* (15) have measured the silicon etch yield when XeF_2 gas and energetic ions are exposed simultaneously. They have shown that the yield has a large dependence on XeF_2 flux, but only a slight dependence on incident ion energy. Their results are in good agreement with ours at the 10% O_2 content.

45% O_2 content.—The F and O atom densities are high. In order to enhance the etch rate, incident ions have to remove O atoms adsorbed on a silicon surface. Probably, the energy of incident ions required to sputter the adsorbed O atoms is larger than that required to enhance silicon etching by F atoms. If a value of V_s larger than 300 V is applied in order to remove adsorbed O atoms sufficiently, the etch rate on the rod at the 45% O_2 content seems to become larger than that at the 10% O_2 content because the F atom density is higher than that at the 10% O_2 content. Paraszczak and Hatzakis (16) show that silicon can be etched in the vertical direction of the mask even when the lateral etch rate is zero at the high O_2 content. This shows that adsorbed O atoms are removed by incident ions in the vertical direction.

Fig. 7. The etch rates on the cathode and on the anode as a function of the O_2 content without the copper rod. About 430 nm/min of the etch rate in this figure are equal to 100 $\mu\text{g}/\text{cm}^2$ min (assuming uniform etching). The solid lines show those without Si loads; the broken lines show those with Si loads.

The following results are obtained: (i) the energy of incident ions needed to enhance silicon etching by F atoms is small; (ii) the physical sputtering is much weaker than the chemical sputtering, which indicates etch-rate enhancement by incident ions with the consumption of active species; and (iii) the etching is prevented by the adsorbed O atoms at even a relatively high energy of incident ions.

Lee and Chen (17) have shown that the etch-rate enhancement by incident ions is proportional to $V_{bi}^{5/2}$, where V_{bi} is a self-bias voltage. We define the etch-rate enhancement by incident ions, ΔE , as the difference between the etch rates at V_s and at $V_s = 0$ V and suppose the ΔE is proportional to V_s^α . An accurate value of α cannot be obtained, because ΔE becomes too small at low V_s to obtain reliable data. However, a value of 2.7 is obtained when data points at $V_s = 300$ V and $V_s = 200$ V are connected linearly at the 45% O₂ content. This is close to a value of 5/2. But at the 10% O₂ content, α is smaller than unity, as seen from the curve in Fig. 6. It is difficult to compare their results with ours due to different experimental conditions. However, when we discuss incident ion effects in a CF₄ + O₂ plasma, it is certainly important to take account of the O atom adsorption, along with the plasma density, pressure, and so on. Tachi *et al.* (18) show that the chemical sputtering yield is smaller than the physical one when silicon is etched by F⁺ ions with the incident energy larger than about 200 eV. Because one source of F atoms is only F⁺ ions in their experiment, the F atom density is insufficient and the chemical sputtering is suppressed.

Under the floating potential, the etch rate also increases. This increase is especially remarkable at the 45% O₂ content. The enhancement seems to be caused by an incidence of electrons or a change in the plasma condition. The latter is suspicious because a change in the Ar emission intensity at the 10% O₂ content is similar to that at the 45% O₂ content when V_s is changed, but the enhancement of the etch rate is hardly observed at the 10% O₂ content. SiO₂ is etched when it is exposed to XeF₂ gas and electrons simultaneously (19). Incident electrons seem to affect the adsorbed O atoms on a silicon surface, though we cannot confirm this at present.

Etch rates on the cathode and on the anode.—The etch rates on the cathode and on the anode are discussed, based on the experimental results. Because no copper rod is used in this experiment, the plasma condition seems to differ from that obtained above. The dc potential at the cathode without the Si load decreases monotonically from 300V at oxygen-free content to 210V at 45% O₂ content and is about 20V smaller than that with the Si load. This potential is considered as the cathode fall potential because the plasma potential seems to be small due to a smaller cathode area than that of the earthed area (20).

Let us consider that the O₂ contents where the etch rates are the largest on the cathode and on the anode are not consistent. Because the amount of adsorbed O atoms on the cathode is smaller than that on the anode by sputtering of O atoms, the O₂ content giving the maximum etch rate on the cathode becomes a little larger than that without the effects of incident ions. If the sample on the anode is not affected by incident ions, the difference between the etch rates on both electrodes shows the etch-rate enhancement by incident ions on the cathode. This difference is 120 nm/min at the 10% O₂ content and 130 nm/min at oxygen-free content without the Si load. Though this difference at the 10% O₂ content has to be larger than that at oxygen-free content according to the previous discussions, these two differences are almost identical. It is probably not assumed, strictly speaking, that the etch rate on the anode is the etch rate without the effects of incident ions. Because the etch rate is enhanced by incident ions with low energy at the 10% O₂ content, the etch rate on even the anode seems to be enhanced by incident ions with approximately the plasma-potential energy. Because the enhancement by incident ions with low energy is possible at the low O₂ content, the etch rate on

Fig. 8. The F and CO emission intensities as a function of the O₂ content when a 3 in. Si wafer is placed on either the cathode or the anode. The solid lines show the F emission intensity, and the broken lines show the CO emission intensity. The difference between the F emission intensities is also shown in this figure.

the anode can be increased by incident ions at the low O₂ content. These are the reasons why the O₂ contents where the etch rates are the largest are different. However, this enhancement on the anode seems not to be large because the dependence of E/I_F , which is the ratio of the etch rate to the F emission intensity, on I_O/I_F , which is the ratio of the O emission intensity to the F emission intensity, becomes linear (8) within an approximate 10% deviation (6).

The F and CO emission intensities are shown in Fig. 8 with a 3 in. Si wafer placed on the cathode or on the anode. The F emission intensity with the Si wafer on the cathode is weaker than that with the Si wafer on the anode. Lee and Chen (17) have measured the F emission intensities in both a plasma etching mode and a reactive ion etching mode when Si loads are etched. They have found that the F emission intensity in the reactive ion etching mode is weaker than that in the plasma etching mode. Our result in Fig. 8 is consistent with theirs. This shows that silicon on the cathode consumes more F atoms than that on the anode. As the enhancement of the etch rate by incident ions consumes F atoms, the chemical sputtering by energetic ions must be induced on the cathode.

Conclusion

The silicon etch rate on the copper rod is examined by changing the potential, V_s , applied to this rod. It is confirmed that a change in V_s hardly affects the plasma. The chemical sputtering can be induced by incident ions with relatively low energy. This chemical sputtering is reduced by adsorbed O atoms, which can be removed by the incidence of energetic ions. The ion energy needed for sputtering O atoms is higher than that needed to induce the chemical sputtering. The physical sputtering is much lower than the chemical sputtering. In our experimental condition, the etch-rate enhancement is limited by the F

atom density, rather than by the incident ion flux at the low O atom density.

At higher potentials than the floating potential, the electron flux is smaller than the ion flux on the rod. However, both fluxes are equal to the cathode and at the anode. If the electron flux influences the silicon etch rate seriously, it will be difficult to discuss the etch rates on both the electrodes from the results on the rod. Incident electrons seem to enhance the etch rate. However, this enhancement is not large, even when the rod current is -5 mA, which is about three times as large as the ion current. The enhancement must mainly be caused by the energetic ions.

Based on these results, the etch rates on the cathode and on the anode are investigated. It is important to consider the effects of adsorbed O atoms and their removal by energetic ions. The etch rate is enhanced even on the anode at the 10% O₂ content.

ABSTRACT

Dielectric isolation (DI) technology has been available for almost 20 years. It was first developed for low capacitance, high speed circuits, and was later adapted to radiation-hardened devices and for high voltage isolation. The conventional DI technology is expensive, and device yields are reduced by mechanical instability of the polycrystalline substrates. We review a novel approach to forming DI structures, based on recrystallization from the melt of thick Si films deposited over oxidized Si wafers, with a regular array of seeding windows opened in the isolation oxide. The recrystallized films are free of grain boundaries and subboundaries and contain few dislocations. Most important, the polycrystalline substrates and the associated wafer bow are eliminated.

Fabrication of single-crystalline thin Si films on SiO₂ has been attempted only in the last few years (1). In contrast, thick Si films on SiO₂ were first demonstrated about 20 years ago (2), and have been commercially produced for many years. The process of making dielectrically isolated (DI) wafers consists of several steps. First, (100) Si wafers are V-grooved to a depth of ~ 50 μm by anisotropic etching and oxidized to form a dielectric isolation layer. A very thick layer of ~ 500 μm of polysilicon is then deposited by a high temperature CVD process over the oxide to form a new mechanical support or "handle." Once this is accomplished, 80%-90% of the initial crystalline substrate is mechanically removed, as shown schematically in Fig. 1. Only small, device-size segments of the original single-crystalline wafer remain embedded in the polysilicon handle, electrically isolated from it and from each other. This procedure, developed and perfected over the years, is expensive and includes grinding

and lapping steps that are difficult to control and automate. Nevertheless, this is still the only proven technique for obtaining dielectrically isolated thick film structures and the only commercial process for fabricating crystalline Si films of any thickness on the SiO₂.

We have recently proposed an alternative to conventional DI technology that is potentially simpler and less expensive (3-5). This method of lateral epitaxial growth over oxide (LEGO) results in crystalline Si dielectrically isolated from a single-crystalline substrate. The process is based on controlled melting and recrystallization of 50-100 μm thick Si films in a special lamp furnace (6). The polysilicon handle is eliminated and with it the problem of wafer deformation caused by volume changes in polysilicon (7).

Below, we describe formation of planar crystalline films over the SiO₂, since this allowed us to prove the concept and examine in detail the kinetics of crystallization. Crystallization of Si over nonplanar structures provides simultaneously vertical and sidewall dielectric isolation necessary for high voltage devices. Formation of

such structures and crystallization results are presented in the third section. The isolated crystalline regions have the same geometry as the conventional device tubs, assuring compatibility with the standard device designs.

Crystallization of Planar Films

Laser (8) and strip heater (9) recrystallization have been used by many groups to form device-quality thin Si films on oxidized Si wafers. In particular, seeded crystallization has been explored in many experimental configurations. In most cases, the molten zone was moved across the surface by the relative motion of the sample and the heat source. This way, if epitaxial growth occurred at the seed region, it propagated a certain distance with the trailing edge of the melt. Tamura *et al.* demonstrated that, in principle, the beam motion is not necessary since the thermal gradients alone can carry lateral recrystallization (10). In their experiments, "bridging epitaxy" was indeed demonstrated, but the lateral growth distance for a $0.5 \mu\text{m}$ film was $\sim 3\text{--}5 \mu\text{m}$. In an experiment with a stationary strip heater, crystallization over a distance of $\sim 10 \mu\text{m}$ was achieved by Fan *et al.* (9).

For recrystallization of thick Si films, heating with one localized source of energy is not acceptable because loss by lateral conduction from the heated spot necessitates a very high local power density, often leading to surface vaporization and always causing large thermal stresses. A high temperature thermal bias superimposed over a localized heat source, such as a laser beam or a scanned graphite filament, can reduce these problems.

Our approach has been to melt uniformly the entire polysilicon film. A regular array of windows cut in the buried oxide provides seeding necessary for epitaxial growth, and also imposes temperature gradients that are the driving force for lateral crystallization. Undercooling of the liquid Si can also play a role in preventing competitive nucleation, since molten Si is contained within amorphous silica walls.

The lamp furnace for large area melting and controlled recrystallization has been described before (6) and is shown schematically in Fig. 2. Briefly, it consists of two rectangular chambers, each 10×12.5 in. in lateral dimensions, positioned one above the other and separated by a quartz window. Air-cooled tungsten halogen lamps are suspended under a gold-plated reflector in the upper chamber. Wafers are placed on quartz pins ~ 0.5 in. above the water-cooled base of the lower chamber. Samples are heated uniformly from one side with a broad-band radiative flux emitted by the lamps. At typical settings required for melting, the spectrum is centered at $\sim 1 \mu\text{m}$ wavelength. Cooling is predominantly by black body radiation from both front and back side of the samples. The presence of the metal base held at a nearly constant temperature $< 100^\circ\text{C}$ assures reproducible cooling rates and a uniform gradient across the wafer thickness of $\sim 100^\circ\text{C}/\text{cm}$.

Fig. 2. Schematic view of the lamp furnace

Fig. 3. Electrical power input and wafer temperature vs. time for a typical thermal cycle. P_M is the power threshold for melting.

Fig. 4. Optical micrograph of surface ripples on solidified Si surface. In the single-crystalline region A, the ripples are caused by freezing that started at regularly spaced solid inclusions floating in the liquid. In regions B and C, an oxide film is buried under a thick Si layer. In C, the surface protrusions (black features) delineate grain boundaries which always are the last to freeze. In region B, large grains were formed by recrystallization, and this is reflected in the surface pattern.

To recrystallize a Si layer on an oxidized Si wafer, the lamps are ramped linearly over 10-30s to a predetermined power setting that exceeds the threshold power for melting, P_M , held at that value for 10-100s, and shut off by a linear reduction of electrical power, as shown in Fig. 3. The sample temperature is monitored with an optical pyrometer focused on the back side of the wafer. After a few seconds lag when the power is first applied, the sample temperature increases rapidly until it reaches the melting temperature T_M . This occurs at $\sim 100 \text{ W/cm}^2$. The onset of melting is easily determined from the pyrometer output even if the absolute temperatures are not known precisely because of some uncertainty in the value of emissivity. The temperature curve has a knee at the melting temperature, and its slope is essentially zero for the melt duration. All the absorbed power exceeding the threshold value is taken by the heat of fusion (for silicon $\sim 1800 \text{ J/g}$). Since all heating is radiative and the reflectivity of molten metallic Si is higher than that of the solid, elongated inclusions of superheated solid are present on the surface of the liquid. These inclusions have the same origin as those observed in laser melting experiments (11), and also as inferred from our experiments on melting of single-crystalline Si in the lamp furnace (12, 13). During solidification, the lamellar pattern of solid and liquid inclusions leaves a very characteristic imprint on the frozen surface, as shown in Fig. 4. The solid inclusions reduce

the surface-averaged reflectivity to a value permitting a steady-state heat flow over a wide range of input powers. Because of this, the melt depth is a complicated function of time and input power.

Samples for crystallization are prepared by oxidation, photolithography, and deposition of silicon and SiO_2 films. Silicon (100) starting wafers are cleaned and oxidized in a steam ambient to form the dielectric isolation barrier. The oxide is patterned by photolithography to obtain an array of seeding windows. CVD deposition of polysilicon is carried out at high temperatures in a conventional vertical epitaxial reactor (14, 15). To achieve epitaxial growth over the windows in oxide, samples are

Fig. 9. The center part of a recrystallized island similar to that in Fig. 8, with edges of etch pits aligned over the entire area.

etched briefly with HCl vapor at 1050°C to remove the native oxide from the silicon surface. Deposition is often done in two steps: (i) nucleation and (ii) rapid growth. Uniform nucleation of Si over SiO_2 is achieved by decomposition of SiH_4 at 1050°C . After a continuous silicon layer has been formed, the temperature is increased to 1150°C and SiH_4 is replaced with SiHCl_3 for a higher, $>1 \mu\text{m}/\text{min}$, growth rate. The $10\text{-}100 \mu\text{m}$ thick films have columnar grain structure with an average grain diameter $>1 \mu\text{m}$ and with a surface roughness of $1\text{-}3 \mu\text{m}$. As a final step, the surface is capped with a $2 \mu\text{m}$ layer of LPCVD oxide that is needed to contain molten silicon. A cross section of a typical precursor structure is shown in Fig. 5, with the grain boundaries delineated by 10s Schimmel etching (15).

Crystallization of the molten Si starts in the seeding windows and proceeds laterally over the oxide. Upon recrystallization, the entire film is single crystalline, and it is free of grain boundaries or subboundaries. A cross section of the recrystallized film is shown in Fig. 6. The maximum depth of melt penetration is delineated by the doping dependent etching rate of the cross-sectional surface. The trace of the solid-liquid interface is not planar, but dips down in the seeding region. Preliminary results from a numerical analysis of heat flow (16) in a similar

Fig. 8. Top view of lamp recrystallized $30 \mu\text{m}$ thick Si film over a buried square island of SiO_2 , 1.6 mm on each side

configuration agree with this observation. The calculated isotherms are shown in Fig. 7, for temperatures $T < T_M$. This computation does not fully reflect our experimental conditions, where the difference in conductivities of the solid and liquid Si and the heat of fusion have to be included. Still, there is no doubt that isotherms should crowd within the oxide, the thermal conductivity of which is ~ 10 times lower than that of the solid silicon.

A top view of recrystallized Si over a square region of SiO_2 , 1.6 mm on each side, is shown in Fig. 8. The surface was polished before Schimmel etching, since the capping layer preserves the roughness of the as-deposited surface through melting and recrystallization. There is a clear pattern of dislocation pits aligned with the diagonals of the square, indicating symmetrical solidification from all four sides and a collision of the solidification fronts along the diagonals. As expected, the highest dislocation density is right in the center of the square, where all four fronts meet. However, even there, the silicon is single crystalline and free of subboundaries. In Fig. 9, a magnified view of this center region is shown, with superimposed pattern of square pits formed by the grid-of-etch-pits (17) technique. The ridges of all the pits are aligned parallel to each other. In Fig. 10, RBS and channeling spectrum are shown for a sample similar to the one in Fig. 9. The He ion beam of ~ 0.6 mm diam probed a region not including the most defective spot in the center of the epitaxially recrystallized square. Any structural misalignment caused by twinning or subboundaries within the beam diameter would increase the scattering yield. The fact that χ_{\min} value is 3% and identical to the bulk Si, indicates lack of such extended defects over large areas of our films. In contrast, for a typical thin film recrystallized with a strip heater, χ_{\min} varies from 20% to 80% because of the subboundaries.

All crystallization processes are necessarily affected by surface tension effects. In order to control the shape of crystals grown by Czochralski, float-zone, and, in particu-

Fig. 10. RBS and ion channeling spectrum for a recrystallized 30 μm thick film. The aligned yield is the same as for the bulk Si.

lar, ribbon growth methods, the relationship between the meniscus angle and the growth direction should be known. The configuration in LEGO experiments is similar to the conditions examined in detail by Surek and Chalmers for the case of a Si wafer melted with an electron beam and recrystallized (18). The variables used in their analysis are defined in Fig. 11. The angle θ is measured between the crystal growth direction and the crystal-vapor interface. ϕ is the angle between the growth direction and the tangent to the meniscus at the growth interface. The relative angle between the free surfaces of the liquid and the solid is $\delta = \phi - \theta$. In their experiments, θ was initially negative, then crossed zero and became progressively more positive, reflecting the initial thinning of the growing crystal and considerable thickening in the last-to-freeze region. The meniscus angle also varied with time. After sectioning resolidified samples, Surek *et al.* measured instantaneous values of θ and derived corresponding values of ϕ from a geometrical analysis. They established that when the uniform thickness growth is momentarily reached in the radially freezing molten zone (*i.e.*, $\theta = 0$), the angle $\phi \sim 11^\circ$. Since $\phi > 0$, there is a pile-up of silicon ahead of the solidification front that leads to reduced crystal thickness at the beginning of crystallization and accumulation of mass at the later stage.

These observations of time-dependent shapes in solidifying bulk crystals also approximate well the behavior of freezing films. Films recrystallized by the LEGO process are thinner near the seeds and considerably thicker in the regions that freeze last, as shown in Fig. 12. This thick-

Fig. 11. Solid-vapor and liquid-vapor interfaces shown schematically for a radially freezing molten zone [After Surek and Chalmers (18).]

Fig. 12. Angle-lapped sample, showing redistribution of Si towards the center of each recrystallized zone.

Fig. 13. Patterned thin film recrystallized in the lamp furnace. Seeding occurred through narrow openings in the oxide at both ends of each stripe (only one end is visible in the photograph).

ness variation is the main limitation in thin film crystallization with extended stationary heaters. Scanning of a narrow molten zone produced with a laser or a hot wire reduces redistribution effects, but does not eliminate them.

One important difference between our experimental configuration and that of Surek is the presence of the capping oxide. This cap reduces the meniscus angle ϕ from 11° to about 1.5° according to Yablonovitch (19). Smaller ϕ means less pile-up of Si and a more uniform film thickness than would be possible with a free surface.

Redistribution of Si through the snowplowing effect of the propagating interface limits the application of LEGO to relatively thick films, $> 10 \mu\text{m}$. Crystallization of thinner films with widely spaced seeding windows often leads to a discontinuous coverage of oxide with Si. This problem can be eliminated by patterning the Si film into sections. For example, Fig. 13 shows four stripes of $0.6 \mu\text{m}$ thick Si on $1 \mu\text{m}$ of oxide successfully recrystallized in the lamp furnace. Seeding occurred through narrow openings in the oxide at the ends of each stripe. This micrograph also shows the presence of subboundaries similar to those obtained by all the other methods of crystallization of thin films.

During high temperature processing of multilayer structures, there is always a risk of wafer bowing. In our configuration, the wafers are supported only at three points during the melting process, and the entire substrate is within a few degrees of melting. Nevertheless, the back surface of 3 in. wafers remains flat to within $10\text{-}50 \mu\text{m}$. The amount of bow is equal or lower than that caused by other processing steps such as growth of a thick isolation oxide or polysilicon deposition.

Strip heaters can also be used to recrystallize seeded thick films. In unseeded crystallization of thin films, (100) texture and in-plane alignment of the $\langle 100 \rangle$ axis with the growth direction is achieved and the crystalline quality is marred mainly by the presence of the subboundaries. For films thicker than $5 \mu\text{m}$, the preferential growth direction and texturing are lost (20). However, thick films were grown successfully from seeding windows (21). They were free of subboundaries just like the films crystallized in the lamp furnace. The main features distinguishing these results from the stationary heater experiments were a different mass transport and a higher density of dislocations. Since the solidification front propagated only in one direction, the film thickness increased somewhat along the scan. Dislocations tended to be concentrated in the center region of the films, away from the upper and lower Si-oxide interfaces.

Crystallization of Nonplanar Films

In the previous section, we showed that high crystalline quality films can be obtained by LEGO. This is not sufficient to obtain device-worthy structures. What is necessary is the means for achieving sidewall as well as vertical isolation.

In principle, three different approaches to sidewall isolation are possible, as shown in Fig. 14. Vertical walls can be formed by etching, oxidation, and backfilling. V-grooves can be formed by anisotropic etching. This process is the simplest for planar recrystallized films but it would cause loss of surface area for devices and would

Fig. 18. Etched vertical section of recrystallized nonplanar film

limit the minimum device size. The “wide-side-up” structure showed in Fig. 14 is most compatible with device fabrication schemes.

Fig. 19. Magnified view of the etched vertical section of recrystallized nonplanar film.

Fig. 20. Top view of recrystallized nonplanar film after isolation was completed by polishing. One small isolated Si tub and a part of a larger one are seen.

Fig. 21. Comparison of device tubs formed by the conventional DI process and by the LEGO process

To obtain such structures, the crystallization procedure was changed. The new sequence is shown in Fig. 15. It starts with formation of nonplanar substrates by KOH etching of rectangular tub-shaped depressions, followed by oxidation and opening of seeding windows in the oxide. A top view of the tubs and seeding windows in the SiO_2 is shown in Fig. 16. Notice that the tubs are truly rectangular with 90° corners, and that their shape is exactly that of the pattern in the mask. In contrast, in the conventional processing sequence the etched pattern is essentially a negative of that used in the LEGO process, and the geometry of etched areas requires corner compensation to achieve approximately rectangular device regions.

Defining seeding windows in the SiO_2 requires conformal coating of a nonplanar substrate with a photoresist. Conventional photoresist spinning does not provide complete surface coverage, especially at the sharp edges. Several approaches are being investigated, and the problem of reliably forming windows in oxide should be resolved soon.

A cross section of the structure after polysilicon deposition but before crystallization is shown in Fig. 17. Notice that epitaxial growth occurred over the window and that columnar crystallites are present over the oxide. The interface between the substrate and the epitaxially grown layer in the window area can be seen. This interface is recessed because of *in situ* surface etching with HCl immediately before the deposition.

After recrystallization, the film is single crystalline, with defect localized outside the potential device area, in the regions that froze last. Cross sections of a recrystallized sample are shown in Fig. 18 and 19. From these micrographs, it is clear that the density of dislocations in the substrate is higher than that in the recrystallized Si on SiO_2 . Although the defects below the buried oxide have no influence on the device performance, we examined the processing steps in detail to determine their origin. We found that oxidation needed to form the dielectric isolation layer introduced a high density of stacking faults that were transformed into dislocations during subsequent high temperature steps. The density of these dislocations was not increased during recrystallization. Any conventional method that prevents formation of the oxidation-induced stacking faults should eliminate most linear and planar defects in LEGO processed substrates.

After crystallization of Si over a nonplanar substrate, excess Si is removed by polishing to complete isolation of individual device tubs. A top view of a magnified segment of a polished wafer is shown in Fig. 20. Buried oxide

intersecting the surface delineates the boundaries between isolated regions and the substrate.

Summary

We have demonstrated that, by melting of large areas with a stationary heater, single-crystalline thick Si films can be formed. Such films are free of grain boundaries and subboundaries and have few dislocations. The thermal gradients necessary for lateral crystallization are defined by a pattern of windows in the buried oxide, and seeded growth can proceed from each window over a distance > 1 mm. The process works best for films thicker than $10 \mu\text{m}$. The continuity of thinner, unpatterned films can be disrupted by Si redistribution that is driven by the nonzero meniscus angle of the liquid Si during solidification. Patterned, seeded films as thin as $0.5 \mu\text{m}$ can be recrystallized, but with subboundaries similar to those formed by the scanning methods of crystallization.

Recrystallization of thick films over substrates with $\sim 50 \mu\text{m}$ deep depressions lends itself to formation of crystalline regions with complete dielectric isolation, sidewall as well as vertical. This should allow simplified fabrication of DI wafers. Moreover, the wafers formed by the LEGO process are entirely crystalline, without the polysilicon handle. Figure 21 illustrates the difference between the two approaches.

Much further effort is necessary to assure reproducible and uniform crystallization of Si over complete 4 in. wafers. The problems related to lithography on nonplanar wafers have to be resolved and the control of crystallization improved. Methods for introducing dopants to form buried layers inside the device tubs also need development. Assuming that these issues are successfully resolved, DI wafers formed by recrystallization will be less expensive to make and will contain fewer yield limiting structural defects.

Autodoping in Silicon Epitaxy

Hsueh-Rong Chang

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12345

ABSTRACT

Vertical and lateral autodoping in silicon epitaxy deposited in a vertical pancake-type reactor were examined as a function of pre-epitaxial bake cycle, dopant type, source gas, and growth parameters. Boron, phosphorus, arsenic, and antimony were used as dopant elements to form a localized buried layer at the center of substrates. Silane, dichlorosilane, and silicon tetrachloride were used as the silicon source for epitaxial growth. The results show that higher prebaking temperature produces more lateral autodoping for boron and phosphorus, while the opposite holds for arsenic and antimony. Autodoping in both vertical and lateral directions decreases with increasing prebake time. A continual decrease in lateral autodoping is found with increasing growth rate for phosphorus; for arsenic, only a slight difference is noticed in the growth-rate range studied. Phosphorus and arsenic show a similar trend at the deposition temperature of lateral autodoping, *i.e.*, autodoping decreases at first, then increases with increasing temperature. For all the dopants studied, vertical and lateral autodoping decrease with increasing number of chlorine atoms in the source gases.

Silicon epitaxy is widely used in semiconductor devices, primarily for its ability to grow lightly doped epitaxial layers over heavily doped substrates in a controlled manner. A high quality epitaxial layer with an abrupt interface is required for high frequency, high efficiency, and high reliability operation of semiconductor devices. Emphasis has been placed on obtaining sharp transition regions between the epitaxial layer and the substrate and on minimizing the autodoping. Dopants can transfer from the substrate to the epitaxial layer by either solid-state diffusion or redeposition via the gas phase, *i.e.*, autodoping. A clear separation of the solid-state diffusion and gas-phase transport effects has been made possible by using high resistivity substrates with localized buried layers (1-6). Such structures are more typical of the processing involved in the fabrication of integrated circuits.

Numerous studies on autodoping in silicon epitaxy have appeared in the literature describing various aspects of this phenomenon. In most cases, RF-heated horizontal-type reactors have been used for epitaxial growth. In the horizontal reactor, the gas flow is straightforward, entering the reactor tube at one end and flowing along the susceptor surface. In this reactor system, the gas flow is typically in the laminar regime (7). Such a flow can be analyzed by established fluid-flow relationships and has been discussed in detail by Eversteijn *et al.* (8), Ban and Gilbert (9), and Berkman *et al.* (10). There is little published information on autodoping using vertical reactor for epitaxial growth (6, 11). The gas-flow pattern in the vertical reactor is very complex. The gases are introduced through the center of the susceptor; they impinge on the hemispherical upper portion of the bell jar and swirl down the sides of the bell jar and across the substrates. The gases recirculate over the substrates many times be-

fore they exit through the annulus between the susceptor and the bell jar. Since the gas-flow dynamics in the vertical reactor are very different from those of the horizontal reactor, they can have a significant influence on autodoping behavior. Previous studies on the growth-rate dependence of autodoping show conflicting results between these two reactor systems. Bozler (11) reports an increase in vertical autodoping with increasing growth rate, using a vertical-type reactor for epitaxial deposition; the opposite result is obtained by Tabe and Nakamura (12) using a horizontal reactor. However, Srinivasan (3, 5) finds that lateral autodoping increases with increasing growth rate using a horizontal reactor. In an attempt to clarify these contradictory results, experiments have been conducted to investigate the influence of growth parameters on vertical and lateral autodoping in a vertical reactor. The results are compared with previously published data.

Arsenic has been used as dopant in most of the autodoping studies. Relatively less work has been carried out on autodoping with boron, phosphorus, and antimony (6, 13-16). Boron and phosphorus have smaller atomic sizes and diffuse much faster in silicon than does arsenic (17). High temperature CVD epitaxial processes can result in different autodoping behavior for different dopants. It has been shown that the major portion of autodoping occurs during the pre-epitaxial bake cycle (5, 12, 13, 18). Many models have been proposed to describe autodoping phenomena. Joyce *et al.* (13) claims that autodoping is controlled by the out-diffusion from the back of the heavily-doped substrates. This model, however, cannot explain the occurrence of lateral autodoping with localized buried layer structures. Bozler (11) assumes that autodoping is dependent on the dopant concentration in the turbulent, well-mixed gas phase. Based on this as-

sumption, lateral autodoping should be independent of the distance from the buried layer, which contradicts experimental evidence (2, 5, 6). Srinivasan (3, 5), on the other hand, assumes that autodoping is directly proportional to the dopant concentration at the substrate surface on the buried layer region just before epitaxial growth. This study gives evidence contrary to this assumption, as will be discussed. Tabe and Nakamura (12) postulate that an adsorbed dopant layer formed during prebaking acts as a dominant reservoir for autodoping. In their derivation, time is used as the independent variable, whereas in practical applications, the epitaxial film thickness is generally used. If time is replaced by film thickness in their model, then it predicts that higher growth rate results in higher autodoping. This relationship is in fact contradicted by the accompanying data. In this study, the effect of pre-epitaxial bake temperature and time on autodoping for boron, phosphorus, arsenic, and antimony is investigated. The dopant concentration at the surface of the buried layer before and after prebake cycles is measured in an attempt to correlate autodoping with surface concentration of the buried layer.

It has been found that different source gases affect autodoping differently (5, 6, 19). Suzuki and Endo (19) report that if arsenic-doped substrate is used under identical growth condition, silane epitaxy gives lower autodoping than SiCl_4 . They attribute this result to the absence of chlorine, which is presumed to be the dopant carrier, in the silane system. However, a conflicting result is reported by Srinivasan (5), based on the use of arsenic-doped buried layer structures. Srinivasan claims that an *in situ* etching by HCl (or Cl_2) released by the H_2 reduction of SiCl_4 reduces the dopant incorporation in the epitaxial layer. A study of the effect of the source gas chlorine on autodoping is included as part of this work. New data are presented concerning the autodoping differences between epitaxial layers using silane, dichlorosilane, and silicon tetrachloride as source gases. A correlation between the number of chlorine atoms in the source gases and autodoping has been obtained.

Experimental

All the epitaxial layers examined in this study were grown in a vertical-type CVD reactor Model AMV 1200 made by Applied Materials, Incorporated. The cross section of the reactor chamber is shown in Fig. 1. The susceptor had a 30.48 cm diameter and was made of high purity graphite coated with a layer of silicon carbide. The gases were introduced from a 9.5 mm (od) injection tube through the center of the susceptor into the reactor chamber. During operation, the susceptor rotated continuously and a constant hydrogen carrier gas flow of 50 liters/min was used. Before loading the wafers for epitaxial growth, the susceptor was etched with hydrogen chloride at 1200°C , then coated with a fresh layer of undoped silicon having an impurity concentration less than $1 \times 10^{14} \text{ cm}^{-3}$.

Fig. 1. Vertical silicon epitaxial reactor

Only one substrate was used per experiment. All the epitaxial deposits were $5 \mu\text{m}$ thick, with no external doping. The temperature of silicon wafers was measured with an optical pyrometer corrected for emissivity and wall transmission losses.

The substrates used in this study were lightly doped p-type and n-type silicon wafers having resistivities of $80\text{--}120 \Omega\text{-cm}$ and $\langle 100 \rangle$ orientation. Boron was implanted on n-type substrates, while phosphorus, arsenic, and antimony were implanted on p-type substrates, to form a 4 cm^2 buried layer at the center of 3 in. wafers. The surface concentrations of boron, phosphorus, arsenic, and antimony were $\sim 3 \times 10^{18} \text{ cm}^{-3}$, $8 \times 10^{19} \text{ cm}^{-3}$, $1.5 \times 10^{19} \text{ cm}^{-3}$, and $2 \times 10^{19} \text{ cm}^{-3}$, with corresponding junction depths of $\sim 3 \mu\text{m}$, $2 \mu\text{m}$, $1.3 \mu\text{m}$, and $1.5 \mu\text{m}$, respectively.

In the pre-epitaxial bake experiments, 1050° and 1150°C were the prebake temperatures, and the prebake time was varied from 10 to 70 min. Depositions were made at 1050°C , with a growth rate of $0.25 \mu\text{m}/\text{min}$, using silane, dichlorosilane, and silicon tetrachloride as the silicon source. In the growth-rate and deposition-temperature experiments, dichlorosilane was used for epitaxial growth. The dichlorosilane flow rate was varied from 60 to 250 cm^3/min , with the corresponding growth rate changing from 0.25 to $1.1 \mu\text{m}/\text{min}$. Deposition temperature ranged from 1050° to 1150°C .

The dopant profiles were measured by the spreading resistance technique using an instrument made by Solid State Measurements, Incorporated.

Results and Discussion

Autodoping from a substrate with a buried layer structure can be classified into two types. One is vertical autodoping, which is in the epitaxial layer over a buried

Fig. 2. Phosphorus profiles in an epitaxial layer on and off the buried layer region.

Fig. 3. Variation of lateral autodoping with prebaking temperature (2 mm from the edge of the buried layer region). Deposition temperature 1050°C; growth rate 0.25 $\mu\text{m}/\text{min}$.

layer region. The other is lateral autodoping, which is adjacent to the buried layer. Vertical autodoping contains out-diffusion of impurities from buried layers, in addition to autodoping from the vapor phase. In order to study autodoping (gas-phase), it is desirable to separate the out-diffusion effect by obtaining impurity profiles laterally away from the buried layer regions, i.e., lateral autodoping. Lateral autodoping has its maximum value at the epitaxy-substrate interface, as illustrated in Fig. 2. It is evident that the maximum dopant concentration decreases with the increase of the lateral distance from the edge of the buried layer. This is true regardless of dopant type. Lateral autodoping can be characterized by either the maximum dopant concentration at a chosen lateral position away from the buried layer or the integrated quantity under the vertical profile at that chosen position. The latter is used in the present study. The results in Fig. 2 indicate that the lateral autodoping is controlled by the evaporated dopant diffusing in a laminar flow regime just above the substrate surface, in which the lateral autodoping is predicted to decrease with increasing distance from the edge of the buried layer (20). The assumption of a well-mixed, turbulent gas flow in the vertical reactor proposed by Bozler (11) does not apply to the region very near the substrate surface. Similar behavior is also observed for arsenic autodoping using silane and SiCl_4 (2, 5) in a horizontal epitaxy reactor system where the gas flow is typically laminar (7).

Pre-epitaxial bake cycle.—Pre-epitaxial bake temperature has shown different effects on autodoping behavior for various dopants. As shown in Fig. 3, for boron and phosphorus, higher prebake temperature results in more autodoping, while the opposite holds for arsenic and antimony. The measurements are taken 2 mm away from the edge of the buried layer. This is true for all the source gases studied. Figure 4 shows the dopant profiles in the epitaxial layers for phosphorus and arsenic 2 mm away from the edge of the buried layer. Because the growth rate (0.25 $\mu\text{m}/\text{min}$) is much faster than the diffusivity at the deposition temperature of 1050°C, a Gaussian distri-

Fig. 4. Impurity concentration profiles in the epitaxial layers 2 mm laterally away from the buried layer regions: a) phosphorus; b) arsenic. Deposition temperature 1050°C; growth rate 0.25 $\mu\text{m}/\text{min}$.

bution centered at the original interface could be expected. These curves suggest that a continuous but slowly decreasing gas-phase source of dopant exists throughout the deposition cycle.

Srinivasan (3) reports that the lateral autodoping decreases with increasing prebake temperature and time when using arsenic as dopant. Based on his findings, Srinivasan proposes a model to describe the lateral autodoping as controlled by the impurity surface concentration over the buried layer region that exists just prior to epitaxial deposition. If this model were valid for all dopants, then the results of Fig. 3 would suggest an increasing surface impurity concentration with an increasing prebake temperature for boron and phosphorus. Experiments were carried out to obtain the surface concentration after the prebake cycle for all the dopants studied. It was found that higher prebake temperature produced lower surface concentration, as illustrated in Fig. 5. The impurity profiles of phosphorus- and arsenic-buried layers before and after the prebake cycles are shown in Fig. 6. Therefore, it is not necessarily true that higher surface concentration produces more autodoping. The dopant redistribution during epitaxial deposition cycle is not controlled only by the evaporation of the dopant from the buried layer; the size of dopant atoms or the adsorption/desorption of dopant at the growing surface can significantly affect autodoping behavior.

The variation of autodoping with pre-epitaxial bake time for phosphorus and arsenic is shown in Fig. 7 and 8.

Fig. 5. Dopant surface concentrations on the buried layers after prebake cycles.

Vertical and lateral autodoping decrease with increasing prebake time. These results are consistent with previously published data on lateral autodoping using arsenic in SiCl_4 epitaxy with a horizontal reactor (3). As prebake time increases, dopant atoms continuously evaporate from the substrate and are carried away by the hydrogen gas. It is believed that the depletion of the buried layer region results in lower dopant concentration in the vapor phase and thus leads to less autodoping in the epitaxial layer.

Growth rate.—Autodoping in the epitaxial layers is a function of the epitaxial growth rate. Figure 9 shows the variation of lateral autodoping with growth rate for phosphorus and arsenic. These results indicate that for phosphorus, autodoping decreases with increasing growth rate, while only a slight change is obtained for arsenic. Similar results are obtained for the vertical autodoping.

Fig. 6. Impurity concentration profiles of buried layers before and after prebake cycles: a) phosphorus; b) arsenic.

Fig. 7. Arsenic concentration profiles in the epitaxial layers on As-buried layer using SiH_2Cl_2 as the silicon source. Deposition temperature 1050°C ; growth rate $0.25 \mu\text{m}/\text{min}$.

phorus and arsenic. These results indicate that for phosphorus, autodoping decreases with increasing growth rate, while only a slight change is obtained for arsenic. Similar results are obtained for the vertical autodoping.

Fig. 8. Decrease in lateral autodoping for phosphorus and arsenic with increasing pre-epitaxial bake time.

Fig. 9. Variation of lateral autodoping for phosphorus and arsenic with growth rate in SiH_2Cl_2 epitaxy. Prebaking cycle: 1150°C , 10 min; deposition temperature 1050°C .

This difference shows that arsenic autodoping behavior cannot be generally attributed to phosphorus. It is not clear why the growth rate has different effects on the autodoping behavior for phosphorus and arsenic. The adsorption/desorption of dopant at the growing surface and the incorporation into the epitaxial layer may play an important role on the growth rate dependence of autodoping. Alternatively, because phosphorus atoms are smaller and diffuse much faster than arsenic atoms in silicon, a high temperature process could enhance solid-phase redistribution of phosphorus and result in different autodoping behavior. Srinivasan (3, 5) reports that in SiCl_4 epitaxy with a horizontal reactor system, lateral autodoping of arsenic increases with increasing growth rate (0.08-1.0 $\mu\text{m}/\text{min}$), as shown in Fig. 9. The cause of this discrepancy is not clear at present, but it is presumably associated with the use of different reactor types.

Deposition temperature.—The effect of epitaxial deposition temperature on lateral autodoping is shown in Fig. 10. Both phosphorus and arsenic show similar autodoping variations with deposition temperature: autodoping first decreases with increasing temperature; further increase in temperature results in higher autodoping. Similar results are reported for silane and SiCl_4 epitaxy using arsenic as dopant (see Fig. 10), and a model is proposed which predicts the decreasing lateral autodoping with increasing deposition temperature (5). However, the model cannot explain the autodoping behavior for deposition temperatures above 1100°C .

Source gas.—Autodoping in the epitaxial layers has been found to be a function of the source gases. For all the dopants studied, both vertical and lateral autodoping decreases with increasing number of chlorine atoms in the source gases. Figure 11 shows the variation of vertical

Fig. 10. Variation of lateral autodoping for phosphorus and arsenic with deposition temperature in SiH_2Cl_2 epitaxy. Prebaking cycle 1150°C , 10 min; growth rate $0.25 \mu\text{m}/\text{min}$.

Fig. 11. Arsenic concentration profiles in the epitaxial layers on As-buried layers using SiH_4 , SiH_2Cl_2 , and SiCl_4 for epitaxial growth. Deposition temperature 1050°C ; growth rate $0.25 \mu\text{m}/\text{min}$.

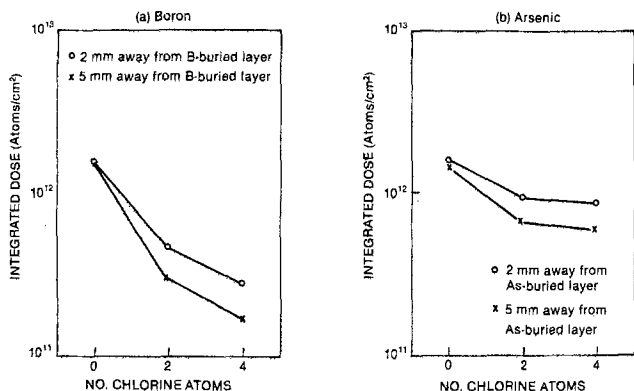

Fig. 12. Increasing lateral autodoping with increasing chlorine number in the source gases: a) boron; b) arsenic. Deposition temperature 1050°C; growth rate 0.25 $\mu\text{m}/\text{min}$.

autodoping with different source gases using arsenic as dopant. Figure 12 shows the variation of lateral autodoping for boron and arsenic. These results are consistent with those obtained by Srinivasan (5), who reports SiCl_4 epitaxy giving lower autodoping than silane, but are opposite to those reported by Suzuki and Endo (19). The HCl released by the reduction of chlorosilane could etch the growing epitaxial film at the impurity lattice sites and hence reduce the dopant incorporation, i.e., autodoping. It is likely that more chlorine atoms in the source gas will produce more HCl and therefore result in lower autodoping in the epitaxial layer. A correlation between autodoping and the number of chlorine atoms in the source gas has been achieved for the first time.

Summary

Intrinsic silicon epitaxial layers are grown on high resistivity substrates with heavily doped buried layers using boron, phosphorus, arsenic, and antimony as dopant elements. Impurity concentration profiles are measured by spreading resistance technique. The following results are obtained using a vertical epitaxial reactor with silane, dichlorosilane, and silicon tetrachloride.

1. Lateral autodoping decreases with increasing distance from the buried layer region. This indicates that the lateral autodoping is controlled by the evaporated dopant diffusing along the substrate surface in a laminar flow layer. The complex gas flow in the vertical reactor plays only a secondary role in determining lateral autodoping.

2. Pre-epitaxial bake temperature affects differently the autodoping behavior of the dopants tested. This is the first time such effects have been reported.

3. Vertical and lateral autodoping decrease with increasing prebake time.

4. Autodoping decreases with increasing growth rate for phosphorus, but only a slight change in autodoping is observed in the growth-rate range studied for arsenic.

5. Phosphorus and arsenic show similar changes in autodoping with epitaxial deposition temperature.

6. Vertical and lateral autodoping decrease with increasing number of chlorine atoms in the source gases. This correlation has been obtained for the first time.

Work is still being done to obtain better understanding of the autodoping mechanisms and to explain the differences between this study and previously reported results.

Dual Diffusion of Gold and Platinum into Silicon

R. Saito, N. Momma, M. Naito

Hitachi Limited, Hitachi Research Laboratory, Hitachi, Ibaraki, Japan

ABSTRACT

Dual diffusion of gold (Au) and platinum (Pt) into silicon is examined. When Au and Pt coexist in silicon, two levels of Au, $E_c - 0.54$ eV and $E_v + 0.35$ eV, and two levels of Pt, $E_c - 0.22$ eV and $E_v + 0.30$ eV, are observed by deep level transient spectroscopy (DLTS). New levels arising from the interaction of Au and Pt are not found. In the case of sequential diffusion (first Pt, then Au diffusion, or vice versa), replacement of the first diffused atoms in substitutional sites by the second ones is found to occur in the lower temperature range of the second diffusion. Replacement does not occur below 600°C of the second diffusion temperature. With the second diffusion above 800°C, replacement is almost complete. In the second diffusion temperature range, between 600° and 800°C, partial replacement occurs, and the sum of substitutional Au and Pt atoms is constant, irrespective of the second diffusion temperature, and is equal to the number of substitutional atoms of the first diffusant. From these facts, it is considered that Au and Pt atoms occupy the same kinds of substitutional sites in silicon.

In the manufacturing of diodes, transistors, and thyristors, deep level impurities such as gold (Au) or platinum (Pt) have been widely used to control carrier lifetime to improve their switching properties. A large number of studies on Au (1, 2) and Pt (3) have been done concerning the mechanism of diffusion, energy levels, and gold and platinum's electrical properties as lifetime killers. It is well known that the diffusion of these impurities is very structure sensitive. Lattice defects in silicon, *e.g.*, dislocation loops, affect the diffusion of these impurities because they act as sources of vacancies (4). Reverse leakage current (I_R) of Au-doped diodes is much larger than that of Pt-doped diodes for the same value of reverse recovery time (t_r). On the other hand, forward voltage drop (FVD) of Au-doped diodes is smaller than that of Pt-doped diodes (5).

Although these impurities have been studied individually, interaction of these impurities has not been studied. Concerning dual diffusion of lifetime killers, Hayashi *et al.* (6) studied the dual diffusion of iron (Fe) and Au. They concluded that by use of Fe and Au dual diffusion, the lifetime was reproducibly controlled and weak temperature dependence of the FVD of the device was obtained. They referred to the diffusion of Fe and Au as an interaction of these atoms.

This paper discusses dual diffusion of Au and Pt into silicon to reveal the interaction of these lifetime killers. We fabricated p^+nn^+ diodes doped with Au and Pt in several conditions and studied their trap concentrations and trap energy levels.

Experimental

The silicon wafers used in this study were FZ grown, n -type, and $\langle 111 \rangle$ oriented, with a resistivity of 35 Ωcm . Phosphorus and boron were diffused into opposite sides of the wafers, resulting in p^+nn^+ diode structure. Experiments were done for the following three cases

- sequential diffusion (Pt \rightarrow Au)
- sequential diffusion (Au \rightarrow Pt)
- simultaneous diffusion of Au and Pt

In case (a), Pt was deposited on the p^+ side of alkali and $\text{HF} + \text{HNO}_3$ etched silicon wafers by sputtering and then was diffused for 40 min in nitrogen atmosphere at different temperatures. The velocity of loading and unloading to the diffusion furnace was more than 1000 mm/min. After Pt diffusion, the wafers were boiled in $\text{HCl}:\text{HNO}_3 = 3:1$ to eliminate the residual Pt on the surface. Then Au was deposited on the p^+ sides of the wafers and diffused in the same way. In case (b), all of the procedures were the same as those in case (a), except for the order of Au and Pt diffusion. In case (c), Pt and Au were diffused simultaneously. As control samples, Au or Pt was diffused individually at different temperatures. After the diffusion of Au and Pt, Al was deposited on both sides of the wafers. From these wafers 1.4 mm diam diodes were prepared.

By using these p^+nn^+ diodes, trap concentrations and trap energy levels of Au and Pt in the n regions of the diodes were measured by DLTS (7, 8).

Results

It is well known that Au or Pt in silicon occupy substitutional and interstitial lattice sites. Only the atoms in substitutional sites are electrically active; therefore, they act as lifetime killers. As is well established, Au in substitutional sites forms two energy levels, a donor level at $E_v + 0.35$ eV and an acceptor level at $E_c - 0.54$ eV. A greater variety of levels has been published for Pt trap levels than for Au. Among them, two levels, a donor level at $E_v + 0.30$ eV and an acceptor level at $E_c - 0.22$ eV, are confirmed by many authors. Our DLTS measurement also shows the presence of these two trap levels.

In the case of the samples in which Au and Pt coexist, no energy levels other than those mentioned above were detected in any diffusion conditions. This result shows that new energy levels are not formed by the interaction of Au and Pt.

Trap concentration was estimated from the DLTS signal peak height of the majority carrier trap in n -type silicon, *i. e.* $E_c - 0.54$ eV (Au) and $E_c - 0.22$ eV (Pt).

Sequential diffusion (Pt \rightarrow Au).—Au and Pt trap concentrations of various diffusion conditions in case (a) are shown in Fig. 1 and Fig. 2, respectively. In these figures,

Fig. 1. Dependence of gold concentration on gold diffusion temperature.

Fig. 2. Dependence of platinum or of sum of gold and platinum concentration on platinum diffusion temperature.

open circles show control samples (Au or Pt diffused singly), and solid circles show Au and Pt double-doped samples. In Fig. 1, Au trap concentrations (N_{Au}) are not simply related to Au diffusion temperatures. For example, N_{Au} of sample A (Pt 850°C → Au 800°C) is higher than that of sample B (Pt 830°C → Au 800°C) and of sample C (Pt 820°C → Au 850°C); Band C in Au is diffused at a higher temperature than in sample A. Also, the N_{Au} of sample A is 10 times higher than that of control samples in which Au is diffused at the same temperature.

Fig. 3. Reverse leakage current (I_R) vs. reverse recovery time (t_{rr}). Solid lines: gold or platinum single doped. Solid circles: gold and platinum double doped.

In Fig. 2, Pt trap concentrations (N_{Pt}) of double-doped samples increases with Pt diffusion temperature, but these values are one order of magnitude less than the control samples. Figure 2 also shows the relation between the sum of N_{Au} and N_{Pt} and the Pt diffusion temperature. It is clear from this figure that the sum of N_{Au} and N_{Pt} is nearly equal to Pt concentration of the control sample. Before Au diffusion, N_{Pt} was the same as that of the control sample, but after Au diffusion, N_{Pt} decreased to less than 10% of the initial value, and the values of N_{Au} corresponded to the decrease in Pt concentration. This phenomenon obviously shows that Pt, which was diffused previously, is replaced by Au, which was diffused later.

This phenomenon is also confirmed by the measurement of the electrical properties of p^+nn^+ diodes. Figure 3 shows the relation between t_{rr} and I_R . In this figure, solid lines indicate the properties of Au single-doped diodes and Pt single-doped diodes; the solid circles indicate those of Au and Pt double-doped diodes.

It is clear that the properties of Au and Pt double-doped diodes are the same as those of Au single-doped diodes. Figure 4 shows the relation between t_{rr} and FVD. The properties of Au and Pt double-doped diodes are the same as those of Au single-doped diodes. These electrical measurements show again that Pt was replaced by Au when Pt and Au were diffused into silicon sequentially.

In order to reveal the replacement phenomenon more precisely, the effect of Au diffusion temperature on trap concentration was studied. Pt diffusion temperature was fixed at 850°C, and the following Au diffusions were performed in a temperature range of 600°-750°C. In Fig. 5, N_{Au} and N_{Pt} were plotted against Au diffusion temperature. As shown in this figure, N_{Au} increased and, correspondingly, N_{Pt} decreased with the increase of Au diffusion temperature. The sum of N_{Au} and N_{Pt} was constant and was equal to the initial Pt concentration before Au diffusion, irrespective of Au diffusion temperature. It is clear from Fig. 5 that the replacement does not occur at an Au diffusion temperature lower than 600°C. In the temperature range of 600°-770°C, replacement occurs partially, hence Au and Pt coexist. When Au was diffused at a temperature higher than 770°C, Pt was completely replaced by

Fig. 4. Forward voltage drop (FVD) vs. reverse recovery time (t_{rr}). Solid lines: gold or platinum single doped. Solid circles: gold and platinum double doped.

Fig. 5. Dependence of gold or platinum concentration or of sum of them on gold diffusion temperature.

Fig. 7. Dependence of gold or platinum concentration or of sum of them on platinum diffusion temperature. Parentheses indicate the levels of the limiting concentration of DLTS measurement.

Au. Figure 6 shows the ratio (R) of N_{Au} to the sum of N_{Au} and N_{Pt} [$R = N_{Au}/(N_{Au} + N_{Pt})$] vs. Au diffusion temperature.

Sequential diffusion (Au → Pt).—In Fig. 7 N_{Au} and N_{Pt} are plotted against Pt diffusion temperatures in which Au diffusion was carried out at 875°C. In this case, a replacement phenomenon also occurred, but it was somewhat more complex than in case (a). Au was not replaced by Pt at temperatures lower than 600°C. The replacement occurred partially at around 650°C, but the replacement did not occur at around 700°C. When Pt was diffused at a higher temperature than 750°C, replacement occurred again. The sum of N_{Au} and N_{Pt} was almost constant, irrespective of Pt diffusion temperature and was equal to the initial Au concentration before Pt diffusion, as was the case for (a). Figure 8 shows R vs. Pt diffusion tempera-

ture. From these facts, it is considered that Au and Pt atoms occupy the same kinds of substitutional sites in silicon.

Simultaneous diffusion of Au and Pt.—Both Au and Pt were detected in case (c), where Au and Pt were diffused simultaneously, as shown in Fig. 9. In this case, N_{Au} and N_{Pt} were lower than the Au and Pt concentrations of the control samples (solid lines). The sum of N_{Au} and N_{Pt} was an intermediate value between the Au and Pt concentrations of the respective control samples.

Discussion

Experimental results can be interpreted qualitatively as follows:

Au and Pt occupy substitutional and interstitial lattice sites in silicon, with the former acting as lifetime killers. Diffusion of interstitial atoms is much larger than that of

Fig. 6. Dependence of concentration ratio (R) on gold diffusion temperature.

Fig. 8. Dependence of concentration ratio (R) on platinum diffusion temperature.

Fig. 9. Dependence of gold or platinum concentration or of sum of them on simultaneous diffusion temperature.

substitutional atoms. A dissociative diffusion mechanism (2, 9) and a kick-out mechanism (10) have been proposed for Au and Pt diffusion. In the dissociative diffusion mechanism, an interstitial metal atom and a vacancy are in thermal equilibrium with a substitutional metal atom. On the other hand, according to the kick-out mechanism, a substitutional metal atom and an interstitial silicon are in thermal equilibrium with an interstitial metal atom.

In the case of Au and Pt dual diffusion, we assume the following reaction

Sources of Au_{int} and Pt_{int} are Au and Pt deposited on the surface of the silicon. Sinks for Au_{int} and Pt_{int} should be dislocations at the surface, or some other kind of defect.

In addition to these sinks and sources, we should assume that other kinds of sinks and sources of Pt_{int} exist, because an instability in resistivity was detected in Pt-doped specimens on low temperature annealing. Figure 10 shows (a) the spreading resistance of Pt-diffused silicon wafer and (b) that of the wafer annealed at 730°C after Pt diffusion. As shown in Fig. 10a, the spreading resistance was almost constant inside the wafer (>50 μm depth). But when it was annealed at about 730°C, the spreading resistance increased and the distribution became irregular. This change of resistance was observed only when it was annealed at around 700°C. When this wafer was annealed again at high temperature, *e. g.*, 900°C, the resistance became constant again, as shown in 10c. The change in resistance occurs reversibly and indicates that some kind of complex state exists in silicon. This state is stable only around 700°C and has a trap level showing a compensating effect on the resistivity which results in the increase of the spreading resistance. This state can be assumed to be a complex compound. We designate this state as $\text{Pt}_{\text{complex}}$ and show the reaction again as follows

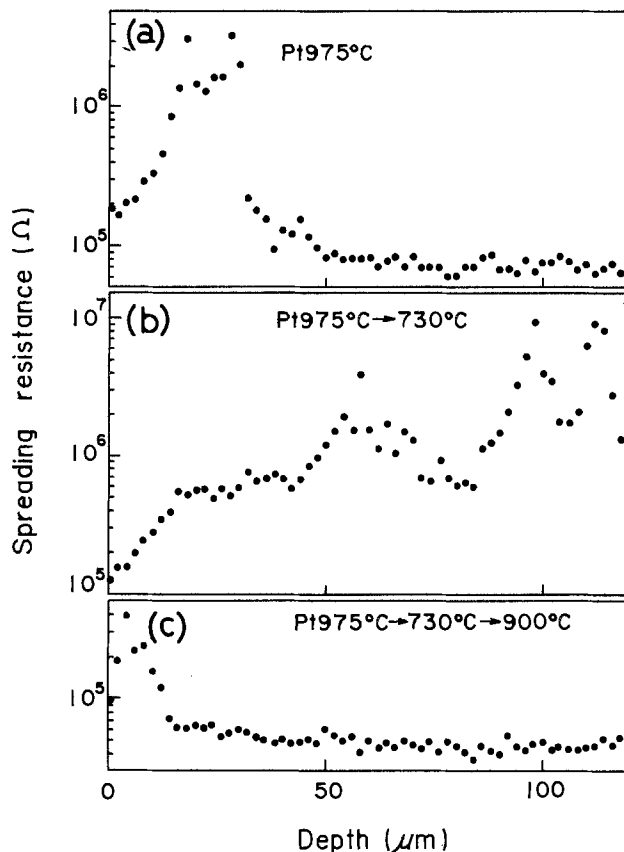

Fig. 10. Distribution of spreading resistance: (a) platinum diffused at 975°C; (b) platinum annealed at 730°C after platinum diffusion; (c) platinum annealed again at 900°C after platinum diffusion and 730°C annealing.

In this reaction, Pt_{int} changes $\text{Pt}_{\text{complex}}$ greatly only around 700°C.

In case (a), Au_{int} diffused into silicon with a large number of Pt_{sub} . Then Pt_{sub} was replaced by Au_{int} . Therefore, Au_{int} and Pt_{sub} decrease, while Au_{sub} and Pt_{int} increase by the replacement until they reach thermal equilibrium state. The increase in Au_{sub} is equal to the decrease in Pt_{sub} . When Au was diffused at a higher temperature, Au_{int} increased; hence, the replacement of Pt_{sub} by Au_{sub} increases with Au diffusion temperature. When Au diffusion is performed at nearly 700°C, Pt_{int} changes to $\text{Pt}_{\text{complex}}$, and the replacement of Pt_{sub} by Au_{sub} increases. At a temperature higher than 700°C, Pt_{int} does not change to $\text{Pt}_{\text{complex}}$. However, the replacement is not retarded because the number of Au_{int} is larger at these temperatures.

In case (b), the replacement of Pt_{sub} for Au_{sub} increases with the increase of Pt diffusion temperature. But when Pt diffusion is performed at around 700°C, Pt_{int} changes to $\text{Pt}_{\text{complex}}$, hence the replacement of Pt_{sub} for Au_{sub} is stopped. At higher temperatures than 700°C, Pt_{int} does not change to $\text{Pt}_{\text{complex}}$, hence the replacement of Au_{sub} to Pt_{sub} occurs again.

Summary

Dual diffusion of Au and Pt into silicon was examined. Measurement of trap energy levels and trap concentrations was performed by DLTS. Results obtained in this paper are summarized here.

1. When Au and Pt coexist in silicon, two levels of Au, $E_c - 0.54$ eV and $E_v + 0.35$ eV, and two levels of Pt, $E_c - 0.22$ eV, and $E_v + 0.30$ eV, are observed. New levels arising from the interaction of Au and Pt are not found.
2. In the case of sequential diffusion, replacement of the first diffusant atoms in substitutional sites by the second ones is found to occur in the lower temperature range of the second diffusion. (i) Replace-

ment does not occur below 600°C of the second diffusion temperature. (ii) Replacement is almost complete above 800°C of the second diffusion temperature. (iii) In the second diffusion temperature range between 600° and 800°C, replacement occurs partially, and the sum of substitutional Au and Pt atoms is constant, irrespective of the second diffusion temperatures, and equals the number of substitutional atoms of the first diffusant.

Vaporization Chemistry and Thermodynamics of the MnS-In₂S₃ System by the Simultaneous Knudsen and Torsion-Effusion Method

J. P. Botor¹ and J. G. Edwards*

Department of Chemistry, University of Toledo, Toledo, Ohio 43606

ABSTRACT

The MnS-In₂S₃ system was investigated in the temperature range of 1065-1246 K by measurements of vapor pressures with the computer-automated simultaneous Knudsen and dynamic torsion-effusion method. This study was the first investigation of vaporization chemistry and thermodynamics of the Mn-In-S system. Between compositions corresponding to In₂S₃ and MnIn₂S₄ the vaporization reaction was In₂S₃(s) = In₂S(g) + S₂(g). For this vaporization reaction, third-law analyses gave $\Delta H^\circ(298\text{ K}) = 617.9 \pm 0.9$ kJ/mol, in good agreement with the literature. Between compositions corresponding to MnIn₂S₄ and MnS, the vaporization reaction was MnIn₂S₄(s) = MnS(s) + In₂S(g) + S₂(g). Third-law analyses gave $\Delta H^\circ(298\text{ K}) = 633.0 \pm 1.0$ kJ/mol. Over the first vaporization reaction, the apparent molecular weight of the vapor was 184.7 ± 3.4 , and over the second, it was 178.3 ± 3.7 . The average molecular weight of In₂S(g) + S₂(g) is 181.5. The $\Delta H^\circ(298\text{ K})$ of combination of 1 mol of MnS(s) with 1 mol of In₂S₃(s) to give MnIn₂S₄(s) was -15.1 ± 2.0 kJ/mol. This value was justified by those for other ternary metal sulfides of the type M^{II}M₂^{III}S₄(s).

The sulfides of transition metals have been the subject of extensive investigation, with particular emphasis put upon the structures, phase equilibria, and electrical and magnetic properties of the solid phases. The compound MnIn₂S₄ was first reported by Hahn and Klingler (1) and later by several investigators, including Schlein and Wold (2) and Kanomata and Ido (3), who reported preparation, crystallographic studies, and electrical and magnetic properties of several indium thiospinels. MnIn₂S₄ has a mixed spinel structure with lattice constant $a = 10.69$ (1), 10.72 (2), or 10.71 Å (3). Electrical resistivity measurements at room temperature indicate that MnIn₂S₄(s) is a semiconductor with resistivity greater than $10^5 \Omega\text{ cm}^2$. It is paramagnetic down to 4.2 K. The magnetic interactions that occur in MnIn₂S₄ are primarily antiferromagnetic with negative Weiss constant at -78 K (2, 3). No information is available on the thermodynamics of the system MnS-In₂S₃, except at the binary extremes.

Considerable information about the thermodynamic properties of MnS and In₂S₃ is available, and much of it has been tabulated by Mills (4). The vapor pressure of MnS is much lower than that of In₂S₃; the vapor pressures are 1 Pa at 1616 K and 1090 K for MnS (8) and In₂S₃ (12), respectively. The vaporization of MnS(s) has been studied by several investigators (4), including Wiedemeier and Schäfer (5), who used the Knudsen effusion method, Colin *et al.* (6), who used mass spectrometry, Wiedemeier and Gilles (7), who also used mass spectrometry, and Viswanadham and Edwards (8), who used simultaneous

Knudsen and torsion effusion. The vaporization reaction was found to be

The vaporization of In₂S₃(s) has been investigated by Colin and Drowart (9) and Miller and Searcy (10, 11), who used mass spectrometry, and by Haque *et al.* (12), who used simultaneous Knudsen and torsion effusion. The vaporization reaction was congruent by

Standard enthalpies of vaporization at 298 K of reaction [2] were 602 ± 13 kJ/mol (9), 617 ± 13 kJ/mol (10), and 613.4 ± 3.0 kJ/mol (12), respectively.

The purposes of this investigation are to learn the vaporization reaction of MnIn₂S₄(s), to use the simultaneous Knudsen-effusion and torsion-effusion methods to measure the vapor pressures, and to calculate equilibrium constants of the vaporization reactions as functions of temperature and then calculate the thermodynamic properties of the vaporization reactions and the reactants and products therein.

Experimental

Samples.—Solid samples with compositions ranging from MnS to In₂S₃ in increments of 10 mole percent (m/o) on the basis of these formulas were prepared by heating the elements in evacuated, sealed, Vycor tubes. The samples were prepared by directly combining stoichiometric amounts of manganese metal powder (purity greater than 99.4%) (Fisher Scientific Company) with indium wire (Indium Corporation of America) and sulfur

*Electrochemical Society Active Member.

¹Present address: Institute of Non-Ferrous Metals, Gliwice, Poland.

(Johnson Matthey Chemicals Limited) (purities greater than 99.99%).

The samples were obtained as polycrystalline, single-phase products after three successive 48h heating periods at temperatures of 400°, 700°, and 1000°C. Each sample was quenched in water. The products were ground with an agate mortar and pestle and stored in a vial inside a desiccator over CaSO₄. Each sample was analyzed for phase content by x-ray powder diffractometry.

Preliminary effusion experiments.—To establish the vaporization reaction of MnIn₂S₄(s), two samples of compositions 10 and 50 m/o MnS were heated under vacuum of 10⁻⁶ torr in graphite effusion cells. Each experiment consisted of several successive heatings, with examination of the sample residue after each heating.

Each preliminary experiment involved the following steps, except as noted below. The Knudsen cell containing the sample was weighed and placed in the vacuum system, and the system was evacuated. The cell was heated for 10-25h (with one exception, when the time was 4h) at 1023 ± 10 K or 1123 ± 10 K. At the end of each heating, the power was switched off and the sample was allowed to cool by radiation. After several hours, when the sample was at room temperature, the system was brought to atmospheric pressure with nitrogen gas, and the cell was removed and weighed. The cell lid was removed, and samples for x-ray analysis were taken from the surface and from the bulk of the residue. The details of the procedure and results of these experiments can be found in Table I. The table's first column gives the sample designation. The second through eighth columns give, respectively, number of the successive heating, initial composition of the sample, mass of the sample, time, temperature, rate of mass-loss, and phases present after heating.

Apparatus.—The apparatus used for vapor-pressure measurements has been described (13, 14). It consists of a dynamically operated torsion-effusion pendulum suspended from one pan of an automatic vacuum semimicrobalance with paper strip-chart output. Data from the pendulum and the strip chart are acquired automatically by a laboratory computer.

Two graphite torsion-effusion cells labeled "1" and "2" were used. The design of the cells has been described (12). Graphite cell 1 had diverging right-circular-conical orifices with semiapex angles of about 30° drilled with a conical tool. The two orifices in cell 2 were cylindrical. The cells were cleaned and then outgassed under vacuum in a radio-induction furnace at 1400 K for about 24h. Moment arms of the orifices and thicknesses of the walls in which orifices were drilled were measured with a traveling microscope. The transmission probability and recoil force factors of the orifices were calculated with computer programs using equations from Freeman and Edwards (15).

Temperatures were measured with a Pt, Pt-10%-Rh thermocouple in a dummy cell identical in design and materials to the torsion-effusion cell. The two cells were

placed symmetrically, the torsion cell above and the dummy cell below the center of the furnace and separated by about 2 mm. The thermocouple was calibrated by observing the temperature of the dummy cell with the thermocouple and a calibrated optical pyrometer. This procedure introduced uncertainties of ± 4 K into the temperature measurements.

The torsion constants, *k*, of the fibers were calibrated before and after each set of vapor pressure measurements by the usual method (12) of observing the period, *τ*, of a calibration pendulum suspended from the fiber.

Data collection and treatment.—On the basis of results from the preliminary heating experiments (Table I), the vaporization of the ternary compound MnIn₂S₄(s) was taken to be incongruent by the reaction

The vaporization reaction of In₂S₃(s) was assumed to be congruent by reaction [2].

Two sets of experiments were done, each with a different sample and effusion cell. The set of experiments with cell 1 will be called set Y and that with cell 2 will be called set Z. The composition region in which the vaporization reaction is given by Eq. [2], where In₂S₃(s) and MnIn₂S₄(s) are in equilibrium with the vapor, will be denoted as region I. The composition region in which the vaporization reaction is given by Eq. [3], where MnIn₂S₄(s) and MnS(s) are in equilibrium with the vapor, will be denoted as region II.

In set Y and set Z, 380 mg of sample were loaded into the effusion cell. In set Y, 190.2 mg of the sample were placed in the first chamber of the cell and 189.2 mg were placed in the second. In set Z, 190.0 mg of the sample were placed in each chamber of the cell. In set Y, the initial sample composition was 40.0 m/o MnS and 60.0 m/o In₂S₃; in set Z, it was 10.0 m/o MnS and 90.0 m/o In₂S₃. Experiments were done in region I and then, as the composition of the solid sample changed, in region II.

Data acquired in the course of each effusion experiment was taken from three types of measurements: (a), the temperature of the effusion cell; (b), the mass of the torsion-effusion pendulum and the time; and (c), the times at which the torsion-effusion pendulum was at a number of preset positions.

The torque, *Q_e*, caused by effusion of vapor from the effusion cell was obtained from the time vs. pendulum-position measurements by a least squares fit of the ideal-torsion-pendulum equation to the data, as previously described (13, 14, 16). The torsion pressure, *P_T*, was calculated (17) with the equation

$$P_T = 2Q_e / (d_1 F_1 A_1 + d_2 F_2 A_2) \quad [4]$$

where the subscripts 1 and 2 identify the effusion orifices, and *d* is the moment arm of the orifice, *A* its area, and *F* its recoil force correction factor (15).

The Knudsen vapor pressure, *P_K*, was calculated from the measured temperatures, *T*, and the rate of mass loss,

Table I. Results of preliminary effusion experiments

Sample	Successive heating	m/o MnS	Mass of sample/mg	Time (min)	T/K (± 10)	Rate of mass loss (mg/min)	Phases present after heating

dg/dt , with the Knudsen equation

$$P_K = (dg/dt)(2\pi RT/M^*)^{1/2}/(W_1A_1 + W_2A_2) \quad [5]$$

in which M^* is the assigned molecular weight of the effusing vapor and W is the transmission probability of the orifice (15).

Vapor pressures were converted to reaction quotients of reactions [2] and [3] with the equation

$$Q_P = P_{\text{In}_2\text{S}_3} P_{\text{S}_2} \quad [6]$$

$$= 0.221P^2 \quad [7]$$

The apparent molecular weight M of the effusing vapor was calculated (17) from

$$M = M^*(P_K/P_T)^2 \quad [8]$$

The assigned molecular weight can be any positive real number, but in order to produce accurate Knudsen pressures, M^* was set equal to the average molecular weight \bar{M} of In₂S₃ vapor effusing by either reaction [2] or reaction [3]. \bar{M} was calculated (17) from the equation

$$\bar{M} = \left(\sum_{j=1}^n m_j M_j^{-1/2} \right)^{-2} \quad [9]$$

where n is the number of species effusing, m_j is the mass fraction, and M_j is the molecular weight of species j in the effusing vapor. The result for In₂S₃ vapor was $\bar{M} = 181.5$.

Pressures were observed to vary as functions of orifice area in comparing results from sets Y and Z. The vapor pressures, P_i , in the effusion cell were related (18) to vapor pressures, P_o , at a given temperature in a hypothetical cell with orifice area of zero by

$$P_o = P_i (1 + WA/\alpha A_s)_i \quad [10]$$

where A is the orifice area, W is the transmission probability of the orifice, A_s is the vaporizing sample area, and α is the condensation coefficient of the vaporizing sample.

In each region, and for each type of measurement, *i.e.*, in four cases in each set, values of P_Y and P_Z were obtained from least squares fits of $\log P$ vs. $1/T$ at five equally spaced temperatures in the experimental range. Values of P_o at a given temperature were obtained by extrapolation of a straight line through the two points from sets Y and Z on a plot of P_i vs. $(PWA)_i$, with $i = Y$ and Z. The uncertainty of P_o was calculated from the standard deviations of P_Y and P_Z . In each case, average ratios of P_Y/P_o and P_Z/P_o were calculated from both torsion and Knudsen results. In each case, the resulting five values of P_o were substituted into Eq. [7], and the assumption was made that the resulting reaction quotient was the corresponding equilibrium constant, K_p .

The equilibrium pressures were calculated from the equation

$$P_{\text{eq}} = 0.942P_o \quad [11]$$

Least squares, straight-line fits were made to the equation

$$\log P_{\text{eq}} = -C/T + D \quad [12]$$

The uncertainty in $\log P_{\text{eq}}$ was calculated from the standard deviations in C and D from a fit of $\log P_m$ vs. $1/T$ and from the standard deviations in P_o/P_m in Table VI.

Third-law values of $\Delta H^\circ(298\text{ K})$ of the vaporization reactions were calculated from ratios of P/P_o , the measured vapor pressures and temperatures, and standard Gibbs energy functions $\Delta\phi^\circ(T)$

$$\phi^\circ(T) = -[G^\circ(T) - H^\circ(298\text{ K})]/T \quad [13]$$

with the equation [Ref. (19)]

$$\Delta H^\circ(298\text{ K}) = T\Delta\phi^\circ(T) - RT \ln(Q_P/P_a^2) + 2RT \ln(P/P_o) + 23.052RT \quad [14]$$

In Eq. [14], Q_P is the reaction quotient of the vaporization reaction from Eq. [7], the third term on the right corrects the results to zero orifice area, and the last term accounts for the fact that standard pressure is 1 atm (= 101,325 Pa).

The values of $\Delta H^\circ(298\text{ K})$ derived from a given type of measurement in each set were averaged. The uncertainty in the average $\Delta H^\circ(298\text{ K})$ was calculated from the standard deviation of the values and the standard deviations in each value resulting from the standard deviation of the ratio P/P_o in Eq. [14].

Second-law values of $\Delta H^\circ(298\text{ K})$ were obtained by a standard sigma treatment (20). Values of Gibbs energy functions for MnS(s), In₂S₃(s), In₂S(g), and S₂(g) were taken from Mills (4). The Gibbs energy functions of MnIn₂S₄(s) were estimated to be the sum of those for MnS(s) and In₂S₃(s). Values of Gibbs energy functions are given in Table II. The first column gives the temperatures, and subsequent columns give the Gibbs energy functions of In₂S₃(s), In₂S₃(g), S₂(g), MnS(s), MnIn₂S₄(s), and the vaporization reactions of In₂S₃(s) and MnIn₂S₄(s), respectively, at the temperatures in the first column.

Results

The torsion constant of the fiber used in set Y was $(3.017 \pm 0.016) \times 10^{-8}$ Nxm/rad, before and after set Y, and that used in set Z was $(3.029 \pm 0.012) \times 10^{-8}$ Nxm/rad, before and after set Z. The mensural properties of the effusion cells used in set Y and set Z are given in Table III. The first column gives the cell and orifice designation. The second through eighth columns give, respectively, the minimum orifice radius, the orifice length, the minimum orifice area, the semiapex angle, the moment arm, the transmission probability, and the recoil force correction factor.

Debye-Scherrer x-ray diffractograms of samples prepared at 10 m/o intervals and the results of the preliminary effusion experiments established that the only stable ternary compound in the MnS(s)/In₂S₃(s) system is MnIn₂S₄(s). In the composition range of 100-50 m/o In₂S₃ (region I), the solid contained In₂S₃(s) and MnIn₂S₄(s). In the range of 50-0 m/o In₂S₃ (region II), the solid contained MnIn₂S₄(s) and MnS(s). X-ray diffractograms gave no evidence of solid solution with concentration greater than 5 m/o in any of the three compounds.

Rates and amounts of mass loss between regions I and II and after region II as the solid became MnS were the best indicators of the extent of solid solutions. They showed that the solubilities of MnS in In_2S_3 and of In_2S_3 in MnIn_2S_4 , in region I, were less than 1 m/o and that the solubility of MnS in MnIn_2S_4 in region II was less than 1 m/o. However, the solubility of In_2S_3 in MnS in region II was 2.6 ± 1 m/o or 7.4 ± 3 equivalent percent. The latter numbers were surely dependent on temperature, but the method did not yield this dependence.

Figure 1 shows the results from the preliminary effusion experiments. The upper, dashed lines represent average rates of mass loss from the first experiment at 1123 K and with an initial sample composition of 50 m/o MnS. The lower, solid lines represent the same from the second experiment at 1023 K and with an initial sample composition of 10 m/o MnS. The dots represent the beginnings and ends of single heatings. The rate of mass loss decreased when the composition region changed and when the composition of pure MnS was reached. Intermediate decreases occurred when the composition during a single heating changed from one region to another.

In set Y, the vapor pressure was measured by both Knudsen effusion and torsion effusion at 22 temperatures in the range of 1065-1192 K in region I and at 56 temperatures in the range of 1091-1228 K in region II. In set Z, the vapor pressure was measured by both methods at 67 temperatures in the range of 1115-1233 K in region I and at 15 temperatures in the range of 1134-1246 K in region II.

Table IV gives results from region I, and Table V gives results from region II. In each table, columns 1, 2, 3, and 4 give the temperature of the measurements, torsion pressure, Knudsen pressure, and apparent molecular weight of the vapor, respectively. Columns 5 and 6 give third-law $\Delta H^\circ(298 \text{ K})$ values derived from torsion pressure and Knudsen pressure, respectively. Second-law results are given at the bottom of columns 5 and 6 in each table. The second-law results were not subsequently used.

Third-law $\Delta H^\circ(298 \text{ K})$ was plotted against temperature for each of the eight cases established by type of measurement, set, and region. The plots were highly scattered, but small trends were evident. Straight lines were fitted through the plots, and variations of $\Delta H^\circ(298 \text{ K})$ over the temperature range were taken from the lines. For a given set and region, the variations were always the same within 0.2 kJ/mol for the Knudsen and torsion measurements. The variations, $\Delta\Delta H^\circ(298 \text{ K})/(\text{kJ/mol})$, were: region I, set Y, -3.5 ± 4.0 , and set Z, $+1.0 \pm 4.0$; region II, set Y, -9.0 ± 4.0 , and set Z, -5.4 ± 4.0 .

Table VI gives ratios of pressures at orifice area of zero to measured pressures, as well as the condensation coefficients obtained from the estimated ratio $A/A_s = 0.01$

Fig. 1. Mean rate of mass-loss of In_2S_3 -MnS vs. the composition of MnS at 1023 and 1123 K. Evidence for two regions with two solid phases is shown.

and slopes of plots of P₁ vs. (PWA)₁ (16). The first column gives the type of measurement, and the second column gives the region. The third through sixth columns give the ratios and the condensation coefficients in sets Y and Z, respectively. Average condensation coefficients of (2.8 ± 0.5) × 10⁻² and (3.2 ± 0.5) × 10⁻² in region I and region II, respectively, can be calculated. The pressures at orifice areas of zero were 33.5 ± 19.0% higher than pressures from set Y, and 11.0 ± 15.0% higher than pressures from set Z.

After application of Eq. [11] to the torsion results from sets Y and Z, equilibrium pressure in region I was represented by

$$\log(P_{eq}/\text{Pa}) = [-(1.5518 \pm 0.00460) \times 10^4 K/T] + (14.060 \pm 0.03957) \quad [15]$$

covariance (C,D) = -1.8209

After application of Eq. [11] to the Knudsen results, equilibrium pressure in region I was represented by

$$\log(P_{eq}/\text{Pa}) = [-(1.5469 \pm 0.00917) \times 10^4 K/T] + (14.037 \pm 0.07880) \quad [16]$$

covariance (C,D) = -7.2208

The equilibrium pressure from the torsion results in region II was represented by

$$\log(P_{eq}/\text{Pa}) = [-(1.6889 \pm 0.00653) \times 10^4 K/T] + (14.910 \pm 0.05644) \quad [17]$$

covariance (C,D) = -3.6826

and the pressure from the Knudsen results was represented by

$$\log(P_{eq}/\text{Pa}) = [-(1.7009 \pm 0.01033) \times 10^4 K/T] + (15.025 \pm 0.08932) \quad [18]$$

covariance (C,D) = -9.2246

The average third-law values of ΔH°(298 K), of vaporization reactions [2] of In₂S₃(s), and of vaporization reactions [3] of MnIn₂S₄(s) are tabulated in Table VII. For vaporization reaction [2], ΔH°(298 K) is 618.3 ± 0.6 kJ/mol from torsion results and 617.5 ± 0.7 kJ/mol from Knudsen results, respectively. For vaporization reaction [3], ΔH°(298 K) is 633.2 ± 0.7 kJ/mol from torsion results and 632.8 ± 0.7 kJ/mol from Knudsen results, respectively. For vaporization reaction [2], ΔH°(298 K) = 617.9 ± 0.9 kJ/mol is selected; for vaporization reaction [3], ΔH°(298 K) = 633.0 ± 1.0 kJ/mol is selected.

From third-law selected data, the enthalpies of vaporization by reactions [2] and [3] yield the standard enthalpy, ΔH_c°(298 K), of the combination reaction

Equation [8] gives values from sets Y and Z for the apparent molecular weight of the effusing vapor of 184.7 ± 3.4 for region I and of 178.3 ± 3.7 for region II, which are in good agreement with the average molecular weight, 181.5, calculated from Eq. [9].

Discussion

The vapor pressure over the system MnS(s) – In₂S₃(s) was measured by both the torsion-effusion and Knudsen-effusion methods in each of two separate experiments in

Table VI. Pressure at orifice area of zero relative to pressures measured and condensation coefficient in set Y and set Z

Measurement	Region	Set Y		Set Z

the temperature range of 1065-1246 K. Manganese indium sulfide, MnIn_2S_4 , was found to vaporize incongruently by reaction [3] in the temperature range of 1115-1245 K. The compound MnIn_2S_4 was found in the residues from all sealed tube experiments and vaporization experiments in which the final overall compositions were between 10 m/o and 90 m/o MnS, inclusive.

Torsion-effusion equilibrium vapor pressures were given by Eq. [15] over $\text{In}_2\text{S}_3(\text{s})/\text{MnIn}_2\text{S}_4(\text{s})$ and by Eq. [17] over $\text{MnIn}_2\text{S}_4(\text{s})/\text{MnS}(\text{s})$. These values are in line with Knudsen-effusion results given by Eq. [16] and [18]. Pressures in region I in this work were 15% lower than those reported by Haque *et al.* (12) for indium sulfide which was a residue from sublimation of PbS from PbIn_2S_4 . They are only 50% lower than those measured by Miller and Searcy (10) for pure indium sulfide. In region I, $\text{In}_2\text{S}_3(\text{s})$ was in equilibrium with $\text{MnIn}_2\text{S}_4(\text{s})$. If the latter solid were significantly soluble in $\text{In}_2\text{S}_3(\text{s})$, the vapor pressure could have been lowered; however, the univariance of the vapor pressure in that region was a strong contradiction to any significant solid solution, and mass losses in the transition from region I to region II showed solid solution to be <1 m/o. An unknown ternary compound with a composition very near that of In_2S_3 might have caused the observed lower vapor pressures in our experiments. But such a compound would have to contain less than 10 m/o MnS because the initial composition of the sample in set Z was 10 m/o MnS, and it would have to exist only at high temperature because x-ray examination of samples with 10-50 m/o MnS revealed only $\text{In}_2\text{S}_3(\text{s})$ and $\text{MnIn}_2\text{S}_4(\text{s})$. The differences between our results and those of Miller and Searcy must be attributed to unknown factors.

Good agreement was found between the apparent molecular weight of the effusing vapor of 184.7 ± 3.4 for region I, 178.3 ± 3.7 for region II, and the calculated average molecular weight of 181.5. This result confirms that the vapor composition was that of In_2S_3 .

The second-law values of ΔH° (298 K) were significantly higher than those obtained by the third-law method. Differences between second- and third-law values of ΔH° (298 K) arise from temperature-dependent trends in temperature or equilibrium-constant measurements, or from wrong Gibbs-energy functions. Minor trends can produce large differences because of the temperature range involved in the second-law calculation. Trends in temperature measurements in this study were small, as indicated by the thermocouple calibration and by comparison between torsion and Knudsen results. There is little reason to suspect large temperature-dependent errors in the Gibbs-energy functions used. Small amounts of solid solution could have introduced temperature dependence into the equilibrium constant measurements, particularly in region II, where up to 7.4 ± 3 equivalent percent of In_2S_3 could have been dissolved in the MnS. A

combination of the factors above probably contributed to the differences between the two types of ΔH° (298 K). None of the factors would have a large effect on the third-law values and, thus, they were used in preference to the second-law values. For instance, the possible solid solution of In_2S_3 in MnS in region II, if ideal, would affect the third-law ΔH° (298 K) of reaction [3] by less than the ± 1 kJ/mol given for that reaction.

The standard enthalpy ΔH° (298 K) of vaporization of the ternary compound $\text{MnIn}_2\text{S}_4(\text{s})$ by reaction [3] was 633.0 ± 1.0 kJ/mol, and that of $\text{In}_2\text{S}_3(\text{s})$ by reaction [2] was 617.9 ± 0.9 kJ/mol. The ΔH° (298 K) of vaporization of $\text{In}_2\text{S}_3(\text{s})$ from this work is in good agreement with that from Haque *et al.* (12), 613.4 ± 3.0 kJ/mol, and is in reasonable agreement with the value 617 ± 13 kJ/mol calculated from the data of Miller and Searcy (10) and the Gibbs-energy functions in Table II. It is also in agreement with the value from Colin and Drowart (9), 602 ± 13 kJ/mol.

In Table VIII are compared enthalpies of combination ΔH_c° (298 K), of ternary metal sulfides of the type $\text{M}^{\text{II}}\text{M}^{\text{III}}\text{S}_4$, where $\text{M}^{\text{II}} = \text{Mn, Pb, Zn, and Cd}$, and $\text{M}^{\text{III}} = \text{Ga or In}$. The enthalpy of combination of $\text{MnIn}_2\text{S}_4(\text{s})$ from its constituent binary sulfides by reaction [19] was -15.1 ± 2.0 kJ/mol. This value is at the smaller end of the range of values for similar ternary sulfides and oxides, *i.e.*, -15 to -50 kJ/mol (16, 21-26), with the exception of $\text{CdIn}_2\text{S}_4(\text{s})$, which is a saturated ideal solid solution (26) with a normal spinel structure.

Table VIII shows that the enthalpies of combination of compounds where $\text{M}^{\text{III}} = \text{Ga}$ are higher than those of compounds where $\text{M}^{\text{III}} = \text{In}$, with the exception of ZnIn_2S_4 . The latter exception may be related to the fact that ZnIn_2S_4 has a unique structure among these compounds. It has a rhombohedral crystal structure in space group C_{3v}^5 (R3m) and may be thought of as a series of layers with strong In-S and Zn-S bonds in the layers and weak S-S bonds between the sulfur atoms belonging to different layers (27).

We cannot explain on the basis of a sound theory why the enthalpy of combination of $\text{MnIn}_2\text{S}_4(\text{s})$ is the lowest

among the listed ternary sulfide compounds. But we have observed that MnIn₂S₄(s) has a mixed spinel structure in which quenched samples have 65% of the Mn²⁺ ions in tetrahedral sites and have 35% in octahedral ones (3, 28). The paramagnetic moment of MnIn₂S₄(s) is 5.68 μB, which corresponds to 4.7 unpaired electrons on each Mn²⁺. MnIn₂S₄(s) is orange. The stable form of MnS(s) is green with the rock salt structure, which places the Mn²⁺ ions in octahedral coordination (30, 31). The paramagnetic moment of MnS(s) is 5.92 μB, which corresponds to 5 unpaired electrons on each Mn²⁺ (30, 31). Clearly, the state of Mn²⁺ in MnS(s) and MnIn₂S₄(s) is different. Indium ions, too, must accommodate a change from octahedral sites in the defect spinel, In₂S₃(s), to 17-18% tetrahedral sites in MnIn₂S₄(s). The energy promotions necessary to transform the states of the positive ions, particularly the Mn²⁺, no doubt are related to the low combination enthalpy.

It is worth noting here that in MnGa₂S₄(s), with a combination enthalpy of 39 ± 2 kJ/mol, Mn²⁺ appears to be in a state much like that in MnS(s), and Ga³⁺ appears to be in a state much like that in Ga₂S₃(s). MnS(s) is green and has a paramagnetic moment corresponding to Mn²⁺ in the high spin state (32). MnGa₂S₄(s) below 1258 K is green and has a monoclinic structure in which Mn²⁺ ions are in octahedral sites and Ga³⁺ ions are in tetrahedral sites (33). Ga₂S₃(s) has a wurtzite-like structure in which Ga³⁺ ions are in tetrahedral sites (33). The energy promotions necessary to transform the states of the positive ions in MnGa₂S₄(s) are probably lower than those for MnIn₂S₄(s). However, such qualitative observations, if valid, must also take into account the unique monoclinic structure of MnGa₂S₄(s).

Vaporization Behavior of Chromium Phosphides

The Solid Two-Phase Regions CrP-Cr₁₂P₇, Cr₁₂P₇-Cr₃P, and Cr₃P-Cr

C. E. Myers,* G. A. Kisacky, and J. K. Klingert

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13901

ABSTRACT

The vaporization reactions $24/5 \text{ CrP(s)} = 2/5 \text{ Cr}_{12}\text{P}_7\text{(s)} + \text{P}_2\text{(g)}$ (1194-1479 K), $2/3 \text{ Cr}_{12}\text{P}_7\text{(s)} = 8/3 \text{ Cr}_3\text{P(s)} + \text{P}_2\text{(g)}$ (1421-1541 K), and $2\text{Cr}_3\text{P(s)} = 6\text{Cr(s)} + \text{P}_2\text{(g)}$ (1543-1768 K) have been studied under mass-loss effusion in the temperature ranges indicated. The reactions are kinetically inhibited. Enthalpies of formation and atomization, respectively, are found to be in kK: for $1/2\text{CrP(s)}$, -5.69 ± 0.18 and 49.67 ± 0.2 ; for $1/19 \text{ Cr}_{12}\text{P}_7\text{(s)}$, -4.48 ± 0.32 and 49.47 ± 0.3 ; for $1/4 \text{ Cr}_3\text{P(s)}$, -3.18 ± 0.04 and 49.08 ± 0.04 . CrP is found to follow the trend in atomization enthalpy to valence state atoms established in the series MnP, FeP, CoP, and NiP.

The atomization enthalpy, $\Delta H_{\text{at}}^{\circ}$, of a solid compound may be used as a measure of its stability and of the strength of its chemical bonds. It has been shown (1), however, that the proper quantity is the atomization enthalpy to valence state atoms, $\Delta H_{\text{at}}^*/R$. The stability of compounds in a series should increase with the number of bonding electrons per atom. As shown in Fig. 1, $\Delta H_{\text{at}}^*/R$ (kK) exhibits a regular decrease in the series MnP (141.3), FeP (130.0), CoP (119.1), and NiP (104.4) as the number of bonding (unpaired) electrons per metal atom decreases from five in MnP to two in NiP for the presumed valence state $3d^{n-1}4s^1$, where n is the total number of valence electrons. Because Cr should have six bonding electrons in the valence state, one should expect $\Delta H_{\text{at}}^*/R$ for CrP to be proportionately larger; an extrapolation produces an estimate of about 150 kK. Trends in the enthalpies of sublimation of the metallic elements to valence state atoms, $\Delta H_{\text{at}}^*/R$, suggest an estimate of 147 kK. A mass-loss effusion study of chromium phosphides has been done to test the extrapolation.

The phase relations in the Cr-P system have been reviewed by Hansen (2), Elliott (3), and Shunk (4). Well-established compounds are Cr₃P, CrP, and CrP₂, which appear to have narrow ranges of homogeneity. Evidence for "Cr₂P" has been contradictory, but Baurecht and co-workers (5) have shown the composition to be Cr₁₂P₇ with a slight range of homogeneity.

It has been established, as shown below, that the vaporization reactions are

The enthalpy changes for these reactions, when combined with the enthalpy of formation (6) of P₂(g)

give the enthalpies of formation of the chromium phosphides

$$\Delta H_5 = \Delta H_{\text{f}}^{\circ}(\text{Cr}_3\text{P}) = 1/2 \Delta H_4^{\circ} - 1/2 \Delta H_6^{\circ} \quad [5]$$

$$\Delta H_6 = \Delta H_{\text{f}}^{\circ}(\text{Cr}_{12}\text{P}_7) = 3/2 \Delta H_4^{\circ} + 4\Delta H_5^{\circ} - 3/2 \Delta H_6^{\circ} \quad [6]$$

$$\Delta H_7 = \Delta H_{\text{f}}^{\circ}(\text{CrP}) = 5/24 \Delta H_4^{\circ} + 1/12 \Delta H_6^{\circ} - 5/24 \Delta H_6^{\circ} \quad [7]$$

Experimental

The samples used in this study were prepared in the manner described in Ref. (7), by direct combination of chromium powder (99.99%) obtained from SPEX Industries, Inc., and red phosphorus (99.9%) obtained from CERAC/Pure, Inc. The products, as well as residues from effusion runs, were characterized by x-ray powder diffraction; the observed patterns were compared with com-

puter-generated patterns (8) based on data from the literature (CrP (9, 10, 11), Cr₁₂P₇ (5), Cr₃P (9, 10, 12)). The channel-orifice effusion cells were machined from 1.59 cm graphite rod and were fitted with a tantalum liner to prevent the phosphide samples from coming into direct contact with the graphite. The effective orifice areas were measured with KCl as a vapor-pressure standard; data for KCl(g) and K₂Cl₂(g) were taken from Ref. (13). The effusion apparatus, with calibration and operation procedures, has been described previously (7, 14). It consists of a vacuum system, an induction heater, and a recording vacuum balance. For the experiments described here, the apparatus was fitted with an eddy current concentrator, and the temperatures were measured with a tungsten, 25% rhenium-tungsten, 3% rhenium thermocouple calibrated as described in Ref. (7).

Results and Discussion

The primary data¹ were temperature, corrected for thermocouple calibration, and the rate of mass loss determined from the readout of the recording vacuum balance. Individual experiments were of sufficient duration to keep the uncertainty in the slope of the mass vs. time plot less than 5%. Partial pressures of P₂(g) were calculated from the rate of mass loss (assuming that P₂ and P₄ were in equilibrium in the gas phase) with the modification of the effusion equation derived in Ref. (7)

$$P(\text{P}_2) = \frac{K}{2\sqrt{2}} \left\{ \left[1 + \frac{8m}{aK} \left(\frac{\pi RT}{M} \right)^{1/2} \right]^{1/2} - 1 \right\} \quad [8a]$$

$$= \frac{K}{2\sqrt{2}} \left\{ \left[1 + \frac{C'm}{aK} \left(\frac{T}{M} \right)^{1/2} \right]^{1/2} - 1 \right\} \quad [8b]$$

When $P(\text{P}_2)$ is obtained in atmospheres from m (the rate of mass loss) in mg/min, T in Kelvins, M (the molecular weight of P₂), and a (the effective orifice area) in cm², the constant is $C' = 2.127 \times 10^{-6}$. K is the equilibrium constant for $\text{P}_4\text{(g)} = 2\text{P}_2\text{(g)}$; this constant was calculated for each temperature from data given in Ref. (13).

Initial heating of two of the samples resulted in apparent univariant behavior at temperatures near 800 K. Further heating with loss of phosphorus developed univariant behavior in the range 1194-1479 K, and the residues from these latter experiments were shown by x-ray powder diffraction to be a mixture of CrP and Cr₁₂P₇. Further heating with additional loss of phosphorus developed both a third univariant condition (1421-1541 K) for which the residues were Cr₁₂P₇ and Cr₃P and a fourth univariant condition (1543-1768 K) for which the residues were Cr₃P and Cr. The first region was presumed to result from the decomposition of small amounts of CrP₂ from the initial preparation; this region was not studied further. The remaining three invariant regions were studied in detail, and the resulting data are shown in Fig. 2.

¹Thermochemical data in this paper are given in "rational" units; values in other units may be obtained by multiplying by the appropriate value of the gas constant, R .

*Electrochemical Society Active Member.

Fig. 1. Sublimation enthalpies of metals and atomization enthalpies (per mole) of some monophosphides to ground-state atoms and to valence-state atoms.

Data taken during the evolution of the samples from one region to another have been omitted. For these two-phase regions, effective orifice areas of $2.39 (\pm 0.06) \times 10^{-4} \text{ cm}^2$ and $8.91 (\pm 0.2) \times 10^{-5} \text{ cm}^2$ gave the same results in each region, within experimental uncertainty, and these runs were presumed to be at equilibrium. Larger orifices gave lower calculated pressures, presumably without achievement of equilibrium. The cross-sectional area of the sample was 1.76 cm^2 in all experiments. Only the equilibrium data from the three two-phase regions were used in

subsequent thermodynamic calculations. These data are presented in Tables I, II, and III, and the lines in Fig. 2 result from a least squares treatment of each set of data. For the $\text{CrP-Cr}_{12}\text{P}_7$ and $\text{Cr}_{12}\text{P}_7\text{-Cr}_3\text{P}$ regions, phosphorus was assumed to be the only volatile component, whereas in the $\text{Cr}_3\text{P-Cr}$ region, the rates of mass loss were corrected for the vapor pressure of elemental chromium.

There are neither entropy nor high-temperature heat-capacity data for chromium phosphides in the literature; hence, these were estimated. Entropy estimates were based (7) on data for chromium silicides (15, 16). Heat capacity estimates were based on data for manganese phosphides (17). These estimated values are given in Table IV. Second-law enthalpies, ΔH^{III} , were calculated for the temperature ranges of the measurements from the least squares slopes of $\log P(\text{P}_2)$ vs. $1/T$ and were corrected to 298.15 K by means of $\Delta(H^{\circ}_T - H^{\circ}_{298.15})$ evaluated from Cp. Third-law enthalpies of reaction, ΔH^{III} , were obtained by means of free-energy functions, $\Phi' \equiv -(G^{\circ}_T - H^{\circ}_{298.15})/T$, calculated from the entropy and heat-capacity data. Tables I, II, and III summarize calculations for reactions [1], [2], and [3], respectively. The agreement of respective second-law and third-law enthalpies is acceptable, partic-

	$-\Delta H_f/R$ (from red P) (kK)	$\Delta H_{\text{at}}/R$ (kK)
1/2 CrP(s)	5.69 ± 0.18	49.67 ± 0.2
1/19 Cr_{12}P_7 (s)	4.48 ± 0.32	49.47 ± 0.3
1/4 Cr_3P (s)	3.18 ± 0.04	49.08 ± 0.04
1/3 CrP_2 (s)	4.8 ± 0.7	47.5 ± 0.7

ularly in view of the limited temperature ranges imposed by the difficulty of obtaining equilibrium. Enthalpies of formation calculated from the third-law enthalpies by Eq. [5], [6], and [7] are given in Table V, together with enthalpies of atomization. Uncertainty limits were assigned in the manner described in Ref. (1). Also included in Table V are the enthalpies of formation and atomization of CrP_2 (s), based on the static vapor-pressure studies

of Faller and Blitz (19) and estimated free-energy functions.

The enthalpy of atomization of CrP to valence state atoms was obtained by adding the valence state preparation energy (18) of chromium (45.9 kK) to the ground-state atomization enthalpy. The resulting value, 145.3 kK, is in excellent agreement with the estimate, 147 kK, based on trends in $\Delta H^*/R$ of the metals. As is pointed out in Ref. (1), this result confirms a similarity in bond type in the series CrP, MnP, FeP, CoP, and NiP. The extrapolation to compounds such as ScP which have significant ionic character gives poor agreement with measured values.

Influence of Growth Temperature on the Physical Properties of Si Films on Yttria-Stabilized, Cubic Zirconia Substrates

Alice L. Lin* and Ilan Golecki*

Rockwell International, Microelectronics Research and Development Center, Defense Electronics Operations, Anaheim, California 92803

ABSTRACT

Epitaxial (100) Si films 0.4-0.5 μm thick were grown by the pyrolysis of silane in a hydrogen atmosphere on (100) yttria-stabilized, cubic zirconia (15 mole percent [m/o] Y_2O_3) at temperatures in the range 910°-1000°C and deposition rates of 0.06-0.58 $\mu\text{m}/\text{min}$. The heteroepitaxial Si films have been characterized by ultraviolet reflectance, Rutherford backscattering/channeling, and Hall effect measurements. It was found that the Si film quality depends strongly on substrate temperature. An optimum growth temperature range between 930° and 960°C was obtained and explained by two defect formation mechanisms: generation at growth temperature and that during cooling from growth temperature to room temperature. The best quality Si/YSZ films produced in this investigation had a value of surface channeling yield, χ_0 , equal to 0.048, as compared to 0.1 for Si/YSZ films reported previously, and 0.12 for typical commercial SOS films, respectively, at 1.5 MeV $^4\text{He}^+$ energy.

Single-crystal silicon films on insulating substrates (SOI) offer many advantages over bulk single-crystal silicon for use in fabricating high speed, very large scale integrated circuits (VLSI); these advantages include low parasitic capacitance, increased radiation hardness, and low power dissipation. The current state-of-the-art SOI material, available commercially in 3 and 4 in. diam wafers, is chemically vapor-deposited (CVD) (100) Si film on (01 $\bar{1}2$) sapphire (SOS), first developed at Rockwell International (1). Submicron-thick SOS films are routinely used in the electronics industry for fabricating high speed, radiation-hard VLSI.

Yttria-stabilized cubic zirconia, $(\text{Y}_2\text{O}_3)_m(\text{ZrO}_2)_{1-m}$, single crystal is potentially a better bulk insulator substrate for growing heteroepitaxial Si film, (Si/YSZ), than sapphire substrate, (SOS) (2). The lattice mismatch between Si and sapphire is about 10%, whereas between Si and YSZ it can be as low as 3.7% by properly adjusting the yttria content. Moreover, constituents of YSZ, such as zirconium and yttrium, do not form shallow levels in silicon. Zirconium, as a group IVB element, is electrically inactive in silicon (3). Yttrium has been known to create deep levels in Si (4). However, the reported concentration of these deep levels is very low, on the order of 10^{13} cm^{-3} (4). Sapphire, however, is well known to act as a source of Al shallow acceptors in Si during CVD and subsequent high temperature processing (5), although state-of-the-art, as-deposited SOS films contain less than $10^{15} \text{ Al}/\text{cm}^3$. Epitaxial Si/YSZ films have been achieved in our laboratory (6, 7). Film crystal quality is indeed found to be better than commercial SOS films in the thickness range 0.4-0.5 μm (6, 7).

One possible drawback of using YSZ material as a substrate for Si film deposition is the high thermal expansion coefficient of YSZ material. The average value between 25° and 1000°C is $11.4 \times 10^{-6}/^\circ\text{C}$ for YSZ with 9 mole percent (m/o) of Y_2O_3 (8, 9) as compared to $3.8 \times 10^{-6}/^\circ\text{C}$ for Si (10). In order to reduce the strain and the lattice defects created in Si film during cooling from growth temperature to room temperature, it is desirable to grow the Si film at a temperature as low as possible. The present work attempts to further improve the Si/YSZ film quality by investigating the optimum growth temperature. The heteroepitaxial Si films have been characterized by UV reflectance, Rutherford backscattering/channeling, and Hall effect measurements. We have obtained an optimum growth temperature ranging between 930° and 960°C. The Si/YSZ films produced in this temperature range have crystal quality better than that of commercial SOS films and Si/YSZ films reported previously (6, 7) of similar thickness.

Experimental Procedures

Single-crystal $(\text{Y}_2\text{O}_3)_m(\text{ZrO}_2)_{1-m}$ boules grown by the skull melting technique (11) at 2700°C in air were obtained

from Ceres Corporation (North Billerica, Massachusetts) and Singh Industries, Incorporated (Cedar Knolls, New Jersey). Nominal yttria mole fraction, m , in YSZ material used in this study was 0.15 and 0.21. The as-received boules were transparent, with an increasingly yellowish hue as the concentration of yttria increased. No gross defects were visible to the eye. The boules were oriented parallel to the $\langle 100 \rangle$ axis to within a few degrees by standard x-ray back-reflection Laue technique (12) and then mounted on an automatic, diamond-blade saw. An 18 mil thick slice was cut off. This was reoriented. The boule was realigned on the saw. The procedure was repeated to obtain a final orientation within less than 1° of the desired crystal axis. After the desired orientation had been obtained, wafers 18 mil thick were sliced from each boule. They were then lapped using mixtures of Al_2O_3 powders of progressively finer particle size in colloidal silica and chemically mechanically polished in a mixture of colloidal silica and phosphoric acid, at pH = 3-4, to obtain specular surface finish. The size of the wafers was larger than 10 cm^2 , but their shapes were irregular. After polishing, wafers were degreased in hot trichloroethane, acetone, and methanol and blown dry with nitrogen gas prior to being loaded in the CVD reactor.

The epitaxial reactor was a vertical, cold-wall quartz reactor containing a 57 mm diam, silicon-carbide-coated graphite susceptor, which was RF heated. The susceptor was rotated continuously during Si growth in order to minimize lateral thermal gradients. Silicon films were deposited through pyrolytic decomposition of silane, SiH_4 (5% in He) in Pd-purified H_2 at atmospheric pressure. Both gases passed through cold traps, acetone (218 K) and liquid nitrogen (78 K) for SiH_4 and H_2 , respectively, before being admitted into the reactor. Typical gas flow rates used were 10-100 cm^3/min and 3000 cm^3/min for SiH_4 and

Fig. 1. SEM photographs of a Si/YSZ film (15 m/o Y_2O_3) 0.53 μm thick, grown at 930°C (a) and a commercial SOS film 0.55 μm thick (b).

H₂, respectively. Before each growth experiment, the quartz reactor was evacuated to at least 10⁻³ torr pressure, and then filled with purified flowing H₂ prior to heating the susceptor. Temperature was monitored on the side of the susceptor using an optical pyrometer. Values given here are uncorrected readings; previous calibrations (13) had shown that the actual wafer temperature on the top of the susceptor was 33°-50°C lower at 950°-1075°C, respectively. Before Si deposition at 910°-1000°C, substrates were annealed in H₂ at ≈ 1250°C for 30 min. As reported earlier (6, 7), this predeposition, high temperature annealing in H₂ resulted in a YSZ substrate with better crystalline perfection and an oxygen-deficient composition. It avoided the presence of oxygen near the substrate surface during Si deposition, which otherwise might have evolved out of the YSZ, reacted with the SiH₄ and H₂ to generate SiO₂ at the surface, and impeded epitaxy. Si films grown in this study were in the 0.4-0.5 μm thickness range. The growth rate was 0.06-0.58 μm/min.

The thickness of the heteroepitaxial Si films was measured routinely with the Nanospec spectrophotometric reflectometer (Nanometrics, Incorporated), using Rutherford backscattering spectroscopy (RBS) for calibration.

The Si surface quality was examined by optical microscopy with a Nomarski interference attachment and by scanning electron microscopy. It was also quantified by the value of ultraviolet reflectance (UVR) parameter, ΔR, which was measured by using an RCA UV reflectometer (14). This instrument measured the difference in reflected intensity from a well-polished, high quality Si wafer and from the sample, and normalized to the lamp intensity of wavelengths of 280 and 400 nm. The value of reflectance parameter, ΔR, was obtained by subtracting the signal level at 280 nm, R₂₈₀, from that at 400, R₄₀₀. It had been found that ΔR was related not only to the surface roughness of the Si films, but also to the crystalline quality, especially the microtwin density of certain SOS films (14).

Depth profiles of the concentration of crystallographic imperfections in the Si/YSZ films were measured by Rutherford backscattering and channeling spectrometry (RBS/C) using 1.5 MeV ⁴He⁺ ions. In particular, the technique of grazing-exit detection (15) of the backscattered ⁴He⁺ particles was shown to largely overcome the basic difficulties inherent in analyzing a low mass film on a heavy mass substrate by RBS.

Hall coefficient and conductivity were measured using six-contact, standard Hall bar by a low noise, high sensitivity, computer-controlled Hall apparatus. The system consisted of four unity-gain high input-impedance amplifiers for each of the four potential lines from the Hall bar, a HP 4140B PA meter/dc voltage source, a HP 3456A digital voltmeter, a Digital Equipment MINC-23 computer/controller, a Varian magnet with Model V2900 regulated power supply, and an Air Products displax closed-cycle refrigeration system. Prior to electrical measurement, samples were degreased, dipped into 10% HF solution for 10 min, rinsed in methanol, blown dry with N₂ gas, and then soldered with In contacts.

Results and Discussion

The thickness of the Si films deposited in this study was in the range of 0.4-0.5 μm, and its uniformity was found to be better than ±5%. The surfaces of the heteroepitaxial Si films grown in this study were specular. Under optical microscopy with a Nomarski interference attachment, Si films grown between 930° and 980°C in general, showed no gross features except a grainy appearance similar to that observed in SOS films. Figure 1 compares the surface morphology of a Si/YSZ film grown at 930°C to that of a commercial SOS film of similar thickness. Si/YSZ films grown at 910° and at 1000°C often showed hillocks on the surface. Results presented in this paper were mainly those of epitaxial (100) Si films grown on (100) YSZ (15 m/o Y₂O₃) substrates. Similar results were also obtained for (100) Si/YSZ (21 m/o Y₂O₃) films grown under the same conditions.

Growth rate.—The dependence of growth rate on substrate temperature is shown in Fig. 2 for gas flow rates of 10 and 3000 cm³/min for SiH₄ and H₂, respectively. The curve shown in Fig. 2 is found to be similar to that reported for homoepitaxial Si films grown on silicon substrate by the pyrolysis of silane (16, 17). Two temperature regions can be distinguished; from 930° to 1000°C; the growth rate is relatively temperature independent. This indicates that gas-phase diffusion of reactants controls the growth process (17). Below 930°C, the growth rate becomes strongly dependent on temperature, suggesting that a thermally activated surface reaction limits the growth process (17). The activation energy calculated from the line at curve of growth rate vs. the reciprocal temperature is ±51 kcal/mol, which is higher than 37 kcal/mol reported for growing homoepitaxial Si film at low temperature (16, 17). In growing Si/YSZ films at low temperature, it is not clear which surface reaction, such as absorption of silane, dehydrogenation of the absorbed silane, or surface diffusion and incorporation of Si adatoms into the lattice, is the rate-limiting step.

UV reflectance.—UVR was used routinely as a rapid tool for quantifying the Si surface quality. Figure 3 shows the growth temperature dependence of relative reflectance from Si films measured at 280 nm, R₂₈₀. Most of the Si films presented here were deposited at a rate of 0.11 ± 0.01 μm/min. At 945° and 910°C, growth rates of both 0.11 and 0.58 μm/min, and of both 0.11 and 0.06 μm/min, respectively, were studied.

It was found that, by varying the growth temperature from 910° to 1000°C, the value of R₂₈₀ started to decrease, reaching a minimum at growth temperature in the range of 930°-960°C, and then increasing at higher temperature. Varying growth rate between 0.06 and 0.58 μm/min showed no effect on surface quality of Si/YSZ films measured by UVR technique. At 1000°C, R₂₈₀ data were scattered, which may be caused by the scattering of light from those hillocks found on the surface. As mentioned earlier, R₂₈₀ corresponded to the difference in reflected intensity from a well-polished, high quality Si wafer and from the Si/YSZ films. Lower R₂₈₀ values indicated a surface quality of Si/YSZ films to be closer to the one of a well-polished, high quality Si wafer. Thus, the optimum growth temperature, as far as surface quality was concerned, was in the range of 930°-960°C. Values of R₂₈₀ for the Si/YSZ films grown in this temperature range were 10-15, as compared to 16-40 for commercial available SOS films of similar thickness, measured by the same UV reflectometer.

Figure 4 shows the dependence of reflectance parameter ΔR (R₂₈₀ - R₄₀₀) on the growth temperature. Again, an optimum growth temperature in the range of 930°-960°C was obtained. The best quality Si/YSZ films produced in

this study had values of ΔR close to -10 , as compared to 0-10 for standard commercial SOS films.

At growth temperatures from 930° to 1000°C, both Fig. 3 and 4, as well as Fig. 7 and 8 in the following sections, show that the surface quality of Si/YSZ films decreases with increasing substrate temperature. As discussed in the last section, the growth of Si/YSZ films in this temperature region is limited by the gas-phase diffusion of reactants towards the growing surface. It suggests that the majority of the defects in Si/YSZ films grown at this

temperature region are generated during cooling from growth temperature to room temperature, and are due to the differences in thermal expansion coefficients of Si and YSZ. In this temperature region, surface reactions, such as adsorption and desorption of gas species, surface diffusion, and incorporation of Si adatoms into the lattice, are relatively fast. The as-deposited Si films at growth temperature must have relatively good quality. As they cool from growth temperature to room temperature, those films grown at high temperature suffer larger thermal compression force, and thus result in larger defect formation.

The surface quality of Si/YSZ films grown below 930°C decreases with decreasing temperature. As discussed earlier, in this temperature region, growth of Si/YSZ films is limited by surface reaction. This suggests that increasing number of defects in Si/YSZ films grown in this temperature region is formed during deposition. As growth temperature is lowered, surface reaction of atoms decreases, leading to an increase in defect formation.

Rutherford backscattering/channeling.—Quantitative depth profiles of the crystalline perfection of selected Si/YSZ films were measured by RBS/C, using 1.5 MeV ⁴He⁺ ions, with a variable scattering-angle detection system. The Si films were first aligned and measured in the glancing exit mode (scattering angle $\theta = 95^\circ$ - 108°). This geometry enabled the top half of submicron-thick Si/YSZ films to be measured without the high intensity, interfering background from the heavy elements Y and Zr in the substrate, and with high depth resolution (15, 18). Figure 5 (curve Si/YSZ) illustrates the result of energy spectra of 1.5 MeV ⁴He⁺ ions, backscattered at 102.5° from a 0.45 μm thick, epitaxial (100) Si/YSZ films grown at 960°C and 0.09 $\mu\text{m}/\text{min}$. After the low scattering angle measurement, the surface-barrier detector was positioned at a larger scattering angle ($\theta = 150^\circ$ - 168°), and the channeling spectra were remeasured without the need to realign the sample with the ⁴He⁺ analyzing beam. This latter geometry provided useful information on the crystal quality of the Si films throughout their thickness, and especially near the Si/YSZ interface. Figure 6 illustrates the energy spectra of 1.5 MeV ⁴He⁺ ions, backscattered at 150° from the same Si/YSZ sample shown in Fig. 5. The concentration of the dechanneling defects present in the Si/YSZ films increased rapidly with depth, and was highest at the Si/YSZ interface, similar to the one found in SOS films.

The effect of growth temperature on surface channeling yield, χ_0 , of Si/YSZ films is shown in Fig. 7. Although four Si/YSZ samples were selected for characterization by the Rutherford backscattering channeling technique, the data shown in Fig. 7 confirm the results taken by the UVR technique shown in Fig. 3 and 4. The χ_0 vs. growth temperature curve can be characterized into two regions. At the lower growth temperature region, the surface quality of Si/YSZ films increases with increasing growth temperature. It then decreases with increasing temperature at high growth temperature. The optimum growth temperature found in Fig. 7 is roughly in the range of 940°-960°C. In this investigation, we have obtained Si/YSZ films in the 0.4-0.45 μm thickness range, with a value of χ_0 equal to 0.048, as compared to 0.1 and 0.12 for Si/YSZ films reported previously (6, 7) and for typical commercial SOS films, respectively.

Figure 5 compares the energy spectra of 1.5 MeV ⁴He⁺ ions, backscattered at 102.5° from a 0.45 μm thick, (100) Si/YSZ film grown at 960°C, a state-of-the-art, commercial (100) SOS film of similar thickness, and a (100) bulk Si. This particular Si/YSZ film was the highest quality (100)-oriented film of this thickness characterized by RBS/C under this program. A number of other (100) Si/YSZ films had similar crystal quality. The SOS sample selected for comparison was the best in this thickness range that we have measured out of a large number of commercial wafers, grown under various conditions in the last 5 yr. Surface channeling yields, χ_0 , and average

NEAR-SURFACE CRYSTALLINE QUALITY OF 0.45 μm Si/YSZ, SOS, AND BULK Si

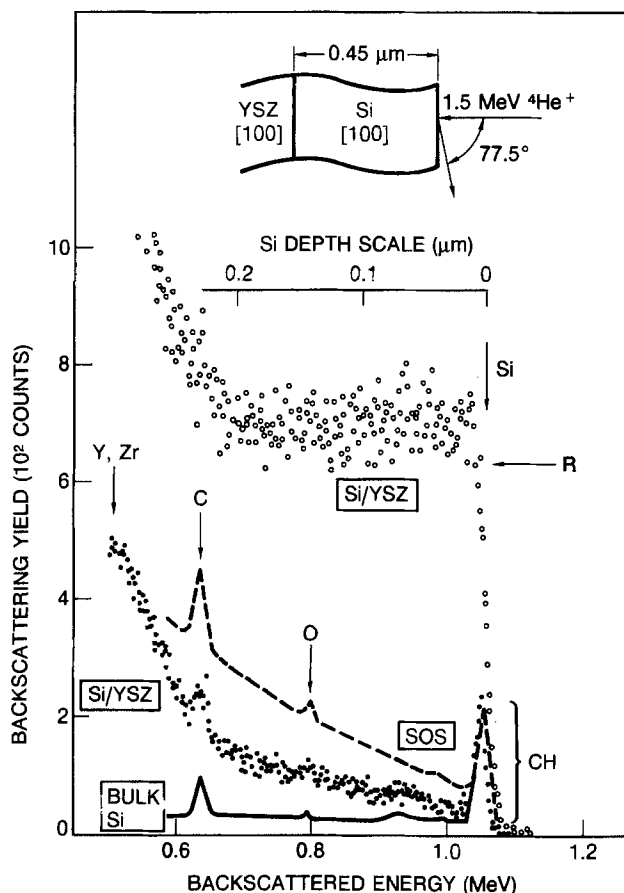

Fig. 5. Energy spectra of 1.5 MeV $^4\text{He}^+$ ions, backscattered at 102.5° from (top) a $0.45 \mu\text{m}$ thick, epitaxial (100) Si/(100) $(\text{Y}_2\text{O}_3)_{0.15}(\text{ZrO}_2)_{0.85}$ film grown at 960°C and $0.09 \mu\text{m}/\text{min}$, (middle) a state-of-the-art, commercial (100) Si/(0112) Al_2O_3 film of similar thickness, and (bottom) a (100), bulk Si single crystal. The small oxygen signal, marked O, is due to the native Si surface oxide; the carbon signal, marked C, is due to a slight contamination by the analyzing beam, and neither of these surface layers results in any measurable dechanneling. See Table I for χ_0 and $d\chi/dz$ values.

dechanneling rates, $d\chi/dz$, calculated for the samples shown in Fig. 5 are summarized in Table I. It is clear that the surface and near-surface crystal quality of the (100) Si/YSZ films grown in our laboratories are far superior to that of state-of-the-art, commercial CVD (100) SOS films of similar thickness. In fact, it is very close to that found in defect-free, (100) bulk Si, although this does not imply that no defects, such as dislocations, are present at the surface of the Si/YSZ films. For both Si/YSZ films and SOS films, the concentration of the dechanneling defects increases rapidly with depth, and is highest at the Si/insulator interface.

Conductivity and Hall mobility.—The undoped Si/YSZ films grown in this study were n-type, high resistivity

Table I. Surface channeling yields, χ_0 , and average dechanneling rates, $d\chi/dz$, for the best quality $0.45 \mu\text{m}$ thick (100) Si/(100) $(\text{Y}_2\text{O}_3)_{0.15}(\text{ZrO}_2)_{0.85}$ film, a commercial state-of-the-art CVD (100) Si/(0112) Al_2O_3 film of similar thickness, and bulk, defect-free (100) Si, measured with 1.5 MeV $^4\text{He}^+$ ions

Sample	χ_0	$d\chi/dz$ (μm^{-1})	
		0-0.2 μm	0-0.45 μm
Si/YSZ	0.048	0.7	1.1
SOS	0.12	1.1	1.3
Bulk Si	0.034	0.062	0.062

EPITAXIAL Si ON $(\text{Y}_2\text{O}_3)_{0.15}(\text{ZrO}_2)_{0.85}$

Fig. 6. Energy spectra of 1.5 MeV $^4\text{He}^+$ ions, backscattered at 150° from the same (100) Si/(100) $(\text{Y}_2\text{O}_3)_{0.15}(\text{ZrO}_2)_{0.85}$ sample as shown in Fig. 3. The dashed lines indicate the background, due to Y and Zr in the YSZ substrate, which must be subtracted in order to calculate the channeling yield in the Si film. See Table I for χ_0 and $d\chi/dz$ values.

material. The resistivity of Si/YSZ films increased with time after being exposed to ambient air. This increase in resistivity from air exposure was reduced after Si films were dipped into 10% HF solution. For the sake of comparison among Si/YSZ films grown at different temperatures, a Hall-effect measurement was made on the Hall bar sample right after it was dipped into 10% HF solution for 10 min. The Hall factor was assumed to be unity for data reduction. The average free electron concentrations of Si/YSZ films measured were found to be 2×10^{14} – 3×10^{15} carrier/cm 3 . The unintentional background doping level in our reactor was close to 3×10^{15} carrier/cm 3 (n-type). The effect of growth temperature on electron Hall mobility of Si/YSZ films is shown in Fig. 8. As growth temperature increases from 910° to 1000°C , electron Hall mobility increases first and then decreases at higher temperature. Again, an optimum growth temperature of 930° – 960°C is obtained, which is similar to that found either by UVR technique or by RBS/C technique.

Electron Hall mobility in undoped Si/YSZ films 0.4 – $0.5 \mu\text{m}$ thick grown at optimum temperature of 930° – 960°C

SURFACE CHANNELING YIELD, χ_0 , AT 1.5 MeV $^4\text{He}^+$, IN SOME OF THE 0.4 - 0.5 μm Si/YSZ FILMS MEASURED BY UVR

Fig. 7. Growth temperature dependence of Si surface channeling yield, χ_0 , measured at 1.5 MeV $^4\text{He}^+$ energy on Si/YSZ films.

were in the range of 200-270 $\text{cm}^2/\text{V}\cdot\text{s}$. These values are about 25% lower than those measured in n-type intentionally doped, CVD SOS films of similar thickness and carrier concentration. There are two possible reasons for this effect. First, at a doping level of $3 \times 10^{15} \text{ cm}^{-3}$ or lower in Si films, considerable surface depletion can occur (19). The current, during Hall effect measurement, is only flowing in the lower portion of Si films, which is close to the Si/YSZ interface. Results of RBS/C showed that, although both surface channeling yield, χ_0 , and average dechanneling rate, $d\chi/dz$, of Si/YSZ films are lower than that of state-of-the-art, commercial, CVD SOS films, opposite results are obtained in the lower portion of Si film near the Si/substrate interface. This suggests that the defect density is probably higher at the interface between Si and YSZ than at the interface between Si and Al_2O_3 . This could lead to a lower carrier mobility in Si/YSZ films when current flows only near Si/YSZ interface. For VLSI applications, using enhancement-mode MOSFET, the speed of the devices is determined only by the surface mobility. The lower mobility found in Si/YSZ films near the substrate area should not inhibit the use of Si/YSZ films for VLSI applications.

Another possible explanation for the lower electron mobility is the high in-plane compressive strain found in Si/YSZ films. Results of double-crystal x-ray diffractometry measurements showed that, at a thickness of $\approx 0.4 \mu\text{m}$, Si/YSZ films had a $\approx 32\%$ higher compressive strain than SOS films (6, 7, 20). This is due to the difference in thermal expansion coefficients between Si film and the substrate, which is higher for Si/YSZ than for Si/sapphire. In SOS films, because of the compressive strain, the electron Hall mobility is 30-40% lower than the drift mobility (21-23). The higher compressive strain in Si/YSZ films could lead to a lower electron Hall mobility, but does not necessarily mean that the drift mobility is lower too.

Conclusion

Epitaxial (100) Si films 0.4-0.5 μm thick were grown by the pyrolysis of silane in a hydrogen atmosphere on (100) YSZ (15% Y_2O_3) at temperatures in the range of 910°-1000°C and deposition rate of 0.06-0.58 $\mu\text{m}/\text{min}$. From 930° to 1000°C, growth rate is found to be limited by gas-phase

DEPTH - AVERAGED HALL MOBILITY IN SOME OF THE 0.4 - 0.5 μm Si/YSZ FILMS MEASURED BY UVR

Fig. 8. Effect of growth temperature on electron Hall mobility of 0.4-0.5 μm thick, (100) Si/YSZ (15 m/o Y_2O_3) films.

diffusion of reactants. Below 930°C, the growth rate becomes surface reaction limited. The heteroepitaxial Si films have been characterized by UV reflectance, Rutherford backscattering/channeling, and Hall effect measurements.

Results of UV reflectance showed that by varying the growth temperature from 910° to 1000°C, the surface quality of Si films starts to improve, reaches the highest degree at an optimum growth temperature in the range of 930°-960°C, and then deteriorates at higher temperature. The best quality Si/YSZ films produced in our laboratory so far have values of ΔR close to -10.

Quantitative depth profiles of the crystalline perfection of Si/YSZ films were measured by Rutherford backscattering and channeling using 1.5 MeV $^4\text{He}^+$. Characteristic surface channeling yield, χ_0 , vs. growth temperature curves also indicate an optimum growth temperature ranging between 940° and 960°C. In this investigation, we have obtained Si/YSZ films with value of χ_0 equal to 0.048, as compared to 0.1 and 0.12 for Si/YSZ films reported previously and for typical commercial SOS films, respectively.

Si/YSZ films grown at different temperatures are all n-type and have high resistivity as measured by the Hall effect technique. Mobility measured on Si/YSZ films grown at temperatures between 930° and 960°C is found to be higher than those grown at either higher or lower temperatures.

The optimum growth temperature found around 930°-960°C is the result of two possible defect generation mechanisms: formation of defects (i) at growth temperature and (ii) during cooling of Si films after growth, which results from the difference in thermal expansion coefficient of Si and of YSZ substrates.

Oxidation of Nickel Sulfides in Oxygen at 700°C

G. M. Mehrotra,* V. B. Tare, and J. B. Wagner, Jr.*

Center for Solid State Science, and Departments of Chemistry, Mechanical, and Aerospace Engineering and Physics, Arizona State University, Tempe, Arizona 85287

ABSTRACT

The kinetics of oxidation of $\text{Ni}_{3\pm r}\text{S}_2$ containing ~38, 39, 40, 41.4, and 42 atom percent (a/o) S and NiS were studied at $700^\circ \pm 5^\circ\text{C}$ in oxygen at 1 atm. The oxidation of $\text{Ni}_{3\pm r}\text{S}_2$ was strongly dependent on its composition. All compositions showed an initial increase followed by a slow decrease in weight. For compositions with 41.4 and 42 a/o S, however, the initial increase in weight was extremely small. Oxidation products of all the compositions were identified by x-ray diffraction as NiO. Oxidation of NiS showed a sharp initial decrease, followed by a slow increase in weight. The oxidation products were identified as Ni_3S_2 and NiO only. The morphology of the oxidized samples was studied using SEM. EDAX was used to identify phases. The possible mechanisms of oxidation are discussed.

Available literature on the phase diagram (1) of the nickel-sulfur system indicates that nickel forms three stable sulfides at 700°C , viz., NiS_2 , NiS, and Ni_3S_2 . Whereas NiS_2 is almost stoichiometric, NiS and Ni_3S_2 are known to deviate from stoichiometric composition to an appreciable extent. The composition of NiS has been reported to vary from NiS to $\text{NiS}_{1.06}$, while that of $\text{Ni}_{3\pm r}\text{S}_2$ from $\text{Ni}_{2.54}\text{S}_2$ to $\text{Ni}_{3.40}\text{S}_2$ in the temperature range $600^\circ\text{--}800^\circ\text{C}$ (1).

The Ni_3S_2 phase is often found as an intermediate corrosion product when nickel is oxidized in sulfur containing gaseous atmosphere (2). High corrosion rates in such atmospheres have been attributed to the presence of this sulfide. Oxidation rates of pure nickel sulfides were, however, not reported in the literature until after completion of the present study. Recently, one paper on this subject has been published by Asaki *et al.* (4). In the present paper, we report results of our studies on the kinetics of oxidation of $\text{Ni}_{3\pm r}\text{S}_2$ in pure oxygen at 700°C as a function of its composition. The oxidation of NiS has also been investigated under similar conditions.

Experimental

Five compositions of $\text{Ni}_{3\pm r}\text{S}_2$ containing ~38, 39, 40, 41.4, and 42 atom percent (a/o) sulfur were prepared from mixtures containing appropriate proportions of powders

of spectroscopic grade nickel, purchased from Johnson-Matthey, and 99.99% pure NiS, purchased from Ventron. These mixtures were sealed in evacuated quartz tubes and then heated at $\sim 700^\circ\text{C}$ for about three days and subsequently near ($\sim 20^\circ$ below) the melting point of the resulting composition for about 12-15h. The capsules were then air quenched to room temperature. The product was ground to a fine powder (~ 325 mesh) and characterized by x-ray diffraction. No phases other than $\text{Ni}_{3\pm r}\text{S}_2$ were detected. The sulfur content of the prepared compounds was confirmed, within ± 0.2 a/o, by hydrogen reduction. Cylindrical pellets of ~ 10 mm diam and 5 mm height were pressed from these powders in a steel die, sintered in evacuated, sealed quartz tubes at $\sim 750^\circ\text{C}$ for three days, and then air quenched to room temperature. The surfaces of these pellets were polished on 4/0 emery paper. Their apparent densities were determined from their dimensions and weights. The total porosity of the sintered pellets varied from $\sim 15\%$ to 25% .

NiS pellets were pressed from as-purchased NiS powder and sintered in evacuated, sealed quartz tubes at $\sim 900^\circ\text{C}$ for 60h. The porosity of these pellets was $\sim 25\text{--}30\%$. The sulfur content of NiS as determined by hydrogen reduction indicated the composition of NiS to be $\text{NiS}_{1.09}$.

Oxidation of $\text{Ni}_{3\pm r}\text{S}_2$ and NiS pellets was carried out in a flowing stream of oxygen (linear flow rate ~ 50 cm/min)

* Electrochemical Society Active Member.

at $700^\circ \pm 5^\circ\text{C}$. Prior to the beginning of oxidation, the $\text{Ni}_{3-x}\text{S}_2$ pellets were annealed at 700°C for at least 1h in a flowing stream of argon (oxygen content ~ 20 ppm) for homogenization. A small weight change (fractional weight change ~ 0.0005 - 0.003) was observed during this period. The kinetics of oxidation were followed by a 1000 Cahn electrobalance thermogravimetric setup. A chart recorder, connected to the electrobalance, continuously recorded the weight changes. These were replotted as the fractional weight changes calculated from the observed changes in weight and the initial weight of the sample. The weight changes observed during the annealing period were included in calculations. The time at which the argon gas flow was terminated and oxygen was started was taken as the starting time ($t = 0$).

Results

Figure 1 shows typical results from oxidation runs on $\text{Ni}_{3-x}\text{S}_2$ of five compositions. All the compositions showed an initial increase in weight, followed by a decrease in weight.

For compositions containing 41.4 and 42 a/o S, the initial increase was extremely small. For the 40.0 a/o S composition, the weight increased slowly for almost 6h, followed by a slow continuous decrease. The sample with 39 a/o S increased in weight within first hour after which the weight remained constant for several hours (~ 24 h). The samples with 38 a/o S showed an initial sharp increase in weight within the first half-hour, followed by an almost linear decrease in weight. Significant initial increase in weight is thus observed for compositions containing 38, 39, and 40 a/o sulfur. The rate of increase, however, decreased with increasing sulfur percentage. The rate of oxidation for composition containing 39 a/o S became negligibly small after 1h.

X-ray powder diffraction patterns of samples after the oxidation runs indicated the presence of NiO and Ni_3S_2 phases only. The pellets were also examined under SEM and analyzed by EDAX for morphological details and phase identification.

Figure 2(A) shows the surface of an oxidized sample of nickel sulfide containing 42 a/o S. The surface appears to be very nonuniform. A line scan for Ni and S across the surface of the sample shows the presence of discontinuous layer of NiO along with unoxidized or partially oxidized porous nickel sulfide. The cross-sectional view of an almost completely oxidized sample is shown in Fig. 2(B). A line scan across this sample shows a sudden drop

Fig. 1. Oxidation of Ni_3S_2 in oxygen at 700°C for various compositions.

Fig. 2. SEM picture of nickel sulfide containing 42 a/o S. (A): Oxidized surface. (B): Cross section of the oxidized specimen.

in nickel concentration and absence of sulfur throughout the specimen, suggesting the presence of a cavity almost at the center of the pellet.

Figure 3(A) shows the cross section of an oxidized specimen containing 40 a/o S. A line scan for Ni and S across this is shown in Fig. 3(B). Two distinct regions identified as NiO and Ni_3S_2 are clearly seen in Fig. 3(A). The presence of occasional cracks in the NiO layer formed during oxidation is seen in Fig. 3(C).

Two distinct regions with nickel oxide at the surface and Ni_3S_2 underneath are also clearly identifiable in the cross-sectional view of the oxidized sample containing 39 a/o S [Fig. 4(A)]. The oxidized surface shown in Fig. 4(B) appears to be uniform and free from cracks.

A large number of cracks are found in the oxidized surface of samples with 38 a/o S [Fig. 5(C)]. Highly oxidized samples show the presence of isolated particles [Fig. 5(A)] identified by the line scan of nickel and sulfur [Fig. 5(B)] as nickel sulfide surrounded by nickel oxide.

Figure 6 shows the change in weight of NiS as a function of time during its oxidation in pure oxygen at 700°C . There is a very rapid, almost linear decrease in weight for the first 10 min, after which the weight slowly increases at a rate which decreases rapidly with time. The x-ray examination of the samples oxidized for 18h showed the presence of Ni_3S_2 and NiO phases only. The composition of Ni_3S_2 formed was not determined.

Discussion

The reaction of $\text{Ni}_{3-x}\text{S}_2$ with oxygen can be represented by the following equations

Fig. 3. SEM picture of nickel sulfide containing 40 a/o S. (A): Cross section of an oxidized specimen. (B): Line scan across the specimen. (C): Surface of an oxidized specimen.

Fig. 4. SEM picture of nickel sulfide containing 39 a/o S. (A): Cross section of the oxidized specimen. (B): Surface of the oxidized specimen.

Fig. 5. SEM picture of nickel sulfide containing 38 a/o S. (A): Unoxidized Ni_3S_2 particle in the interior of the specimen. (B): Line scan across the above specimen. (C): Surface of the oxidized specimen.

Reaction [1] is characterized by the increase in weight of the sample due to oxidation without evolution of SO_2 , whereas reactions [2] and [3] are associated with the decrease in weight because of evolution of SO_2 and/or SO_3 as one of the reaction products. The initial weight increase observed during oxidation of $\text{Ni}_{3 \pm x}\text{S}_2$ is thus suggested to be due to the formation of NiO and simultaneous change in the stoichiometry of $\text{Ni}_{3 \pm x}\text{S}_2$, in accordance

Fig. 6. Oxidation of NiS in oxygen at 700°C

with reaction [1]. This is followed by reaction [2] and/or [3], resulting in subsequent weight loss.

In the present studies, negligibly small increase in weight during the initial stages of oxidation of nickel sulfide containing 42 a/o sulfur indicates that this is probably close to the limiting composition which favors the formation of NiO directly by reaction [2] and/or [3]. Any composition of nickel sulfide which contains nickel in excess of this limiting composition would result in a weight gain owing to the oxidation of excess nickel to NiO. The fractional weight increase calculated assuming that all the excess nickel oxidizes to form NiO is shown in Table I along with experimentally observed fractional weight increase. The agreement between the calculated and experimentally observed values, except for the starting composition of 39 a/o sulfur, is extremely good.

It is interesting to note that similar results were obtained by Asaki *et al.*, who studied the oxidation of dense pellets of FeS (3) at 750°-850°C and $p_{\text{O}_2} \sim 0.01$ -0.2 atm, and of nickel sulfide ($X_s = 0.4$ -0.44) (4) at 650°-750°C and $p_{\text{O}_2} \sim 0.2$ atm. They analyzed the exit gases formed during oxidation by infrared gas analysis and found that during oxidation of stoichiometric FeS, a very small amount of SO_2 was evolved in the initial 5s, and then it stopped for several hours afterward. The initial weight increase was explained by them to be due to the formation of Fe_3O_4 with the simultaneous change in the stoichiometry of FeS. In the case of oxidation of nickel sulfide, their results show that there is a weight increase in the initial stages of oxidation and that the progress of oxidation is dependent on the composition of nickel sulfide and temperature of oxidation. They found that, in the oxidation runs in which an increase in weight occurred, a very small amount of SO_2 was evolved during the initial 30s, and the evolution was even less during the subsequent period of weight increase. This shows that during the initial stages of oxidation with a weight increase, the rate of oxidation due to reaction [2] and/or [3] is negligible. No increase in the weight of the sample containing 44 a/o sulfur was observed by them during its oxidation at 700°C. The results of Asaki *et al.* are thus qualitatively in agreement with our results.

During the initial stages, the rate at which nickel oxide is formed is expected to be higher on compositions containing higher concentrations of nickel because of the larger concentration gradients. The subsequent reaction rate will, however, depend upon the morphology of the nickel oxide formed. It is interesting to note that, except for the composition containing 39 a/o S, the rate of weight loss after the initial weight gain is approximately the same. This is consistent with the view that, irrespective of the starting composition, the compositions at the start of reaction [2] and/or [3] above are approximately the same.

Almost complete protection offered by the formation of NiO on composition containing 39 a/o S may be attributed to the slow formation and hence a compact layer of NiO. In the case of nickel sulfide containing 38 a/o S, the rate of formation of NiO is relatively high and hence the resultant NiO layer is full of cracks as observed experimentally. However, the large number of cracks observed in NiO formed on compositions containing 40, 41.4, and 42 a/o S are possibly due to the simultaneous occurrence of reactions [1], [2], and/or [3] above, leading to the formation of SO_2 .

Table I. Calculated and experimentally observed fractional weight increase during the initial stages of oxidation of various Ni_3S_2 compositions

Initial a/o S in Ni_3S_2	Fractional weight calculated	Increase experimental
42	0.000	~0.000
41.4	0.007	0.005
40	0.015	0.015
39	0.023	0.010
38	0.031	0.030

Asaki *et al.* (3, 4) suggested that, during initial stages of oxidation of FeS or Ni₃S₂, diffusion through sulfide may control the overall rate of oxidation. Yagi and Wagner (5) studied the chemical diffusivity in Ni_{3±x}S₂ as a function of composition and showed that, although there is a small compositional dependence of diffusivity, the diffusivity values for all the compositions are very high. The concentration gradients in Ni₃S₂ throughout its oxidation may, therefore, be regarded as negligibly small.

The oxidation reaction leading to the formation of SO₂ and NiO may take place either at NiO/O₂ interface or at Ni₃S₂/NiO interface. The former requires transport of nickel and sulfur through a compact NiO layer. This is extremely slow and may be the cause of the observed negligibly small rates of oxidation of nickel sulfide containing 39 a/o S. For all the other compositions, because of the presence of cracks in the nickel oxide layer formed, oxygen can migrate through the cracks and react with nickel sulfide at the NiO/Ni₃S₂ interface forming fresh NiO and SO₂, which is again carried away by the diffusion through cracks in NiO. The rate is thus governed by either the diffusion of O₂ or of SO₂ through cracks in NiO. It is surprising, however that even after 16h of oxidation only 25% of the reaction is complete. The rate after this period becomes extremely slow. This suggests that the number and/or size of cracks present in NiO are likely to be very small.

Unlike Ni₃S₂, the oxidation of NiS at 700°C in oxygen exhibits a very fast initial weight loss within the first 10 min, followed by a weight gain, the rate of which becomes so small that the oxide formed offers virtual protection against further oxidation. X-ray and EDAX indicated the presence of NiO and Ni₃S₂ phases only.

The initial oxidation of NiS may be represented by

or

Once the Ni_{3±x}S₂ is formed, subsequent oxidation takes place by the mechanisms discussed above. The subsequent slow rate of oxidation suggests that nickel sulfide with either 39 or 40 a/o S is probably formed as the intermediate oxidation product. However, from the observed fractional weight loss in the initial stage, it seems that nickel sulfide containing ~42.7 a/o sulfur is formed.

The Standard Gibbs Energy of Formation of Ni_{3±x}S₂

G. M. Mehrotra,* V. B. Tare, and J. B. Wagner, Jr.*

Center for Solid State Science, Arizona State University, Tempe, Arizona 85287

ABSTRACT

The standard Gibbs energy of formation of Ni_{3±x}S₂ has been determined in the temperature range ~973-1173 K using galvanic cells of the configuration.

Pt, air/yttria-stabilized zirconia//NiO, Ni_{3±x}S₂, SO₂ (1 atm), Pt or Au

In the temperature range of the investigation, the open-circuit EMF of the cell, at any given temperature, was found to be independent of the starting composition of Ni_{3±x}S₂ within the experimental error limits. With the composition of Ni_{3±x}S₂ in equilibrium with NiO and SO₂ (1 atm) being Ni_{2.666}S₂, the results in calories per gram mole are

$$\Delta G^{\circ}_{\text{Ni}_{2.666}\text{S}_2}(\text{s}) = -68,670 + 27.257T \quad (973-1089 \text{ K})$$

$$\Delta G^{\circ}_{\text{Ni}_{2.666}\text{S}_2}(\text{l}) = -55,035 + 14.734T \quad (1089-1173 \text{ K})$$

The temperature and enthalpy of fusion of Ni_{2.666}S₂ are, therefore, 1089 K and 13,635 cal/mol, respectively. For the stoichiometric Ni₃S₂, we obtained

$$\Delta G^{\circ}_{\text{Ni}_3\text{S}_2}(\text{s}) = -74,740 + 31.007T \quad (973-1089)$$

$$\Delta G^{\circ}_{\text{Ni}_3\text{S}_2}(\text{l}) = -60,420 + 17.855T \quad (1089-1173)$$

The enthalpy of fusion of Ni₃S₂ is 14,320 cal/mol.

The thermodynamics of nickel sulfides has been the subject of several investigations. Rosenqvist (1) studied the NiS₂/H₂S/H₂ equilibria and reported thermodynamic data for solid Ni₃S₂, Ni₃S_{2±x}, Ni₇S₆, NiS_{1±x}, and NiS₂ compounds. Lin *et al.* have also studied the nickel-sulfur system, in the temperature range 823-1023 K, using a gas equilibration technique. More recently, Schaefer (3) has carried out electrochemical determination of the free energy of formation of solid Ni_{2.515}S₂ phase. Nagamori and Ingraham (4) have investigated the nickel-sulfur melts by

measuring the equilibrium weight of the melt in gas streams of H₂ and H₂S and have reported the standard Gibbs energy of formation of liquid Ni₃S₂ and liquid NiS. However, there appears to be no thermodynamic investigation over a wide temperature range covering both solid as well as liquid Ni_{3±x}S₂. Moreover, the data obtained by various investigators separately for solid and liquid Ni₃S₂ do not yield consistent values for temperature and enthalpy of fusion of Ni₃S₂. In the present work, the thermodynamics of solid and liquid Ni_{3±x}S₂ have been studied using solid electrolyte galvanic cells in the temperature range ~973-1173 K.

*Electrochemical Society Active Member.

Experimental Materials and Procedure

Four compositions of $Ni_{3\pm x}S_2$ containing 38, 40, 42, and 44 atom percent (a/o) sulfur were prepared from 99.999% pure nickel powder (Johnson-Matthey) and 99.99% pure NiS (Alfa/Ventron) or 99.999% pure sulfur. The mixtures, containing appropriate proportions of nickel and NiS powders, or of nickel and sulfur powders, were sealed in evacuated quartz tubes. The sealed ampules were held at ~ 970 K for ~ 72 h and subsequently at ~ 1020 - 1070 K for 24 h, after which they were air quenched. The product was then ground to a fine powder. The chemical compositions of the prepared compounds were verified by reducing them completely in hydrogen. These agreed within 0.3% of the expected sulfur content. Phase identification was done by x-ray diffraction.

Galvanic cells of the scheme

were used. One-end closed tubes of yttria-stabilized zirconia, ~ 7 mm id, purchased from Zirconium Corporation of America, served as the solid electrolyte. Moghadam and Stevenson (5) have reported that the conductivity of partially stabilized YSZ in a SO_2 atmosphere is greater than its conductivity in air and that its ionic transport number is decreased to 0.95-0.67 in the temperature range 773-1273 K by exposure to SO_2 . In separate experiments in our laboratory, we have measured the ac conductivity of 9 mole percent (m/o) yttria-stabilized zirconia in air and in flowing SO_2 (1 atm). In the temperature range 873-1273 K, no significant difference in the values of conductivity was observed for this composition of YSZ. This indicates that the electronic transport number of 9 m/o Y_2O_3 -ZrO₂ is negligible under our experimental conditions. This is in contrast to the results of Moghadam and Stevenson for yttria-stabilized zirconia containing 4.5 m/o Y_2O_3 .

In our experiments, SO_2 was passed over Drierite and P_2O_5 . Since, under our experimental conditions, the pressure of SO_3 in equilibrium with SO_2 and O_2 is negligible ($\sim 8 \times 10^{-7}$ - 3×10^{-6} atm), no correction for SO_3 has been applied and the pressure of SO_2 has been taken to be 1 atm. The open-circuit EMF of cells was measured in the temperature range ~ 973 - 1173 K using a Keithley high-impedance multimeter. The temperature of the cell was measured using a Pt-10%Rh/Pt thermocouple.

Results and Discussion

Figure 1 shows the open-circuit EMF as a function of temperature. The results shown are for cells with four different starting compositions of $Ni_{3\pm x}S_2$ and also with NiS. For each composition, the results were obtained from at least two cells. It can be seen that, irrespective of the starting composition of nickel sulfide, the values of EMF at any given temperature, in the range ~ 973 - 1173 K, are identical within the experimental error limits. This suggests that, at a given temperature, the composition of $Ni_{3\pm x}S_2$ in equilibrium with SO_2 (1 atm) and NiO is fixed and that any other $Ni_{3\pm x}S_2$ initial composition will convert

Fig. 1. Cell EMF as a function of temperature

to this composition. The value of EMF at any temperature remained steady for several hours and was reproducible within ± 1 mV during random heating and cooling of the cell, the measurements on which were carried out for a period of up to ten days, and within ± 2 mV between independent runs. However, in any run, when the cell was cooled from a temperature above the melting point of Ni_3S_2 to a temperature of ~ 1000 K or lower, the EMF values obtained were lower than the original values. The values of EMF at temperatures higher than 1000 K could be reproduced any number of times. The values of EMF at temperatures less than ~ 1000 K could be reproduced in heating and cooling cycles if the cell was not heated to a temperature above ~ 1073 K.

In order to determine the composition of $Ni_{3\pm x}S_2$ in equilibrium with SO_2 (1 atm) and NiO at various temperatures, two compositions of $Ni_{3\pm x}S_2$ containing 38 and 42 a/o sulfur were equilibrated, without NiO present, at ~ 973 , 1073, and 1173 K in a flowing stream of SO_2 . These were subsequently analyzed for sulfur using x-ray fluorescence and gravimetric chemical analysis. The results indicate that the average sulfur content of the $Ni_{3\pm x}S_2$ is ~ 42 a/o, although it must be mentioned that the accuracy of these methods for sulfur determination, in the presence of oxygen, was not optimum, the error limits being $\pm 2\%$ a/o sulfur. However, the fact that the EMF values fall on a straight line, in the temperature ranges 973-1089 K and 1089-1173 K, suggests that the variation in the composition of $Ni_{3\pm x}S_2$ with temperature, if any, is not appreciable. This composition is very close to $Ni_{2.666}S_2$ or Ni_4S_3 (i.e., 42.86 a/o sulfur) which has been suggested to be a stable phase (β_2 - Ni_4S_3), in the temperature range 845-1040 K, according to the Ni-S phase diagram reported by Lin *et al.* (2) (shown in Fig. 2). Schaefer (3) has, however, reported that the composition of $Ni_{3\pm x}S_2$ in equilibrium with NiO and SO_2 (1 atm) is $Ni_{2.515}S_2$ (i.e., 44.3 a/o sulfur). Moreover, he has reported no change in the composition of $Ni_{2.515}S_2$ with temperature in the temperature range (969-1054 K) of his investigation.

The EMF vs. temperature relationship has been found to be linear in the present studies. Linear regression analysis of our data in the temperature ranges 973-1053 K and 1083-1173 K yielded the following relationships

$$E = 827.24 - 0.23634T \quad (973-1089 \text{ K}) \quad [1]$$

and

$$E = 871.62 - 0.27707T \quad (1089-1173 \text{ K}) \quad [2]$$

where E is the EMF of cell [A] in mV and T is the temperature in degrees Kelvin.

The change in the slope of the E vs. T straight line at 1089 K corresponds to the melting temperature $Ni_{3\pm x}S_2$. This is in good agreement with that (1083 K) reported by Rosenqvist and is higher than that (1063 K) reported for Ni_3S_2 by Turkdogan (6), and by Kubaschewski and Alcock (7). However, it must be pointed out that the tem-

Fig. 2. Nickel-sulfur phase diagram, after Lin *et al.* (2).

perature at which the change in slope occurs is extremely sensitive to the terms which correspond to the entropy in the above equations, and hence the errors in the melting temperature are likely to be large. The EMF values obtained from Eq. [1] are in good agreement with those obtained by Schaefer (3) after correcting for the oxygen pressures of the reference electrodes. Our EMF data are also in agreement within ± 2 mV with those reported subsequently by Chang and Hsieh (8) for solid $\text{Ni}_{3\pm x}\text{S}_2$ in the temperature range 945-1070 K.

The virtual cell reaction for cell [A] is

Therefore

$$\Delta G^\circ_{\text{cell}} = 2\Delta G^\circ_{\text{SO}_2} + (3 \pm x) \Delta G^\circ_{\text{NiO}} - \Delta G^\circ_{\text{Ni}_{3\pm x}\text{S}_2} - \left(\frac{7 \pm x}{2}\right) RT \ln 0.21 \quad [4a]$$

or

$$\Delta G^\circ_{\text{Ni}_{3\pm x}\text{S}_2} = 2 \Delta G^\circ_{\text{SO}_2} + (3 \pm x) \Delta G^\circ_{\text{NiO}} + 2F(7 \pm x)(E + 0.03362T) \quad [4b]$$

where $\Delta G^\circ_{\text{Ni}_{3\pm x}\text{S}_2}$, $\Delta G^\circ_{\text{SO}_2}$, and $\Delta G^\circ_{\text{NiO}}$ are the standard Gibbs energies of formation of $\text{Ni}_{3\pm x}\text{S}_2$, and SO_2 , and NiO , respectively, and F is Faraday's constant.

Using the reported data for $\Delta G^\circ_{\text{NiO}}$ and $\Delta G^\circ_{\text{SO}_2}$, one obtains

$$\Delta G^\circ_{\text{Ni}_{3\pm x}\text{S}_2}(\text{s}) = 74,740 + 31.007T \pm x(-18,160 + 11.221T) \quad (973-1089 \text{ K}) \quad [5]$$

and

$$\Delta G^\circ_{\text{Ni}_{3\pm x}\text{S}_2}(\text{l}) = -60,420 + 17.855T \pm x(-16,110 + 9.343T) \quad (1089-1173 \text{ K}) \quad [6]$$

For the composition of the $\text{Ni}_{3\pm x}\text{S}_2$ in equilibrium with NiO and SO_2 (1 atm) to be $\text{Ni}_{2.666}\text{S}_2$ (42.86 a/o S), we obtain

$$\Delta G^\circ_{\text{Ni}_{2.666}\text{S}_2}(\text{s}) = -68,670 + 27.257T \quad (973-1089 \text{ K}) \quad [7]$$

and

$$\Delta G^\circ_{\text{Ni}_{2.666}\text{S}_2}(\text{l}) = -55,035 + 14.734T \quad (1089-1173 \text{ K}) \quad [8]$$

From Eq. [7] and [8], the enthalpy of fusion of $\text{Ni}_{2.666}\text{S}_2$ is found to be 13,635 cal/mol.

For the sake of comparison with the data reported in the literature, it is also possible to obtain the Gibbs energy of formation of stoichiometric Ni_3S_2 by assuming the composition in equilibrium with NiO and 1 atm SO_2 to be 40 a/o sulfur. One thus obtains from Eq. [5] and [6]

$$\Delta G^\circ_{\text{Ni}_3\text{S}_2}(\text{s}) = -74,740 + 31.007T \quad (973-1089 \text{ K}) \quad [9]$$

and

$$\Delta G^\circ_{\text{Ni}_3\text{S}_2}(\text{l}) = -60,420 + 17.855T \quad (1089-1173 \text{ K}) \quad [10]$$

The enthalpy of fusion of Ni_3S_2 , as obtained from Eq. [9] and [10], is 14,320 cal/mol. This is much higher than the estimated value of 5800 cal/mol reported by Kubaschewski and Alcock (7) and is comparable to 11,300 cal/mol reported by Nagamori and Ingraham(4).

Figure 3 shows $\Delta G^\circ_{\text{Ni}_{2.666}\text{S}_2}$ and $\Delta G^\circ_{\text{Ni}_3\text{S}_2}$, as obtained from Eq. [7]-[10], as functions of temperature. It also shows some of the data reported in the literature. The values of Gibbs energy of formation of solid and liquid Ni_3S_2 obtained from our Eq. [9] and [10] are in good agreement with those reported by Rosenqvist (1) for solid Ni_3S_2 and with those reported by Nagamori and Ingraham (4) for liquid Ni_3S_2 . The values of Gibbs energy of formation of solid $\text{Ni}_{2.666}\text{S}_2$ obtained from our Eq. [7] are also in good agreement with those calculated from Rosenqvist's data in the temperature range 918-1083 K. The enthalpy and entropy terms in our equations are, however, different from those reported by Rosenqvist and by Nagamori and

Fig. 3. Standard Gibbs energy of formation of Ni_3S_2 and $\text{Ni}_{2.666}\text{S}_2$

Ingraham. The agreement between our $\Delta G^\circ_{\text{Ni}_{2.666}\text{S}_2}$ values and those calculated for the same composition from Schaefer's EMF data is good. The values reported by Lin *et al.* (2) for $\beta_2\text{-Ni}_4\text{S}_3$ (or $\text{Ni}_{2.666}\text{S}_2$) phase are also in good agreement with those obtained from our Eq. [7]. However, their values for $\beta_1\text{-Ni}_3\text{S}_2$ (40 a/o sulfur) phase are higher than those obtained from our Eq. [9]. The values obtained from the equation for $\Delta G^\circ_{\text{Ni}_3\text{S}_2}$ (298-1063 K) in Turkdogan's (6) and Kubaschewski and Alcock's (7) compilations, which are actually Rosenqvist's data for the temperature range 673-808 K, are higher by 3-4 kcal/mol than the values obtained in the present work. Because of the very good reproducibility of cell EMF's over the entire temperature range (973-1173 K) and extended durations (4-10 days) of our experiments, and also because of the accuracy of the EMF method itself, the data obtained in the present work may be considered to be more reliable.

Combining the heat capacity data for nickel, sulfur, and Ni_3S_2 reported in literature (7, 9, 10) with the EMF data obtained in this work, one obtains, from the third law analysis, for the enthalpy of formation of Ni_3S_2 from the elements, ΔH°_{298} , a value of -47.9 ± 2.2 kcal/mol. This is in fair agreement with the value of -51.6 ± 2.5 kcal/mol reported by Kubaschewski and Alcock (7). The values of ΔH°_{298} calculated from our EMF data for various temperatures show a random variation and therefore are considered to be free from systematic experimental errors.

A Study of Lapping and Polishing Damage in Single-Crystal CdTe

Donald F. Weirauch

Texas Instruments, Incorporated, Dallas, Texas 75265

ABSTRACT

The surfaces of single-crystal CdTe specimens subjected to lapping and polishing operations were studied. Optical microscopy was used to establish that lapping with an abrasive creates damage principally in the form of microcracks extending below the surface. The depth of damage was similar to that reported for single-crystal Si and was 50 μm from 240 grit (47 μm) SiC and 15 μm from 600 grit (28 μm) SiC. Polished surfaces were studied using a dislocation revealing etchant. Lapping-induced microcracks could be removed by sufficient polishing with an abrasive, but the specimen always possessed a surface layer of very high dislocation density, with the average depth of the dislocations being a function of abrasive particle size. The maximum dislocation depths were found to be 9 μm from a 5 μm Al_2O_3 polishing abrasive and 3 μm from 0.3 μm Al_2O_3 . The correlation of this surface layer of high dislocation density with the frequently reported "amorphous" or "Beilby" surface layer was demonstrated. It was shown that during the formation of this layer, small microcracks and surface defects could be covered and rendered invisible by a lateral movement of material along the specimen surface. A chemical polishing technique employing a bromine-methanol solution was shown to be capable of creating damage-free CdTe surfaces.

The quality of the polished surface is of critical importance to many materials' applications. The growth of an epitaxial film on a single-crystal substrate is an example where an improperly polished surface can seriously affect the quality and properties of the film or even cause it to grow with a randomly oriented or polycrystalline character. Ideally, the substrate surface should have the same crystallographic perfection as its interior. CdTe is a material which is useful as a substrate in the growth of epitaxial (Hg, Cd)Te. It is soft (2.75 on the Moh's hardness scale) and brittle, with a strong tendency to cleave along (110) planes. The purposes of this study are to investigate the nature of lapping and mechanical polishing damage associated with CdTe substrate preparation and to evaluate chemical polishing as a method of creating a damage-free surface.

The lapping and polishing of all brittle materials possess similarities which transcend the individual differences in the materials' physical properties (1-5). Thus, materials such as diamond, one of the hardest of materials, glass, an amorphous material of intermediate hardness, and gypsum, one of the softest materials, all exhibit the same phenomenological events during lapping and polishing; only the rates are significantly different. In contrast, though lapping and polishing operations appear to be nearly identical processes (as, for example, when a rotating wheel and an abrasive are employed), the effects of the two operations on the specimen surface are dramatically different, as described below.

The lapping process is a grinding operation in which an abrasive, a lapping surface, and suitable pressure are combined to create microcracks in the surface of the material being lapped. Microcracks propagating from the surface intersect within the material to release chips. The grinding action is the formation and removal of these chips from the surface. Finer abrasives result in shorter microcracks and finer chips. However, under normal lapping conditions, the grinding action ceases when the abrasive size decreases below approximately 4 μm . After the lapping operation, the surface will contain numerous microcracks. Associated with the microcracks will be strained material and dislocation arrays.

There are two types of polishing: chemical and mechanical. Chemical polishing relies on a chemical to dissolve the surface of the specimen so that a smooth polished surface results. A polishing pad might or might not be used in this process. Mechanical polishing bears a resemblance to lapping in that an abrasive and polishing surface are used in a manner similar to lapping. However, during polishing, microcracks are not created in the surface, as they are in lapping. Instead, material is displaced from the high spots, either to be transferred to valleys of the surface or to be removed totally. During the initial polishing with coarser polishing agents, fine scratches will be introduced into the material; associated with these scratches will be deformation of the material and dislocations. As the polishing process continues with finer polishing agents, the surface quality will continue to improve until no surface defects are visible — even under a microscope. This appearance can be misleading because x-ray or etching studies will often reveal considerable damage in the form of filled-in scratches, microcracks, and pits, as well as dislocation arrays concealed by the surface flow of the material being polished. The flow or smearing of the surface has been observed for several materials and has been referred to as the "Beilby layer" (1). Figure 1 is a cross-sectional representation of a partially polished crystalline specimen in which microcracks created during lapping are still present. At the surface is the "amorphous," or "Beilby," layer. This layer can totally conceal the underlying damage of pits, scratches, and microcracks. The zone of microcracks represents lapping damage which has not yet been removed by polishing. Dislocations arrays extend below the microcracks; beneath these arrays lie "good" material with a crystallographic perfection representative of the interior of the specimen.

Experimental Procedure

Both lapping and polishing damage were studied using $\langle 111 \rangle$ oriented CdTe single crystals. Lapping damage was investigated by lapping the specimen on a glass plate previously conditioned by thoroughly abrading the surface with the abrasive size under study. After lapping the

CdTe sufficiently to create a representative surface, the specimen was cleaved along the (110) plane, which was then examined microscopically. The abrasives studied were 240 grit (47 μm) and 600 grit (28 μm) SiC.

Both the mechanical and the chemical polishing studies were conducted using a Strasbaugh polishing machine¹ with Rodel² 600 polishing pads. "Mechanical" polishing refers to the polishing of CdTe using only an abrasive having no apparent chemical action on the specimens. For these studies, 5 μm and 0.3 μm polishing suspensions³ of Al_2O_3 were used. "Chemical" polishing refers to the polishing of CdTe using a reagent known to chemically react with the specimen. For this study, the reagent was 0.5 volume percent (v/o) bromine dissolved in methyl alcohol. During the polishing, the reagent was dripped onto the polishing pad at a rate sufficient to keep the pad saturated with the chemical. Prior to the chemical polishing, the specimens were mechanically polished with 5 μm , then 0.3 μm , Al_2O_3 .

To determine the extent of damage caused by the polishing, the specimens were coated with an organic wax which covered all of the specimen except for a small (0.25 cm^2) region that was to be directly exposed to chemical reagents. Two reagents were used in the polishing damage evaluation. One reagent (6), composed of 10 ml H_2O , 5 ml conc HNO_3 , and 2g $\text{K}_2\text{Cr}_2\text{O}_7$, was very effective in isotropically removing CdTe from the specimen surface. Because this chemical technique did not introduce dislocations into the specimen, it was possible to "chemically mill" into the specimen's surface and examine the dislocation etch-pit structure at selected locations. Dislocation etch pits were revealed by dipping the specimen for 20s in a reagent (7) composed of 29 v/o H_2O , 29 v/o H_2O_2 , and 42 v/o conc HF. This process created on the specimen surface a dark film which was removed by a 1s immersion in the $\text{K}_2\text{Cr}_2\text{O}_7$ reagent described above. When sufficient material had been chemically milled from the surface so that the dislocation etch-pit structure was characteristic of the underlying crystal, the etch mask was removed with a chemical solvent, and the step height between the chemically milled regions and the protected regions was measured microscopically.

To determine if CdTe could be displaced at the specimen surface during mechanical polishing to fill in pits and low spots, a scratch was made in a specimen surface with a diamond point. The specimen was then dipped for 15s in a saturated AuCl_3 solution which reacted slightly with the CdTe to effectively open up microcracks and coat all exposed surfaces with a layer of elemental gold. The specimen was lightly polished with 5.0 μm Al_2O_3 and, after a microscopic examination, was immersed for 2s in the $\text{K}_2\text{Cr}_2\text{O}_7$ solution diluted 4-to-1 with H_2O . The specimen was then examined with an optical microscope and an electron microprobe. Because the action of the diamond point across the CdTe surface was somewhat analogous to the action of an abrasive particle during the polishing operation, the associated surface deformation and dislocation generation in the specimen surface were studied in greater detail.

Results and Discussion

The most pronounced defects created during the lapping operations were a myriad of microcracks in the surface; dislocations were undoubtedly present also, but they were not examined. The microcrack damage to CdTe caused by lapping with 240 grit SiC is shown in Fig. 2 (top view) and Fig. 3 (cross-sectional view). The cross-sectional view revealed microcracks of irregular depth, but of an average of 50 μm depth. The surface lapped with 600 grit SiC was similar, but on a finer scale, with the average observed microcrack depth being 15 μm . These results were very similar to lapping damage reported for silicon (4).

Fig. 1. Cross-sectional view of lapping and mechanical polishing defects.

Fig. 2. Surface of CdTe after lapping

The damage created by mechanical polishing was primarily in the form of dislocations, and these were evaluated using chemical milling and an etchant. Figure 4 shows the surface of the specimen polished with 5 μm Al_2O_3 ; fine scratches were evident. Figure 5 shows the same area after being exposed to the dislocation revealing etchant. Most of the existing polishing scratches were enhanced (although some disappeared), and new ones appeared. For example, the prominent horizontal line in Fig. 5 was imperceptible in the original polished specimen. When 4 μm of the surface was chemically removed and then etched, the surface had the appearance seen in Fig. 6. Only the deepest polishing scratches were still visible (as dense linear arrays of etch pits), but etch pits delineating subgrain boundaries of the crystal were now present as a mosaic pattern. After chemically removing an additional 9 μm from the specimen, the etch pits associated with the polishing scratches were gone, although remnants of a smooth groove remained, as shown in Fig.

Fig. 4. Mechanically polished CdTe surface

Fig. 7. Etch-pit structure 13 μm below the mechanically polished surface.

Fig. 5. Mechanically polished CdTe surface after chemical etching

7. The mosaic etch pit pattern was virtually unchanged from that observed in Fig. 6. Because the additional chemical milling and etching steps had revealed the same mosaic structure, it was evident that gross crystallographic changes caused by the polishing did not extend to even 4 μm below the surface. The major mechanical polishing damage found by this technique consisted of

Fig. 6. Etch-pit structure 4 μm below the mechanically polished surface.

linear dislocation arrays created by individual abrasive particles. The maximum depths of damage were 9 μm from the 5 μm Al_2O_3 and 3 μm from the 0.3 μm Al_2O_3 .

The appearance of new polishing marks after exposure to a chemical etchant (Fig. 5) was strong evidence that scratches had been "filled in" during the polishing operation. Added support to this conclusion was obtained using CdTe specimens scratched with a diamond point. Figure 8 shows well-defined grooves created using light and moderate pressures. Slip lines (the parallel lines on each side of the groove) and microcracks (short, irregular lines visible primarily on one side of the groove) emanated from the deeper groove. When lightly polished, many of the microcracks vanished only to reappear when exposed to an etchant. To ensure that this was not simply a result of having polished to a region of the microcrack too thin to be seen optically, a similarly scratched specimen was immersed in a AuCl_3 solution to deposit a thin gold layer on all exposed surfaces, including the interior of microcracks. The specimen was then lightly polished with 5 μm Al_2O_3 such that many microcracks were no longer visible (see Fig. 9). Localized regions of smeared gold in otherwise featureless areas indicated the presence of the gold-coated microcracks, and this presence was confirmed using a very light etch which exposed previously-invisible microcracks (see Fig. 10). An examination with an electron microprobe revealed that the microcracks were coated with gold, which confirmed that they were the ones originally present and established that they had been of a sufficient size to be easily detect-

Fig. 9. Partially polished surface scratch

Fig. 10. Partially polished surface scratch after chemical etching

able with an optical microscope prior to the chemical etch. Therefore it was unambiguously established that during polishing, a "Beilby" layer had been created on the CdTe specimen surface.

Using a diamond point, a fresh groove was made in a specimen surface, and a thin glass sheet was placed over it. When illuminated by a monochromatic light source with a wavelength of $0.589 \mu\text{m}$, a series of interference fringes, as shown in Fig. 11, were generated in the air gap between the specimen surface and the transparent glass. These fringes revealed the topographical profile of the specimen surface and showed that the diamond point had created a furrow with edges extending above the specimen surface by at least $0.5 \mu\text{m}$. Thus, even though the CdTe was extremely brittle, it was possible for substantial deformation to occur without fracture. This was possible because of the generation of dislocations in the vicinity of the groove. Figure 12 shows dislocation arrays associated with a series of four parallel grooves of various depths made in CdTe by a single pass with an irregular diamond point. Also present were dislocations associated with the crystal's mosaic subgrain structure. The width of the dislocation bands on each side of a groove were related to the depth of the groove. The etch pits associated with the two shallowest grooves were indistinct, showing that the depth of those dislocations had been less than the amount of CdTe removed by the etchant (less than $1 \mu\text{m}$). The pressure of the diamond scribe had not been perpendicular to the specimen surface, and this is believed responsible for the fact that the bands of dislocations were not of equal width on each side of the grooves.

Fig. 11. Surface scratch topography

The results of these tests suggest that the origin of the amorphous Beilby layer, created during mechanical polishing, was from abrasive particles acting on the specimen in a manner similar to the diamond point to create grooves and dislocation arrays and to cause material deformation in the specimen surface. During this process, sufficient lateral movement of material occurred at the specimen surface to fill and seal the surface of microcracks and small surface pits (a cold welding type of mechanism is assumed). The surface layer, appearing completely continuous, then contained an extremely high dislocation density which was very similar to the "amorphous" or "Beilby" layer. The depth of this layer was dependent upon the abrasive particle size, but also was sometimes dependent upon the hardness of the polishing surface. During this process, of course, there also occurred the relatively slow removal of surface material normally associated with polishing.

No evidence of a Beilby layer was found on the specimen chemically polished in the bromine-methanol solution. The as-polished surface was featureless, with a very slight trace of an "orange peel" texture which could be

Fig. 12. Dislocation etch pits associated with surface deformation

Fig. 13. Chemically polished surface after chemical etching

seen microscopically only with Nomarski interference contrast. When exposed to the dislocation revealing etchant which removed less than $1 \mu\text{m}$ of CdTe surface, only a mosaic pattern of etch pits was produced (see Fig. 13). No linear dislocation arrays characteristic of the mechanical polishing were seen. Chemically removing additional CdTe from this specimen did not appreciably change the mosaic etch-pit structure, which indicated that any polishing-induced damage did not extend more than $1 \mu\text{m}$ below the original surface. Thus, within the limits of resolution of this technique, the surface of the chemically polished specimen possessed a crystallographic perfection representative of the crystal interior. This result was substantially different from that obtained from the mechanically polished specimen, and it gave added evidence that the amorphous Beilby layer was a mechanically induced surface layer of high dislocation density. Because of the similarity in polishing behavior of most materials, these results are believed to be generally applicable and not limited to CdTe.

Conclusions

The "amorphous," or "Beilby," layer created during mechanical polishing was shown to be a surface layer of

very high dislocation density created by the abrasive particles during polishing. The creation of this layer was associated with sufficient material deformation to effectively cover and conceal microcracks, small surface pits, and other defects. The thickness of the surface layer was dependent upon the abrasive particle size used during polishing.

A chemical polishing technique employing a bromine-methanol solution was shown to be capable of creating a CdTe surface free of polishing damage. The mechanical polishing of CdTe with Al_2O_3 abrasive created damage in the form of shallow surface scratches and dislocation arrays penetrating into the material. The maximum observed depth of the dislocations ranged from $9 \mu\text{m}$ from a $5 \mu\text{m}$ Al_2O_3 polishing agent to $3 \mu\text{m}$ from a $0.3 \mu\text{m}$ Al_2O_3 polishing agent.

The lapping of CdTe with SiC created a surface zone of microcracks which averaged $50 \mu\text{m}$ depth from 240 grit abrasive and $15 \mu\text{m}$ depth from 600 grit abrasive.

Corrosion Study of a Carbon Steel in Neutral Chloride Solution by Impedance Techniques

A. Bonnel, F. Dabosi, C. Deslouis, M. Duprat, M. Keddou, and B. Tribollet

(pp. 753-761, Vol. 130, no. 4)

F. Mansfeld:¹ In their paper, Bonnel *et al.* investigate the electrochemical behavior of a C-Mn steel in 3% NaCl, using a rotating disk electrode. We have been carrying out similar studies of the important subject of corrosion in aerated neutral media and its inhibition²⁻⁴ and have noted some important discrepancies in the impedance spectra reported by Bonnel *et al.* and by ourselves. In the paper under discussion, two capacitive loops are shown in Nyquist plots obtained at the corrosion potential. In our previous studies of steel in 0.5M Na₂SO₄³ and in tapwater², only one capacitive semicircle was observed in experiments with rotating iron² or 4340 steel³ cylinder electrodes (RCE). Our unpublished data for steel RCE's in 0.5N NaCl have been repeated to extend the frequency range to 5 mHz. For frequencies between 10⁵ Hz and 0.1 Hz, a Solartron transfer function analyzer (TFA) (Model 1174) was used, while a fast fourier transform technique (FFT) was used between 0.5 Hz and 5 mHz. The software program for the FFT technique was provided by Princeton Applied Research Corporation. The results of this study show clearly that only one depressed capacitive semicircle occurs between 10⁵ and 5 × 10⁻³ Hz. The Bode plots in Fig. 1 show excellent

agreement between experimental data and a fit to a theoretical model of the impedance as

$$Z = R_{\Omega} + \frac{R_p}{1 + (j\omega CR_p)^{\alpha}} \quad [1]$$

where R_{Ω} is the ohmic electrolyte resistance, the capacitance C is calculated from the frequency ω_m of the maximum of the imaginary component Z'' ($C = (\omega_m R_p)^{-1}$), R_p is the polarization resistance, and α relates to the depression of the semicircle as discussed before⁵. R_p and R_{Ω} were calculated using the CIRFIT computer program⁵. The FFT data in Fig. 1 were taken 2h after the end of the TFA data. Due to the continuous increase of corrosion rates with time, the R_p value obtained from the FFT data is lower than that obtained from the dc limit of the TFA data. Nevertheless, it is obvious that a second time constant does not occur at the lowest frequencies. It should be noted that an accurate fit of the frequency dependence of the impedance $|Z|$ and the phase angle δ is a more severe test than a Nyquist plot of both types of data.

These experiments have also been conducted at other rotation speeds r . Table I summarizes the results of an analysis according to Eq. [1]. As expected, R_p decreases with increasing r , while E_{corr} becomes more noble. With increasing exposure time, R_p becomes smaller. After exposure for more than 24h, a thick rust layer has developed, which is reflected in the more than ten-fold increase of the capacitance C . The value of α does not change significantly with experimental conditions. The following additional comments need to be made.

1. It is not clear why the high-frequency loop depends on rotation speed in galvanostatic conditions but not in potentiostatic conditions (Fig. 9 and 10 of the paper under discussion). The caption for Fig. 10 seems to imply that the experiments for 600 and 2400 rpm were conducted at the same applied potential (the E_{corr} for 1000 rpm?).

2. An experiment with the TFA technique down to 5 mHz takes many hours, depending on the integration

Fig. 1. Agreement between experimental data and a fit to a theoretical model of the impedance.

Table I. Impedance data for 4340 RCE in 0.5N NaCl

t (h)	r (rad/s)	E _{corr} (mV)	R _p (Ω · cm²)	C (μF/cm²)	α
1.3	144	-549	120	955	0.79
3.1	144	-544	96	685	0.77
4.5	16	-554	251	1,473	0.76
5.5	16	-627	297	1,337	0.79
6.0	324	-545	60	846	0.78
22.5	324	-580	143	11,100	0.71
24.0	144	-592	170	9,352	0.74
25.5	16	-615	245	6,490	0.74

time. Because E_{corr} and R_p vary with time, it is very likely that the data in Fig. 12 are strongly affected by this time dependence, especially for $t \sim 0$ and 30 min. What appear to be two capacitive loops could be due to these time effects.

3. The statement "the product $R_p I$ which remains close to 30 mV above 750 $\mu\text{A}/\text{cm}^2$ indicating a simultaneous transfer of the two electrons" is incorrect, because the Tafel slope is $b_a = 2.3 R_p I = 69$ mV, which is not consistent with anodic Tafel slopes derived for accepted mechanisms of iron dissolution. According to Bonnel *et al.*'s Table I, b_a increases continuously with applied anodic current from 27 to 79 mV, which suggests that no true Tafel slope exists in the current region studied.

A. Bonnel,⁶ F. Dabosi,⁶ C. Deslouis,⁷ M. Duprat,⁶ M. Keddad,⁷ and B. Tribollet:⁷ The introducing remarks of the discussion concern some divergences observed between the work of Mansfeld *et al.*⁸ and our work⁹. This is not so surprising, because the electrolyte, on one hand, and almost the metal, on the other hand, particularly concerning the contents of Ni, Cr, and Mn, are different.

The impedance diagrams reported by these authors displayed only one capacitive loop, rather than two, in our case. Nevertheless, it must be emphasized that the diameter of this single loop (R_p) is decreased with the rotation speed (Ω) (see Table I of the comments), thus indicating a probable influence of the mass transport process; in our case, the influence of this last process is clearly evidenced by the occurrence of a low frequency capacitive loop. The reason for the existence of two time constants has therefore been clearly explained as follows.

—The corrosion rate is controlled by the cathodic process, *i.e.*, oxygen reduction, and the role of mass transport was quantitatively established by plots (I_d , $\Omega^{1/2}$) and by EHD impedance measurements.

—Hence, the high-frequency (HF) loop corresponds to the charge-transfer process, whereas the low-frequency (LF) loop corresponds to mass transport.

The following answers can then be given to points 1-3 of the comments.

1. The influence of the rotation speed on the HF loop only observed in galvanostatic conditions results from the mixed nature of the corrosion potential.

—In potentiostatic conditions, the anodic process is obviously not modified, and there are no meaningful variations of the diameter of the HF loop. The decrease of the LF loop when Ω is increased is consistent with a mass transport process.

—When a galvanostatic control is applied, the change in Ω modifies the cathodic current I_d . Therefore, the anodic current I_A evolves so that the overall current $I_A + I_d$ remains constant, leading to a variation of the diameter of the HF loop.

2. We reported (Fig. 12) at time zero only one capacitive loop (flattened) which is in agreement with the conclusions of Mansfeld. However, a second loop is clearly evidenced at longer times ($t \geq 2$ h). Because a layer of corrosion products develops, it constitutes, as demonstrated in our paper, a hindrance to diffusion. With increasing elapsed time, the time constant due to diffusion becomes higher and, therefore, sufficiently different from that corresponding to charge transfer, and the two loops can be well separated. It is thus likely that these two time constants are not separated at time zero and exhibit only a frequency dispersion, as is probably the case for the experiments reported by Mansfeld.

3. Concerning the anodic Tafel slope b_a for the iron dissolution, Mansfeld asserts that a value of 69 mV for b_a is incorrect as regards the "accepted mechanisms," but he does not mention any reference. In a recent paper of his¹⁰, he stated that anodic slopes b_a of 60 ± 5 mV can be clearly observed for the iron dissolution; this is consistent with our results. Somewhat earlier, a work by a member of our group¹¹ led to the same conclusion. In addition, the $R_p I$ values at low anodic currents must be disregarded, due to the significant contribution of the cathodic process in this potential range.

Formation of Salt Films during Anodic Dissolution in the Presence of Fluid Flow

Richard Alkire and Antonia Cangelari

(pp. 1252-1259, Vol. 130, no. 6)

M. Keddad¹² and R. Oltra:¹³ This very interesting paper, particularly its experimental part, has suggested to us the following remarks.

It is concluded from the data shown in Fig. 8 that repassivation can occur only when the intensity and mass-transfer conditions for precipitation of an iron sulfate layer are fulfilled.

Experiments are said to be performed by stepping the potential to 0.8, 1.0, and 1.2V, whereas experimental points in Fig. 8 are in the range 1.2-1.7V. If the data of Fig. 7 are added to Fig. 8, passivation is shown to occur well above the theoretical line for $f_{sc} = 1.3$. What about 0.8V?

It is clear that the model does not intend to account for the passivation process, because the surface overpotential is taken as a Tafel polarization. However, when discussing the experimental data, it must be kept in mind that even in the simplest view, the active-to-passive transition of a metal cannot take place when the electrode potential, corrected for ohmic drop, is lower than a critical passivation potential close to 0.8V/NHE for iron in 0.5M H_2SO_4 .

Using the data of Fig. 7 and $R_d = 1/4\kappa\tau_0$, it is easily shown that during the active part of the transient, the applied potential is pure ohmic drop in the solution; hence, the metal is not polarized in the passive range. This explains why the active current density is independent of R_e , a rather strange result for active iron. Also, it would be of interest to consider the dependence of the active current in Fig. 7 with respect to the applied potential. Therefore, the most important role of salt precipitation in passivation phenomenon must be related to its influence on ohmic drop.

It is not certain that iron/ H_2SO_4 is the most convenient system for testing simple views of the onset of passivity. It is known as a very complicated system at the active-passive transition (see our work and recent papers by J. Newman and co-workers).

R. Alkire¹⁴ and A. Cangelari:¹⁴ As indicated in the paper, potentials given in Fig. 7 (denoted ϕ_a) are with respect to NHE, whereas those in Fig. 8 (ϕ_A) are with respect to the rest potential of the system as defined by Eq. [1] on p. 1253. There is no inconsistency between data of which the same set appears in both figures; the potential of 0.8V in Fig. 7 corresponds to approximately 1.24V in Fig. 8.

of an anodic potential in the passive range to a bare metal surface, the ensuing sequence of events includes: (a) rapid metal dissolution under IR-limited conditions, causing an increase in metal-salt concentration near the surface; (b) precipitation onto the surface of a metal-salt film; (c) formation on the surface of a passive-oxide film; and (d) dissolution of the metal-salt film, leaving only the passive-oxide film on the surface. Rapid metal dissolution under IR-limited conditions was also reported by Alkire and Perusich,¹⁵ who used focused ultrasound to cause localized cavitation damage to the passive film on Fe in H₂SO₄. Figure 6 of that work showed that the IR-limited dissolution rate varied linearly with applied potential and that the slope was given by the ohmic resistance of the solution, as computed from the primary current distribution.

Keddam and Oltra are correct in recognizing that the data in Fig. 7 of the paper under discussion also correspond to IR-limited conditions. It should not be surprising that an IR-limited current exhibits no dependence upon flow rate. The IR-limited current plateau shown in Fig. 7 depends only upon applied potential, solution conductivity, and electrode geometry.

It has been our experience that the Fe/H₂SO₄ system is a well-behaved model system for investigation of high-rate metal dissolution-precipitation phenomena. It is reproducible and convenient for study, and it exhibits stable behavior which is free of oscillations and which can be analyzed by basic principles of convective transport. We have found essentially identical results for single-crystal iron, for 99.99% polycrystalline iron, and for commercial cold-rolled steel. While other features of the Fe/H₂SO₄ passivation phenomena are undoubtedly complex, the dissolution and precipitation of metal-salt films in that system appears to be straightforward in comparison.

Preparation and Open-Circuit Potentials of Silver-Intercalated 2H-TaS₂ and 1T-TiS₂

G. A. Scholz and R. F. Frindt

(pp. 1763-1767, Vol. 131, no. 8)

B. Scrosati:¹⁶ The study of the silver-intercalated electrodes reported in this paper closely resembles that described in a paper that we published five years ago¹⁷. The only difference lies in the fact that we used a solid electrolyte cell in order to avoid all problems of self-intercalation and corrosion which the authors have faced with their liquid electrolyte cell.

Indeed, Scholz and Frindt have prepared their Ag_xTiS₂ samples in the same way we did, *i.e.*, both thermally and electrochemically, and the trend of their Ag_xTiS₂ EMF-composition curve is identical to ours¹⁷. The EMF values reported by Scholz and Frindt are slightly lower than ours and, in my opinion, this is due to the fact that the time allowed for the measurements (8h) was too short to reach equilibrium.

In fact, we¹⁷⁻¹⁹ and other authors²⁰ have found that the diffusion of silver in Ag_xTiS₂ and in Ag_xTaS₂ is very slow, so that long times are required for the equilibration of the intercalation electrodes.

It was also interesting to read that the authors were surprised to "discover" that the silver intercalation reac-

tions in TaS₂ and in TiS₂ are reversible, since we clearly demonstrated such reversible behavior some years ago¹⁸.

It is now well recognized that the kinetics of the intercalation processes are generally controlled by the diffusion of the guest species in the layer structure of the dichalcogenides. Therefore, the apparent lower reversibility that the authors observed for the intercalation process in TiS₂ with respect to that in TaS₂, is not at all unclear and unexpected, because silver diffuses much slower in the former ($D \sim 10^{-10} \div 10^{-12} \text{ cm}^2 \text{ s}^{-1}$)¹⁸ than in the latter ($D \sim 10^{-6} \div 10^{-9} \text{ cm}^2 \text{ s}^{-1}$)²⁰ dichalcogenide.

G. A. Scholz²¹ and R. F. Frindt:²¹ The work presented by us²² is a detailed discussion of the techniques used by us in preparing Ag_xTaS₂ and Ag_xTiS₂ intercalation compounds which we did not have the space to discuss in earlier publications.

We agree with B. Scrosati that our EMF *vs.* degree of intercalation (x) curve for Ag/Ag_xTiS₂ is very similar to their curve,²³ and we sincerely regret the oversight of not referencing their work. We were in fact familiar with their work and had referred to it in an earlier publication²⁴ in which we pointed out that the voltage drops observed for the Ag/Ag_xTiS₂ cell were due to staging. The slightly lower EMF values observed by us may be related to equilibration times to some extent, but other factors, such as the electrolytes, should also be considered, considering that neither of us reported standard EMF values.

We would also point out that we are aware of the diffusion constants for Ag in layered crystals. In fact, we measured the diffusion constants of Ag for single crystals using optical methods and reported the value of $\sim 10^{-10} \text{ cm}^2 \text{ sec}^{-1}$ for Ag in Ag_xTiS₂ and $\sim 10^{-8} \text{ cm}^2 \text{ sec}^{-1}$ for Ag in Ag_xTaS₂ at the Yamada Conference in 1980²⁴. In addition, we also reported at that time that the intercalation rate is strongly dependent on the crystal thickness, so in view of this finding, it would appear that measurements on dichalcogenide powders are actually somewhat ill-defined.

With respect to the reversible intercalation of Ag in Ag_xTiS₂ and Ag_xTaS₂, we are somewhat puzzled on three counts by B. Scrosati's comments.

1. The reversible behavior that he refers to was for silver in the range $0 < x < 0.06$ for Ag_xTaS₂²⁵ and in the range $0 < x < 0.03$ for Ag_xTiS₂²⁶. In our study,²² the intercalated mole fractions were over the much larger range of $0 \leq x \leq 2/3$ for Ag_xTaS₂ and of $0 \leq x \leq 0.42$ for Ag_xTiS₂.

2. Contrary to B. Scrosati's comments that we found the intercalation of Ag in TiS₂ reversible, we did not find this to be the case; we found only partially reversible behavior. Stage 1 ($1/5 \leq x \leq 2/5$) could be deintercalated, but stage 2 ($0 \leq x \leq 1/5$) could not. However, although the unsuccessful deintercalation of stage 2 may be a consequence of parasitic reactions caused by the electrolyte, we believe it is certainly not due to a low diffusion rate. Of course, it may certainly be the case that in the very low concentration range ($0 < x < 0.03$), intercalation occurs reversibly.

3. We were indeed surprised to discover the reversible intercalation behavior for Ag in Ag_xTaS₂ in the range $0 \leq x \leq 2/3$, in view of the gross stacking rearrangements that occur in the host layers for $x \approx 1/6, 1/3$, and $2/3$ ²⁷.

Electrochemical Reduction of Carbon Dioxide to Methane, Methanol, and CO on Ru Electrodes

K. W. Frese, Jr.,* and S. Leach*

SRI International, Menlo Park, California 94025

An important goal of research on CO_2 reduction is the synthesis of methane in an aqueous electrochemical process. Electrochemical reduction of CO_2 to CH_3OH with high faradaic efficiency has already been demonstrated (1,2). The standard electrode potential for the electrochemical half-cell

is only +0.17 V (SHE). Under standard conditions it is expected that reaction [1] should occur at potentials close to that for the hydrogen evolution reaction. Ruthenium was chosen because it is a known catalyst (3) for the gas phase conversion of CO_2 to CH_4 and is also known to be active at rather low temperatures, (3,4), e.g., $\sim 100^\circ\text{C}$.

EXPERIMENTAL

Both electroplated and teflon-supported Ru electrodes (geometrical area, 1-3 cm^2) were used for CO_2 electrolysis. The former were formed on spectroscopic pure carbon rods using a plating bath consisting of 0.0084 M $\text{Ru}(\text{NO})\text{Cl}_3$ and 0.4M reagent H_2SO_4 . The latter type of electrode was fabricated by pressing a mixture of 4-5 gm of Ru sponge (99.99%, Matthey-Bishop) with 5-12 weight % Halon TFE resin, type 6-80 onto a Cu mesh. The resulting pellets were contacted by a Cu wire and sealed in a glass tube with epoxy resin (Epoxy Patch). A 5 min. dip in conc. HCl was used to clean the Ru surfaces.

Electrolytes were prepared from reagent grade Na_2SO_4 or H_2SO_4 and purified, distilled H_2O (Milligard filtered). A Pine RDE-3 potentiostat was used for controlled potential electrolysis in a closed system that was described before (1,2). Current-time plots were obtained and manipulated by a laboratory microcomputer. Product analysis by gas chromatography was described earlier (1,2).

RESULTS

The faradaic efficiencies for CH_4 , CO, and CH_3OH are given in Table 1. These results were obtained with the electroplated electrodes in

CO_2 -saturated 0.2M Na_2SO_4 or 0.1M H_2SO_4 electrolytes. The average current obtained by dividing the integral charge (Column 5) by the total elapsed time is given in Column 3. The apparent increase in CH_4 yield with increasing temperature is not surprising in view of the expected kinetic complications for an 8e^- reduction. The efficiency for CO was always 1 to 5% with the exception of one datum. Rather high yields of CH_3OH were also found as shown in the last column of Table 1. A portion of the CO and CH_3OH may be due to CO_2 reduction by localized cathodic and anodic reactions at the Ru electrode (see below). Recent attempts of reaction [1] in 0.5M H_2SO_4 at -0.15 to -0.3 V(sce) ($55-60^\circ\text{C}$) gave faradaic efficiencies of 0.4%. Perhaps too high a coverage with H_{ad} is obtained in such strongly acidic solutions.

It was necessary to show that CH_4 could be produced in the absence of the carbon substrate because of the potential reactivity of carbon atoms adsorbed on the Ru surface (5). For this reason, teflon-supported Ru sponge electrodes were utilized. The results of two trials in 0.1N H_2SO_4 at 46°C were faradaic decimal efficiencies of 0.059 and 0.098 for CH_4 . The electrode potential was -0.37 to -0.39 V(sce) and the average current was 0.3 to 0.6 mA. Clearly the carbon substrate is not essential to the formation of CH_4 .

It was also shown that the Ru surface is active in CO_2 reduction under open circuit conditions in 0.2M Na_2SO_4 , pH 4-5. The data in Table 2 reveal that CO and small amounts of CH_3OH are produced by a localized cell reaction. The time of these open circuit experiments was equivalent to the 15-20 coulomb runs in Table 1. Note the similar pH change accompanying the CO_2 reduction. Importantly, no CH_4 was detected in these trials.

Studies on Electrochemical Photovoltaic Cells Formed with Bi₂CdS₄ Film Electrodes

S. H. Pawar, S. P. Tamhankar, and C. D. Lokhande

Department of Physics, Shivaji University, Kolhapur 416004, India

CdS and Bi₂S₃ are promising semiconductors in the conversion of solar energy into electrical energy by means of electrochemical photovoltaic processes. However, the bandgaps of CdS ($E_g = 2.4$ eV) and Bi₂S₃ (1.4 eV) do not lie close to the solar energy spectrum maximum. Thus new solar energy materials need to be considered which satisfy desirable technical properties such as bandgap matching with the solar spectrum, high mobility and lifetime of the charge carriers and low cost (1). In this connection, we have reported a new material, Bi₂CdS₄, with a bandgap energy equal to 2 eV (2). The electrical and optical properties are reported in earlier communications (3,4).

In this communication, we report the electrochemical properties of Bi₂CdS₄ film electrodes. The experimental procedure for the deposition of Bi₂CdS₄ films by the spray pyrolysis technique is reported elsewhere (4). In short, aqueous solutions of Bismuth nitrate, cadmium chloride and thiourea were mixed in appropriate volumes in order to obtain Bi:Cd:S ratio as 2:1:4. The concentration of the solutions was 0.08 M. The substrate temperature was optimized as 250°C. The solution was sprayed at a rate of 3 cm³/min and total quantity sprayed was 200 C.C. Bi₂CdS₄ films with thicknesses of about 0.5 μm were deposited by spray pyrolysis technique. X-ray diffraction (XRD) pattern showed that the films were amorphous in nature. Compositional analysis of film based on energy dispersive analysis of x-rays (EDAX) showed that the films were deficient in cadmium and sulphur.

Key words: Bi₂CdS₄ films, spray pyrolysis technique, electrochemical photovoltaic cells

The electrochemical photovoltaic (ECPV) cells of the configuration, SnO₂:Bi₂CdS₄/1M NaOH - 1M Na₂S - 0.2 M S/C were formed. The electrical and optical properties of the cell were studied with the help of the Aplab nanoammeter, TFM 13 and PLA digital voltmeter DPM 10. A tungsten filament lamp (500 Watt) was employed for illuminating the cell. A water filter was interposed between the lamp and the ECPV cell in order to avoid heating of the cell. Spectral response of the cell was studied with the monochromator (Carl Zeiss Jena, Germany make) by noting variations of short circuit photocurrent, I_{sc} , with wavelength, λ . The capacitance-voltage (C-V) measurement was carried out with digital capacitance meter type VCM.13A.

To reveal the nature of the junction, current-voltage characteristics of the cells in dark were studied. In a electrode-electrolyte system the nature of the charge transfer reaction is given by Butler-Volmer equation as (5)

$$I = I_0 e^{(1-\beta)VF/RT} - e^{-\beta VF - RT} \quad 1$$

where I_0 is equilibrium exchange current density, β is the symmetry factor, V is the over voltage, R is the universal gas constant and F is the Faraday constant.

For voltage greater than 100 mV equation (1) reduces to

$$I = I_0 e^{(1-\beta)VF/RT} \quad 2$$

and when $\beta \neq 0.5$, the junction shows rectifying property. The magnitude of β was calculated by plotting $\log I$ versus V . The typical plot for the cell is shown in Fig.1. The magnitude of β was 0.6 which shows that the junction is rectifying in nature.

Fig. 1. Log I versus V plot for the ECPV cell formed with Bi_2CdS_4 film.

The films were etched in 50% dilute HCl for 5 seconds and heated in air at 150°C for 30 minutes before employing in the ECPV cells. A typical photovoltaic power output curve under illumination of $100 \text{ mW}/\text{cm}^2$ is shown in Fig. 2. The I_{SC} of the order of $0.2 \text{ mA}/\text{cm}^2$ and V_{OC} of the order of 260 mV were obtained under illumination. Recently, I_{SC} of the order of $0.2 \text{ mA}/\text{cm}^2$ and V_{OC} of the order of 100 mV with the ECPV cells formed with Bi_2S_3 films and polysulfide electrolyte were reported (6). The increased voltage for Bi_2CdS_4 films may be attributed to the increased bandgap of Bi_2CdS_4 films. The conversion efficiency η and fill factor, ff , were estimated as 0.03% and 40% respectively.

The spectral response of the cell was studied by noting variation of I_{SC} with wavelength, λ . Fig. 3 shows relative spectral response of the cell; I_{SC} peaks at 520 nm giving bandgap equal to 2.4 eV while the optical absorption studies of Bi_2CdS_4 films showed the cut off at 600 nm giving the bandgap equal to 2 eV . Such shifting of peak towards high energy side in the case of CdS ECPV cell is also reported (7). The lower photocurrent on the shorter wavelength side may be due to the absorption of light in the electrolyte and large amount of surface recombination of photogenerated minority carriers. Similarly lower photocurrent at the longer wavelength

Fig. 2. A typical photovoltaic power output for the ECPV cell formed with Bi_2CdS_4 film; intensity of illumination was $100 \text{ mW}/\text{cm}^2$.

side is attributed to the lower absorption of light at the photoanode used (8).

The flat-band potential, V_{fb} , of $\text{Bi}_2\text{CdS}_5/\text{Polysulfide}$ redox electrolyte was estimated by carrying out C-V measurements. In fact, capacitance observed in this case corresponds to the semiconductor depletion region capacitance and hence amount of band bending of the semiconductor can be estimated from C-V measurements. The flat band potential, V_{fb} , is calculated using the relation as (9)

$$\frac{1}{C^2} = \frac{2}{q\epsilon_0\epsilon N_D} \left(V - V_{\text{fb}} - \frac{kT}{q} \right) \quad 3$$

where ϵ is dielectric constant; ϵ_0 is permittivity of vacuum, N_D is carrier concentration and V is applied voltage. Fig. 4 shows Mott-Schottky plots for Bi_2CdS_4 cell, in which two regions with different slopes are seen. This is attributed to the presence of defect and surface states in Bi_2CdS_4 films. The V_{fb} was determined as -1.1 V (SCE) .

Minority Carrier-Diffusion Length Measurement on p-CuInSe₂/Electrolyte Diodes

C. L. Johnson

Department of Chemistry, Princeton University, Princeton, New Jersey 08544

S. Wagner^{*,1}

Department of Electrical Engineering and Computer Science, Princeton University, Princeton, New Jersey 08544

K. J. Bachmann^{*}

The n-(Zn,Cd)S/p-CuInSe₂ heterodiode has elicited much interest as a candidate for an efficient (1-3) and stable (3) thin film solar cell. The cell is fabricated by deposition of the n-type window layer onto the CuInSe₂ substrate. In both the single crystal and thin film form, the CuInSe₂ has been observed to change during the deposition process. The net acceptor concentration near the interface declines in single crystal devices (4). For thin films, type conversion from n to p has been reported (3). It is therefore important to characterize the CuInSe₂ substrate before and after the growth of the window layer. The characterization technique must not alter the substrate. In this note we report the use of a temporary semiconductor/electrolyte barrier. We employed this barrier for a measurement of the diffusion length L_n of the photogenerated minority carrier (electron). For this measurement we used the constant surface photovoltage (SPV) technique (5). The same technique can be applied to the finished (Zn,Cd)S/CuInSe₂ diode, for a determination of L in CuInSe₂ after diode fabrication.

The SPV technique, adapted to semiconductor/electrolyte barriers (6) can be applied easily to direct gap semiconductors which have high optical absorption coefficients (7). The conditions for a straightforward application of the SPV technique pertain to the optical absorption length in the range of measuring wavelengths $1/\alpha$, the sample thickness d , the space charge width W of the collecting junction and the minority carrier diffusion length L . They are

- (1) $1/\alpha \ll d$,
- (2) $1/\alpha \gg W$,
- (3) $d \gg L$ and
- (4) $W \ll L$.

CuInSe₂ is noted for its high optical absorption coefficient (8). $\alpha(\lambda)$ lies in the vicinity of 10^5 cm^{-1} for photon energies above its band gap value of 1.0 eV. The SPV

measurements were carried out near the band gap energy with $0.34 \mu\text{m} < 1/\alpha < 0.76 \mu\text{m}$. C-V measurements on the electrolyte barrier showed that the semiconductor/electrolyte barrier had a depletion width of $\sim 0.01 \mu\text{m}$. Therefore, condition (2) was met. The measured diffusion length was $1.08 \mu\text{m}$. All four conditions were satisfied in our measurement.

Two values of L_n have been published earlier. One is a value of $L_n = 0.5 \mu\text{m}$, derived from photoelectromagnetic measurements on a single crystal (9). The other, $1.43 \mu\text{m} < L_n < 2.5 \mu\text{m}$, was determined from the electron beam induced current on a single crystal CdS/CuInSe₂ heterodiode (10).

The CuInSe₂ crystal studied here had been grown from the melt by the gradient freeze technique. The Se pressure was kept high to obtain a p-type crystal. At room temperature the Hall mobility of the holes was $16 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and the hole density, $1.9 \times 10^{17} \text{ cm}^{-3}$. From a Mott-Schottky ($1/C^2$ vs. V) plot, we obtained an acceptor density in the depletion layer of $3 \times 10^{18} \text{ cm}^{-3}$, a value supported by the small width of the depletion layer. We tentatively ascribe the large difference between the densities of free holes in the bulk and of acceptors in the space charge to a high degree of compensation (11,12). Platelets were cut parallel to and including the free selenium ($\bar{1}\bar{1}\bar{2}$) surface of the crystal. The back was contacted with Ag epoxy and a Cu wire which was encased in a glass tube. The package, except for the front (electrolyte) face, was sealed with epoxy resin resistant to acetonitrile. After a 10 sec. etch in 2 vol.% Br_2/MeOH , the semiconductor electrode was inserted into the measuring cell. For routine measurements, the sample would be mounted at an opening in the cell with a temporary O-ring seal. A Pt wire served as the counterelectrode. The electrolyte was a solution of ~ 10 millimole of ferrocene and ferricenium (equal amounts by weight) as the

redox couple, and a supporting 1 molar concentration of tetrabutylammonium perchlorate in acetonitrile. The acetonitrile had been dried by distillation and was stored over a molecular sieve. The electrolyte was added to the N₂-purged cell by positive N₂ pressure. The cell was sealed from air. The measurement equipment includes a white light source, a mechanical chopper (22 to 175 Hz), a monochromator, and a split optical wave guide. Half of the beam was directed onto the sample, the other half onto a liquid-nitrogen cooled InSb detector for measurement of the photon flux. Both the sample and detector signals were processed through lock-in amplifiers.

During the SPV measurement, a value for the SPV is set by adjusting the photon flux $\Phi(\lambda)$ onto the sample. The wavelength λ is then varied and Φ is re-adjusted to restore the initial SPV. Assuming low-level injection and a constant sample reflectance, the following relation holds:

$$(5) \quad \Phi(\lambda) = \text{Const.} (L + 1/\alpha) \quad .$$

Extrapolation of the Φ vs. $1/\alpha$ data to $\Phi = 0$ therefore results in an intercept at $1/\alpha = -L$. A typical plot is shown in Fig. 1. The average L_n of a series of measurements was 1.08 μm . This value, reasonable in view of the earlier data, again underscores the high current collection efficiency of CuInSe₂-based solar cells.

Figure 1. Plot of the intensity of the probing beam vs. absorption length. Note that the origin of the coordinates lies to the lower left, outside of the graph.

As mentioned above, we also carried out a series of C-V measurements to determine the net ionized acceptor density and the flatband voltage. These measurements equally demonstrate that CuInSe₂/electrolyte diodes are practicable for the electrical characterization of CuInSe₂ crystals.

A Novel Effect. Changes in the Electrochemical Response of Polycrystalline Platinum Promoted by Very Fast Potential Perturbations

R. M. Cerviño, W. E. Triaca, and A. J. Arvia*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas (INIFTA), Casilla de Correo 16, Sucursal 4, 1900 La Plata, Argentina

It is well established that the voltammogram of polycrystalline platinum in acid electrolyte in the potential range corresponding to the stability of bulk water depends on the electrochemical history including the type of perturbation applied to the electrode and on the electrolyte composition. Thus, the voltammogram obtained with polycrystalline platinum in 1 M sulphuric acid at 25°C under a repetitive triangular potential sweep at 0.1 V.s⁻¹, exhibits the conventional three regions, namely, the H- and O-adatoms electroadsorption/electrodesorption and the so-called double layer regions (Fig.1). The former region shows a multiplicity of reversible current peaks each pair of conjugated current peaks being generally associated with the electrochemical response of a determined type of single crystal face (1-8).

Figure 1 - Stabilized voltammograms (third cycle) run at 0.1 V.s⁻¹ in 1 M sulphuric acid at 25°C (—) after 5 s cycling at 2000 V.s⁻¹ between 0.4 and 1.6 V; (---) polycrystalline platinum electrode.

*Electrochemical Society Active Member.
Key words: platinum, oriented Pt surface, potential perturbation

When such an electrode is perturbed with a very fast repetitive triangular potential sweep at $v = 2000 \text{ V.s}^{-1}$ between $E_{\ell} = 0.4 \text{ V}$ and $E_u = 1.6 \text{ V}$ during 5 s, the voltammogram run immediately afterwards at 0.1 V.s⁻¹ is much more similar to that of a Pt(111) single crystal surface after it has been cycled at a relatively low v (e.g. 0.1 V.s⁻¹) a few times through the anodic oxide region (2,3,5-8) (Fig. 1).

On the other hand, when the potential perturbation conditions are changed to 10⁴ V.s⁻¹ in the 0.04 V to 1.5 V range during 5 min, the following voltammogram run at 0.1 V.s⁻¹ in the H-adatom potential range approaches closely the characteristics described in the literature for Pt(100) single crystal surface (1,3-5, 7,8) (Fig. 2). The electrochemical characteristics of the resulting platinum surface remain unchanged after 2 h cycling between 0.04 V and 1.5 V at 0.1 V.s⁻¹, except for a small surface reconstruction.

Figure 2 - Stabilized voltammograms (third cycle) run at 0.1 V.s⁻¹ in 1 M sulphuric acid at 25°C (—) after 5 min cycling at 10⁴ V.s⁻¹; (---) polycrystalline platinum electrode.

The surface structures achieved after the potential perturbation at high v are stable for at least four weeks by keeping the electrode in contact with distilled water. The poly-

crystalline structure is recovered after etching the electrode in aqua regia.

The above described experiments were made with a low resistance designed electrochemical cell consisting of a polycrystalline platinum wire working electrode (ca. 0.15 cm² geometric area) concentrically surrounded by a large area platinum counterelectrode (ca. 50 cm²). The potential of the working electrode was measured against a hydrogen reference electrode in the same acid electrolyte solution. The shape of the triangular potential signal was increasingly distorted accordingly to v and the shift from linearity at $(E_\ell + E_u)/2$ was ca. 10 percent at 10^4 V.s⁻¹.

The voltammograms run at 0.1 V.s⁻¹ imply no charge increase above that corresponding to the monolayer of adsorbed either H or O atoms, at least for the platinum surface obtained after cycling at 10^4 V.s⁻¹ during 5 min. However, for the surface resulting after cycling at 2000 V.s⁻¹ when the duration of the potential perturbation extends to 30 s, then a charge increase is noticed which is probably related to surface roughening.

The type of surface restructuring achieved during these experiments depends on E_ℓ , E_u and v . The results show that there is a frequency threshold for producing definite changes in the electrochemical response of polycrystalline platinum, which is ca. 0.5 kHz. This figure coincides with that of the repetitive square wave potential sweep which was able to produce a preferential orientation of grains at polycrystalline platinum electrodes (9) and its reciprocal was associated with the half life time of electroadsorbed OH species on platinum produced in the initial underpotential electrooxidation of water. Furthermore, similar changes in the electrochemical response of polycrystalline platinum as those described in the present communication were also achieved by applying to the electrode in acid electrolyte other very fast periodic potential perturbations such as either a repetitive square wave or a sinusoidal signal within the H- and O- adatom electroadsorption/electrodesorption potential range (10). Therefore, the metal surface modification promoted by the very fast potential perturbations should be related to the occurrence of the initial reversible underpotential electrooxidation of water. When the probable rate constants of the various stages involved in the O-electroadsorption are considered (11) it is concluded that at frequencies greater than 0.5 kHz, either (O)Pt electroformation or ageing effects of the O-adsorbed monolayer can be ignored. The latter processes are relevant when relatively slow repetitive triangular potential sweeps are applied to platinum electrodes in acid electro-

lyte into the region of oxide formation. In this case, when single crystal electrodes are used, it results in oriented but atomically stepped surfaces (12). Further studies on the optical and electrocatalytic properties of these electrodes as well as the mechanism involved in the modification of their electrochemical response are in progress.

The Influence of Thallium on the Redox Reaction $\text{Cr}^{3+}/\text{Cr}^{2+}$

D. Sh. Cheng and E. Hollax

Fraunhofer-Institut für Solare Energiesysteme, D-7800 Freiburg, Germany

ABSTRACT

Investigations on the kinetics and electrocatalysis of the $\text{Cr}^{3+}/\text{Cr}^{2+}$ reaction were carried out. By means of cyclic voltammetry, it was discovered that the addition of thallium-I-chloride not only accelerates the $\text{Cr}^{3+}/\text{Cr}^{2+}$ reaction in HCl electrolytes catalytically, using graphite electrodes with small amounts of Au, but also raises the hydrogen overvoltage more than lead and bismuth, the heavy metal catalysts already tested in the practical redox cells. Investigations concerning the reaction rate, the influence of chrome ion concentrations, the electrolyte storage time, temperature, and the presence of iron are being conducted.

It has been shown that the course of the reaction [1] is slow

in both directions when carried out on carbon. This material is used in practical redox electrodes, because it is cheap and relatively durable in acidic as well as basic electrolytes (1, 2).

In addition, the hydrogen liberating reaction

poses problems during the Cr^{3+} reduction, because the coulombic efficiency diminishes and the increasing number of cycles throws the system out of electrical balance. This reaction makes it difficult to use the redox couple in practical redox cells (3-6). The following is, therefore, necessary: (i) the acceleration of the reaction [1] with catalysts, and (ii) the shifting of reaction [2] to a more negative potential value (compared to the thermodynamic approachable standard potential) by increasing in the hydrogen overvoltage.

The standard potential for the $\text{Cr}^{3+}/\text{Cr}^{2+}$ redox reaction is approximately -0.401V vs. NHE , which corresponds to -0.645V vs. SCE . The hydrogen liberation on carbon begins at about -0.600V vs. SCE . It has been stated in the literature that traces of lead chloride or bismuth chloride, and gold, silver or copper are advantageous additions for the cathodic and anodic reactions, respectively (7-9).

Bonhoeffer (10) discovered that the larger the catalytic effectiveness of the surface is, regarding the gas reaction, the smaller the overvoltage will become. Considering the constant a in the Tafel equation

$$\eta = a + b \log j \quad [3]$$

(where η = average potential, j = current density, and a , b = values characteristics of the electrode), the following orders can be expected for the hydrogen overvoltage (11-19)

Investigations carried out regarding the influence of thallium on the kinetics of the $\text{Cr}^{3+}/\text{Cr}^{2+}$ reaction, and its suitability as catalyst in combination with gold for practical electrodes are described.

The high overvoltage of Tl compared to the cathodic hydrogen overvoltage had already been noted by Pietzsch and Josephy (20).

Experimental

Measurements were made at 25°C (unless indicated otherwise) with a Potentiostat POS73 (Bank), an X-Y recorder 2000 (Houston Instruments), and an electrolysis cell EA-875-10 (Methrom) with a working electrode, counterelectrode, and reference electrode. Figure 1 shows the working electrode with exchangeable measuring head

Fig. 1. Working electrode with exchangeable measuring head of high pressure graphite.

developed at the Fraunhofer-Institut für Solare Energiesysteme Freiburg.

The geometric surface area is 0.113 cm^2 , and the electrode material is high pressure graphite. A platinum electrode was the counterelectrode and a sat. KCl, Hg/Hg₂Cl₂ electrode (SCE) was the reference electrode. Before measuring, the solution was purged for 10-30 min with N₂. The SEM photos were made with a JEOL/35-LF scanning electron microscope.

All chemicals were analytical grade. Solutions were made using doubly distilled water. The following standard-(stock-) electrolytes were used when not otherwise stated

Results and Discussion

Electrode pretreatment.—The pretreatment of the graphite electrode has a substantial influence on the form of catalyst deposition and therefore on the catalytic activity. The pretreatment of the electrode surface by polishing with corundum paste (particle size: $1 \mu\text{m}$) did not result in a completely smooth surface, because, under these conditions, graphite tends to smear. The roughness was, however, reduced. This could be confirmed by our electron microscope photographs. From literature results (21-24), it was estimated that the roughness factor of polished electrodes should be smaller than 15. This value has been derived by double-layer capacitance measurements.

The measured double-layer capacitance for a smooth graphite electrode are $3 \mu\text{F cm}^{-2}$ for a basal plane and for an edge plane $60 \mu\text{F cm}^{-2}$ (23, 24).

It was found that the cathodic thallium deposition on the polished surface occurred evenly over the entire sur-

a

b

Fig. 2. SEM photographs after (a) cathodic thallium deposition and (b) anodic dissolution. Standard electrolyte I, 25°C.

face. This was established by SEM photographs and also by x-ray microprobe analysis (Fig. 2a).

Fig. 3. Cyclic voltammogram of various heavy metals ($v = 100 \text{ mV/s}$, 25°C) $1M \text{ HgCl}_2$, $6.3 \times 10^{-4}M$ salt concentration. Curve 1, HgCl_2 ; curve 2, GaCl_3 ; curve 3, BiCl_3 ; curve 4, ZnCl_2 ; curve 5, PbCl_2 ; curve 6, TiCl_4 .

In addition, the thallium dissolves quantitatively when anodically loaded (Fig. 2b). Uneven catalyst deposition and dissolution were observed using an unpolished electrode.

Hydrogen overvoltage and catalytic activity.—In Fig. 3, the location of the deposition and dissolution peaks of HgCl_2 , GaCl_3 , BiCl_3 , ZnCl_2 , and TlCl in 1N HCl using a polished electrode are shown. The scan rate was 100 mV/s, and the concentration was $6.3 \times 10^{-4}\text{M}$. The result shows that thallium has a slightly higher hydrogen overvoltage than that of lead chloride, and, comparing the peak heights of PbCl_2 and TlCl , it can be seen that the latter has in addition a higher catalytic effectivity (Fig. 4).

Under these conditions, the optimal TlCl concentration was found to be $6.5 \times 10^{-4}\text{M}$ (Fig. 5). A stronger inhibition effect, which was found in the case of underpotential deposition of Pb on silver (21), has not been observed even at higher Tl^{1+} ion concentrations.

The mechanism of hydrogen liberation has been frequently investigated (11), and there are numerous mechanisms discussed in the literature: for example, the Volmer-Heyrovsky and Tafel reactions.

In the Tafel reaction, the rate-limiting step is the recombination of the hydrogen atoms

Until now, there has been no universally valid reaction mechanism. The dependency on electrode material, electrolyte solution, current density, and temperature complicated matters.

In reaction [4], it is expected that the overvoltage is dependent above all on electrode material because it is ac-

Fig. 4. Comparison of the influence of thallium and lead on the $\text{Cr}^{3+}/\text{Cr}^{2+}$ redox reaction and the hydrogen overvoltage (scan rate $v = 100$ mV/s, polished graphite surface, 25°C). Curves 1 and 2: without chromium ions; curve 3: stock electrolyte [I]; curve 4: stock electrolyte [II].

Fig. 5. Dependence of peak current density on thallium concentration ($v = 100$ mV/s, polished graphite surface, 25°C , 1M CrCl_3 , 1M HCl , $4.5 \times 10^{-7}\text{M HAuCl}_4$). Curve 1: $1 \times 10^{-5}\text{M TlCl}$. Curve 2: $1 \times 10^{-4}\text{M TlCl}$. Curve 3: $6.5 \times 10^{-4}\text{M TlCl}$. Curve 4: $1 \times 10^{-3}\text{M TlCl}$. Curve 5: $1 \times 10^{-2}\text{M TlCl}$.

celerated by the catalytic reaction. The large shift of the H_2 liberation to a negative potential in the presence of thallium chloride is only conceivable when there is an even Tl deposition as an inhibition of the active centers of the H_2 formation. We found that, as with Pb (3, 6, 7), very small amounts are sufficient to cover the deposited gold. There is not direct proof, but it can be assumed that there is an especially high reaction overvoltage of the reaction [4] in the presence of thallium in the temperature and current density regions of our measurements.

Reaction rate, reversibility.—Kinetic and thermodynamic data can be obtained with cyclic voltammetric measurements (25-30). It was observed that the peak potential difference, ΔE_p , for reversible reactions, that is, for processes that follow the Nernst relation, is approximately 58 mV. As the scan rate $v = dE/dt$ ($t = \text{time}$) increases, the peak current and the peak potential difference ΔE_p ($E_{pa} - E_{pc}$) also increase (25, 27, 31). This points to the onset of the heterogeneous electron-transfer rate. Through the variation of v and, therefore, ΔE_p , the rate constant k_s of heterogeneous reactions can be calculated with good approximation using a method developed by Matsuda and Ayabe (25) and Nicholson (27) and through the use of the kinetic parameter ψ introduced by Nicholson (26-28). This is portrayed in Eq. [5]

$$k_s = \psi \sqrt{\pi D a} \quad [5]$$

where $a = v(nF/RT)$, $v = \text{scan rate}$, $D = \text{diffusion coefficient}$, $\psi = \text{kinetic parameter for } \Delta E_p$ (32), and ΔE_p peak potential difference.

When $k_s \leq 10^{-5}$ cm/s, the reaction is irreversible, and if $10^{-5} \leq k_s \leq 1$ cm/s, according to Matsuda and Ayabe (25), the reaction is quasireversible. As shown in Table I, k_s has values of approximately 1.5×10^{-3} cm/s under the given conditions. This suggests that a quasireversible reaction proceeds.

For a Nernstian wave with stable product, the ratio of anodic and cathodic peak current density j_{pa}/j_{pc} is equal to 1.

This is true regardless of scan rate, switching potential E_s , and diffusion coefficients when j_{pa} is measured from the extrapolated decaying cathodic current. Because of the inaccuracy of this baseline determination, Nicholson (27) suggests that the ratio can be calculated from the uncorrected anodic peak current density $(j_{pa})_0$ with respect to the zero current baseline, the current density at switching potential $(j_{sp})_0$, and cathodic peak current density j_{pc} , with respect to the zero current baseline (Eq. [6])

$$\frac{j_{pa}}{j_{pc}} = \frac{(j_{pc})_0}{(j_{pc})} + \frac{0.485(j_{sp})_0}{j_{pc}} + 0.086 \quad [6]$$

The ratios are approximately equal to 1 (see Fig. 6).

Chromic ion concentration.—The peak current densities of reaction [1] increase linearly with the Cr^{3+} ion concentration as shown in Fig. 7. The concentration in the double layer is directly proportional to that in the solution.

Cycle numbers and electrolyte storage time.—It was determined that there is no strong decline of catalytic activity after up to 100 cycles measured after one another (Table II). The results are different, however, when the electrolyte storage time increases (Table III). A clear decline in activity resulted already after 25 days (25°C).

Table I. Heterogeneous rate reaction dependence on scan rate ($D_{\text{Cr}^{3+}} = 6 \times 10^{-6}$ cm²/s (22), 2M CrCl_3 , 2M HCl , $6.5 \times 10^{-4}\text{M TlCl}$, $4.5 \times 10^{-7}\text{M HAuCl}_4$, 25°C)

v (mV/s)	ΔE_p (mV)	ψ	k_s (cm/s)

It is known that chromium forms complexes very easily and, with a few exceptions, has a coordination number of 6. According to Eq. [7] chromium forms relatively stable hexaquo complexes where ligand substitution reactions proceed with half-lives on the order of an hour. We have shown that aged chromium-III-hexaquo complexes can be reactivated with N-alkylimines (33, 34).

Temperature.—The influence of the temperature was measured between 20° and $60^\circ C$ using the standard electrolytes I.

The cyclic voltammograms in Fig. 8 show the expected peak current density enhancement with increasing temperature. The increase of peak current density of $20 mA/cm^2$ between 20° and $60^\circ C$ corresponds to 40% enhancement. This result was to be expected because the transport process inside the Nernst diffusion layers ($<10^{-3} cm$), as well as the charge transfer, is accelerated by the rise in temperature. However, since ΔE_p changes only minimally, the result is actually due to the former effect.

Noteworthy is the hydrogen gas formation between 0.5 and 0.6V at $60^\circ C$. This is probably due to the extreme decline of the reaction overpotential of the Tafel reaction [4].

Conclusions

1. The use of Tl results in a higher catalytical activity for the Cr^{3+}/Cr^{2+} reaction and in a slightly higher hydrogen overvoltage than Pb.

2. The reaction rate declines quickly even in the presence of thallium as a result of the "aging effect" due to the hexaquo chrome-(III) complexes.

3. An observable peak current density can be increased through a temperature, but hydrogen formation also increases because of the decline in reaction overvoltage for the Tafel reaction. The increasing of the peak current density can be explained by the acceleration of transport phenomena.

Fig. 8. Temperature dependence (stock electrolyte [I], $50 mV/s$)

ABSTRACT

Accelerating rate calorimetry (ARC) has been used to define the thermal and pressure behavior of Li/SO₂ cells during overdischarge as a function of cell balance and operating temperature. Lithium-limited cells are shown to be intrinsically safe while cells containing excess lithium at end of life have been shown to be capable of undergoing thermal runaway through a series of coupled reactions. The most serious thermal hazards occurred upon overdischarge at low temperature. ARC analyses of cell components, *in situ* FTIR analyses, and mass spectroscopic analyses of discharged cathodes have been used to investigate the chemistry associated with the thermal behavior of Li/SO₂ cells. As expected, the lithium/acetonitrile reaction and the thermal decomposition of lithium dithionite contribute to the thermal runaway process observed in cells overdischarged at ambient temperature. In addition, however, two other reactions have been identified; one initiating at approximately 140°C involving lithium and the electrolyte solution and another initiating at approximately 190°C which is believed to involve lithium and the decomposition products of lithium dithionite. Further investigations are needed to elucidate the chemistry involved in the low temperature safety problems.

The high energy battery most widely used for military applications employs the Li/SO₂ electrochemical system. However, concern for the safety of personnel has precluded its widespread acceptance and full utilization. Although safety hazards occur from such abuse modes as shorting or charging, the problems encountered during normal operation are of particular concern. These include additional discharge of stored cells that have already been partially discharged, resistive overdischarge (when a resistive load is not removed at the end of cell life) and forced overdischarge, which occurs when a weak or prematurely depleted cell in a series of cells is overdischarged by the remaining cells. This paper focuses on the hazards resulting from overdischarge of Li/SO₂ cells.

Previous investigations on overdischarged Li/SO₂ cells have described cell behavior and some of the chemistry involved in the observed safety problems (1-5). In those studies, analyses were made on cell reaction products and gases recovered from vented cells, and it was shown that the materials balance in the cells plays a major role in the observed safety characteristics.

Based on those investigations, thermal runaway produced by exothermic chemical reactions is believed to be a primary cause of safety problems arising from overdischarge of Li/SO₂ cells. DTA studies have identified a number of exothermic chemical reactions that could contribute to a thermal runaway (6, 7). The most important are believed to involve the thermal decomposition of lithium dithionite, the major discharge product of Li/SO₂ cells, or the reaction of lithium or lithium/aluminum alloy with acetonitrile.

The objective of the present work, therefore, was to quantitatively define the thermal effects of exothermic reactions resulting from overdischarge of Li/SO₂ cells and to determine if thermal runaway was indeed the cause of the observed safety problems. Accelerating rate calorimetry (ARC) has been employed to study the thermal and pressure behavior of observed exothermic reactions. Component analyses involving both ARC and mass spectroscopy, along with *in situ* FTIR studies of cell electrolysis products, have been employed in an attempt

to identify the key reactions involved in cell exothermicity.

Experimental

Mass spectroscopic studies were performed employing a Finnigan Model 4000 GC chemical ionization electron impact mass spectrometer.

Infrared spectra of electrolysis products of Li/SO₂ cells were recorded *in situ* using a Digilab Model 14 FTIR spectrometer. Spectroelectrochemical cells were constructed with either AgCl or KBr windows separated by polyethylene spacers to permit insertion of electrodes. The cell assembly had a path length of <1.0 mm and was sealed with epoxy. The anode consisted of a nickel minigrad current collector, with or without lithium, located in the center of the cell in the direct path of the infrared radiation. The cathode collector was Shawinigan carbon black with Teflon pressed on an aluminum grid and located on the inside periphery of the cell. A lithium reference electrode was included. An external jacket was built to permit subambient operation (to -22°C) by circulating nitrogen cooled by dry ice and acetone. The cells were filled in a glove box with the electrolyte solution cooled to -10°C to prevent loss of SO₂.

The accelerating rate calorimeter was manufactured by Columbia Scientific Industries. The experimental 1/2 C-size Li/SO₂ cell used in the ARC studies was a spirally wound cell employing conventional components and housed in a 316L stainless steel case acting as the negative terminal. The primary electrolyte consisted of 6.4 weight percent (w/o) LiBr, 25.6 w/o acetonitrile (AN), and 68.0 w/o SO₂. One experiment employed propylene carbonate (PC) electrolyte with 6.4 w/o LiBr, 33.6 w/o PC, and 60.0 w/o SO₂. The PC was vacuum distilled prior to use.

In the ARC experiments, discharge and overdischarge at ambient temperature was carried out in the calorimeter but not under adiabatic conditions. Periodically, the testing was interrupted and the cells checked for exothermicity while on open circuit. Exotherms were monitored under adiabatic conditions to completion before electrical testing was continued. Force overdischarge tests were carried out for a minimum 200%, based on ini-

tial SO₂ capacity. Resistive overdischarge was continued until the cell potential dropped below 0.1V.

Results and Discussion

The ARC is a microprocessor-controlled adiabatic calorimeter that automatically searches for exothermic reactions by elevating the temperature of a sample or a complete cell by a fixed increment and then checking for a self-heating rate exceeding a preselected threshold. Once an exotherm is detected, the instrument maintains the sample in an adiabatic environment and continuously monitors its thermal and pressure behavior. In this way, the ARC can provide a complete hazard analysis for each exothermic reaction detailing the kinetics of the reaction, the rate and quantity of heat generated, and the rate and magnitude of pressure generated. Additional details concerning the theory and operation of the ARC can be found in the literature (8, 9).

Hazards associated with exothermic reactions occurring in Li/SO₂ cells during and following overdischarge have been characterized by six parameters relating to cell thermal and pressure behavior. They are (i) initiation temperature, (ii) total heat output, (iii) total pressure rise, (iv) maximum rate of temperature rise, (v) maximum rate of pressure generation, and (vi) maximum observed pressure. The ARC thermal data have been presented as a log temperature rate vs. temperature plot. The temperature data are plotted as 1/T K while the temperature axis is labeled in degrees centigrade for convenience. This is essentially an Arrhenius plot of the data which is very useful for interpreting the ARC results since each exothermic reaction occurring will show up as a separate peak. Discontinuity in the ARC thermal curves represents a heat/search mode of operation where self-heating was not observed in the sample.

A description of the ARC cells tested, the test conditions and cell performance are summarized in Table I. Three cell types have been investigated, each having a different coulombic Li/SO₂ ratio, as follows: lithium limited ≈ 0.5 , balanced ≈ 1.0 , and excess lithium ≈ 1.5 . These ratios were chosen so that the lithium would always be completely consumed in lithium-limited cells at end of life while lithium would always remain at end of life in excess-lithium cells, regardless of operating conditions. Balanced cells are balanced in theoretical terms only and may or may not have lithium remaining at end of life, depending on operating conditions. For example, operation at low temperatures or high rates of discharge can severely degrade cathode utilization efficiencies, causing a theoretically balanced cell to contain significant quantities of lithium at end of life.

All cells used in these studies incorporated a reverse wrap configuration in which the cathode is on the outside of the wrap. In this configuration, all lithium is electrochemically accessible, making the lithium-limited cells truly lithium limited. In contrast, most commercial cells employ a conventional wrap, with the lithium anode on the outside of the wrap. In these cells, part of the lithium on the last turn of the wrap assembly is not electrochemically accessible and will remain at end of life regardless of the initial materials balance in the cell or the operating conditions employed. Such cells are never truly lithium limited.

Ambient temperature tests.—Lithium-limited cells.—Table II summarizes the hazard analysis data for lithium-limited cells resistively overdischarged at ambient temperature. Typical thermal behavior is illustrated by cell no. 3 in Fig. 1. Initial exothermicity generally occurred near 104°C, the result of a low activation energy exotherm, as evidenced by the minimal acceleration of rate with increasing temperature. All the cells exhibited a second exotherm between 210° and 260°C. Two of the

Fig. 1. ARC thermal behavior for lithium-limited cell no. 3 resistively overdischarged of ambient temperature.

cells exhibited a third exotherm initiating between 280° and 290°C. In the remaining cell, cell no. 1, the two high temperature exotherms appeared to be combined as a single exotherm. The reproducible innocuous thermal and pressure data appear to confirm the intrinsic safety of the lithium-limited design.

Forced overdischarge of a lithium-limited cell could cause oxidation of the electrolyte solution, anode grid material (if a grid is employed), and/or the cell case material, generating products that could significantly affect cell safety.

Conventional Li/SO₂ employs nickel-plated steel cases (10, 11), while some cells manufactured for special applications incorporate a nickel grid as an anode collector (12). Overall, nickel is used in virtually all Li/SO₂ cells and is a key material to consider when investigating the effects of overdischarge of lithium-limited cells. For this reason, our test cells incorporated nickel anode grids. FTIR analysis on electrolyte solutions stored 15 days with nickel confirmed the stability of this system.

In situ FTIR analysis during electrolysis of a lithium-limited cell, containing a bare nickel grid as an anode (Fig. 2A), showed distinct changes in the solution spectra when compared to the spectra of a cell containing a lithium anode (Fig. 2B). In the cell with the lithium anode, the IR spectra remains unchanged from that of the original electrolyte solution when electrolyzed to 23% of its SO₂ capacity, indicating the absence of any soluble discharge products. In the cell with the bare nickel grid, however, the water bands at 3460 and 1630 cm⁻¹ disappear and a band at 2665 cm⁻¹ decreases. Small bands appear at 980, 1060, and 1265 cm⁻¹. A 880 cm⁻¹ shoulder becomes a peak at 900 cm⁻¹ on continued electrolysis. A new band appears at 800 cm⁻¹.

Interestingly, several of these bands were also observed under some cell conditions involving a lithium anode. For example, if the partially discharged cell of Fig. 2B is stored at 25°C for 11 days, some IR bands split, major bands appear at 500, 560, 800, 880, 920, and 980 cm⁻¹, and some minor bands, indicative of sulfate (13), form at 445, 615, and 1100 cm⁻¹ (Fig. 2C). With the exception of the 800 and 880 cm⁻¹ bands, the other bands have been observed in the spectra of solid discharge products (14, 15). Also, when a fresh Li/SO₂ cell is charged at 25°C, major IR bands appear at 800, 880, 980, and 1260 cm⁻¹ (Fig. 2D).

The effects of solvation by SO₂ make *in situ* identification difficult. The bands near 1265, 1060, 980, and 660 cm⁻¹ generally grow or appear upon discharging a cell with no lithium or on charging a fresh Li/SO₂ cell. Similar bands have been identified with metabisulfite, S₂O₅²⁻ (16, 17). However, it is plausible these bands arise from redox reactions involving SO₂ to form an indistinguishable solvated sulfite, SO₃²⁻ · SO₂.

The 800 cm⁻¹ band is strongly IR active (18) and is attributed to an asymmetric stretching frequency of a —SOS— group (19). This band appears to be influenced by kinetic factors. It develops on storage (Fig. 2C), on charging, but only at current densities ≥0.5 mA/cm² (Fig. 2D) and upon loss of lithium in cells overdischarged at 25°C (Fig. 2A) but not at -22°C.

Presumably, this 800 cm⁻¹ band involves the interaction of the highly reactive [SO₂]⁻ ion with [SO₂]⁻, SO₂ or other sulfur oxy-anions. An ion pair, [Li⁺ · SO₂⁻] (20), and a charge transfer complex, S₂O₄⁻ formed between SO₂ and SO₂⁻ (21), have been reported. Also, a reactive form of dithionite [SO₂ · SO₂]²⁻ with —SOS— bonding (22) has been proposed to be the reactive intermediate in which metals, such as nickel, are oxidized by organic-SO₂ solvents to disulfates or sulfates (23, 24).

To determine if these oxidation products affect cell safety, a cell containing no lithium at all and employing a bare nickel grid as an anode was force discharged at 1 mA/cm² for 7.63 Ah, 3.75 times the initial SO₂ capacity. Occasionally, the discharge was interrupted and the cell was checked by ARC for exothermicity. No exotherms were detected. Next, the cell was subjected to a heat and search operation in the ARC; only one small exotherm

occurred at approximately 225°C. The self-heating rate was only 0.06°C/min with a pressure of 100 psig. Although

oxidation products in the absence of lithium at the anode revealed no intrinsic safety problems, we have not ruled out hazards that may occur in "anode"-limited cells containing some electrochemically inactive lithium. This is more likely to occur in cells using a standard wrap configuration.

Excess lithium cells.—ARC analysis revealed very complex thermal behavior for Li/SO₂ cells containing excess lithium. The hazard analysis data for excess lithium cells overdischarged at ambient temperature are tabulated in Table III. Figure 3 illustrates ARC thermal data for cell no. 5 force overdischarged at 1 mA/cm². Both the thermal and pressure ARC curves are displayed in Fig. 4 for a similar cell, no. 7, which has been resistively overdischarged using a 5Ω load. All excess lithium cells, whether forced overdischarged or resistively overdischarged, exhibited initial exothermicity shortly after overdischarge began, often with the cells still near ambient temperatures. In addition, all the resistively overdischarged cells exhibited an exotherm, beginning at approximately 110°C. A similar peak was observed in the forced overdischarged cell at approximately 125°C. All the cells exhibited several addi-

tional exotherms in the temperature range 140°-200°C and displayed a common high temperature exotherm near 260°C.

Fig. 3. ARC thermal behavior for excess lithium cell no. 5 forced overdischarged at 1 mA/cm² at ambient temperature.

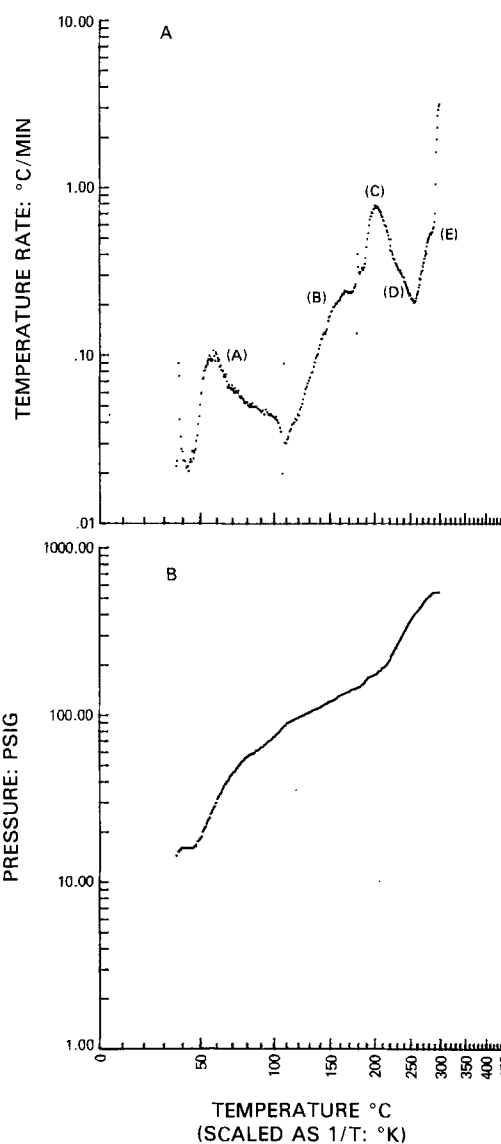

Fig. 4. A: ARC thermal behavior for excess lithium cell no. 7 resistively overdischarged at ambient temperature. B: ARC pressure behavior for cell no. 7.

In general, overdischarged excess lithium cells exhibited one continuous exotherm, resulting in self-heating to temperatures of 300°C or more. The ARC data indicate that several coupled reactions are responsible for the self-heating rather than one single reaction. Although thermal runaway did occur, the observed rates of heat and pressure generation were low, indicating the absence of explosion hazards but the magnitude of overall pressure generation was sufficient to cause venting in commercial cells.

Low temperature tests.—Significant safety hazards have been observed in Li/SO₂ cells force overdischarged at ~3 mA/cm² at low temperatures and allowed to warm to room temperature (25). To simulate these conditions, cells coulombically balanced at ambient temperature were force overdischarged at -35°C under a constant current of 3 mA/cm². Three replicate cells were tested. One cell, cell no. 11, vented during the overdischarge, generating an internal pressure of greater than the 2500 psig required to rupture the disk vent incorporated in the ARC hardware. The two remaining cells were successfully overdischarged but exhibited distinctly different thermal behavior. Cell no. 12 became exothermic at 35°C and continued self-heating to 182°C. This cell generated only a maximum pressure rate of 8.51 psi/min to a total of 160 psig. The exotherm at 32°C was similar to the reactions observed in the cells overdischarged at ambient temperature, attributed to reaction of lithium with acetonitrile. At 61°C, a second reaction occurred exhibiting a maximum temperature rate of only 1.84°C/min. The other cell, cell no. 10, did not become exothermic until 77°C, but, near 110°C, a very rapid reaction occurred producing heating rates of >180°C/min and pressure generation rates exceeding 1700 psi/min (Fig. 5). The maximum observed pressure was 881 psig.

The results obtained with cell no. 10 and 11 confirm that overdischarge of Li/SO₂ cells at low temperature can indeed produce explosion-type hazards. The fact that cell no. 11 vented while still at low temperature before being allowed to warm up raises even more concern.

Cell component study.—The near ambient temperature exotherms observed in the cells with excess lithium are attributed to the reaction of lithium and acetonitrile (AN) at the end of cell life. Since AN could also be involved in some of the elevated temperature reactions, an experiment was conducted to define the role of AN in the thermal runaway process. An excess lithium cell was activated with electrolyte solution containing propylene carbonate (PC) in place of AN. PC was selected because of its good stability with lithium (6, 26). The cell was discharged and force overdischarged at 1 mA/cm² beyond 234% of its original SO₂ capacity. No exothermic behavior was detected by the ARC during the discharge-overdischarge process. Following overdischarge, ARC analysis revealed an exotherm occurs on warming the cell to 45°C. A second exotherm occurs at 80°C, and continues to the 300°C cutoff temperature. The thermal and pressure behavior, illustrated in Fig. 6, reveals extremely high rates of heat generation (358°C/min for PC vs. 3.18°C/min for AN, cell no. 7, Table III) and pressure generation (13,000 psi/min for PC vs. 7.19 psi/min for AN, cell 8, Table III). The total pressure generated in this PC system was 2325 psig, compared to a maximum 690 psig for an AN system, (cell no. 8, Table III).

Contrary to expectations, the thermal runaway threat that can occur in overdischarged Li/SO₂ cells was not diminished when AN was replaced with PC. The near ambient temperature exotherm still occurs using PC. The overall rate of heat and pressure generation was significantly enhanced as a result of subsequent exotherms arising from coupled reactions. In view of the stability of lithium in PC, these results support the contention that either a Li-Al alloy (2) or an intercalated lithium-carbon black compound (27) may contribute to cell safety. Propylene carbonate is known to be reduced with high efficiency by lithium amalgam and lithium-

carbon compounds (27, 28). The reaction may be delayed by passivation from residual SO₂, similar to the observed SO₂ passivation of the Li-PC reaction (29). This may allow Li-Al or Li-C to accumulate to a greater degree than in AN, whereupon the reaction, beginning near 45°C, occurs with increased intensity.

On the assumption that reactions observed in the lithium-limited cells were due to cathode reaction products, ARC analyses were performed on various cathode samples from commercial Li/SO₂ 2/3 A and D-size cells discharged at constant current to a 2.0V cutoff.

The D cells were discharged at 10 mA/cm² at ambient temperature and at 71°C. The cathodes were removed from the cell hardware, rolled up with the grid intact, and while still wet with electrolyte were inserted into the ARC bomb under inert gas. The ambient temperature cathode displayed two uncoupled regions of exothermicity, one near 80°C and the other at 280°C. The cathode from the 71°C discharge displayed an exotherm peaking at 130°C and coupled exotherms initiating at 246° and 280°C. No significant thermal or pressure hazards were observed by ARC analysis of the cathodes from either D cell.

The 2/3 A cells were discharged at 1 mA/cm² to 2.0V at ambient temperature. Under an inert atmosphere, the cathodes were removed, subjected to vacuum for 1/2h to remove bulk SO₂, the grid removed, and the powdered cathode placed in the ARC bomb. Lithium dithionite has been reported to be the sole product formed after analysis of cathodes taken from identical cells discharged in a sim-

Fig. 5. A: ARC thermal behavior for coulombically balanced cell no. 10 forced overdischarged at 3 mA/cm² at -35°C. B: ARC pressure behavior for cell no. 10.

ilar manner (30). Figure 7 shows reproducible ARC thermal data from this cathode, presumably representing a mixture of carbon, Teflon, Li₂S₂O₄, with some residual electrolyte. The first exotherm begins at 91°C and gives rise to a pressure of about 150 psig. The second exotherm beginning near 116°C and rising to near 200°C is very re-

Fig. 7. ARC thermal behavior for a carbon cathode from a 2/3 A size Li/SO₂ cell discharged at 1 mA/cm² at 25°C to a 2.0V cutoff.

producible and is characterized by a rise near 155°C. The final exotherm begins near 230°C and generates gaseous pressure.

Both the 2/3 A- and D-size cathodes from cells discharged at ambient temperature displayed similar pressure and thermal behavior from reactions near 80°-90°C. These appear to be relatively low activation energy reactions, as evidenced by the absence of any significant increase in temperature rate with increasing temperature. However, unlike the D-cell cathodes which exhibited thermal and pressure behavior similar to lithium-limited cells, the 2/3 A-cell cathodes display an additional exotherm starting near 116°C, similar to those observed on all the resistively overdischarged excess-lithium cells (see Fig. 4, part B of curve A). The reason for this difference in behavior is not understood at this time, but may have to do with the amount of electrolyte solution present with the cathode sample. Another factor may be the amount of moisture contained in the cathode. Mass spectroscopy revealed that the D-cell cathodes contained significantly more moisture (as much as 15% of the volatiles exclusive of air) than the <1% moisture found in the 2/3 A cell cathodes.

In contrast to the thermal behavior observed in lithium-limited cells and discharged cathode samples, the excess lithium cells exhibited distinct peaks in the 100°-180°C region, indicating that reactions other than dithionite decomposition may be occurring. In overdischarged cells, likely candidates were either a lithium/electrolyte reaction or reaction between lithium and lithium dithionite. Both possibilities were investigated.

The results of an ARC analysis between 0.27g of lithium metal and 3.49g of commercial 68 w/o SO₂ electrolyte solution reveals a large exothermic reaction occurs at 140°C. Sulfur dioxide is completely inert toward lithium metal up to 320°C (31). Therefore, the observed lithium/electrolyte reaction probably represents the lithium/acetonitrile reaction pushed to higher temperatures by the inhibiting effects of SO₂. The initiation temperature of this reaction has been previously demonstrated to be sensitive to the SO₂ concentration of the electrolyte (7). Figure 8 shows the lithium/electrolyte ARC data compared with the ARC data obtained from an excess lithium cell resistively overdischarged (cell no. 8). The lithium/electrolyte reaction was found to coincide with one of the cell exotherms.

In order to examine the behavior of lithium metal with cell discharge products, a cathode from a D cell discharged to a 2.0V cutoff at 10 mA/cm² at ambient temper-

Fig. 8. Comparison of lithium + SO₂ electrolyte solution ARC behavior with excess lithium cell no. 8 resistively overdischarged at ambient temperature.

ature was sandwiched between two layers of lithium foil (0.68g) and subjected to ARC analysis. The cathode had the aluminum grid intact and contained some residual electrolyte solution. A very large exotherm was observed initiating at 190°C following the melting of lithium. Presumably, this was due to the reaction of lithium with decomposition products of lithium dithionite. Figure 9 compares this exothermic behavior between lithium and a discharged D cell cathode with ARC data for a resistively overdischarged excess lithium cell (cell no. 7). As the figure illustrates, the exotherm at 190°C coincides with a major exothermic reaction found in the cell.

Included in Fig. 9 is a mass spectroscopic temperature profile of the total ion intensity in relative units found on warming a carbon cathode from a similarly discharged D cell. The spectral profile shows that volatiles begin to appear near 100°C and peak at 150°C. Examination of the component gases shows the initial evolution is mostly due to masses 41 (CH_3CN) and 64 (SO_2), with the bulk evolution starting near 125°C. The profile for mass 256 (sulfur) exhibits identical behavior. Major evolution begins near 130°C and peaks at 152°C. This sulfur is attributed to the decomposition of dithionite.

A double peak appears in the 130°-150°C region of curve A, Fig. 9 (lithium and cathode). The first peak agrees well with the lithium-electrolyte reaction (Fig. 8), whereas the second peak coincides with the decomposition of dithionite.

The initiation temperature and kinetics of each of these exothermic reactions may be interdependent and could also be affected by the amount of electrolyte present. Decomposition of lithium dithionite will generate SO_2 , thereby affecting the lithium/electrolyte reaction, which has been shown to be dependent on SO_2 concentration. In turn, the thermal stability of lithium dithionite has not been fully explored. Its decomposition may be a function of its degree of wetness with electrolyte.

It has been postulated that one of the major causes of safety in the Li/SO_2 system is the reaction of lithium with molten sulfur formed from the thermal decomposition of lithium dithionite. Consequently, ARC analysis was performed to evaluate the role of the lithium/sulfur reaction in cell safety. A sample of 0.14g lithium was pressed onto the bottom of the sample bomb and an equal mass of sulfur was smeared onto its surface to maintain intimate contact. Electrolyte solution, 2.01g 68 w/o SO_2 , was added

last. ARC analysis revealed no low temperature exotherm due to the lithium/sulfur reaction, as previously reported to occur near 142°C if the molten sulfur "wets" the lithium (26). Presumably, the electrolyte inhibits this wetting by film formation. Conversely, the sulfur may have affected the lithium/electrolyte reaction. A much reduced lithium/electrolyte reaction was observed in this experiment. Additional exotherms were observed to start near 190° and 226°C. The 190°C exotherm was observed before, and exotherms between 220° and 240°C have been consistently observed. Depending on conditions, either exotherm could be from a lithium/sulfur reaction. The reaction at 226°C produced relatively low rate of heat generation. However, a substantial quantity of heat is liberated, which could propagate a thermal runaway.

Conclusions

ARC analysis reveal that resistively overdischarged lithium-limited cells exhibited simple thermal behavior. The exothermic reactions that occur are attributed to the thermal decomposition of dithionite and are characterized by slow self-heating rates and initiation temperatures above 100°C and are not coupled, thus eliminating the thermal runaway hazard. Forced overdischarging of lithium-limited cells produced no additional hazards.

In contrast, cells containing excess lithium at end of life have been found to be capable of undergoing thermal runaway when overdischarged at ambient temperature in either a resistive or forced mode. The rates of temperature rise and pressure generation occurring during thermal runaway, however, were found to be low, indicating the absence of any explosion hazard. The magnitude of overall pressure rise, however, was large enough to cause venting in commercial cells.

The thermal runaway process was found to be the result of a series of coupled, exothermic chemical reactions, as illustrated in Fig. 4A. Exotherm (A), which initiates at near ambient temperature (30°-50°C), is attributed to the low activation energy reaction of lithium and acetonitrile. This reaction did not initiate in any of the cells until the potential dropped below 2.0V implying that a triggering mechanism may be necessary. This could involve depletion of SO_2 , localized heating effects, or perhaps a reaction with freshly deposited lithium, Li-Al, or Li-C formed at the start of overdischarge.

The reactions occurring in the second temperature region (B) are critical to Li/SO_2 safety since they provide the pathway for the propagation of thermal runaway to the melting point of lithium. Exotherms in this region have been shown to involve the thermal decomposition of lithium dithionite and a reaction of lithium with the electrolyte solution.

The exotherm observed in region C upon the melting of lithium is believed to involve lithium with dithionite or a decomposition product of dithionite. Causes of exotherms produced in the high temperature regions at approximately 230°C and in regions D and E are speculative. Possible reactions include lithium with sulfur and lithium with the Teflon contained in the carbon cathode (26).

Replacing acetonitrile in the electrolyte solution with propylene carbonate did not eliminate the thermal runaway hazard in excess lithium cells. In addition, much higher rates of heat and pressure generation were observed indicating that PC-based cells would constitute a much more serious safety hazard than the standard AN-based cells.

Cells coulombically balanced at ambient temperature and force overdischarged at -35°C have been shown to lead to serious safety problems, potentially with explosion-type hazards. The results indicate that these cells can become hazardous during the overdischarge process, even before they are allowed to warm up.

The *in situ* IR study revealed kinetic parameters such as current density and storage time may be contributing factors in the observed low temperature or excess lithium cell safety problems. Additional studies are needed to elucidate this chemical, kinetic, and thermal relationship.

Fig. 9. A: ARC thermal behavior for lithium + cathode from D cell discharged at 10 mA/cm² to 2.0V at 25°C. B: ARC thermal behavior for cell no. 7 (excess lithium cell resistively overdischarged at ambient temperature). C: Mass spectra showing total ion intensity in arbitrary units from D cell carbon cathode. Peak intensity occurs at 150°C. Identical curve occurs for mass 256 (sulfur), presumably from dithionite decomposition.

Li/Li_{1+x}V₃O₈ Secondary Batteries

III. Further Characterization of the Mechanism of Li⁺ Insertion and of the Cycling Behavior

ABSTRACT

The reduction mechanism of the bronze Li_{1.2}V₃O₈ in nonaqueous Li cells has been elucidated. Upon Li⁺ insertion, a solid solution is formed with an upper composition of Li_{1.3}V₃O₈. Within this composition range, Li⁺ progressively fills the tetrahedral sites available in the unit cell. Four such sites are supposed to be filled at the upper composition limit. Beyond this, a new phase is nucleated to accommodate excess Li⁺, this resulting in a constant cell's OCV. Li⁺ insertions not greater than 3.0 eq/mol are reversible, as shown by the cycling behavior and the x-ray patterns. Owing to the outstanding structure stability and to the high speed of Li⁺ diffusion in Li_{1.2}V₃O₈, extended cycling at high rates is achievable with cells based on this bronze. 445 cycles at discharge rates variable in the range of 2-10 mA/cm² have been obtained.

In previous communications (1, 2), we have reported data on the features of Li_{1+x}V₃O₈ as a reversible cathode for Li cells. This bronze, a layered compound whose layers are held together by Li⁺ ions (3), has proven to be able to insert Li⁺ in its structure with outstanding energy, power, and cycling capability.

Given the difficulties encountered with V₆O₁₃ (both stoichiometric and nonstoichiometric), which had shown

promise for successful use in rechargeable Li batteries (4-6), the search for new materials is even more justified. On the other hand, by directly comparing the characteristics of Li_{1+x}V₃O₈ with those of V₆O₁₃ (S) (2), we obtained evidence that the former could be estimated superior to the latter in such aspects as energy density, rate capability (power density), cycle life, and resistance to overdischarge. On this basis, this ternary oxide did seem worthy

of a further investigation aimed at assessment of the mechanism of Li^+ uptake/removal and at evaluation of those parameters which are relevant to practical rechargeable batteries.

The first commitment may perhaps be easier to fulfill, whereas the second requires a larger number of tests eventually oriented to batteries with practical characteristics. So, we feel that with our previous papers and the present one, the mechanistic aspects of the redox reactions occurring in $\text{Li}/\text{Li}_{1+x}\text{V}_3\text{O}_8$ cells have been sufficiently elucidated. On the other hand, as for the technological aspects, the contribution presented here is still partial and will be followed by a more substantial work.

Experimental

The relevant experimental procedure has already been reported (2). The bronze used in the present investigation was prepared by melting Li_2CO_3 and V_2O_5 (obtained by decomposing NH_4VO_3) in quartz vessels at 680°C in the air. Although this temperature is higher than that reported in the phase diagram for the existence of only $\text{Li}_{1+x}\text{V}_3\text{O}_8$ (7), we found that the sample so prepared has a satisfactory electrochemical behavior. However, a more complete evaluation of the influence of the preparation procedure on performance is now under way and will be reported in a forthcoming paper.

The composition of the sample so prepared was checked by both atomic absorption spectroscopy and chemical analysis (7). With the latter, the relative amounts of V^{+4} and V^{+5} were evaluated, and the former was found to be present as 7.45% of total V. From this value, an average oxidation number of 4.92 was derived for V, so that the composition of the bronze may be represented as $\text{Li}_{1.2}\text{V}_3\text{O}_8$. Compositions close to this have often been found when trying to prepare low-lithium $\text{Li}_{1+x}\text{V}_3\text{O}_8$ (7-9).

1M LiClO_4 in PC-DME was used as a solution because of its satisfactory chemical and electrochemical stability. The latter was checked in this work by galvanostatic and sweep voltammetry experiments.

The electrodes were mostly prepared by pressing at 800 kg/cm^2 on an expanded Ni net a mixture ($20\text{-}30\text{ mg/cm}^2$) of $\text{Li}_{1.2}\text{V}_3\text{O}_8$ (70%), acetylene black (20%), and Teflon (10%). For extended cycle tests, relatively thin electrodes were prepared by rolling a nonexpanded Ni net prior to and after applying about 10 mg/cm^2 of the above mixture on it.

For the cyclic voltammetry experiments, a cell of the type described by Shaw (10) was used with Li as both reference and counterelectrode. The working electrode was prepared as reported above.

Results and Discussion

The main features of the structure of $\text{Li}_{1+x}\text{V}_3\text{O}_8$ have been described by Wadsley (3) and summarized in a previous work of this series (2). It is sufficient to emphasize here that the basic structural elements of the bronze, *i.e.*, octahedra and trigonal bipyramids, are arranged to form puckered layers with the Li^+ ions arranged in between by occupying octahedral sites (Fig. 1). In the unit cell, dashed in the figure, there are two such sites to which six tetrahedral sites have to be added (1-6 in Fig. 1). The latter can be filled by excess Li^+ as supposed by Wadsley (3) and experimentally checked by us (2) and others (9) through the observation of a solid solution formation upon Li^+ uptake.

However, based on the evidence presented by the coulometric titration curve (Fig. 2), incomplete filling of the tetrahedral sites occurs. Indeed, the single-phase behavior typical of solid-solution formation (EMF decreasing with x) is only visible up to an x value of about 1.7. By adding to this figure excess Li^+ with respect to stoichiometric LiV_3O_8 (0.2 Li^+ ions per molecule), one obtains about 2 Li^+ ions added to each molecule. As the unit cell is based on 2 $\text{Li}_{1+x}\text{V}_3\text{O}_8$, up to 4 Li^+ may be accommodated

Fig. 1. Structure of $\text{Li}_{1+x}\text{V}_3\text{O}_8$, projected onto (010), showing both octahedra and trigonal bipyramids. The unit cell is dashed.

Fig. 2. 1: Compositional variation of OCV during the first discharge. 2: OCV after stopping at $x = 2.5$ and recharging. 3: OCV after stopping at $x = 3.0$ and recharging. 4: discharge curve at 0.2 mA/cm^2 .

in its tetrahedral sites. On the basis of the interatomic distances, they may for instance correspond to the numbers 1, 3, 4, and 6. Indeed, from the data reported by Wadsley (3), one may assign to sites 1-2 and 5-6 (close to the octahedra) a distance of about 1.7 \AA , whereas sites 3-4 (close to the bipyramids) have a distance of about 2.2 \AA . The latter value is exceeded by the distances between tetrahedral and octahedral Li^+ . Therefore, simultaneous occupation of the couples of sites 1-2 and 5-6 is less probable, owing to the repulsion forces between Li^+ ions ($r_{\text{Li}^+} = 0.7\text{ \AA}$).

Beyond a total Li^+ insertion greater than 2 eq/mol, further Li^+ may only be accommodated if a structural rearrangement occurs. The structure has to be partially distorted by excess Li^+ until a new phase is nucleated which is in equilibrium with that corresponding to the solid solution. A constant EMF is then observed (Fig. 2), as is typical of a two-phase region. Attempts to characterize the new phase were thwarted by the low number of its peaks.

In their preliminary investigation on the same phase, $\text{Li}_{1+x}\text{V}_3\text{O}_8$, Raistrick and Huggins (9) obtained a similar EMF/ x curve, although the single-phase region ends somewhat earlier in their work ($x = 1.5$).

The initially high and rapidly falling EMF's indicate a high value of the Li chemical potential and its sharp decrease after occupation of the first sites. We may define $\mu_{\text{Li}}^{\text{cathode}} - \mu_{\text{Li}}^{\text{anode}} = -FE$ as the variation of μ_{Li} in the cathode with respect to that in the anode. The latter may be assumed to be zero (11). As a consequence of the rapid decrease of μ_{Li} , the overall energy of intercalation, defined as $\Delta G_1 = -F \int_0^x E \cdot dx$, has a minor increase in this region. After this stage, E diminishes less rapidly with x . The flat final part of the E/x curve at $E = 2.62$ and the high x value observed allow for a high free energy of intercalation ΔG_1 to be calculated for the overall process. For $x = 3.1$ ($\text{Li}_{\text{tot}} = 4.3$) ΔG_1 is equal to -200 kcal/mol , a large value which is in turn related to the high energy capacity shown by this

compound. As a comparison, ΔG_1 for LiTiS₂ is -57.4 kcal/mol (11).

A value of 815 Wh/kg (cathode only) may be calculated for $x = 3.1$ and $\bar{E} = 2.83$ V. By considering the weight of Li consumed in the reaction, a value of 758 Wh/kg is obtained, which represents the maximum energy density of a Li/Li_{1.2}V₃O₈ cell. For comparison, the theoretical specific energies of V₆O₁₃ (NS), V₆O₁₃ (S), and TiS₂ are reported to be 890, 710, and 490 Wh/kg, respectively (5, 12).

The complex reduction mechanism of Li_{1+x}V₃O₈ is also reflected in the pattern of the linear sweep voltammograms. Figure 3 shows that, especially at low scan rates, all the features shown by the titration curve are present and even more evident. In particular, the 3 small peaks above ~3.15 V point to the inequivalence of the sites about 1 per unit cell; see titration curve) initially occupied by Li⁺. The large peak corresponding to the single-phase region with a lower slope is split to match the inflection noted at $E = \sim 2.8$. Finally, the last peak corresponds to the biphased region noted at $x > \sim 1.7$.

The x-ray diffractograms of Fig. 4 show the structure evolution following Li⁺ insertion. At $x = 1.6$, the pattern is very similar to the one initially observed, apart from a limited structure expansion testified by the shifting of the peaks to lower angles. In particular, the peak corresponding to the interlayer distance, at $2\nu = \sim 14.0^\circ$, is only shifted by about 0.1° , i.e., less than 1%. At $x = 2.7$, the

Fig. 4. X-ray diffractograms of Li_{1.2}V₃O₈ electrodes after discharge and cycling.

main peaks of the original structure are still present, but some new peaks (especially the one at $2\nu = \sim 14.7^\circ$) reveal the nucleation of a new phase.

The x-ray analysis also shows that the structural integrity is highly preserved even after injecting massive amounts of Li⁺, in spite of the observed nucleation of a new phase and of the hysteresis of the EMF/ x curve shown in Fig. 2. Indeed, the pattern after discharge to $x = 2.7$ and recharge to $x = 0.15$ (Fig. 4) is very similar to that of the undischarged material ($x = 0$). It can be noted that the peaks corresponding to the new phase have disappeared. The limited expansion of the structure, possibly

Fig. 6. Cyclic voltammetry of a $\text{Li}_{1.2}\text{V}_3\text{O}_8$ electrode with a cathodic limit of 1.0V. The dashed line refers to a blank electrode (Teflonized acetylene black on Ni) in $\text{LiClO}_4/\text{PC-DME}$. Sweep rate, 1 mV/s.

related to the pinning effect of Li^+ over the layers, is believed to be the main reason for this structural stability.

As for the hysteresis of the EMF/x curve, it was ascertained that its extent is a function of the depth of discharge. This phenomenon was observed even when the discharge was limited to the solid-solution range. We obtained evidence that the structural reorganization shown by the hysteresis is maintained after the first cycle. Indeed, the E 's measured during the second discharge lie substantially on the same curve obtained during charge. However, this is valid for x values not greater than about 3.

Another feature observed in the E/x curves (both under load and on OCV) is the absence of plateaus and steps on charging. The potential values smoothly increase up to about 3.0V where a change in slope is observed. Similar behavior has been reported for V_2O_5 (13).

This pattern is confirmed by the cyclic voltammetry at low rates (Fig. 3). During the anodic sweep, the 3 main peaks observed during discharge tend to merge into a single peak, and only a shoulder is still distinguishable. It looks like the Li^+ ions leave the structure randomly in an environment in which the site energies seem to have leveled off.

We have ascertained the effect on the cycle life of discharging a cell to a 1.0V cutoff on the charge efficiency (Fig. 5). At 1.0 mA/cm², 0.24 Ah/g were obtained during the first discharge, this corresponding to 2.6 eq Li^+ /mol (87% d.o.d. with respect to $x = 3$). The capacity decline over about 30 cycles (after which the cell was voluntarily stopped) was comparable to that of a cell cycled with a limit of 1.8V. In general, it was observed that cycling $\text{Li}/\text{Li}_{1+x}\text{V}_3\text{O}_8$ cells at such regimes limits the Li^+ uptake to about 3 eq/mol; repeated overdischarges had no adverse effects on the cycle life. The situation tends to change at lower discharge rates when greater amounts of Li^+ may be inserted. A cell cycled at 0.2 mA/cm² between 1.0 and 3.5V reached an x value of 3.1 during the first discharge, but showed a more rapid capacity decline. This behavior is also reflected by the cyclic voltammetry curve of Fig. 6, where the cathodic limit was set to 1.0V. The anodic peak is here highly shifted and merges with the 3 small peaks observed above 3V. This provides clear

Fig. 7. Extended cycling at high c.d. of a $\text{Li}/\text{Li}_{1.2}\text{V}_3\text{O}_8$ cell in $\text{LiClO}_4/\text{PC-DME}$. Charge c.d. = 2 mA/cm² for all. Voltage limits: 1.6 and 3.5V.

evidence of major structural rearrangements for $x > 3$, rearrangements which were indeed confirmed by the x-ray analysis (new peaks were still present after recharge).

Finally, the ability of the structure to sustain a high number of cycles at high rates was checked by using a relatively thin cathode (10 mg/cm²) made with the rolling technique. The results are reported in Fig. 7. The average d.o.d. at 7, 10, 5, and 2 mA/cm² were 42, 30, 32, and 33%, respectively. During cycling, neither Li nor the solution were replaced. The performance shown in Fig. 7 is remarkable and has to be related at the same time to the high speed of Li^+ diffusion (2) (high rate) and to the ruggedness of the structure (high cycle number). The latter was confirmed by the pattern of Fig. 4, showing a substantial retention of the structure after cycling.

Conclusions

This further characterization of the bronze $\text{Li}_{1+x}\text{V}_3\text{O}_8$ has confirmed that it can act as a cathode capable of high energy, high rates, and outstanding reversibility in non-aqueous Li cells.

The Li^+ insertion, even though leading eventually to the nucleation of a new phase and to the onset of a permanent hysteresis in the E/x curve, is highly reversible even at high Li^+ contents (below about $x = 3.2$, being the initial Li^+ excess included in this figure).

From now on, this material will be mainly characterized from a technological point of view, which has led to a final assessment of its capability of being used in practical secondary Li batteries. In this respect, an investigation on several aspects of the bronze, cathode, and complete cells' preparation is under way, and a progressive scaling up to cells of practical characteristics has been planned.

Ellipsometer Studies of Surface Layers on Lithium

F. Schwager,¹ Y. Geronov,² and R. H. Muller*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720

ABSTRACT

The growth of surface layers on lithium in propylene carbonate solutions can be followed by ellipsometry, although the refractive indexes of many potential film materials are close to those of the electrolyte. Film thicknesses calculated from ellipsometer measurements increase over periods of several days at open circuit; they are several times larger than those derived from galvanostatic pulse measurements. Films are found to be inhomogeneous with properties continuously varying as a function of distance from the substrate; compact regions are located adjacent to the metal and porous regions are located adjacent to the solution. Electrode capacitance measurements are sensitive to the thin compact region, which can also be generated by reaction with water vapor. Ellipsometer measurements are primarily affected by the thicker, porous region, which may be formed by the precipitation of decomposition products of the solution.

Surface layers formed under open-circuit conditions on lithium in propylene carbonate (PC) solvent and its solutions of lithium perchlorate and lithium hexafluoroarsenate have been investigated by ellipsometry. The present study was conducted in conjunction with galvanostatic pulse measurements reported earlier (1), and the results obtained by the two techniques are compared.

Experimental

Ellipsometric and electrochemical measurements were conducted *in situ* in a hermetically sealed polypropylene cell consisting of an electrode compartment with two strain-free quartz windows arranged for 75° angle of incidence of the light beam, and a solution container located above the electrode compartment. The Fig. 1 configuration enables one to take measurements very soon after the electrode is brought in contact with the solution. The ellipsometer used was of the self-compensating type in the polarizer-quarter wave plate-sample-analyzer configuration (2). Corrections for component imperfections were derived from four-zone measurements. A mercury lamp (150W with interference filter for the wavelength of 5461Å) and an argon-ion laser (Lexel Model 75 at a wavelength of 5145Å) were used as light sources. The mercury lamp could be used only for smooth, well reflecting electrode surfaces.

Working and counterelectrodes consisted of high purity (Foote) lithium disks, of 25 mm diam and 3 mm thickness. The cross section of a freshly extruded lithium wire of 1 mm diam served as reference electrode. The working electrodes were prepared by scraping the lithium with a scalpel and pressing it with a polycarbonate sheet in a recirculating purified helium atmosphere (<0.5 ppm O₂, H₂O, 5 ppm N₂) as described previously (1). No significant difference between the native film of an electrode which was only cleaned and one which was also pressed was found by depth profiling Auger spectroscopy (PHI Model 590). Solutions of LiClO₄ or LiAsF₆ with and without added water were investigated; their preparation has also been described before (1). In the purified helium atmosphere, the electrodes were inserted in the electrode compartment, and the solution compartment was filled with electrolyte. The closed cell was then transferred to air for conducting the measurements. A delay of about 1 min after contact of the electrodes with solution was required to optically align the cell.

Film growth was followed simultaneously by ellipsometry and electrochemical pulse techniques. After the experiment, the working electrode was washed with pure propylene carbonate, then dried and transferred into an UHV-chamber for Auger spectroscopy and ellipsometry of the dry film.

Results

The ellipsometric results are presented as plots of the relative amplitude change ψ vs. the relative phase change Δ due to reflection. Figure 2 shows a plot obtained for film growth on lithium in propylene carbonate of low water content (~10 ppm) without salt and with 1M LiClO₄. The immersion time is indicated on both curves. The presence of the electrolyte has a great effect on the rate of film formation. Ellipsometer parameters ψ and Δ change

faster for lithium immersed in pure PC, indicating faster film growth. However, both electrochemical measurements at the end of the experiment (small amounts of salt were added to provide conductivity), as well as depth profiling with Auger spectroscopy, indicate the presence of a thin film, which shows a nonporous appearance in micrographs. Scanning electron micrographs have shown that film formation (by corrosion or precipitation) on lithium in PC with small amounts of added water is faster than in PC-LiClO₄ solutions with the same amount of added water (1). The difference between electrochemical and ellipsometric measurement for pure PC with no water added is, at present, difficult to explain. It may involve the formation of a poorly adhering, highly porous film and its loss during the rinsing and drying operations.

Ellipsometer measurements of film growth in solutions of 0.5 and 1.0M LiClO₄ in PC did not show much difference. Addition of water to LiClO₄ solutions seems to slow down the rate of film formation slightly (Fig. 3). This finding is in agreement with electrochemical measurements (1), where it was also found that films formed in these solutions are less conductive.

LiAsF₆ solutions form much thicker films in shorter time than LiClO₄ solutions (Fig. 4). This result emphasizes the importance of the anion for film formation and is in agreement with the findings from electrochemical measurements.

Fig. 3. Effect of water content of 1M LiClO₄ solution in PC on film formation. No water added (10 ppm) and 0.1% water added. Measured ellipsometer parameters.

Fig. 4. Effect of the nature of electrolyte on film formation. I) 1M LiClO₄, II) 0.5M LiAsF₆ in PC, measured ellipsometer parameters. Period of immersion in days given along the curves.

Elemental film compositions were determined by Auger spectroscopy. Typical spectra are given in Fig. 5. The prominent peaks are those for carbon and oxygen. Films grown in LiClO₄ solution show a small chlorine content. No arsenic could be detected in films grown in LiAsF₆ solution. Depth profiles given in Fig. 6 indicate composition varying with depth. A positive secondary ion mass spectrum (SIMS) given in Fig. 7 shows a large number of peaks between masses of 2 and 50.

To investigate the precipitation of solution decomposition products as a possible mechanism for the formation of porous layers, a polished silver surface was used as an inert electrode in 1M LiClO₄ in PC. Ellipsometer measurements on this surface showed only small changes, which

could be interpreted as the growth of a highly porous layer. SEM micrographs of the same surface showed discrete hillocks which were principally composed of C, O, and Cl, according to the Auger spectrum. Positive ion SIMS showed three principal mass peaks above 60, namely 63 (H₃CO₃⁺, not present in the film, Fig. 7), 73, and 81.

Discussion

Optical models.—Two features in the Δ/ψ plots of Fig. 2-4 are characteristic: the first one is a loop at the beginning of the experiment, the second is an almost-straight section with ever increasing ψ values at the later stages of the experiment. Calculations have shown that the real part of the refractive index of the film is primarily responsible for the size of the loop, the imaginary part for the slope of the straight part (Fig. 8). Refractive indexes for some possible film materials, solution, and substrate are listed in Table I. It was not possible to fit the experimental results satisfactorily with calculated values, assuming a homogeneous film with refractive indexes for any of the materials listed or their combination with solu-

tion in a uniformly porous film. Film thicknesses indicated along the theoretical curves of Fig. 8 are also much larger than those derived by capacitance measurements, which reach values of 200-400Å at the most. This discrepancy indicates a more complex film structure. Micrographs of a film grown in a 1M LiClO₄/PC solution for two weeks indeed show densely packed particles of approximately 2000-3000Å diam.

In an attempt to reconcile the results obtained by electrochemical transient techniques and those obtained by ellipsometry, a dual film model was investigated (Fig. 9, inset). In this model, both films are assumed to be homogeneous. The bottom film (film 2) is a thin (max 200-400Å) nonporous dielectric which is responsible for the electrode capacitance. The upper film (film 1) is thick and porous and is mainly responsible for the ellipsometer measurement.

The dual film model provides a means for explaining the discrepancy between ellipsometric and electrochemical results and gives improved, although not satisfactory, agreement between experimental and theoretical Δ/ψ plots. It was found that a rather high real part of the refractive index of the bottom films had to be assumed. Literature values for different lithium compounds (Table I) show that LiCl or Li₂O would have to be present in a mixture with low refractive index compounds to account for values of 1.55 and higher. Li₂CO₃, which had been proposed as the film material (3-5) shows too low a refractive

Fig. 9. Dual film model. Computed ellipsometer parameters for a dual film (broken curve) with compact, thin bottom layer (film 2) and a porous, growing top layer (film 1). index to be the primary constituent of the bottom (barrier) film. Polymerization products of the solvent, which had also been suggested as film material (6, 7), could make up the top film. Depth profiling by Auger spectroscopy showed that only small amounts (~2 atom percent [a/o]) of chlorine (for which Auger spectroscopy is very sensitive), but large amounts of oxygen (35-50 a/o), are present in the film. Lithium oxide is thermodynamically the favored product of a reaction between Li and water (or oxygen), which could be present in sufficient amounts in the solution. Keil *et al.* (8) found in gas phase experiments that oxygen reacts faster than water with Li. Auger peaks at 37 and 31 eV found in films are attributed (8) to Li in Li_2O . A dual-film structure of adsorbed oxygen and porous lithium carbonate has been proposed by Leif and Gilmour (9).

In order to improve agreement with ellipsometer measurements in the first stages of film growth, several inhomogeneous film models with continuously varying refractive index (Fig. 10) were investigated. The real and imaginary parts of the complex refractive index were assumed to decrease from the metal/film boundary to the film/solution boundary. Such an inhomogeneity could be due to variable porosity. It was found that predictions based on a linear profile of refractive index were in best agreement with the experimental results. Again, a rather high value of the real part of the refractive index had to be chosen for the part of the film close to the substrate; at the film/solution interface, the refractive index of the film was chosen to be equal to that of the solution.

Figure 11 illustrates the satisfactory agreement between experimental results and calculations based on a linear profile of the refractive index. The loop in the curve is determined by the high real part at the bottom of the film. The small imaginary part is introduced to adjust the slope of the curve at the later stages of growth and indicates a slightly absorbing film. Light absorption in the film could be due to nonstoichiometry or the presence of F-centers. F-centers have been extensively studied for

lithium halides. According to Hunderi (10), the F-center excitation energy for LiOH should be about the same as that for LiCl .

The model of a porous inhomogeneous film with continuously variable refractive index (or porosity) has been tested in a different way. By changing the refractive index of the immersion medium from a value of 1.43 for the solution to 1.0 for vacuum, one can change the effective refractive index of a film with fluid-filled pores drastically, as illustrated for a homogeneous porosity in Fig. 12. A realistic physical film model should produce the same film thickness for measurements in solution and in vacuum if the pore structure remains the same in the two immersion media. Table II shows a comparison of film thicknesses obtained from ellipsometer measurements in solution and in vacuum for a linear and a parabolic profile of the film refractive index with the same values at the inner and outer edge. The data support a refractive index (or porosity) varying linearly with thickness.

Film growth.—Film growth derived from ellipsometer and galvanostatic pulse measurement are presented in

Fig. 12. Effect of immersion medium on the effective refractive index of a porous film illustrated with a homogeneous film of 50% porosity, pores evacuated or filled with electrolyte.

Fig. 13. Film growth on Li in 1M LiClO_4 in PC derived from ellipsometer measurements for a linear refractive index profile and film growth derived from galvanostatic pulse measurements ($\epsilon = 4.9$).

Fig. 14. Rate laws for film formation on Li; (a) capacitance measurements, 1M LiClO_4 in PC, $\epsilon = 4.9$; (b) ellipsometer measurements, 1M LiClO_4 in PC; (c) ellipsometer measurements, water vapor 1 ppm in He, thickness based on $n = 1.46$ (LiOH).

Fig. 13. An approximately parabolic rate law (exponent 1.6) holds for film growth derived from capacitance measurements (curve (a), Fig. 14, based on a dielectric constant $\epsilon = 4.9$ corresponding to Li_2CO_3). Film growth derived from ellipsometer measurements (curve (b), Fig. 14) follows a near-linear rate law initially (exponent 0.7), but approaches the parabolic law later (exponent 1.5). A parabolic rate law (exponent 2.2) has also been found to hold for film growth with water vapor [Fig. 14, curve (c)]. Figure 15 shows ellipsometer measurements and interpretation for the latter case. A homogeneous optical film model appeared to be satisfactory over most of the range of measurements if apparent optical constants of the substrate ($n = 0.35\text{--}2.14i$), indicative of a surface layer formed during electrode preparation in the glove box, were used. This simplification is responsible for the different origins of the computed and measured curves.

Conclusions

Ellipsometer measurements have shown that surface layers on lithium are inhomogeneous, with porosity increasing approximately linearly from a dense region facing the electrode to a highly porous region facing the liquid. The refractive index of the dense region is higher than that of Li_2CO_3 or LiOH and supports the presence of Li_2O . Ellipsometer measurements qualitatively agree with results obtained by electrochemical transient techniques (except for film growth in pure PC), because the dense region only is detected by electrical measurements.

Films are formed more rapidly in pure propylene carbonate than in the presence of electrolyte salts. LiClO_4 solutions form slower growing (more protective) films than LiAsF_6 solutions. Perchlorate also reduces the effect of water. Reaction with water is the most likely origin of the dense region, and its protective properties are confirmed by the parabolic rate law. A continuing growth of the porous region could indicate a different film origin, and precipitation of insoluble products resulting from the decomposition of the solution may be a contributing factor.

Corrosion Inhibition in Neutral, Aerated Media

University Karlsruhe, Karlsruhe, Germany

ABSTRACT

The concepts of interface and interphase inhibition as two different types of corrosion inhibition mechanisms are discussed briefly. Most of the studies reported in the literature have dealt with interface inhibition in acid media. Experimental results of interphase inhibition have been obtained for a 4340 steel rotating cylinder electrode (RCE) by impedance measurements during exposure over 48h in aerated, neutral 0.5M Na₂SO₄, 0.5M NaCl, tapwater and deionized water containing 10 mM NaNO₂, and mixtures of phosphonic acid/fatty amine or polyacrylic acid/fatty amine. An optimized approach for collecting impedance data for high R_p values and a low frequency limit between 0.4 mHz and 5 mHz has been applied in this study. A very good fit of the experimental data to a theoretical model is observed. For the phosphonic acid/fatty mixture, a second time constant occurs at high frequencies in Na₂SO₄ and NaCl, from which the porosity of the inhibitor layer can be calculated.

Generally, inhibition represents retardation of electrode reactions, especially of corrosion processes. Two types of inhibition can be distinguished: interface and interphase inhibition (1-4).

Interface inhibition presumes a strong interaction between the corroding substrate and the inhibitor (1-10). In this case, the inhibitor is potential-dependently adsorbed. The two-dimensional (2-D) adsorbate layer can affect the basic corrosion reactions in various ways which may be discussed in terms of the inhibition efficiency, ϵ , defined by

$$\epsilon = \frac{i - i_{inh}}{i} \quad [1]$$

where i and i_{inh} represent the current densities of the electrode reaction at constant potential in the absence of and presence of inhibitor, respectively. The three types of interface inhibition are

1. Geometrical blocking effect of the electrode surface by an indifferent adsorbate at a relatively high degree of coverage, θ_{inh} .

In this case, $(1 - \theta) i = i_{inh}$, and therefore

$$\epsilon = \theta \quad [2]$$

where $\theta = \Gamma/\Gamma_s$; Γ denotes the potential-dependent surface concentration of inhibitor, and Γ_s represents its saturation value.

2. Blocking of active surface sites by an indifferent adsorbate at a relatively low degree of coverage.

In this case, Eq. [2] holds again, if Γ_s is replaced by a surface concentration $\Gamma_{a,s}$ necessary for a complete blocking of all active surface sites.

3. The adsorbate is not indifferent, but reactive.

Two cases may be distinguished. The inhibitor acts as a positive or negative electrocatalyst on the corrosion reaction, or the adsorbate itself undergoes an electrochemical redox process. In the latter case, primary and/or secondary inhibition can occur, depending on the retardation effects caused by the original adsorbate and its reaction product, respectively.

In the case of a reactive coverage, ϵ will be a more complex function of θ than Eq. [2] and can also be negative

$$\begin{aligned} \text{Inhibition } 0 \leq \epsilon(\theta) \leq 1 \\ \text{Stimulation } \epsilon(\theta) < 0 \end{aligned} \quad [3]$$

These three types of interface inhibition are mostly observed in corrosion systems involving a bare metal surface in contact with the corrosive medium. This condition is often realized for the active metal dissolution in acid solutions.

*Electrochemical Society Active Member.

Interphase inhibition presumes a three-dimensional (3-D) layer between the corroding substrate and the electrolyte (3, 4, 11-13). Such 3-D layers generally consist of weakly soluble compounds of corrosion products and/or inhibitors. The inhibition efficiency depends strongly on the mechanical, structural, and chemical properties of the 3-D layers which are formed under the particular experimental conditions. This type of inhibition is mostly observed in corroding systems forming porous or nonporous protective layers. Porous 3-D layers are built up, for example, in neutral media in the absence of or presence of oxygen, whereas nonporous 3-D layers are formed in the passive metal state.

Maximum protection of such 3-D layers is obtained in passive systems without pitting corrosion. On the other hand, the density and distribution of pores will determine the inhibition efficiency in the case of porous 3-D layers, retarding mainly the transport-controlled corrosion processes. The inhibition efficiency can then be correlated with the rate of the mainly transport-controlled cathodic corrosion reaction taking place within the pores of the 3-D layers

$$\epsilon(t) = \frac{i_-(t) - i_{-,inh}(t)}{i_-(t)} \quad [4]$$

where $i_-(t)$ and $i_{-,inh}(t)$ denote the cathodic current densities at constant electrode potential and defined hydrodynamic conditions in the absence of and presence of the inhibitor, respectively. Since the cathodic current density depends on both the corrosion time and the hydrodynamic conditions, the protective properties of the 3-D layer are also a function of both variables.

Effective interphase inhibitors should not only be adsorbed at the metal/oxide and oxide/electrolyte interfaces, but should also be incorporated in the 3-D layers, leading to more homogeneous and more densely packed networks of less porosity and higher stability.

Most of the previous studies have dealt with interface inhibition in acid-deaerated systems. However, the corrosion mechanisms of non-noble transition metals in alkaline media and in neutral-aerated media, even in the absence of corrosion inhibitors, are strongly determined by the formation of 3-D oxidic layers, which are porous in the active, transition, and prepassive ranges.

Experimental results of interphase inhibition in neutral-aerated media have been collected as part of a program in which interphase inhibition will be evaluated for a number of different metal/environment/inhibitor systems. In this paper, the results of the corrosion behavior of steel in aerated neutral 0.5M Na₂SO₄, 0.5M NaCl, tapwater and deionized water containing NaNO₂, and mixtures of phosphonic acid/fatty amine or polyacrylic

Fig. 1. Frequency dependence of the imaginary component Z'' . The integration method is used to determine R_p , Eq. [5] to determine C .

acid/fatty amine will be discussed. The corrosion behavior has been studied by determining the polarization resistance R_p from ac impedance measurements and from dc measurements in the case of 0.5M Na_2SO_4 . Only the ac impedance was measured for the remaining systems. A rotating cylinder electrode was used to ensure constant hydrodynamic conditions and adequate current distribution.

Experimental Approach

Rotating cylinder electrodes were prepared from 4340 steel, and experiments were carried out with a modified IBM EC 219 rotating disk electrode system at 144 rad/s in solutions which were open to air. A concentric Pt band or mesh served as the counterelectrode. Exposure time was usually 48h. Impedance measurements were carried out as discussed before (14-17), using a computerized system and a Solartron 1174 transfer function analyzer. The high impedance values of well-inhibited systems make it necessary to accurately measure impedance data over a large range of values between those of the solution resistance R_Ω and the polarization resistance R_p . Previously, this was accomplished by manually adjusting the gain of the current-measuring amplifier several times during a run to be within a factor of ten of the measured impedance. Additional experimental problems arise from the fact that corrosion systems usually have time-dependent kinetics and the fact that the measurements have to be extended to very low frequencies in the case of high inhibitor efficiencies. These problems have recently been solved to a large extent (18), using the autoranging capabilities of the PAR Model 276 interface and a low-pass filter. In this manner, the gain of the current amplifier interface is optimized and data sampling is reduced to one cycle with filtering at each frequency below 1 Hz, thereby improving both speed and signal-to-noise resolution for collection of the low frequency data. Impedance measurements have been extended to 0.4 mHz.

The solutions were prepared from reagent grade chemicals and deionized water. The inhibitor mixtures were made from polyacrylic acid (avg M.W. = 2000), phosphonic acid (tri-nitrilo-tris methylene phosphonic acid), and fatty amine (N-oleyl-1,3-propane diamine).

Data Analysis

R_p values from dc measurements at a scan rate of 0.2 mV/s have been determined as the slope of the current-

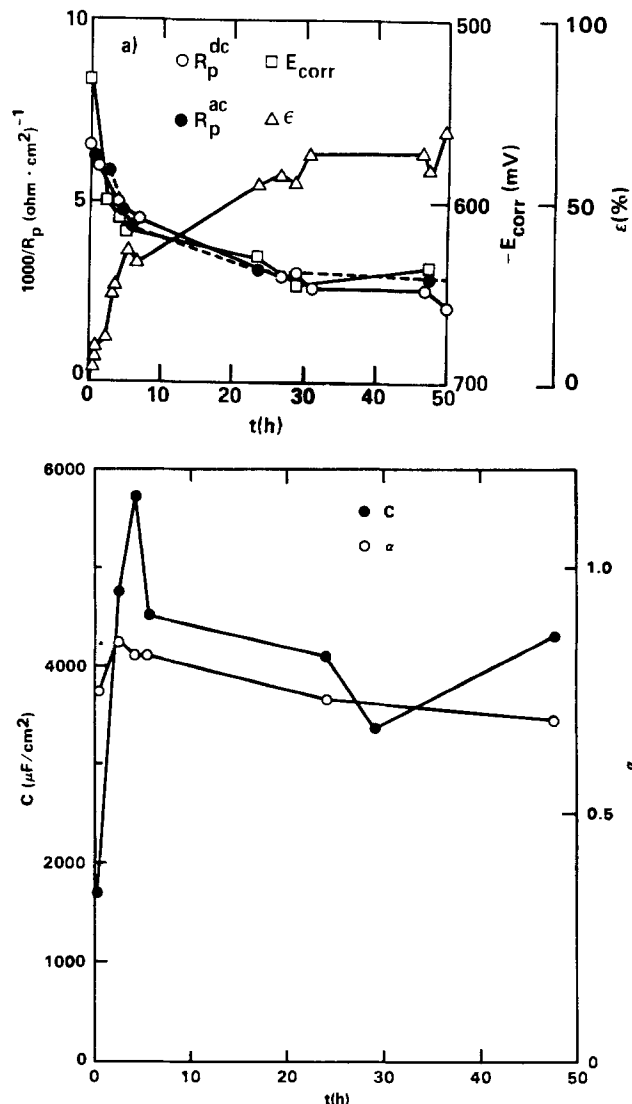

Fig. 2. Time dependence of R_p^{ac} , R_p^{dc} , E_{corr} , ϵ , C , and α for 4340 steel in neutral 0.5M Na_2SO_4 .

potential curve at the corrosion potential E_{corr} as a function of time and, in some instances, of rotation speed. Various methods for analysis of the impedance data, from which R_Ω , R_p , and the electrode capacitance C can be determined, have been discussed recently by the authors (14, 15, 17, 19, 20). Since in most cases a simple impedance diagram in the form of a depressed semicircle in a Nyquist plot is obtained, the CIRFIT-computer program (19) or the integration method (20) can be used to determine R_Ω , R_p , C , and α , where α is related to the deviation from ideal capacitive behavior ($0 \leq \alpha \leq 1$), which could be caused by surface inhomogeneity (21). The latter method has the advantage that the capacitance can be determined more accurately from the plot of the imaginary component Z'' of the impedance $|Z|$ as a function of $\log \omega$, where ω is the frequency f in rad/s ($\omega = 2\pi f$). C is calculated as

$$C = \frac{1}{\omega_m R_p} \quad [5]$$

where ω_m is the frequency of the maximum Z'' and R_p is determined by integration of the $Z'' \log \omega$ curve down to ω_m (20). The parameter α can be determined from the ratio $2Z''_m/R_p$. Figure 1 gives an example of this method in the case of 0.5M Na_2SO_4 and polyacrylic acid/fatty amine.

These methods of analysis are sufficient, since it has been found for all cases studied that the impedance spectra fit very well to a theoretical model of the impedance as

$$|Z| = R_\Omega + \frac{R_p}{1 + (j\omega CR_p)^\alpha} \quad [6]$$

Fig. 3. Bode plots for 4340 steel RCE in 0.5M Na_2SO_4 containing inhibitors.

Experimental Results and Discussion

The experimental data for 4340 steel in 0.5M Na_2SO_4 with the three inhibitors have been analyzed. For NaCl, tapwater, and deionized water, examples of the experimental data will be given.

Na_2SO_4 .—In inhibitor-free Na_2SO_4 , corrosion rates (qualitatively expressed as R_p^{-1}) decrease with time in parallel with a shift of E_{corr} to more negative values (Fig. 2). This result suggests that the rate of the cathodic reaction decreases due to formation of 3-D layers of porous oxides. Excellent agreement was found between R_p^{ac} and R_p^{dc} . An inhibitor efficiency $\epsilon = (R_p - R_p^0)/R_p$ can be calculated, based on R_p^0 at $t \rightarrow 0$. It increases continuously during the 50h exposure time. The capacitance C has very high values, between 2000 and 6000 $\mu\text{F}/\text{cm}^2$, averaging about 4000 $\mu\text{F}/\text{cm}^2$ (Fig. 2) and not representing the double layer capacitance.

Figure 3 compares the impedance spectra in neutral 0.5M Na_2SO_4 containing NaNO_2 and mixtures of phosphonic acid and fatty amine (inhibitor A) or polyacrylic acid and fatty amine (inhibitor B). The impedance spectra for the inhibitor-free solution and for the presence of NaNO_2 or inhibitor B conform to the model in Eq. [6]. The effect of the inhibitors is seen in the increase of R_p (low frequency limit of the impedance $|Z|$) and a lowering of the capacitance. For inhibitor A, an additional time constant occurs at high frequencies, with a maximum of the phase angle at about 25 kHz. The impedance spectra are similar to those for polymer coatings such as polybutadiene on steel (22, 23). From the high frequency portion of the impedance, the pore resistance R_{p0} of the inhibitor film and its changes with exposure time can be calculated. The polarization resistance R_p^{ac} , which is the limit of the impedance for $\omega \rightarrow 0$, will be compared in the following with R_p^{dc} , which is determined from the linear sweep at E_{corr} .

In the presence of NaNO_2 , corrosion rates were reduced and E_{corr} was shifted to more noble values (Fig. 4), which

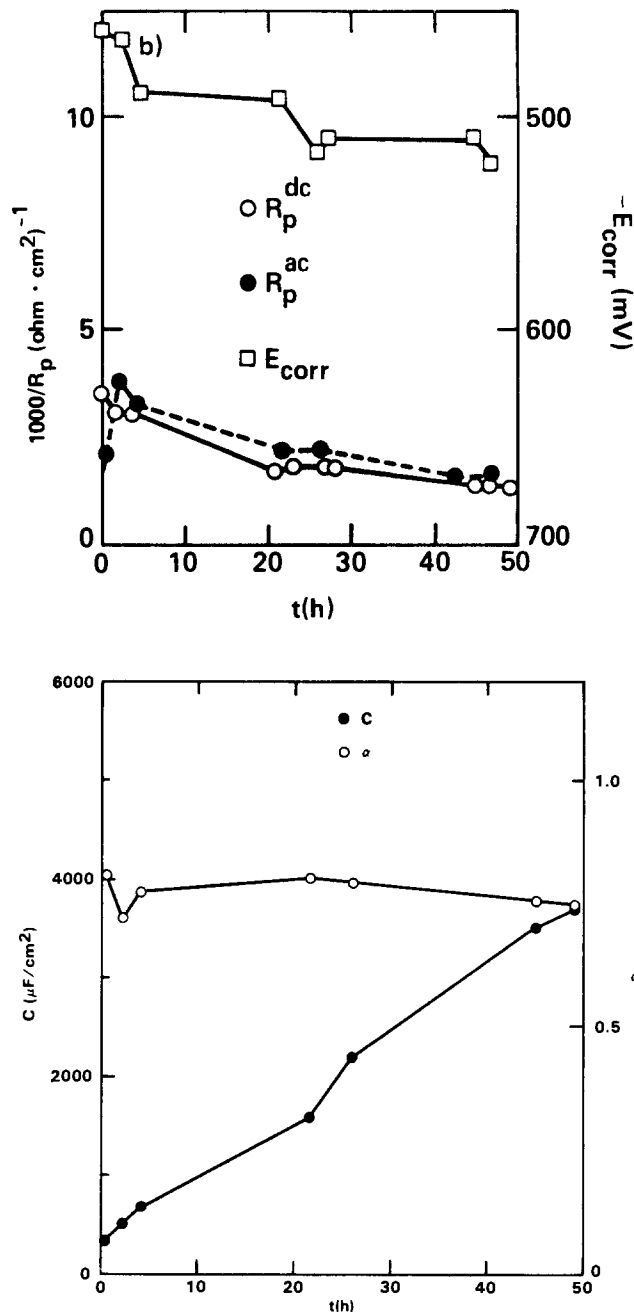

Fig. 4. Same as for Fig. 2, but in 0.5M Na_2SO_4 + 10 mM NaNO_2 .

suggests that the rate of the anodic reaction was decreased. Very little rusting was observed. Since the corrosion rate decreased by only about 60%, it is surprising that the capacitance increased by about a factor of ten in 50h. The value of α remained close to 0.8.

The corrosion rate in the presence of the phosphonic acid/fatty amine mixture (inhibitor A, Fig. 5) is similar to that observed in the presence of NaNO_2 and decreases only slightly with time. The porosity of the coating, R_{p0}^{-1} , decreases as the inhibitor layer is formed and then doubles to a more or less constant value for longer exposure times, without a corresponding change of the corrosion rate. As for the case of NaNO_2 , the capacitance C increases continuously with time. The capacitance C_p , which is associated with the reactions in the pores, is very small and decreases with time to about 1.2 $\mu\text{F}/\text{cm}^2$ based on the total geometrical surface area.

In the presence of the polyacrylic acid/fatty amine mixture (inhibitor B), corrosion rates were very low initially, but increased with time to values similar to those determined at longer exposure times in the presence of other inhibitors (Fig. 6). As for the other inhibitors, the capacitance increased continuously, but not as sharply as for

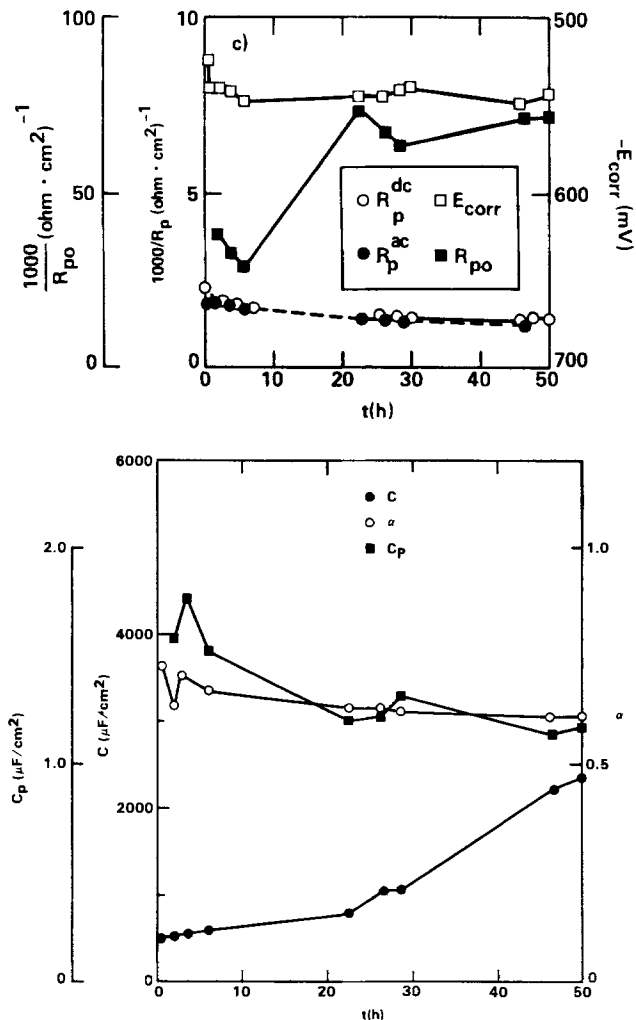

Fig. 5. Same as for Fig. 2, but in 0.5M Na₂SO₄ + inhibitor A; R_{p0} and C_p relate to the porous inhibitor layer.

NaNO₂ (Fig. 4) or inhibitor A (Fig. 5). The value of α stayed more or less constant at about 0.7.

The dependence of E_{corr} and $(R_p^{dc})^{-1}$ on rotation speed $\tau^{0.7}$ (turbulent flow) is shown in Fig. 7. Without an inhibitor, a pronounced effect of τ can be seen. This effect is much smaller in the presence of NaNO₂ and absent in the presence of inhibitor A, indicating that mass transport does not affect the corrosion kinetics in the presence of the porous inhibitor film.

NaCl.—Figure 8 gives an example of the impedance characteristics observed in 0.5M NaCl. Only one time constant is observed between 10⁵ Hz and 5 mHz. Excellent agreement is observed between the experimental results, as shown in Fig. 8 for 3.5h and for longer exposure times, and the model in Eq. [6]. These results cast some doubt on the experimental data and the model proposed by Bonnel *et al.* (24) and Duprat *et al.* (25), who reported the occurrence of a second time constant at low frequencies (<0.1 Hz) for a carbon steel rotating disk electrode in 3% NaCl. Since the measurement in Fig. 8 was performed in 76 min, and since corrosion rates did not change very much in the first hours of exposure, time effects do not affect the analysis of the impedance data according to Eq. [6].

The addition of 10 mM NaNO₂ increases the polarization resistance R_p^{ac} by about a factor of 10 at similar exposure times (Fig. 9). As in Na₂SO₄, R_p and C increase continuously with exposure time, but to a lesser extent. The agreement between the theoretical model and the experimental data in Fig. 9 is not as good as for the inhibitor-free solution in Fig. 8, which can be seen to be due to the lack of symmetry around the frequency of the maximum phase angle in Fig. 9.

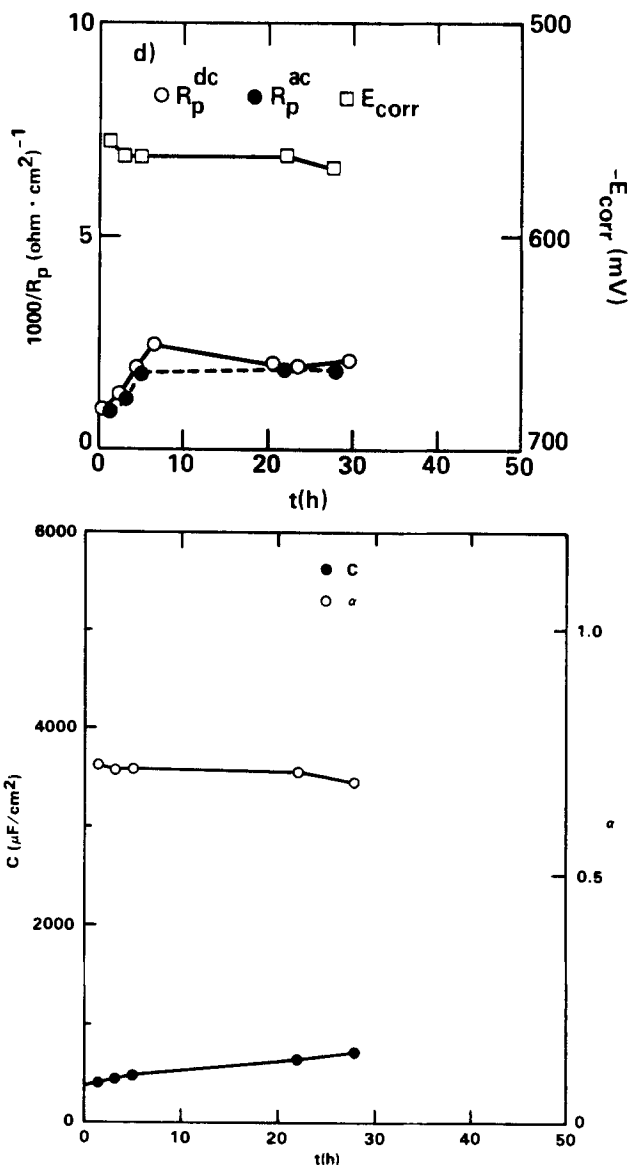

Fig. 6. Same as for Fig. 2, but in 0.5M Na₂SO₄ + inhibitor B.

As for Na₂SO₄ (Fig. 3), a second high frequency maximum occurred at about 100 kHz in the presence of inhibitor A. Similar effects have been observed by Duprat *et al.* (24). To obtain accurate data without excessive phase shift at these high frequencies, a gold wire connected to the saturated calomel reference electrode through a 0.1 μF capacitor is used as a reference electrode at high frequencies.

Tapwater.—Some experimental data have been reported for tapwater containing NaNO₂ (16). Data obtained with the optimized technique (18) are shown in Fig. 10 with a lower frequency limit of 0.4 mHz at 29h exposure, as compared to a lower frequency limit of 25 mHz in the earlier measurements. By curve-fitting according to Eq. [6], $R_p = 4.15 \times 10^6 \Omega$ ($2.78 \times 10^6 \Omega\text{cm}^2$) was determined for $t = 29\text{h}$. Very good agreement between the experimental data and the curve according to Eq. [6] with the parameters shown in Fig. 10 is found in the capacitive part of the Bode plot; however, some deviation occurs at the lower frequencies. The capacitance changed very little with time. The example in Fig. 10 shows clearly that in the case of very high R_p values, the impedance measurements must be extended to very low frequencies. The low-frequency breakpoint f_1 (14)

$$f_1 = \frac{1}{2\pi C (R_p + R_s)} \quad [7]$$

lies at 1.3 mHz for the parameters calculated for $t = 29\text{h}$. It

Fig. 7. Effect of rotation speed of the RCE on E_{corr} and R_p .

Fig. 8. Bode plot and fit to model in Eq. [6] for 4340 steel RCE in 0.5M NaCl.

should be noted that a dc measurement of R_p in this case had to be carried out with a scan rate of less than 4×10^{-3} mV/s or 14 mV/h (26). Many reported disagreements between electrochemical and weight-loss measurements can be traced to a choice of an excessively high scan rate, which leads to a R_p value which is too low.

For inhibitor A, the high-frequency time constant indicating presence of a porous inhibitor layer was not observed. Over a 48h exposure period, R_p increased slowly from about 1×10^5 to $4 \times 10^5 \Omega \text{ cm}^2$, with little change of the capacitance. Similar results were obtained for inhibitor B, which was less effective than inhibitor A (Fig. 11).

Deionized water.—The optimized method for obtaining accurate impedance data, which was developed for this study, also makes it possible to obtain impedance spectra in low-conductivity media such as deionized water. Data

Fig. 9. Bode plots for 4340 steel RCE in 0.5M NaCl + 10mM NaNO_2 , $t = 4\text{h}$.

for short exposure times could not be analyzed, since $R_\Omega > R_p$. Figure 12 shows data for exposure times of 2.5h and a fit to the model in Eq. [6] and for 4.5h. The agreement between the model and the experimental data is remarkable, considering the difficulty of conducting this experiment.

Figure 13 shows the time dependence of the corrosion rate (expressed as R_p^{-1}), E_{corr} , and R_Ω . The increase of the corrosion rate with time is accompanied by a continuous decrease of the solution resistance R_Ω and a shift of E_{corr} to more negative values.

For deionized water containing 10 mM NaNO_2 (Fig. 14), two time constants can be resolved. The R_p value in-

Fig. 10. Bode plots for 4340 RCE in tapwater + 10 mM NaNO_2 .

Fig. 11. Same as Fig. 10, but for inhibitor B.

Fig. 12. Bode plots and fit to theoretical model in Eq. [6] for 4340 steel RCE in deionized water.

Fig. 13. Time dependence of R_p^{-1} , R_Ω , and E_{corr} for 4340 steel RCE in deionized water.

increases by more than a factor of 20 during the 48h exposure test. For the inhibitor B, a continuous decrease of R_p with time was observed, combined with a decrease of R_Ω , a shift to more negative values of E_{corr} , and an increase of the capacitance C (Fig. 15). A very good fit to the theoretical model (Eq. [6]) was observed for the parameters shown in Fig. 15 for $t = 7h$.

It will be noted that the experiments in deionized water allow the study of the effects of inhibiting ions without the presence of any other ions (except corrosion products), which could have synergistic effects. This question will be addressed when all data of this test series have been collected and analyzed.

Summary

The concepts of interface and interphase inhibition have been discussed briefly. Examples of interphase inhibition have been given for steel in a variety of neutral, aerated solutions containing corrosion inhibitors using ac impedance spectroscopy. For Na_2SO_4 solutions, the polarization resistance has been determined from the impedance spectra and from dc measurements, with good agreement between both data. The impedance data fit a theoretical model with deviations from ideal capacitive behavior which could be due to surface inhomogeneities.

Recent Developments with High Temperature Stabilized-Zirconia pH Sensors

ABSTRACT

The pH response of 8 weight percent yttria-stabilized zirconia sensors is examined over a temperature range of 373-573 K. Good pH response was found throughout the temperature range. The internal half-cell was discovered to be poisoned by oxygen, which permits some simplification in the calibration of the sensor. Activation energy measurements imply that the primary conduction process involves the oxide ion. An improved electrical/mechanical seal is also discussed.

pH is the most important variable in water chemistry. It is often overlooked today, but pH electrodes operating at 298 K lead to the determination of the thermodynamic properties of many aqueous species. The lack of a simple and reliable pH electrode for environments above 373 K has been a great impediment to assembling the thermodynamic data base to make aqueous chemistry at elevated temperatures a quantitative science.

Niedrach (1) was the first to publish the high temperature (558 K) pH response of yttria-stabilized zirconia closed-end tubes. pH response was shown to be independent of the redox state of the solution. This initial design used an aqueous internal buffer, but all later designs featured a solid-state Cu/Cu₂O internal cell. No doubt the change to a solid-state design was needed because (i) the sensors have an extremely high impedance at lower temperatures and the complicated electrical/pressure seal with an aqueous fill could result in a shunting of the internal cell, and (ii) the pH of the internal buffer can easily degrade with time resulting in a potential drift. Niedrach (2) was awarded a patent on pH sensors which are oxide-ion conductors. In later papers, (3, 4), his work was extended to lower temperatures and to the geothermal environment. The sensors have nearly perfect Nernstian response at 558 K and do not suffer degradation even after weeks at elevated temperature. However, their 368 K response has been less ideal, with reports that the probes become sluggish with duration of exposure (at 368 K) and that temperature cycling between 558 and 368 K results in a loss of pH response at the lower temperature. Very little work has been carried out at temperatures between 368

and 558 K. Niedrach has successfully used both 8 and 17 weight percent (w/o) yttria-stabilized zirconia sensors in his investigations. Until recently, all electrical/pressure seals were made at the open end of the tube using Conax (Buffalo, New York) fittings. Tube breakage, as well as solution leakage into the seal region (especially with temperature cycling), has been a problem which results in shunting out of the pH sensor. Niedrach and Stoddard (5) have recently replaced the Conax pressure fitting by brazing the sensor directly to a titanium fitting. In this latest paper, they show that the pH response at 368 K is free of sodium-ion error in alkaline solutions and is Nernstian throughout the entire pH range. However, the pH response becomes increasingly sluggish with time of exposure, and they suggest it is due to slow hydrolysis reactions at the grain boundaries where second phase materials exist. One recurring problem with Niedrach's pH measurements in his lack of success in using a high temperature reference electrode. Consequently, his potential data could not be placed on the Standard Hydrogen Electrode (SHE) scale.

Tsuruta and Macdonald (6) examined the pH response of one 17 w/o yttria-stabilized zirconia sensor at 373, 423, 573, 498, 523, and 548 K. Design details are sparse on the electrical/mechanical seal. The closed-end sensor tube penetrates into the autoclave and is in contact with the solution whose pH is to be measured. The inside of the sensor tube is filled with an aqueous buffer containing KCl. The Ag/AgCl portion of the electrode sits at ambient temperature (resulting in a thermal liquid junction potential), though the pressure on the inside of the tube is at the saturation pressure fixed by the highest temperature. Degradation of the internal buffer was a problem until it

* Electrochemical Society Active Member.

was replaced with 0.01M KOH. A hydrogen electrode was included within the autoclave so that the pH could be measured, and the pH response of the sensor was evaluated over a wide range of pH buffers (approximately 3-9). In general, they found a good Nernstian pH response at temperatures above 473 K, although there was a small deviation on the acid side (pH of 3-5). Large, unexplained deviations from Nernstian response were observed at 373 and 423 K. Niedrach *et al.* (5) do not observe with this brazed sensor any significant deviations from Nernstian response at 368 K throughout the entire pH range. Because Tsuruta *et al.* (6) observe their largest deviations in pH response at 373 and 423 K, where the impedance of the sensors is greatest, the most likely explanation for their results is electrical shunting of the Ag/AgCl termination by some lower impedance path made possible by aqueous solutions on both sides of the sensor.

In this paper, we will discuss some observations and improvements with yttria-stabilized zirconia pH sensors which will bring them closer to successful and convenient use in the laboratory and field.

Experimental

A total of 62 zirconia tubes of 8 w/o yttria were purchased from Coors (ZDY-4 composition; Golden, Colorado) and Corning (Solon, Ohio) in the standard dimensions of 0.64 cm od (0.25 in.) and 0.48 cm id (0.19 in.). They were mounted in standard Conax fittings (Buffalo, New York) and installed in a 3.8 liter Hastelloy-C autoclave. Four lid penetrations were used for zirconia pH sensors. Two other penetrations were used for the Ag/AgCl external reference electrode (7) (0.100 molal KCl) and a platinized-platinum hydrogen electrode. The hydrogen electrode was replatinized at the beginning of each experiment using the standard procedure (8). The hydrogen electrode was necessary because the buffers degrade with time, and it permitted the determination of the actual pH change with which to compare the response of the zirconia pH sensors. Buffers were stored in 208 liter (55 gal) polyethylene barrels in which high-purity hydrogen was continuously sparged. The hydrogen was passed through a catalyst (Deoxo; Engelhard, Union, New Jersey) to remove the final traces of oxygen before entering the tanks. A high-pressure pump recirculated the buffer solution through the autoclave at 2.6 l/h with a pressure of 10.1 MPa (1450 psig). Solution exited the autoclave through a cooler, the pressure relief valve, and back to the storage tank. Only two buffers were used in this study and were chosen to bracket the values expected in natural ground water. They were 0.01M B(OH)₃ and 0.01M B(OH)₃ + 0.01M NaOH. Table I shows the pH values at temperatures calculated using the data of Baes and Mesmer (9). Dimer formation of boric acid was taken into account, as well as activity coefficients, using the Debye-Huckel relation. A separate instrumentation-grade high input impedance preamplifier (>10¹¹Ω, Beckman Model 633100; Fullerton, California) was used for each of the five pH sensors, and all shared the common external reference electrode. Data was stored at 30 min intervals on a Model 2240B Fluke Datalogger (Seattle, Washington). pH response was studied in 50 K increments over a temperature range of 373-573 K. Duration of experiments varied from 5 to 30 days.

The electronic assembly illustrated in Fig. 1 was used to determine the resistive impedance. The sinusoidal frequency for the ac interrogation was 10⁻³ Hz with an am-

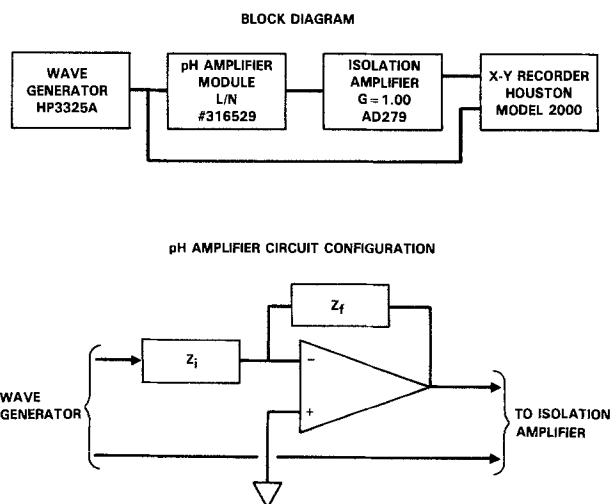

Fig. 1. AC measurement system

plitude of 1V peak to peak. The pH/reference electrode pair was used either in the input (Z_i) or feedback circuit (Z_f), whichever suited the following criteria: (a) the feedback impedance was lower than 10⁹Ω to ensure that the bandpass and bias offset currents of the amplifier made no contribution to the observed results; (b) the current level was insufficient to polarize the reference electrode; and (c) the output voltage of the amplifier was substantially below saturation. The resistive impedance changes approximately by a factor of 10 for each 50 K. The temperature range of the study was 373-573 K; therefore, four decades of resistance values were required to optimize the amplifier gain. Lissajous plots of the current vs. potential behavior were recorded on an X-Y recorder. From these plots, the impedance of the sensors was determined. At low temperatures, the pH response is a low frequency phenomenon. At 368 K, the ac response is independent of pH at frequencies above 10⁻² Hz.

Sensor Mounting

The two major problems with mounting the ceramic pH sensors are their fragility and high impedance. Polytetrafluorethylene (PTFE) is used as the pressure sealant in a Conax (Model PG2-250-B-T; Buffalo, New York) packing gland. This design is shown in Fig. 2. The soft sealant applies the compressive load in a uniform manner to minimize tube breakage. Unlike Niedrach's (1-4) early designs, the electrical termination region of the sensor was moved outside the PTFE pressure sealant region to ensure that any traces of moisture leaking out of the seal could not shunt the pH signal. A ceramic collar is cemented to the sensor barrel (Cotronics 940; Brooklyn, New York) to prevent the sensor from being extruded out of the pressure fitting. Belleville spring washers are used to spring load the PTFE sealant to improve the seal reliability during temperature cycling.

pH Response Amongst New Tubes

To understand how frequently natural pH response appears in 8 w/o yttria-stabilized zirconia sensor tubes, a total of 62 tubes were purchased from Coors and Corning and subjected to a rapid pH screening test at 358 K. The test protocol was to place the sensors in a National Bureau of Standards (NBS) pH 4 buffer thermostated at 358 K. 1M KCl with an Ag/AgCl electrode was used inside each tube, and the potential was measured against a 4.0M KCl, Ag/AgCl reference electrode at temperature. They were exposed to the pH 4 buffer for no more than 30 min before they were placed in a NBS thermostated pH 9.8 buffer, and the potential was recorded after 60 sec. This test was only for screening, not for steady-state pH response; however, 60 of the tubes responded with >80% Nernstian response. Two tubes had no response and were found to be cracked. This test demonstrated that pH response is a common phenomenon at least among these

Table I. pH buffer data

batches of tubes. Unlike the glass pH electrode, long hydration times are not needed to develop pH response.

Activation Energy

The activation energy of the pH sensors was determined over a temperature range of 373-573 K by measuring the ac impedance at 10^{-3} Hz. AC methods are preferred because the pH sensors polarize when using dc methods. Four different types of internal electrodes were used

1. An Ag coat applied by brushing silver paint (Aremco no. 525; Ossining, New York) on the bottom of the tube to a height of about 2.5 cm; oven baking at 573 K to remove the organic binder; and electrical contact made with a copper wire.
2. 99.9% silver powder placed inside the tube to a depth of about 2.5 cm and contact made with a copper wire.
3. Graphite powder placed inside the tube to a depth of 2.5 cm with contact by a copper wire.
4. A Cu/Cu₂O (A. R. grade chemicals) made according to Niedrach's recipe (3) of 1:1::Cu powder:Cu₂O powder (by mass) to a depth of 2.5 cm; contact made with a copper wire.

A least squares fit of the impedance data as a function of temperature is shown in Fig. 3 for sensors in the basic buffer. Activation energies were lowest for the Cu/Cu₂O and Ag coat electrodes at 22.9 kcal. Data (12) on the high

Fig. 3. Arrhenius plots of pH sensors

temperature (673-923 K) behavior of 8 w/o yttria-stabilized zirconia oxygen probes where the conduction mechanism is known to be due to the oxide ion reveals an activation energy for conduction of 23 kcal. Similarity in the activation energies indicates that the conduction mechanism with the pH sensors is most likely due to oxide-ion conduction.

The graphite fill had the highest activation energy (33.6 kcal), and this demonstrates that the internal electrode can dominate the conduction process. Measured potentials from this electrode were also several hundred mV more negative than the others, and its pH response was poor. Little further work was done with it.

Figure 3 data illustrate the impedance encountered with pH sensors. Values of 10^9 - $10^{10}\Omega$ at 373 K are common, though the values fall dramatically with increased temperature. It is at the lowest temperatures that other researchers have had the most trouble with the pH sensors, and we believe this is partially due to shunting of the high-impedance pH signal. Shunts could easily result from traces of moisture. The impedance of the electrodes which have an Ag fill are almost a factor of 10 lower than electrodes which use the Cu/Cu₂O fill, and for that reason most of our work has used Ag. An additional problem with the Cu/Cu₂O fill is that it continues to oxidize with time. The molar volume of the oxide is larger than that of the metal, and the tubes will ultimately be placed under tension. One tube with Cu/Cu₂O fill failed by cracking from the inside at the fill region.

The high impedance of the sensors increases the time constant of the system, which also places a low temperature limitation on their practical use because four time constants must pass before the measured voltage is 99.9% of the final value. For example, the Beckman instrumentation-grade preamplifiers require about 60 min to reach full response for a purely resistive $10^{11}\Omega$ load. Either pH sensors must be developed with a much lower resistance, or electrometers must be developed which have a lower input capacitance if zirconia pH sensors are to have a practical use below 373 K.

pH Response

The pH and potential data for a 20-day experiment is shown in Table II. All sensors were subjected to a 573 K "seasoning" (48h) before the autoclave was cooled to 373 K and the pH response was determined using the two buffers. The hydrogen electrode response to the buffer was used as the primary standard, with the response of the zirconia pH sensors compared to it. Standard deviations of the data are also shown. Temperatures were increased in 50 K increments to 573 K, whereupon the autoclave was again cooled to 373 K. The pH response of three

Table II. pH response

^b New sensor.

^c Sensor previously subjected to 40 days of autoclave testing ≥ 373 K.

of the sensors is good, with two of them (no. 2 and no. 4) exceptional throughout the entire temperature range. Sensors no. 2 and no. 4 have since been subjected to over 45 days of autoclave testing with continued excellent results. One of the sensors (no. 3) is defective because its pH response at 373 and 423 K is less than 50% of theoretical. At ≥ 473 K, the pH response of this sensor (no. 3) is Nernstian, though it is completely unresponsive when returned to 373 K. All our tests show that excellent pH response is common to sensors at temperatures ≥ 473 K. This general observation has been confirmed by Niedrach (3, 4) and Tsuruta *et al.* (6). The low temperature failure of sensor no. 3 is not understood because the impedance has not decreased (which would indicate micro-cracking) and a replacement of the internal half-cell did not restore the performance. A large enough population of aged pH sensors has not been examined as yet to understand the failure modes at low temperature. It is not possible to state whether the behavior of sensor no. 3 is representative or anomalous.

The potentials for "seasoned" sensors in Table II are measured between the zirconia pH sensor and the hydrogen electrode in the autoclave. They are representative of the values measured in other experiments. Table III contains the calculated standard potentials (10) for the hydrogen-oxygen electrode, as well as the potentials expected for the system studied in the autoclave. As Niedrach (5) has pointed out in a consideration of the electrochemical equilibrium at each interface, only the fundamental pH-determining reactions show up in the final pH-potential expression. In this case, we consider those reactions to be

Oxygen in the air ($f_{O_2} = 0.2$) is assumed to control the oxygen fugacity on the inside of the zirconia sensor, and dissolved hydrogen in solution is assumed to control the hydrogen fugacity in the autoclave. The data in Table III show the theoretical potentials for the hydrogen-oxygen electrode under standard conditions (E°) and corrected for hydrogen fugacity temperature effects (E^*). Hydrogen is sparged into the buffer solutions at 298 K where f_{H_2} is defined as unity. Therefore, a Henry's law correction factor (11) is necessary to calculate the f_{H_2} and theoretical potential (E^*) at elevated temperatures. Equation [5] should not show any pH response. It is surprising to discover the good agreement between the measured potentials of Table II and the calculated thermodynamic potentials of Table III. This indicates that the internal half-cell of the zirconia sensors is "poised" by the oxygen electrode, even

Table III. Theoretical potentials for hydrogen-oxygen electrode

Temperature	E° (mV)	E^* (mV)
298 K	1229	—
373 K	1167	1158
423 K	1127	1112
473 K	1088	1062
523 K	1050	1009
573 K	1013	951

at temperatures as low as 373 K. Four different internal fills have been used: 1) graphite; 2) Cu/Cu₂O; 3) Ag; and 4) Ag/AgCl. Once they have been seasoned at 573 K, fills 2-4 all act as oxygen electrodes between 373 and 573 K. The potential of the graphite fill is several hundred millivolts more reducing.

A test was performed to determine if the internal fill is poised by gas-phase reactions. Hydrogen gas was introduced into the inside of the Ag fill sensors at 438 and 573 K. An almost instant change of potential in the reducing direction was noticed. Unfortunately, steady-state potentials measured during this test do not exactly correspond to the potential difference expected for the hydrogen fugacity difference between the inside of the autoclave and the inside of the sensor. The more negative potential seen with the graphite is apparently due to its tendency to create a reducing environment resulting in a low-oxygen fugacity. Hydrogen is apparently working in an analogous manner.

Between 523 and 573 K, newly made Cu/Cu₂O or Ag fill sensors suddenly jump several hundred millivolts in the oxidizing direction and become poised by oxygen. Once poised, they remain poised when returned to 373 K. Tests as long as two weeks at 373 K indicate that they are still poised. However, if a "seasoned" sensor (Cu/Cu₂O or Ag fill) is permitted to stand at ambient temperature for more than a couple of days and is retested at 373 K, it will no longer be poised to oxygen and suffers a significant loss of pH response. These sensors can be restored by autoclaving between 523 and 573 K or baking (in air) in a 623 K oven. An example of this behavior can be seen in Table IV, in which the sensors were kept at ambient conditions for a week before testing at 373 K. The optimum restoration procedure has not been investigated as yet. Silver oxide forms below 425 K when in equilibrium with the oxygen in air. It was hypothesized that the reformation of silver oxide at ambient conditions resulted in a loss of pH response. However, tests with hydrogen (which would reduce the silver oxide) at 438 K had no effect on poisoning the potential. We currently believe the problem is due to the absorption of moisture at the zirconia-metal (internal) interface which interferes with the kinetics of the electrochemical conversion of oxygen (gaseous) into oxide ion. If the reaction rate becomes sufficiently slow, even the small current demands of the electrometer can polarize the interface and result in an apparent loss of pH response. The result of the high temperature bakeout may be to dehydrate the surface. The oxygen electrode is so irreversible in aqueous solutions that the thermodynamic potential is never observed. Yet it is observed

when a ceramic oxide is used as the electrolyte connecting the aqueous side of the cell with the gaseous portion. It may be that water slows down the oxygen-oxide kinetics.

Compositional Differences

Theoretically, if all the interfaces are at equilibrium, the composition of the stabilized zirconia will not affect the potential. Two different manufacturers of 8 w/o yttria-stabilized zirconia were used in this study. The Coors material (ZDY-4 composition) is white and is found by x-ray diffraction to be cubic in structure (13). X-ray spectrophotometric analysis of the grain boundaries with a SEM (scanning electron microscope) revealed significant amounts of Ca, Al, and Si, implying that some second-phase glassy materials are present (possibly added to assist the sintering process of manufacture). Re-examination of the grain boundaries with a SEM after several days of autoclaving at 573 K revealed a significant widening, indicating that the second-phase materials were dissolving. A higher purity composition (ZDY-8) has not been evaluated.

The Corning material is yellow-colored. X-ray diffraction revealed both a cubic and tetragonal structure. SEM analysis indicated only small amounts of Ca at the grain boundaries, and the grain boundaries did not show significant widening after several days at 573 K. No iron was found.

The data will not be shown, for brevity, but for "seasoned" sensors, there was no significant difference in potentials between the Coors and Corning zirconia throughout the temperature range of study.

Calibration

A major deterrent to the use of high-temperature pH sensors is problems associated with their calibration at a given temperature. Now that we have recognized that poised (seasoned) sensors are acting in a thermodynamic manner to oxygen, it should be possible to calibrate them at a lower temperature and predict their pH-potential behavior at higher temperatures. We have not done this as yet, but in principle the following procedure could be carried out

1. Prepare new sensors and season them in a 623 K oven.
2. Verify their pH response and that the potentials are poised by oxygen at 368 K (open beaker) using NBS buffers.
3. Install pH electrodes in the high-temperature process.

4. pH-potential response can be interpreted by using a reference electrode whose potential is known with respect to the standard hydrogen electrode. The data in Table III can be used to convert the potential into pH using the Nernst equation.

The pH accuracy using this method would be estimated by considering the difference between the poised potential the sensor developed and the calculated thermodynamic value. Using the data of Table II for 573 K, if the measured potential was within ± 30 mV of the calculated thermodynamic value, the uncertainty in the measured pH would be $\pm 30 \text{ mV} / (114 \text{ mV/pH}) \approx \pm 0.3$ pH units. If greater pH accuracy is needed, then the sensor should be calibrated in an autoclave at the process temperature for later installation into the process. Another method in which the calibration plumbing is combined with installation in the high-temperature process has been discussed by Niedrach (4) for geothermal applications.

Discussion

There is no problem with using zirconia pH sensors above 473 K. Once they are poised, they appear to be stable with regard to potential and pH response over a period of at least 4-6 weeks. Longer term stability has not been pursued at this time. The principal deterrent for use above 473 K is difficulty with the calibration. Our discovery that the sensors are reversible to oxygen will assist in their calibration.

Table IV

Sensor	Description	373 K	
		pH response	$E_{Zr} - E_{H_2}$ (mV)
1	Corning, Ag	84 \pm 1%	1061 \pm 3 1106 \pm 2
3	Corning, Ag	84 \pm 1%	1068 \pm 2 1114 \pm 1
573 K			
Sensor		pH response	$E_{Zr} - E_{H_2}$ (mV)
1		103 \pm 5%	966 \pm 1 972 \pm 16
3		102 \pm 6%	959 \pm 2 964 \pm 17
373 K (return)			
Sensor		pH response	$E_{Zr} - E_{H_2}$ (mV)
1		100 \pm 2%	1116 \pm 2 1117 \pm 2
3		98 \pm 0%	1118 \pm 0 1122 \pm 0

A more serious problem is their performance below 473 K. Currently, for a pH sensor to be used below 473 K, it must first be subjected to an autoclaving of 523-573 K in order for its potential to become poised. Sensors not autoclaved above 523 K will still have pH response, but their pH response is superior and their calibration more stable when they are poised. Another separate problem is the degradation of their response below 473 K due to aging effects from extended autoclave exposure. We have only seen this behavior with a couple of sensors and have not been able to relate it to any other parametric changes. Other tubes have performed well at 373-473 K at a similar exposure age. It is uncertain whether we are dealing with a statistical failure or a general aging phenomena because the population of evaluated sensors is too small. However, even these degraded sensors perform well ≥ 523 K.

Presently, the pH sensors have too high an electrical resistance to have any practical use below 373 K. A fruitful study would be to examine other zirconia compositions or different ceramic oxide systems for improved pH response. Some guidelines for this study are

1. The major ceramic conduction process must be ionic. Electronic conductivity will result in the sensor responding to the redox environment.

2. The ac impedance of the ceramic must be low enough that the small current demands made by an electrometer will not result in a significant potential drop across it.

3. The hydrogen ion exchange reaction with the solution-ceramic interface must be kinetically fast enough to appear reversible. Judging from how common pH response is with metal-metal oxide systems in a corroding environment, adequate rates of the hydrogen ion reaction may be common with ceramic systems as well.

4. The electrical connection with the ceramic must be reversible so that space charges or other polarization effects will not occur when the sensor is interrogated by the electrometer. We feel this region will be the major problem area with all sensors because an electrochemical equilibrium must exist to interconnect the pure electronic conduction of the metal to the ionic conduction of the ceramic.

Conclusions

1. Good pH response was demonstrated throughout the temperature range of 373-573 K.

2. The internal half-cell of the pH sensors is reversible to oxygen. This behavior suggests that the sensors can be easily calibrated and maintain their calibration for useful periods of time.

3. The pH sensors have the same activation energy as high temperature oxygen sensors, implying that the conduction mechanism is by the oxide ion.

4. An improved electrical/mechanical seal is demonstrated.

The Kinetics of Platinum-Oxygen Local Cells

James P. Hoare*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090-9055

ABSTRACT

A model of the local cell established at bright Pt electrodes immersed in O₂-saturated acid solution was constructed from which the potential dependence on the partial pressure of O₂ and on the pH was determined. The calculated coefficients agreed with those experimentally determined so that $E_m = 1.06 - 0.048 \text{ pH} + 0.012 \log P_{O_2}$. The equilibrium O₂ potential can be observed by eliminating this local cell action by passivating the Pt surface.

An inert electrode behaves only as a sink or source of electrons and provides a catalytic surface on which the electrode process takes place. To construct an electrode system for which one of the reactants is a gas, one plunges an inert electrode into the proper electrolyte and

*Electrochemical Society Active Member.

bubbles the gas over the electrode. An oxygen electrode is made by immersing a Pt wire or gauze in a solution of H₂SO₄ or KOH and by bubbling O₂ gas over the Pt electrodes.

From thermodynamic studies, the standard potential for the oxygen electrode in acid solution

is calculated (1-4) to be 1.229V. When O_2 is bubbled around a Pt electrode immersed in 2N H_2SO_4 solution, the observed potential is no higher than 1.06V measured against a Pt/ H_2 reference electrode in the same solution.

Although a number of explanations for this depressed potential of the O_2 electrode at rest have been put forth (5), it is generally agreed (6-10) that the potential is a mixed potential even though agreement about the nature of the oxidation and reduction processes responsible for the local cell is not met.

A Local Cell Model

It was concluded (11) from various rest potential studies that Pt is not inert to O_2 -saturated acid solutions. Consequently, a local cell is set up with the reduction of O_2 , Eq. [1], occurring at cathodic sites and the oxidation of Pt, Eq. [2], at anodic sites where Pt-O represents

a hydrated layer of adsorbed O atoms. Since the overall local cell reaction is $2\text{Pt} + \text{O}_2 \rightarrow 2\text{Pt-O}$, the Pt surface should become covered with the conducting layer of Pt-O, the local cell should not exist, the potential should be determined only by Eq. [1], and the rest potential should rise to 1.229V. Because this behavior is not observed, a complete layer of Pt-O must not be formed. Only a partial layer of Pt-O is formed since the adsorbed oxygen can be dissolved in the Pt through a place-change mechanism (12, 13)

producing an uncovered Pt site. When the rate of formation of Pt-O by local cell action equals the rate of oxygen dissolution by the place-change mechanism, a steady state is set up. Under these conditions, the Pt surface coverage with Pt-O is about 30% (9, 14), the rest potential is 1.06V (11), and the local cell current is about 10^{-7} A/cm² (15, 16). It has been estimated that it would require 190,000 days to saturate a 1 cm³ of Pt at the local cell corrosion rate (17).

At cathodic sites, the dissociative adsorption of oxygen from solution on the Pt surface is the first step in the reduction of O_2

A square root relationship between the partial pressure of oxygen and the amount of oxygen adsorbed has been reported (9, 18). The next step is the first electron discharge step

and is considered to be the slow or rate-determining step. This step is followed by reaction with a hydrogen ion to form an adsorbed OH radical

Then two OH_{ads} can combine to form an H_2O molecule and an adsorbed O_{ads} , which can undergo Eq. [5], [6], and [7]

to form another molecule of H_2O and complete the overall reaction, Eq. [1]. This mechanism requires that the rate-determining step, Eq. [5], occur four times for each overall reaction, Eq. [1], to take place. That is, the stoichiometric number, ν , (19) is 4.

The rate of the cathodic reaction, v_c , is

$$v_c = k_2(\text{O}_{\text{ads}})e^{-\alpha_c(E-E_c^0)/FRT} \quad [8]$$

where α_c is the cathodic symmetry factor and E_c^0 is the equilibrium potential of Eq. [1]. According to steady-state

theory, the concentration of all intermediates is constant with time

$$\frac{\partial(\text{O}_{\text{ads}})}{\partial t} = 0 = k_1(\text{O}_2) - k_2(\text{O}_{\text{ads}})^2 e^{-2\alpha_c(E-E_c^0)/FRT} - k_{-1}(\text{O}_{\text{ads}})^2 \quad [9]$$

Note that Eq. [5] has to occur twice for each occurrence of Eq. [4]. Then

$$(\text{O}_{\text{ads}})^2 = \frac{k_1(\text{O}_2)}{k_2 e^{-2\alpha_c(E-E_c^0)/FRT} + k_{-1}} \quad [10]$$

However, $k_2 \ll k_{-1}$, so that

$$(\text{O}_{\text{ads}}) = (k_1/k_{-1})^{1/2} (\text{O}_2)^{1/2} \quad [11]$$

With the substitution of Eq. [11] into Eq. [8], we obtain

$$v_c = k_2(k_1/k_{-1})^{1/2} (\text{O}_2)^{1/2} e^{-\alpha_c(E-E_c^0)/FRT} \quad [12]$$

At anodic sites, "bare" Pt surface sites, Pt_{surf} react with water to form adsorbed oxygen atoms, $\text{Pt-O}_{\text{surf}}$

Some $\text{Pt-O}_{\text{surf}}$ sites can flip over by the place change mechanism, Eq. [3], to produce derisorbed (20) oxygen, $\text{Pt-O}_{\text{derm}}$ (oxygen dissolved in the surface layers or skin of the metal)

It is Eq. [14] that is considered to be the slow or rate-determining step. The derisorbed oxygen can diffuse into the bulk metal to regenerate Pt_{surf} sites and adsorbed oxygen, O_{abs}

and to maintain the local cell action.

The rate of the anodic reaction is

$$v_a = k_2(\text{Pt-O}_{\text{surf}}) \quad [16]$$

Then, at steady state

$$\frac{\partial(\text{Pt-O}_{\text{surf}})}{\partial t} = 0 = k_1(\text{Pt}_{\text{surf}})(\text{H}_2\text{O})e^{2(1-\alpha_a)(E-E_a^0)/FRT} - k_2(\text{Pt-O}_{\text{surf}}) - k_{-1}(\text{Pt-O}_{\text{surf}})(\text{H}^+)^2 e^{-2\alpha_a(E-E_a^0)/FRT} \quad [17]$$

where α_a is the anodic symmetry factor and E_a^0 is the equilibrium potential of Eq. [2]. By solving for $(\text{Pt-O}_{\text{surf}})$

$$(\text{Pt-O}_{\text{surf}}) = \frac{k_1(\text{Pt}_{\text{surf}})(\text{H}_2\text{O})e^{2(1-\alpha_a)(E-E_a^0)/FRT}}{(k_2 + k_{-1})(\text{H}^+)^2 e^{-\alpha_a(E-E_a^0)/FRT}} \quad [18]$$

and substituting into Eq. [16], noting that $k_2 \ll k_{-1}$, we obtain

$$v_a = \left(\frac{k_1 k_2}{k_{-1}} \right) \frac{(\text{Pt}_{\text{surf}})(\text{H}_2\text{O})}{(\text{H}^+)^2} e^{2(E-E_a^0)/FRT} \quad [19]$$

For the steady-state local cell shown in Fig. 1, $v_c = v_a$, E becomes the mixed potential, E_m , the activity of H_2O is unity, and $I_c = I_a = I_{\text{loc}}$, the local cell current. Equating Eq. [12] to Eq. [19]

$$K(\text{O}_2)^{1/2} e^{-\alpha_c(E_m-E_c^0)/FRT} = K' \frac{(\text{Pt}_{\text{surf}})}{(\text{H}^+)^2} e^{2(E_m-E_a^0)/FRT} \quad [20]$$

After rearranging terms

$$e^{-(2+\alpha_c)E_m/FRT} e^{(\alpha_c E_c^0 + 2E_a^0)/FRT} = \frac{K'(\text{Pt}_{\text{surf}})}{\text{O}_2^{1/2}(\text{H}^+)^2} \quad [21]$$

and take logarithms of both sides, we have

$$\alpha_c E_c^0 + 2E_a^0 - (2 + \alpha_c)E_m = \frac{2.3RT}{F} \log(\text{Pt}_{\text{surf}}) - \frac{2.3RT}{F} \log(\text{O}_2)^{1/2} - \frac{2.3RT}{F} \log(\text{H}^+)^2 + \frac{2.3RT}{F} \log K'' \quad [22]$$

Fig. 1. Sketch of local cell diagram for the rest potential of a Pt/O₂ electrode showing curves for the reduction of O₂ at three values of P_{O₂} and for the oxidation of Pt. Where curves cross is the observed rest or mixed potential (1.06V at P_{O₂} = 1) and the current is the corrosion current (I_o - I_a = I_{loc}). The value for E_a⁰ is taken from Ref. (11). P_{O₂}' < P_{O₂} < P_{O₂} = 1 atm.

One now can obtain the coefficients for the dependence of E_m on the partial pressure of O₂, P_{O₂}, and the pH

$$\frac{\partial E_m}{\partial \log P_{O_2}} = \left(\frac{1}{2}\right) \frac{2.3RT}{F} \left(\frac{1}{2 + \alpha_c}\right) \quad [23]$$

$$\frac{\partial E_m}{\partial pH} = - \frac{4.6RT}{F} \left(\frac{1}{2 + \alpha_c}\right) \quad [24]$$

From electrochemical kinetic studies of the reduction of O₂ on a number of metals (21), α is found to be very close to 0.5. At 25°C, ∂E_m/∂ log P_{O₂} = 0.012V and ∂E_m/∂pH = -0.048V.

Test of the Model

According to the model, the equilibrium potential of Eq. [1] could be observed if the local cell could be eliminated. It has been found (22-23) that the Pt surface may be passivated by a complete layer of electronically conducting oxide or adsorbed oxygen atoms by exposing the Pt to concentrated nitric acid for periods of time greater than 30h. When such a passivated Pt electrode is immersed in O₂-saturated acid solution, a potential of 1.2295V is observed. A number of other workers have also reported this equilibrium potential using Pt electrodes passivated in various ways (24-28). The ∂E_c⁰/∂ log P_{O₂} is 0.015V and the ∂E_c⁰/∂pH is 0.060V (23) as warranted by the Nernst equation.

It was found (22) that passivation of Pt in HNO₃ caused the Pt to be charged with dissolved oxygen to a greater extent than that produced by anodization of Pt (14). Platinum which has been charged with dissolved oxygen will be referred to as the Pt-O alloy. Under the driving force of anodization or passivation in HNO₃, the bulk Pt reservoir becomes increasingly charged with dissolved oxygen. As a result, the rate of dissolution of adsorbed Pt-O into the bulk Pt decreases. To increase this dissolution rate to that of the local cell, the activity of Pt-O must be increased by increasing the steady-state coverage of Pt with Pt-O. According to Eq. [22], the rest potential, E_m, increases with an increase in the Pt-O coverage. Experimentally, it has been reported by a number of researchers (14, 15, 22, 29-31) that E_m does increase with surface coverage.

In a series of experiments, Pt diaphragms were mounted between the halves of a two-compartmented cell (17, 32). In the front side filled with O₂-saturated 2N H₂SO₄, the rest potential of the Pt foil was monitored. After steady state was reached, the back side of the foil was anodized in N₂-saturated 2N H₂SO₄ against a Pt gauze counterelectrode. As shown in Fig. 2, the rest potential increased towards E_c⁰ with the time of anodization, and the rate of increase in E_m depended on the thickness of the foil or volume-to-surface ratio.

When the potential of the front side of the Pt diaphragm had reached 1.148V, the partial pressure of O₂ in the front compartment was varied by using O₂-N₂ mixtures. The data are presented in Fig. 3 with a line of slope 0.012V to show that the data are not inconsistent with the 0.012V slope. By replacing a measured amount of solution drawn from the front compartment with a hypodermic syringe by the exactly same amount of water, the pH was varied. The rest potential as a function of the pH is plotted in Fig. 4 with a line of slope 0.048 drawn to demonstrate the consistency of the data with the 0.048V slope. These data lend strong support to the validity of the local cell model of the Pt/O₂ electrode. The local cell diagram for a Pt-O alloy appears in Fig. 5.

Since it was not possible to saturate the Pt metal with dissolved oxygen by anodization alone, the Pt diaphragm studies were continued with O₂-saturated 2N H₂SO₄ in the front compartment and air-saturated concentrated HNO₃ in the back compartment (33). After 54h, Fig. 6, the potential on the front side of the thinnest Pt foil reached a value of 1.227V and ∂E/∂ log P_{O₂} was 0.015V, as expected if Eq. [1] were potential determining. By saturating the Pt metal with dissolved oxygen, the local cell can no longer exist because "bare" Pt sites no longer exist and Eq. [1] is potential determining.

Fig. 2. A plot of the rest potential of the front side of a Pt diaphragm in O₂-saturated 2N H₂SO₄ for three thicknesses (0.00127 cm, circles; 0.00254 cm, triangles; 0.00508 cm, squares) as a function of the time for which the back side was anodized.

Fig. 3. A plot of the rest potential of the front side of a Pt-O alloy diaphragm in O₂-saturated 2N H₂SO₄ as a function of the log P_{O₂}. A line with a slope of 0.012V is drawn through the points.

Fig. 4. A plot of the rest potential of the front side of a Pt-O alloy diaphragm in O₂-saturated 2N H₂SO₄ as a function of the pH. A line with a slope of 0.048V is drawn through the points.

At this point, the front side of the Pt diaphragm was polarized against a Pt-gauze counterelectrode. The oxygen overvoltage, O₂-η, at low current densities (34) is presented in Fig. 7. It is noted that the η passes from anodic to cathodic values through E_c⁰ without a change of slope. A value of 4.2 × 10⁴Ω is obtained for dη/di from which a value of the exchange current, i₀, can be obtained from i₀ = (RT/nF)(di/dη) = 1.40 × 10⁻⁶ A/cm², where n is the number of electrons transferred in the rate-determining step. In Fig. 8, the complete polarization curve for the reduction of O₂ is plotted. Extrapolation of the Tafel slope to η = 0 gives a value of 1.48 × 10⁻⁶ A/cm² for i₀. The good agreement between these two values for i₀ indicates that

Fig. 5. Sketch of the local cell diagram for the rest potential of a Pt-O alloy/O₂ electrode, showing curves for the reduction of O₂ at three values of P_{O₂} (P_{O₂}¹ < P_{O₂}² < P_{O₂}³ = 1 atm). Explanation same as in Fig. 1. A value for E_a⁰ is not known, but probably lies near 1V (22).

Fig. 6. Oxygen overvoltage obtained on the front side of a Pt-O alloy diaphragm (rest potential: 1.227V) in 2N H₂SO₄ at low current densities; open symbols for increasing and filled symbols for decreasing current.

Fig. 7. A plot of the rest potential on the front side of a Pt diaphragm in O₂-saturated 2N H₂SO₄ for four thicknesses (0.00127 cm, circles; 0.00254 cm, triangles; 0.00508 cm, inverted triangles; 0.00762 cm, squares) as a function of the time the back side was in contact with air-saturated HNO₃. Potential of an auxiliary Pt gauze in the front compartment is given by the filled circles.

the same mechanism for O₂ reduction takes place at low and at high current densities on a Pt-O alloy cathode. A value for the stoichiometric number ν can be obtained (35) from

$$\nu = - (d\eta/di)(nF/RT)i_0 \quad [25]$$

Fig. 8. Oxygen overvoltage obtained on the front side of a Pt-O alloy diaphragm (rest potential: 1.227V) in O₂-saturated 2N H₂SO₄ over entire range of current densities studied. At very high current densities, H₂ evolution takes place (low Tafel slope of 0.03); at medium current densities, high Tafel slope (0.38) shows influence of dissolved oxygen in Pt on reduction of O₂; Tafel slope extrapolates to 1.48 × 10⁻⁶ A/cm² for i₀.

where n is the number of electrons transferred in the overall electrode process and we take $d\eta/di$ from the low current data and i_0 from the high current data

$$\nu = -4.2 \times 10^4 \times 4 \times (-1.48 \times 10^{-6})/0.059 = 4.2$$

This experimentally found value for ν agrees very well with that value obtained from the proposed mechanism with Eq. [5] rate determining. A value of 3.5 has been reported (36) for the reduction of O_2 on Pt in 1N $HClO_4$.

The Pt-O Alloy

When the Pt diaphragm was removed from the two-compartmented cell after being saturated with dissolved oxygen ($E = 1.227V$), that portion of the foil exposed to the HNO_3 had buckled out (34, 37), indicating that the Pt lattice had expanded. This expansion of the lattice was confirmed by x-ray diffraction studies (37). Scanning electron micrographs (SEM) of a HNO_3 -passivated Pt surface show a surface covered with tiny hexagonal pits ($\sim 1 \mu m$ diam) (37). It is proposed (37) that the sides of the micro-etch-pits expose high index planes similar to the stepped surfaces studied by Somorjai and co-workers (38). They observed that both hydrogen and oxygen are more readily adsorbed and more readily dissolved in Pt with stepped surfaces. There was no sign of pitting on the SEM of an anodized Pt surface (39). These observations may account for the fact that Pt-O alloys with greater oxygen content are obtained by passivation in HNO_3 than by anodization. Most likely, the oxygen enters the octahedra holes of the face-centered cubic lattice of the Pt, causing the lattice to expand. Apparently, oxygen can also enter into the grain boundaries first (39) without lattice expansion, but with higher O contents, the oxygen enters the lattice.

Whenever Pt is anodized, it is charged with oxygen and is no longer Pt but a Pt-O alloy. The Pt-O alloy is a better catalyst for H_2 , O_2 , and various redox reactions (40). This observation accounts for the greater reversibility of freshly anodized, indicator electrodes (40) and for the required 5-10 cycles of polarization before a steady-state, cyclic voltammogram can be obtained (41) on Pt.

Conclusions

The rest potential of an oxygen electrode on bright Pt in acid solution is a mixed potential arising from a local cell composed of the reduction of O_2 at cathodic sites and the oxidation of Pt at anodic sites. The rest potential as a function of P_{O_2} and pH is

$$E_m = 1.060 - 0.048 \text{ pH} + 0.012 P_{O_2}$$

The thermodynamic equilibrium potential can be observed on Pt by eliminating the local cell by passivating the Pt surface or by saturating the bulk Pt with dissolved oxygen. In this case

$$E_c^0 = 1.229 - 0.059 \text{ pH} + 0.015 P_{O_2}$$

Oxygen may be dissolved in Pt to form a Pt-O alloy which offers a more catalytically active surface for a number of electrode reactions than pure Pt. The rest potential on a Pt-O alloy electrode is

$$E_m = E_m^0 - 0.048 \text{ pH} + 0.012 P_{O_2}$$

where E_m^0 has values, in general, between 1.1 and 1.2V, depending on the oxygen content of the alloy. On clean, bright Pt, the rate of the dissociative adsorption of O_2 is greater than the rate of electron transfer (42) and the four-electron reduction of O_2 takes place with $\nu = 4$.

Localized Corrosion of Fe-B-Si Glassy Alloys

M. Janik-Czachor

Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT

The glassy alloys $\text{Fe}_{75}\text{B}_{25-x}\text{Si}_x$ with $x < 12\%$ at. exhibit a breakdown of passivity in borate buffer solution with no aggressive ions added. This instability of the passivating film, leading to a localized corrosion, ceases at $x \geq 12\%$ at. XPS analysis suggests that at $x = 12\%$ the passivating film consists mainly of SiO_2 , the minor components being Fe_2O_3 and B_2O_3 . At $x = 9\%$ the main constituents of the film are silicates, which exhibit a lower protective ability and cannot efficiently counteract the detrimental effect of boron compounds. Chlorides are harmful for passivity of the Fe-B-Si alloys; severe pitting occurs even at a chloride concentration as low as 10^{-4}M .

The passivating film cannot provide protection to the substrate metal when, for some reason, it becomes unstable and an activation follows. Activation can occur over a whole surface or can be confined to highly localized regions.

In the former case, general corrosion follows. Conditions for a total depassivation depend upon metal composition and environmental factors and are defined theoretically according to the thermodynamic diagrams of Pourbaix (1).

When activation occurs only at certain points on a metal surface, localized corrosion follows. The mechanism of this type of depassivation (breakdown of passivity) is still a subject of controversy (2-5). Therefore, it is of importance not only from a practical, but from a fundamental viewpoint to identify factors enhancing resistance of the passivating film to localized breakdown.

Some glassy alloys are remarkably corrosion resistant (6) and exhibit an extremely stable passivating film which does not undergo localized breakdown, even under very severe conditions. Detailed analysis of the existing experimental data suggests that the composition of the substrate is of much greater importance than its homogeneous structure. The corrosion resistant glassy alloys rely on passivating films formed by such metal elements as Cr, Ti, and W (7).

Corrosion resistance of glassy alloys which do not contain any of the above mentioned film-forming elements is rather poor (8-12). It has been found, however, that Si may improve it (11-13). Si, when substituted for B, in Fe-Ni-B or Fe-B glassy alloys enhances stability of the passive state. Enrichment of Si in the passivating film is responsible for this enhancement in Fe-Ni-B-Si alloys (11) and probably also in Fe base alloys (12, 13).

In this paper the effect of Si on the stability and composition of the passivating film on Fe-B-Si alloys is considered in more detail.

Experimental

A series of $\text{Fe}_{75}\text{B}_{25-x}\text{Si}_x$ glassy ribbons with $x = 6-18\%$ at. was investigated. $\text{Fe}_{80}\text{B}_{20}$ alloy was used for comparison. The amorphous nature of the ribbons was confirmed by x-ray diffraction.

Details concerning the samples preparation and electrochemical measurements are given elsewhere (11). Optical microscopy was used to examine the samples before and after the electrochemical measurements. XPS technique was employed for surface analysis.

XPS measurements were performed in a 555 XPS/AES/SIMS spectrometer (Physical Electronics) by using a Mg anode at 300W. Ar^+ ion etching was used to obtain information on composition as a function of depth into the passivating film. 1 keV ion beam with $1 \mu\text{A}/4 \text{mm}^2$ ion c.d. was used to remove the film gradually.

Results

Effects of Si on the stability of passivating film on Fe-B-Si alloys in borate buffer solution.—Si in Fe-B-Si alloys not only affects their ability to passivate, but also influences stability of the passive state. As can be seen

from Fig. 1, the maximum c.d. (the apparent critical c.d. for passivation, I_{cr}) and the critical passivation potential (E_{cr}) both decrease with Si content in the alloy. Moreover, the width of the stable passivity range increases with Si content, being only $\sim 300 \text{mV}$ for $\text{Fe}_{80}\text{B}_{20}$ alloy, and attaining a maximum width of $\sim 1300 \text{mV}$ practically at 12% Si; an estimate can be obtained from Fig. 1.

Microscopic examinations have revealed that a sharp increase in c.d. for the alloys with $< 12\%$ Si is caused by a breakdown of passivity followed by localized corrosion similar to pitting. The active spots grew quickly in depth and could perforate the ribbons (Fig. 2), although no aggressive ions were present in solution.

In order to obtain information about the relative resistance of the passivating film to general activation, the open-circuit potential decay curves for prepassivated samples were measured.

Figure 3 shows some examples of potential decay curves for the alloys prepassivated at -100mV (this potential value lies within the stable passivity range for all the alloys under investigation; see Fig. 1). The potential decays slowly and then, after a period of time which is longer the higher Si concentration is, it reaches the activation potential (E_a). Then it sharply drops down to E_{corr} .

Effect of Si on the composition of the passive film.—In order to gain some insight into the chemical state of the film components, as well as to distinguish between the signals from the substrate and from the film itself, XPS analysis of the prepassivated samples was performed. Attention was focused on the 9% Si and 12% Si alloys, since the first exhibits an unstable, and the second a stable, passivity in borate buffer solution (see Fig. 1). The analysis revealed presence of the following elements at the surface: silicon, iron, boron, oxygen, and carbon. The last element is an impurity and is not taken into account for the following analysis.

Identification of the chemical state of the surface constituents was made on the basis of the position of individual lines in the spectrum. Figure 4 gives some examples for 9% Si alloy. The Fe^0 , B^0 , and Si^0 signals come from the

Fig. 1. Anodic polarization curves (2 V/h)

Fig. 2. Localized corrosion of Fe₇₅B₁₉Si₆ alloy in borate buffer solution at +120 mV.

substrate, whereas Fe_{ox}, B_{ox}, Si_{ox}, and O signals come from the passivating film. Since the signals from the substrate are quite visible in the spectrum, an assumption can be made that in this case the passivating film is thinner than the corresponding escape depth of photoelectrons. Under the present experimental conditions this is about 2 nm.

For the 12% Si alloy the B^o and Si^o signals are relatively smaller than for the 9% Si alloy and the Fe^o signal appears only as a shoulder. This suggests that the film thickness here is larger than that for the 9% Si substrate. This conclusion is in agreement with a previous finding (13). The AES/ion milling experiments have shown that the time necessary to sputter the passivating film away was longer the higher the Si content in the substrate.

Ar⁺ ion etching was used alternately with XPS analysis to obtain information on composition as a function of depth into the film material. Use of this method of surface removal is likely to change the chemical nature of the surface. Thus caution was exercised in analyzing the data.

Table I gives some examples of the binding energies of photoelectrons coming from the passivating film and from the substrate, for the two alloys. The positions of Fe^o2p, B^o1s, and Si^o1s signals coming from the substrate do not change with sputtering time. They compare with literature data for pure elements (14). On the other hand,

Fig. 3. Open-circuit potential decay curves

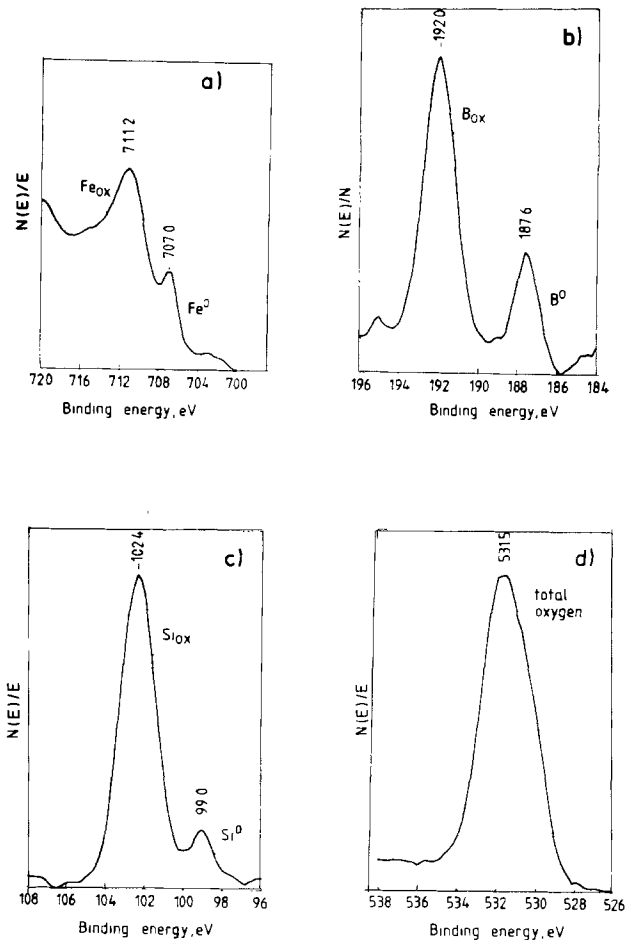

Fig. 4. XPS spectra obtained for Fe₇₅B₁₉Si₆ alloy prepassivated at -100 mV in borate buffer: a) Fe 2p_{3/2}; b) B 1s; c) Si 2p; d) O 1s.

the positions of some signals coming from the passivating film exhibit a variation with sputtering. It is not clear, however, whether this reflects the original changes in chemical state of various components, or some sputtering effects.

The relative concentrations of various constituents of the surface were estimated by quantifying the XPS measurements utilizing peak area sensitivity factors. This method is known to be more accurate than that using peak height (14). The following sensitivity coefficients were used: S_{Fe} = 3.0, S_B = 0.13, S_{Si} = 0.26, S_O = 0.67, each determined using special standards.¹

¹The data were kindly provided by Dr. J. A. Taylor from the University of Minnesota.

^a The binding energies were determined with an accuracy of ± 0.1 eV.

Fig. 5. Depth profiles of the passivating film formed on Fe-B-Si glassy alloys in borate buffer solution.

Composition profiles of the films are shown in Fig. 5. The main feature of these profiles is that the Si_{ox} concentration is much higher than that of Fe_{ox} and B_{ox} . The main difference between the two profiles is that the time necessary to produce a rise in the $\text{Fe}2p$ signal is much larger for the 12% Si containing substrate. This may again suggest that the film is thicker in this case, although structural factors may also affect the sputtering time (15).

For the 12% Si substrate the concentration of Si_{ox} is about 3.5-fold higher than that of Fe_{ox} and B_{ox} [Fig. 5 (bottom)]. Taking into account corresponding binding energies of the photoelectrons of $\text{Fe}_{\text{ox}}2p$, $\text{Si}_{\text{ox}}2p$, and $\text{B}_{\text{ox}}1s$, we assume that the constituents of the film are: SiO_2 , Fe_2O_3 , and B_2O_3 . Considering the concentrations of individual constituents in the middle of the composition profile, we obtain the following molar film compositions: $\sim 80\%$ SiO_2 , $\sim 10\%$ Fe_2O_3 , and $\sim 10\%$ B_2O_3 . The amount of the total oxygen in such a mixed film (62%) compares with the value of $\sim 65\%$ from the XPS data [Fig. 5 (bottom)].

For the 9% Si alloy the atomic concentration of Si_{ox} is 3-fold higher than that of Fe_{ox} and over 2-fold higher than that of B_{ox} . However, the above assumption about the mixed oxides as the constituents of the film does not seem to be reasonable in this case.

From the calculations it follows that only about 43% of oxygen could be engaged in the oxides. Since XPS analysis gives about 60-70% at. of oxygen in the passivating film [Fig. 5 (top)], the question arises as to what the chemical state of the remaining 20% of oxygen is. We can resolve this question, assuming that some oxygen reaches species, other than SiO_2 , are the main components of the passivating film on the 9% Si substrate. This subject will be discussed later in more detail.

Effect of chlorides.—The stable passivity of Fe-B-Si glassy alloys with $\geq 12\%$ Si breaks down easily in

Fig. 6. Effect of chlorides on the anodic polarization curves

chloride-containing solutions. These alloys appear very susceptible to chloride attack; they undergo pitting at only $10^{-4}M$ Cl^- . One should note that the critical chloride concentration for pitting of crystalline iron is $3 \times 10^{-4}M$ (16, 17). An estimate of the effect of chloride concentration on the anodic behavior of 12% Si alloy can be obtained from Fig. 6. The results for 18% Si alloy are similar, but the increase in c.d. due to breakdown of passivity is not as sharp as that in Fig. 6.

Discussion

Fe-B-Si glassy alloys with $\leq 12\%$ Si exhibit a passivity in borate buffer solution that is partly unstable. They undergo a breakdown of passivity in this solution, in the absence of any halide ions. The breakdown potential increases with Si content in the substrate (Fig. 1), and only at $\geq 12\%$ Si does it attain the oxygen evolution potential value.

XPS analysis suggests that the film formed on the 12% Si alloy is relatively thicker and consists mainly of SiO_2 , the minor constituents being B_2O_3 and Fe_2O_3 . The film formed on 9% Si alloy is also enriched with Si, but its O/Si ratio seems to be higher than 2/1. In order to get an idea about the chemical composition of the main component of the film in this case, the O 1s and Si 2p line energy difference must be considered.

Studying various Si compounds, Wagner *et al.* (18) have found that the magnitudes of the O 1s and Si 2p binding energies have a high positive correlation. This can be seen from Fig. 7. All the oxides, hydroxides, and silicates lie in a narrow band corresponding to a line difference of 429.0-429.6 eV. However, for the oxides and hydroxides the binding energies are relatively higher than those for the silicates.

Three points for each passivating film are shown in Fig. 7: they represent the energy line differences (I) before sputtering, (II) after several minutes of sputtering, and (III) near the end of sputtering close to the film/substrate interface. The arrows indicate an evolution of the energy line difference with sputtering.

It is interesting to note that the location of the data points for the passivating film on 12% Si alloy confirms the assumption already made that the main constituent of the film is a silicon oxide. The location of the points does change a little with sputtering, but all the three points lie in the same narrow band where the other three points corresponding to oxides do.

The location of the data points for the 9% Si alloy suggests that silicates rather than oxides are the main components of the passivating film in this case. According to literature data, the O/Si ratio for silicates can attain 4/1 (19). Apparently oxygen-rich silicates are formed in the course of passivation. These silicates exhibit lower protective abilities than the oxides formed at the 12% Si substrate. In this way one can understand the difference in anodic behavior of both alloys.

Fig. 7. O 1s binding energy vs. Si 2p binding energy for various oxides, silicates, and passivating films on Fe-B-Si alloys.

It has been found that B is detrimental for corrosion resistance of Fe-B alloys in acid solution (9) and for the stability of the passive state in borate buffer solution (20). The present results show that Si compounds in the passivating film on Fe-B-Si alloys can counteract the detrimental effect of B compounds. Evidently, silicon oxides are more effective than the silicates. Unfortunately, even the silicon oxide containing films are very susceptible to chloride attack.

A question may arise as to what is the effect of the amorphous structure on the behavior of these alloys in the passive state. Unfortunately, no direct comparison with a single phase crystalline alloy at the same composition can be made, since the Fe-B-Si alloys are multiphase systems after crystallization (21). One should note, however, that the stationary rate of the passive metal dissolution is determined by dissolution of metal ions from the passivating film. As pointed out by Kapusta and Heusler (9), the passivating film over both the glassy and crystalline substrate is in the vitreous state anyway. Thus, no difference of the dissolution rate is expected to be influenced by the substrate structure.

Conclusions

1. Si, when substituted for B in Fe-B glassy alloys, improves their ability to passivate. It extends the otherwise

narrow range of their stable passivity in borate buffer solution, thus eliminating localized corrosion, when the Si content attains 12% at.

2. XPS analysis suggests that at Si < 12%, silicates, and at Si ≥ 12%, silicon oxides, are the main components of the passivating film. The oxides efficiently counteract the detrimental effect of boron compounds in the film and provide much better protection to the metal substrate than the silicates.

3. Chlorides cause a severe breakdown of passivity of the Fe-B-Si alloys at concentration as low as 10⁻⁴M.

Transport Number Measurements in Silica

J. K. Srivastava,* V. B. Tare, and J. B. Wagner, Jr.*

Center for Solid State Science, and Departments of Chemistry, Physics, and Mechanical and Aerospace Engineering, Arizona State University, Tempe, Arizona 85287

ABSTRACT

Using an open-circuit emf method, the average transport number for ions, \bar{t}_i , has been determined for quartz crystals, vitreous silica, and amorphous silica grown thermally on silicon. Results for all types of silica show that \bar{t}_i increases with temperature between about 550° and 950°C.

Silica exists in three commonly occurring forms, namely, crystalline, amorphous, and a supercooled liquid or vitreous state (1). Schmalzried (2) reported that at 1000°C and between 10^{-16} and 1 atm of oxygen pressure, the transport number of ions in silica glass is close to unity. For silica thermally grown on silicon, Jorgensen (3) and Mills and Kroger (4) suggested that the charges associated with the transport of oxygen ions through SiO_2 are less than the conventionally accepted values of four per mole of oxygen under certain conditions.

Diffusion of oxygen through silica has been studied by several investigators (5). The results indicate that the diffusion of oxygen in quartz is strongly anisotropic. The diffusion of oxygen through various forms of silica has been suggested to be due to transport of oxygen as an uncharged molecule or as O_2^- or $\text{O}_2^{\cdot-}$ (4). When bulk diffusion of ions and electrons (to preserve electroneutrality) governs the kinetics of oxidation of silicon, the rate of oxidation can be calculated by C. Wagner's equation (6), provided the transport number of ions and electrons through the growing oxide layer is precisely known. The main reason for the observed discrepancy between the experimentally determined rates of oxidation and the rates estimated from the available data on transport number and the diffusion of oxygen is possibly the lack of reliable information on the transport numbers and diffusivities.

This paper describes the measurement of transport number by an emf method (2) in all three types of silica, namely, single-crystal quartz, vitreous silica, and amorphous silica thermally grown on single-crystal Si. This method essentially involves measurements of open-circuit emf of a cell in which silica is an electrolyte separating two different oxygen partial pressures. In the case of silica thermally grown on silicon, the partial pressure of oxygen at Si/SiO_2 interface is the dissociation pressure of SiO_2 . The other oxygen pressure was fixed by a metal/metal oxide mixture. For the vitreous and single-crystal quartz, the oxygen pressures on two sides of the electrolytes were fixed by a metal/metal oxide mixture.

Experimental Procedure

Single-crystal quartz used in the present investigation was obtained from Bell Laboratories and had $\langle 010 \rangle$ growth directions. It was free from sodium and potassium impurities (less than detectable level, < 1 ppm). The principal impurities were Fe, 30 ppm, and Al, 30-50 ppm. Rectangular pieces of $1.5 \times 1.5 \times 0.2$ cm with $\langle 010 \rangle$ orientation were cut from a large crystal with the help of a diamond saw. The pieces were cleaned with a HF-water mixture, degreased with acetone, finally washed with distilled water, and again cleaned in an ultrasonic cleaner in acetone.

Vitreous and SiO_2 thermally grown on silicon were obtained from Motorola. 20 kÅ thick SiO_2 was thermally grown on n-type silicon $\langle 100 \rangle$ with 3-4 Ωcm resistivity. The vitreous silica was 1 mm thick. These were cut into pieces in dimensions similar to the crystalline quartz, and were also cleaned by the same procedure described for crystalline quartz. The samples were of semiconductor-grade purity.

*Electrochemical Society Active Member.

Three different metal/metal oxide mixtures used to obtain different partial pressures of oxygen were $\text{Cu}/\text{Cu}_2\text{O}$, Ni/NiO , and Fe/FeO . These were prepared by using the metal and its oxide powder, both of 99.99% obtained from Alfa Products. They were mixed in 1:1 volume ratio in an agate mortar and were pressed into pellets of 3 mm thickness and 1 cm diam in a steel die. These pellets were sintered for 15h in purified argon at temperatures varying from 500° to 700°C to increase their density and improve the mechanical strength. These were then lightly polished with 3/0 emery paper and cleaned with acetone before use.

To obtain the open-circuit emf, the silica pellets were sandwiched between two different metal/metal oxide pellets. The whole assembly was held together by means of a spring assembly and an alumina sample holder. The details were similar to those described elsewhere (7). Platinum wires, spot-welded to platinum foils pressed on the metal/metal oxide electrodes, were used as leads to measure open-circuit emf. A Pt-Pt + 10% Rh thermocouple placed very near the electrolyte was used to measure temperature. The whole assembly was introduced in another alumina tube in which a continuous flow of argon purified by passing it over Drierite, phosphorous pentoxide, and copper heated at 400°C flowed. The complete assembly was kept in a resistance furnace whose temperature was kept within $\pm 1^\circ\text{C}$ with a proportional temperature controller. The cell was electrically shielded from the furnace to avoid external stray pickup.

The open-circuit emf was measured using a 117 Keithley Digital Voltmeter with an impedance of 10 MΩ. The following cell configurations were used to obtain the open-circuit voltages.

$\text{Cu}/\text{Cu}_2\text{O}$	Quartz crystal	Ni/NiO	I
Fe/FeO	Quartz crystal	Ni/NiO	II
Fe/FeO	Vitreous silica	Ni/NiO	III
Pt, Si	Thermally grown SiO_2	Ni/NiO	IV

Measurements were repeated on at least two cells of the same cell configuration. Measurements were restricted to 900°C, because above this temperature there was some evidence of the electrode-electrolyte reaction, particularly in cell I at the quartz $\text{Cu}-\text{Cu}_2\text{O}$ interface. The emf values were, however, reproducible during several heating and cooling cycles if the measurements were restricted to temperatures below 900°C.

Results and Discussion

According to C. Wagner (6), the open-circuit emf, E , of the above cells is given by

$$E = \frac{1}{nF} \int_{\mu'_{\text{O}_2}}^{\mu''_{\text{O}_2}} \bar{t}_i \cdot d\mu_{\text{O}_2} \quad [1]$$

where n is the charge per mole of oxygen ion migrating through the sample, F is Faraday's constant, and μ'_{O_2} and μ''_{O_2} are the chemical potentials of oxygen on each of the two sides of the electrolyte. The derivation of Eq. [1] assumes transport by ions.

The chemical potentials are given by

$$\mu_{\text{O}_2} = \mu''_{\text{O}_2} + RT \ln P_{\text{O}_2} \quad [2]$$

where $\mu^{\circ}_{\text{O}_2}$ is the chemical potential of oxygen in its standard state, 1 atm of oxygen. Thus Eq. [1] can be written as

$$E = \frac{RT}{nF} \int_{P'_{\text{O}_2}}^{P''_{\text{O}_2}} \bar{t}_i \cdot \frac{dP_{\text{O}_2}}{P_{\text{O}_2}} \quad [3]$$

If an electrolyte is completely ionic, i.e., $\bar{t}_i = 1$, Eq. [3] becomes

$$E_{\text{ion}} = \frac{RT}{nF} \ln \frac{P''_{\text{O}_2}}{P'_{\text{O}_2}} \quad [4]$$

where E_{ion} is the theoretical voltage as calculated. The P'_{O_2} and P''_{O_2} can be easily calculated from the free energies of formation of respective oxides used to fix the oxygen pressures.

However, if $\bar{t}_i \neq 1$, the voltage will, in general, be a complex function of oxygen pressure [see Ref. (2)]. As a first approximation, however, we may take it outside the integral by replacing \bar{t}_i with \bar{t}_i , the average transport number at oxygen pressures between P'_{O_2} and P''_{O_2} .

Dividing Eq. [3] by Eq. [4], the expression for average transport number is

$$\bar{t}_i = \frac{E_{\text{obs}}}{E_{\text{ion}}} \quad [5]$$

where E_{obs} is the measured open-circuit emf.

The data obtained on all the cells are tabulated in Table I. To estimate E_{ion} , free energies of formation of the respective oxides were taken from the data compiled by Turkdogan (8). Also, in calculating E_{ion} , the value of n is assumed to be 4 per mole of oxygen.

Figure 1 shows the observed, as well as theoretical, open-circuit emf's (E_{ion}) for cell I. The corresponding values of \bar{t}_i are shown in Table I. It can be seen that the \bar{t}_i for quartz is nearly equal to 1 only between 700° and

Fig. 1. Observed (E_{obs}) and theoretical (E_{ion}) open-circuit emf's (OCE) of cell I, Cu, Cu₂O|quartz crystal|Ni, NiO, in the temperature range 550°-900°C.

900°C. The values of \bar{t}_i at temperatures less than 700°C deviate considerably from unity.

Figure 2 shows the open-circuit emf, E_{obs} , for cells II and III as a function of temperature. E_{ion} is also shown for comparison. In this oxygen pressure range also, crystalline quartz has $\bar{t}_i \cong 1$ at the temperatures above 700°C. The values of \bar{t}_i drop steeply below 700°C. Data above 900°C could not be obtained because of the possible reaction of electrolyte with the electrodes. \bar{t}_i for vitreous silica (cell III) is much lower than 1 for all temperatures (see Table I). The transport number, however, increases with increase in temperature and attains a maximum value of 0.7 in the temperature range of 800°-900°C.

A similar trend in the variation of average transport number with the increase in temperature is observed for cell IV (Fig. 3). In this case, the average oxygen pressure is, however, very low. The maximum in average transport number is 0.4 and occurs also in the temperature range of 750°-950°C, although the scatter in the data is very large.

As mentioned earlier, the average transport number has been obtained assuming the value of n in Eq. [4] to be 4.

Fig. 2. Observed (E_{obs}) and theoretical (E_{ion}) open-circuit emf's (OCE) of cell II, Fe, FeO|quartz crystal|Ni, NiO, and cell III, Fe, FeO|vitreous silica|Ni, NiO, in the temperature range 500°-950°C.

Fig. 3. Observed (E_{obs}) open-circuit emf's (OCE) of cell IV, Pt, Si|thermally-grown SiO_2 |Ni, NiO, in the temperature range 600°-950°C.

In the temperature range of 700°-900°C, these average ionic transport numbers were found to be maximum values for all the three forms of silica samples. The transport number of crystalline quartz is close to unity, while for vitreous silica $\bar{t}_i = 0.7$ and for SiO_2 thermally grown on Si, it is ~ 0.2 - 0.39 . A value of $\bar{t}_i = 1$ for crystalline quartz in the temperature range of 700°-900°C suggests that the assumption that $n = 4$ is justified. Lower values of \bar{t}_i for the vitreous silica at the same average oxygen activity as that for crystalline quartz may be caused by the electronic conductivity or by the deviation of n from 4. Vitreous silica is considered to be a supercooled liquid. Liquid-like structures generally favor higher ionic transference numbers. It is therefore suggested that lower transference number in vitreous SiO_2 may be due to a value of n different than 4. In other words, the oxygen ions migrating in these samples may have charges varying from almost 0 to 4 per molecule, as has been suggested earlier (5).

The small ionic transference number for SiO_2 thermally grown in silicon can also be explained in a similar way. In fact, this ionic transport number is so low that the possibility of the transport of neutral oxygen cannot be ruled out (9).

The above explanation is consistent with the one offered by several investigators on transport properties of

SiO_2 . However, further experiments are essential in resolving the nature of transporting species unambiguously. The ionic transport number in SiO_2 thermally grown on Si, obtained independently by polarization technique (7), is found to be approximately 0.9 in the temperature range of 750°-875°C. This is consistent with the hypothesis that uncharged oxygen is involved in the transport, as has been reported by Costello and Tressler (10) from oxidation studies at 1000°C. The polarization technique involving measurements of current-voltage characteristics on a material where the electronic conductivity is due to the electrons only is influenced by the transport of only charged species, whereas, as mentioned earlier, the open-circuit voltage data depends upon the effective charges n in the migrating oxygen.

Effect of Rhodamine-B on the Electrodeposition of Lead on Copper

Joseph C. Farmer^{*,1} and Rolf H. Muller*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Rhodamine-B chloride ($10\ \mu\text{M}$) has been used as a model plating additive in a study of the electrodeposition of Pb from 1M NaClO_4 , 0.5 and 5 mM Pb^{2+} (pH 3) on Cu. Ellipsometer measurements during cyclic voltammetry have shown that the addition of dye results in a more compact bulk deposit than obtained in its absence. It also prevents complete monolayer coverage during formation of the Pb underpotential deposit and shifts the bulk deposition peak to more cathodic potentials during the first potential cycle. Dye effects on potential and micromorphology disappear during subsequent cycling, but reappear after relaxation periods at open circuit. Depletion and readsorption of dye on the surface have been confirmed by spectroscopic ellipsometry. Different optical film models have been investigated for the interpretation of spectroscopic ellipsometer measurements by use of multidimensional analysis.

Surface active agents (additives, inhibitors) have long been used on an empirical basis to control surface finish in electrolytic metal deposition. Indications are that uncontrolled impurities often cause similar effects. Few fundamental studies have been undertaken to define the role of these agents during the initial stages of electrocrystallization, despite the great technical importance of their use (1). The objectives of this work were to correlate variations in adsorbate coverage on the electrode with differences in overpotential and micromorphology of the deposit. Deposit thicknesses investigated ranged from a monolayer (the underpotential deposit, UPD) to thicknesses of about 100 nm . The principal experimental techniques used were cyclic voltammetry and ellipsometry (both spectroscopic and fixed wavelength). A self-compensating instrument with rapid spectral scanning capabilities for the visible range and automated data collection has been built for this purpose and is discussed elsewhere (2, 3).

Selection of Electrochemical System

The materials used in this study were selected to satisfy electrochemical and optical criteria. Most of the experimental investigations were conducted with Cu as the electrode substrate, Pb as the deposited metal, and rhodamine-B chloride as the model inhibitor. The supporting electrolyte was composed of 1M sodium perchlorate, acidified to pH 3 by use of perchloric acid. The inhibitor concentration was typically $10\ \mu\text{M}$ and Pb^{2+} ion concentration was 5.0 mM (as nitrate).

The materials chosen have optical constants which are distinguishable over the spectral range accessible to the optical instrumentation ($370\text{--}720\text{ nm}$). Cu shows a distinctive absorption in the visible (around 550 nm), which is believed to be due to electronic transitions from the filled d bands into the sp conduction bands (4-6). In contrast to Cu, Pb shows no such characteristic in the visible and has relatively flat optical constants (7). Dissolved rhodamine-B has a characteristic absorption band at about 555 nm , believed to be due to an electronic transition from a singlet ground state to an excited triplet state (8). The electronic transition moment related to this absorption process lies parallel to the three conjugated rings of the rhodamine-B molecule. Rhodamine-B can be expected to adsorb on the surface with a preferential orientation of the transition moment, resulting in a birefringent (dichroic) adsorbate layer. This birefringence, and its spectral dependence, can be interpreted in terms of molecular orientation of the adsorbate on the surface (9, 10).

Electrochemically, Cu is stable to dissolution and oxidation at the reversible potential for Pb deposition from acidic solutions (11), and Pb forms a well-defined underpotential deposit on Cu substrates (12). In screening studies with over 30 materials, 14 of which were indicators or

laser dyes, rhodamine-B was found to induce the largest increase in overpotential (125 mV) for bulk Pb deposition.

Experimental Procedure

The automatic spectroscopic ellipsometer used in this study employed the polarizer-compensator-sample-analyzer optical configuration. It was self-nulling by use of a magneto-optic polarizer and analyzer, and could be operated in either a spectroscopic or fixed wavelength mode (2, 3). The spectral range was $370\text{--}720\text{ nm}$, the angle of incidence used was 75° . A complete scan of spectroscopic measurements (Δ and Ψ at different wavelengths) could be made in 3s although improved signal-to-noise ratios were obtained with slower scanning (*e.g.*, one scan per 15s) or by averaging multiple scans. Slower scanning was essential to observe dye adsorption. Faster scanning gave sufficient signal quality for resolution of deposit micromorphology. Data acquisition was fully automated with a LSI-11/02 microcomputer system, which was also used for instrument calibrations and to interpret measurements by use of optical models.

The electrochemical cell used for experiments with Cu substrates was made of Teflon. It was designed for clean operation and low light absorption in the solution with a small liquid volume (2 ml) and a short optical path (2.5 cm) through the solution. The cell was pie-shaped, with windows made of polished and annealed optical-quality quartz, oriented normal to incident and reflected light beams for operation at an angle of incidence of 75° .

The round working electrodes were machined from polycrystalline oxygen-free Cu with an exposed surface of 1.27 cm diam. The electrodes were polished mechanically with a final alumina abrasive of $0.05\ \mu\text{m}$. Air-formed oxide on the electrode surface was removed by prepolarization in the acidic electrolyte. The counterelectrode consisted of a Pb wire (99.999% purity) wound into a flat spiral, positioned 0.8 cm from the working electrode and of equal diameter. Lead oxide resulting from the corrosion of the counterelectrode was removed by cathodic prepolarization, using a second Pb wire electrode and an initial electrolyte charge. The initial electrolyte charge was replaced when the Cu working electrode was inserted, without exposing the anode to air.

A double-junction Ag/AgCl reference electrode (Dow-Corning 476067), inserted into a Teflon reference electrode compartment, was connected to the electrochemical cell with a Teflon capillary (0.16 cm od). The reference electrode was connected to the potentiostat via an electrometer probe (PAR).

Two syringes (15 ml each) were used to supply electrolyte to and withdraw from the cell. The electrolyte consisted of $5\text{ mM Pb}(\text{NO}_3)_2$, 1M NaClO_4 at pH 3, with or without $10\ \mu\text{M}$ rhodamine-B addition. It was prepared from deionized, singly distilled ($10\text{ M}\Omega$) water and analytical-grade salts. The electrolyte was nitrogen stripped for about 15 min prior to experiments, and the cell was purged with nitrogen before filling. The syringes and a

*Electrochemical Society Active Member.

nitrogen purge stream were connected with Teflon capillaries.

The potential of the working electrode was controlled with a potentiostat (PAR 173), and the charge passed was determined with a digital coulometer (PAR 179). The coulombic efficiencies between deposition and dissolution were always greater than 95%. Film thickness d_q based on charge is that given for a compact lead layer. Cell potential and current, together with the measured ellipsometer parameters Δ and Ψ (measured as Faraday cell currents), were recorded by the LSI microcomputer system via an eight-channel analog-to-digital converter (Datel MST-LSI2).

Spectroscopic Ellipsometry

Electrochemical deposition of Pb films.—Thin films of lead on copper substrates were prepared by potentiostatic deposition (-600 mV vs. Ag/AgCl) from an electrolyte consisting of 5 mM $\text{Pb}(\text{NO}_3)_2$ and 1M NaClO_4 at pH 3, with deposition times of 1-8 min.

Based upon charge passed, the film thicknesses d_q would have been 31, 60, and 110 nm if the deposit had formed uniformly and had been compact. However, it was found that the deposit was not homogeneous and compact, and multilayer optical models had to be used to explain the spectroscopic ellipsometer measurements.

Single-layer optical models.—Film models investigated for the interpretation of measurements are illustrated in Fig. 1 (2). Examples of interpretations given below illustrate the use of the high information content of spectroscopic ellipsometer measurements for the derivation of wavelength-independent film parameters. Predictions based upon the following three optical models for single-layer films (Fig. 1a-1c) are compared to experimental spectroscopic ellipsometer measurements in Fig. 2-4. In the compact film model, the entire deposit was treated as bulk Pb and there was only one adjustable parameter, the deposit thickness. Figure 2 shows spectroscopic simulations of Δ for various assumed thicknesses (solid lines labeled 0, 1, 5, 10 nm, etc.). Comparison with experimental measurements also shown on the figure (dotted lines for 31, 60, and 110 nm compact thicknesses) illustrates that this model is inadequate.

The second single-layer optical model was that of a porous film in which porosity was taken into consideration by use of an effective refractive index. Pores were treated as microinclusions of electrolyte ($n = 1.34$) in a Pb host medium ($\hat{n} = 2.1-4.2i$), and the optical properties of an isotropic homogeneous film were computed by use of the Maxwell-Garnett or Bruggeman equations. These equations have been used in the literature for modeling rough

Fig. 1. Schematic of film models investigated for the interpretation of spectroscopic ellipsometer measurements of thin Pb deposits on Cu substrates. Number of adjustable parameters given in parentheses. (a): Compact single film (1). (b): Porous single film, optical constants of effective medium determined according to Maxwell-Garnett (2) or Bruggeman (2). (c): Island single film, reflection coefficient determined by coherent superposition of polarization states, islands compact (2), porous (3) or anisotropic (6). (d): Multilayer films, three layers: compact and porous layers, dendritic islands (6) or two layers: compact and porous films (3).

Fig. 2. Spectroscopic simulations for compact film model (solid lines). Pb deposits of thickness 0, 1, 5, 10, 20, 31, 60, 110 nm. Experimental measurements (dotted lines) for 31, 60, 110 nm equivalent compact Pb deposits (d_q , based upon coulometric measurements) on Cu.

Fig. 3. Spectroscopic simulations of porous film model (solid lines). Volume fractions of Pb 0.1-0.9, amount of deposit corresponding to a 31 nm compact Pb layer on a Cu substrate. Simulations based upon the effective medium approximation (Bruggeman equation). Experimental measurements (dotted lines) for 0 and 31 nm equivalent compact film.

Fig. 4. Spectroscopic simulations of island film model (solid lines). Surface coverage 0.1-1.0, amount of deposit corresponding to 31 nm compact layer, Cu substrate. Simulations based on coherent superposition of polarization states. Experimental measurements (dotted lines) for 0 and 31 nm equivalent compact film.

surfaces and particulate films (13-16). This model involved two adjustable parameters: the deposit thickness and porosity. Spectroscopic simulations of the ellipsometer parameter Δ for this model are shown in Fig. 3 for an amount of deposit corresponding to a 31 nm thick, compact Pb layer (based upon coulometric measurements) redistributed on a Cu substrate as deposits of

various porosities. Simulations are represented by solid lines, and experimental measurements are represented by dotted lines. It is evident that this model alone is also inadequate to explain experimental measurements of delta and deposit thickness based on charge.

The third model was based on the coherent superposition of polarization states resulting from reflection of adjacent film-covered and bare elements of a patchwise covered surface (17-19). The island film may be compact, porous, or anisotropic. In the latter case, at least six unknown film parameters would have to be determined, which results in unacceptable parameter variances. The dimensions of the islands are assumed to be smaller than the transverse and longitudinal coherence of the incident light at the specimen surface. For the present spectroscopic ellipsometer, the longitudinal coherence ranges from 16 μm at 400 nm to 49 μm at 700 nm (20); the transverse (lateral) coherence ranges from 10 μm at 400 nm to 17 μm at 700 nm (21). These estimates assume (conservatively) a bandwidth twice that of the source (20 nm). Since complementary SEM studies of the films investigated here have shown the dimensions of dendritic islands to be less than 15 μm , use of the coherent superposition model is justified for the present experiments.

Spectroscopic simulations of delta for films corresponding to a 31 nm thick, uniform, compact Pb deposit (based upon coulometric measurements), redistributed on a Cu substrate as compact islands, are shown in Fig. 4. The island model used for these simulations employed two adjustable parameters: fractional surface coverage and island thickness. Combinations of these two parameters which were consistent with the amount of Pb known to be in the film from coulometric measurements were used. It can be seen that this model is also incapable of explaining the experimental measurements.

For all single-layer optical models, disagreement of the computed spectral dependence of psi was similar to that shown for delta. It is important to note that interpretations of measurements at a single wavelength often are possible, but the entire spectral range cannot be fitted with any of the models. This fact illustrates the greatly increased information content of spectroscopic measurements.

Multiple-layer optical models.—A three-layer model (2) is illustrated in Fig. 1d. The first layer was assumed to be an isotropic film representing the underpotential deposit. Optical properties of this layer were determined in a separate study (22).

The second layer was assumed to be a granular, porous deposit with optical constants computed from the properties of Pb and electrolyte, by use of the Bruggeman theory for a binary mixture, Eq. [1]-[5]. Incorporation of this layer into the optical model was motivated by light scattering measurements (22)

$$\frac{\hat{\epsilon}_{\text{ph}} - \hat{\epsilon}_f}{\hat{\epsilon}_{\text{ph}} + 2\hat{\epsilon}_f} \theta_{\text{ph}} + \frac{\hat{\epsilon}_s - \hat{\epsilon}_f}{\hat{\epsilon}_s + 2\hat{\epsilon}_f} (1 - \theta_{\text{ph}}) = 0 \quad [1]$$

$$\hat{\epsilon}_f = \frac{1}{2} [-\hat{A} \pm (\hat{A}^2 - 4\hat{B})^{1/2}] \quad [2]$$

$$\hat{A} = \frac{1}{2} [\hat{\epsilon}_{\text{ph}}(1 - 3\theta_{\text{ph}}) + \hat{\epsilon}_s(3\theta_{\text{ph}} - 2)] \quad [3]$$

$$\hat{B} = -\frac{1}{2} [\hat{\epsilon}_{\text{ph}}\hat{\epsilon}_s] \quad [4]$$

$$\hat{n}_f = \hat{\epsilon}_f^{1/2} \quad [5]$$

The root with the largest modulus was used as solution of Eq. [1] (23).

The third layer represents dendritic Pb islands, visible in scanning electron micrographs, and was modeled by an island film and coherent superposition of polarization states (Eq. [6]) resulting from reflection on adjacent surface elements with and without island coverage

$$\hat{r}_v = \theta_f \hat{r}_{v,f} + (1 - \theta_f) \hat{r}_{v,s} \quad [6]$$

Use of coherent superposition implies that the diameter of islands is smaller than the spacial coherence of the illuminating light. The total amount of Pb contained in the three layers was adjusted to agree with the coulometric measurements.

Although the three-layer model provides very good agreement between predictions and measurements, the computations have shown that the optical effect of the third (dendritic island) layer is often negligible, because the surface coverage by islands is small (5-10%). A simplified two-layer model was therefore used for interpretations. Only three unknown parameters have to be determined with this model (thickness of the first, compact layer, and thickness and porosity of the second, porous layer), as opposed to six parameters required for the three-layer model. Despite the insignificant optical effect of the dendritic island layer, it usually contained about two-thirds of the Pb deposit known to be present from coulometric measurement. All optical constants were determined experimentally from independent measurements, and were not treated as adjustable parameters.

Optimization of the two-layer model.—Optimized values of the wavelength-independent parameters of the two-layer model (thicknesses and porosity) were obtained by minimizing the sum-of-squares error between measurements and model predictions over the entire spectral range. As outlined in a previous paper (22), parameter confidence intervals are calculated from the variance of the measurements by use of the student t-statistic at a 95% confidence level for $2N-P$ degrees of freedom, where N is the number of delta-psi measurements over the spectral range (from a single spectroscopic scan) and P is the number of adjustable parameters. Wavelengths of individual measurements are spaced at intervals greater than the source bandwidth; measurements at each wavelength are treated as independent observations of the same surface.

Optimization of the wavelength-independent parameters required to specify only the first two layers resulted in smaller parameter variances than if all three layers were included, because the variance for any parameter increases dramatically as the total number of model parameters P approaches the number of data points ($2N$) used in the optimization. This strategy is based on the results of optical computations which had shown that the third (island) layer has an insignificant optical effect. All deposited Pb not accounted for in the first two layers after optimization was assumed to be contained in the dendritic islands.

Results of the optimization are shown in Fig. 5 and 6 (delta and psi vs. wavelength). The solid lines represent experimental measurements, and the circles represent points calculated by a multidimensional optimization routine. Very good agreement was obtained by optimization of the thickness and porosity of the second layer, which are wavelength-independent adjustable parameters. Table I summarizes the results of the optimization. Measured and calculated values of delta and psi at particular wavelengths are tabulated for three thicknesses. The amount of material, based on coulometric measurements,

Table I. Spectroscopic ellipsometry of Pb deposits: optimization of two-layer model. Confidence intervals for model parameters given for 95% confidence limits

Thickness of compact deposit d_c based on charge	30 nm	60 nm	110 nm

Thickness of compact (UPD) layer (nm)	0.48 \pm 0.11	0.48 \pm 0.11	0.48 \pm 0.11

Fig. 5. Spectroscopic simulation for optimum fit of ellipsometer parameter delta for a two-layer film model (circles) and measurements (solid lines) for equivalent deposit thicknesses of 0, 31, 60, and 110 nm. Film parameters derived from optimum fit of model predictions to measurements given in Table I.

Fig. 6. Spectroscopic simulation for optimum fit of ellipsometer parameter psi for a two-layer film model; other comments as in Fig. 5.

present in these films corresponds to compact layers of thickness 31, 60, and 110 nm. By minimizing the sum-of-squares error (24) between the model predictions and measured values of delta and psi over the entire spectral range, one determines the optimum values of the wavelength-independent adjustable parameters (thickness and porosity). Table I shows the values of the thickness and porosity of the porous layer with their statistically determined confidence interval and the thickness of the compact layer which corresponds to that of the underpotential deposits (19, 22). Thicknesses and porosities of the second layer are thus found to be 31 nm and 41%, 50 nm and 22%, and 87 nm and 3%, respectively.

The large error limits given for the film thickness in the last column of Table I (87 ± 266 nm) are caused by the fact that a layer of that thickness is just barely penetrated by the light (conventional penetration depth for normal incidence 8 and 13 nm at wavelengths 400 and 700 nm, respectively) and behaves optically almost like bulk lead. The measurements are therefore insensitive to deposit thickness, resulting in a wide confidence interval.

Inhibitor Effects

Conclusions about the effect of rhodamine-B on deposit porosity were derived from spectroscopic ellipsometer measurements by the methods discussed in the preceding section. Figures 7 and 8 show, for a thin deposit (31 nm, based on charge), how the distinctive spectral properties of the Cu substrate, which are still visible through the deposit obtained without dye, were completely masked by a deposit of equal lead content obtained in the presence of the dye. The large optical difference is due to differences

Table II. Effect of rhodamine-B on the morphology of bulk Pb deposits during cyclic voltammetry. Comparison of thickness d_q of bulk deposit derived from charge passed with thickness d and volume fraction θ_{pb} obtained from ellipsometer measurements. in porosity (45% without dye, < 10% with dye). Spectral scans of delta for a thicker deposit (110 nm, based on charge) are shown in Fig. 9. Here, deposits made with and without rhodamine-B show similar optical characteristics, which can be interpreted as Pb layers too thick to be penetrated by the light, even for deposits obtained without dye. The optical interpretations were similar for deposits obtained with constant or cycling potential. The underpotential deposit can be represented as a compact monolayer in the absence of the dye and an incomplete monolayer in its presence.

Fig. 8. Spectroscopic measurement of ellipsometer parameter psi, data as for Fig. 7.

Fig. 9. Spectroscopic measurement of ellipsometer parameter delta for thick Pb deposit on Cu (corresponding to 110 nm compact thickness). Substrate obscured.

Fig. 10. Effect of rhodamine-B on the micromorphology of thin (1 min, 30 nm) and thick (8 min, 110 nm) Pb deposits; scanning electron micrographs. Potentiostatic deposition at -600 mV vs. Ag/AgCl.

The scanning electron micrographs shown in Fig. 10 illustrate the fine-grained initial (1 min, corresponding to 30 nm compact thickness) deposit obtained with the dye and the dendritic islands obtained without it. At a later stage of deposition (8 min, corresponding to 110 nm compact thickness) the effect of the dye begins to wear off and patches of porous deposit appear, while without dye the dendrites continue to grow into a matted layer. Energy dispersive x-ray analysis has shown that the dendrites are composed of lead, and that, without dye, the deposit between dendrites is very thin, while it is thick and uniform with the dye, as had been inferred from the ellipsometer measurements.

Ellipsometry and Cyclic Voltammetry

Cyclic voltammetry and ellipsometry measurements (at 550 nm wavelength) were conducted simultaneously. A potential ramp (+100 to -800 mV vs. 4M Ag/AgCl reference, 2.8 V/min) and current response are shown in Fig. 11. The corresponding ellipsometer measurements are given in Fig. 12. They show a response which coincides with the onset of a cathodic deposition current (points A and D for first and second sweep). The deposit thickness and porosity ($1 - \theta_{ph}$) were determined by fitting the ellipsometer measurements to the two-layer optical model discussed above.

Interpretations for selected measured points B-F, Fig. 11 and 12, are given in Table II. It can be seen that, during the first potential cycle, the presence of the dye results in

Fig. 11. Potential cycles (+100 to -800 mV vs. Ag/AgCl, sweep rate 2.8 V/min) applied to working electrode (1.13 cm²) and resulting current response. Pb deposition on Cu from 5 mM Pb(NO₃)₂, 1M NaClO₄, pH 3, 10 μM rhodamine-B. Evaluation of measurements at points B to F shown in Table II.

Fig. 12. Ellipsometer measurements collected during potential cycles shown in Fig. 11; wavelength 550 nm (10 nm bandwidth), angle of incidence 75°.

a higher volume fraction (lower porosity) of lead in the bulk deposit. The effect of the dye gradually disappears in the second and subsequent cycles, where volume fractions close to those without dye are obtained (22). Thus, a 15% porosity obtained in the first potential sweep for a layer 29.6 nm thick compares to a 34% porosity obtained in the second sweep at 42 nm thickness. This increase in porosity is responsible for the change from a positive to a negative response in delta to deposition between the first and subsequent sweeps. Depletion of dye at the electrode surface is the cause for this change in behavior. The effect of rhodamine-B on deposit porosity reappears after relaxation periods at open circuit. The optical constants of compact lead ($\hat{n} = 2.1-4.2i$) were combined with the refractive index of the electrolyte ($n = 1.34$) to compute the optical properties of the porous deposits by use of the Bruggeman equation. The optical constants of the copper substrate were measured as $\hat{n} = 0.7-3.4i$.

The amount of lead in the bulk deposit derived from the ellipsometer measurements (product of thickness d and volume fraction θ_{ph}) is always less than the amount based on the charge passed (thickness d_u), as shown in the last column of Table II. The ratio is lower for deposits without dye, in agreement with the formation of more dendritic islands, which are not measured optically (2).

Measurement of the Inhibitor Layer

Underpotential and bulk peaks in the cyclic voltammograms are shifted to more cathodic potentials by adsorbed rhodamine-B. Due to depletion of the dye, this potential shift disappears, however, after several uninterrupted potential cycles, but it reappears after relaxation periods (10-60 min) at open circuit, during which

Fig. 13. Readsorption of rhodamine-B on Cu during 5-60 min relaxation at open circuit after removal by multiple potential sweeps; effect on cyclic voltammograms, 2 V/min, 1M NaClO₄, 5 mM Pb²⁺, 10 μM dye, pH 3, 1.27 cm².

adsorption can take place by diffusion from the electrolyte (Fig. 13). The repopulation of the electrode surface with rhodamine-B adsorbate has also been observed by spectroscopic ellipsometry; differential measurements with and without dye (Fig. 14 and 15) show the development of spectral features due to the adsorbed dye. These spectral scans were taken immediately preceding the corresponding cyclic voltammograms of Fig. 13, the relaxation times in minutes are indicated along the curves. A study of the adsorbed dye layer (25) which will be presented elsewhere, has shown that molecules oriented normal to the electrode surface, forming an adsorbate layer 32 Å thick, appear to be responsible for the inhibition of Pb deposition.

The long relaxation times required to restore rhodamine-B coverage of the surface are due to the slow diffusion from the very dilute (10 μM) solution (26). For a coverage between 4×10^{13} and 2×10^{14} molecules/cm², assuming a linear adsorption isotherm with an equilibrium constant of 0.01-0.03 cm (27), a 30 min time to half-coverage would require a diffusion coefficient between 5.6×10^{-8} and 5.0×10^{-7} cm² s⁻¹, which appears reasonable.

Conclusions

Rhodamine-B acts as a deposition inhibitor for the electrodeposition of Pb on Cu and Ag. Potentials required for deposition are more cathodic in the presence of rhodamine-B than in its absence.

Fig. 14. Differential spectroscopic measurements of ellipsometer parameter Δ for readsorption of rhodamine-B on Cu after multiple potential sweeps. Fig. 15. Differential spectroscopic measurements of ellipsometer parameter ψ for readsorption of rhodamine-B on Cu. Experimental conditions as in Fig. 13.

Less porous deposits are formed in the presence of the dye and the underpotential deposit is less than a complete monolayer. The observed decrease in bulk deposit porosity resulting from the addition of rhodamine-B can be attributed to an increase in nucleation density on the surface and inhibition of dendrite growth.

If nucleation of the bulk deposit is favored at imperfections of the first monolayer of the underpotential deposit, the partial monolayer formed in the presence of rhodamine-B may provide a higher density of nucleation sites. Also, because deposition occurs at more cathodic potentials in the presence of the dye, the equilibrium size of nuclei on the surface is smaller and their number larger. Kinetic effects of the adsorbed dye molecules may involve a decrease in the surface diffusion of Pb adatoms, which would also result in a higher nucleation density.

The selective reduction of rhodamine-B at easily accessible (high activity) sites, such as tips of dendrites, in favor of Pb²⁺ reduction, could shift the deposition to less accessible sites close to the surface which would preferentially be supplied by Pb²⁺ because of its higher diffusion coefficient.

The dye is reduced at the surface and inhibitory effects on the deposit micromorphology disappear until the surface is repopulated with adsorbate during relaxation periods at open circuit.

Spectroscopic ellipsometry allows one to calculate confidence intervals of wavelength-independent parameters for micromorphological optical models and to justify the use of more sophisticated optical models on the basis of the greater degrees of freedom.

For three electrolytically formed Pb deposits (compact thickness 31, 60, and 110 nm) the best agreement between measurements and model predictions was obtained for a three-layer model or a two-layer simplification of it. The distribution of deposited material between compact, porous (granular), and dendritic island layers could be determined.

Electrochemical Deposition of Cadmium Sulfide Thin Films from Organic Solution

I. Sulfur Reduction and Cadmium-Polysulfide Complex Formation

François Mondon

Laboratoire de Spectrométrie Physique, CNRS et Université de Grenoble I, 38402 Saint-Martin d'Heres Cedex, France

ABSTRACT

The reduction of sulfur in an aprotic solvent (DMSO) is known to be a two-stage process; each stage involves a bielectronic electrochemical step followed by a chemical dismutation reaction. When reduction is performed at a rotating electrode, it is shown that the electrochemical steps alone are involved in the electrode process. The voltammetric waves then correspond to the simple scheme

The slower dismutation reactions appear only in the bulk of solution. They lead to electron numbers which differ from 2 when S_8 is electrolyzed. The addition of Cd^{2+} ions to a polysulfide ion solution yields soluble polysulfide-cadmium 2:1 complexes $[Cd(S_x)_2]^{2-}$ with $x = 8, 6,$ and 4 . The stability of the complex is increased when x decreases from 8 to 4, which leads to dismutation and exchange reactions between complexes, polysulfide ions, and sulfur.

Cadmium sulfide CdS is a potential material for fabrication of low-cost solar cells based on thin polycrystalline films (1, 2). Besides several chemical or physical processes (3-5), thin cadmium sulfide films are obtained by means of electrochemical reduction of an organic solution containing molecular sulfur S_8 and a cadmium salt (6-9). Although it is sometimes written as a simple reaction $(Cd^{2+} + 1/4 S_8 + 2e^- \rightarrow CdS)$ (7), the electrochemical deposi-

tion of CdS soon proves to be a rather intricate process. The purpose of this paper (and of our next one on the same topic) is to demonstrate how sulfur reduction is implied with further chemical and electrochemical reactions to yield CdS deposits.

Chemical reaction between molecular sulfur S_8 and monosulfide ion S^{2-} in various solvents yields a mixture of different polysulfide ions S_x^{2-} . The sulfuration index

x varies according to the $S_8 : S^{2-}$ ratio in a range which depends upon the solvent (10-13). An alternative way for polysulfides preparation is the electrochemical reduction of molecular sulfur dissolved into a suitable solvent, *e.g.*, dimethylsulfoxide (DMSO) or dimethylformamide (DMF). Both means of preparation yield similar mixtures of S_8^{2-} , S_6^{2-} , and S_4^{2-} ions.

Electrochemical reduction of sulfur in aprotic organic solvents proceeds through complex reaction paths. It was demonstrated in previous studies that the electrochemical steps of the process may be followed by chemical reaction between sulfur and polysulfides (14, 15).

Scanning potential voltammograms for reduction of S_8 at a rotating electrode (*e.g.*, platinum electrode and DMSO) show two waves of equal amplitudes (Fig. 1). The simplest scheme consistent with this behavior is the following

When reduction of S_8 is carried on at a potential corresponding to the first wave, the electrolysis first proceeds through a two-electron reaction. However, the current vanishes only when S_8 is reduced by $8/3$ electrons. This unusual behavior is related to the dismutation of S_8^{2-} (15)

At the end of the electrolysis, the whole process is then

The polysulfide S_6^{2-} may be reduced to S_3^{2-} at a potential corresponding to the second wave of the voltammograms

Besides the above-mentioned "two-electron" process (Eq. [1] and [2]), another interpretation of the two reduction waves is an "8/3-electron" process involving Eq. [4] and [5]. It is thus desirable to demonstrate clearly which process takes place at a rotating electrode, prior to investigating the role of S_8 reduction in CdS deposition.

Experimental

Chemicals.—Reagent grade DMSO was purified by means of distillation under reduced pressure. The supporting electrolyte, tetraethyl-ammonium-perchlorate (TEAP), was twice recrystallized from cold water and

Fig. 1. Voltammetric plot for a sulfur solution in DMSO before and during electrolysis at $-0.9V$: (1) before electrolysis; (2) at $f = 2$ F/mol; and (3) at $f = 8/3$. $C_0 = 2.5 \times 10^{-3}$ mol/liter S_8 ; 4 mVs^{-1} ; 600 rpm ; 60°C .

thoroughly dried under vacuum. Sulfur was recrystallized from benzene. Cadmium salts were cadmium chloride or nitrate. Water was removed from cadmium nitrate solutions by means of molecular sieves and by nitrogen bubbling at 80°C . All solutions were deaerated by nitrogen bubbling before and during all experiments. The sulfur concentration was 2.5×10^{-3} mol S_8 /liter.

Apparatus and methods.—A Tacussel potentiostat and integrating coulometer (PRT 40-1X, IG6-N) were used in electrochemical measurements. Voltammetry was performed at a rotating platinum disk electrode (a 2 mm diam platinum wire fitted into a 10 mm PTFE rod). This electrode was polished with $0.3 \mu\text{m}$ alumina powder before each run. Unless otherwise specified, the electrode was rotated at 600 rpm. Controlled potential electrolysis was carried out at a large platinum foil cleaned in aqua regia. The auxiliary electrode was a platinum foil; it was isolated from the working solution by means of a bridge (filled with DMSO + TEAP) fitted with two glass frits. A commercial aqueous calomel reference electrode (SCE) was used in all experiments. In order to exclude any water diffusion, this reference electrode was connected to the working solution by means of a bridge containing DMSO + TEAP and molecular sieves. Most electrochemistry experiments were carried out at 60°C ; the water-jacketed airtight vessel was continuously flushed with purified nitrogen. Absorption spectra were recorded on a Beckman DB-GT spectrophotometer; the solutions were transferred from the electrolysis vessel to the spectrophotometric cells by means of PTFE tubing in a nitrogen-flushed airtight arrangement.

Sulfur Reduction in DMSO

Potentiodynamic plots.—Potentiodynamic scans were run at several temperatures from 20° to 110°C with voltage scan rates ranging between 2 and 20 mV s^{-1} . The scan rate had no effect on the voltammograms, and the ratio of the limiting currents of the two waves remained very close to 1 at any temperature. The rate of rotation ω of the electrode was varied between 200 and 5000 rpm at 20° and 60°C . In each case, the two limiting currents' variations satisfied the Levich equation (*i.e.*, proportional to $\omega^{1/2}$).

Controlled potential electrolysis.—Reduction of the working solution was performed at -0.9 V/ECS (*i.e.*, on the first wave). The concentration of unreduced sulfur was monitored from time to time by means of voltammetry at a rotating platinum electrode (Fig. 1). Figure 2 shows a plot of the remaining sulfur concentration against the charge flowing during electrolysis. This

Fig. 2. Variation of the unreduced sulfur S_8 concentration during electrolysis at $-0.9V$ (60°C).

charge is expressed as the number f of F/mol of S_8 initially present in the solution.

Voltammetry is also used to monitor S_8^{2-} and S_6^{2-} evolution during electrolysis. These polysulfides are indeed oxidized into S_8 with loss of two electrons (13)

Whatever the stage of reduction, only one oxidation wave is obtained and the half-wave potential remains unchanged (-0.19 V/ECS). The oxidation limiting current increases linearly with f , and no variation of the slope occurs at $f = 1$ (Fig. 3). In addition, the current variation against electrode rotation speed satisfies Levich's law. The reduction of S_8^{2-} and S_6^{2-} takes part in the second wave limiting current i_2 , which displays a complex behavior, first decreasing, then increasing to ca. 10% above its initial value (Fig. 4).

When the electrolysis is performed at -1.5 V/ECS (second wave), identical results are obtained from voltammetric plots, as long as $f < 8/3$. The sulfur and polysulfide ion content of the solution thus depends only on f and not on electrolysis potential. As soon as f exceeds $8/3$, the rest potential of the Pt working electrode is shifted from -0.7 to -1.0 V/SCE, and a new oxidation wave appears ($E_{1/2} \approx$

Fig. 3. Variation of the oxidation limiting current during controlled potential electrolysis (at -0.9 V until $f = 8/3$, and then at -1.5 V). Same conditions as Fig. 1.

Fig. 4. Relative variation of the second wave limiting current during electrolysis at -0.9 V. Experimental points and calculated curves.

-0.8 V/SCE). Between $f = 8/3$ and $f = 3.8$, the reduction appears to be a one-electron process.

Discussion.—It can be concluded from the above results that the limitation of the current in potentiodynamic plots arises from diffusional transport of S_8 only. Therefore, it can be inferred either that the dismutation reaction [3] is slow and takes place only outside the diffusion limiting layer or, on the contrary, that this reaction is fast enough to go to completion inside the diffusion layer. This result precludes a middle hypothesis set between the former "two-electron" case and the latter "8/3-electron" one.

The results concerning the controlled-potential electrolysis are similar to those of Badoz-Lambling (15). The one-electron process occurring beyond $f = 8/3$ is the reduction of S_6^{2-} into S_3^{2-} [5], followed by the reaction between S_3^{2-} and S_6^{2-}

The limitation of the oxidation current is also a diffusional process. The lack of variation in the slope of the plot of the limiting current between $f = 0$ and $f = 3.5$, strongly suggests that the diffusion coefficients of S_8^{2-} and S_6^{2-} are equal, according to Levich's equation. Their value is then

$$D_2(S_8^{2-}) = D_3(S_6^{2-}) = (6.3 \pm 0.3) \times 10^{-6} \text{ cm}^2 \text{ s}^{-1} \text{ at } 60^\circ\text{C}$$

Assuming either $n = 2$ or $n = 8/3$ for the electron number for sulfur reduction in voltammetric conditions, two values of the S_8 diffusion coefficient are derived from the reduction limiting current

$$n = 2e^- : D_1 = (8.9 \pm 0.4) \times 10^{-6} \text{ cm}^2 \text{ s}^{-1} \quad \text{at } 60^\circ\text{C}$$

$$n = 8/3 e^- : D_1' = (5.8 \pm 0.3) \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$$

A previous study in our group (16) showed that, owing to electrostatic interactions and ion pairing, the diffusivity of a charged species in an electrolytic solution is lower than the diffusivity of a similar neutral species. For instance, with tetramethyl phenylenediamine (TMPD/TMPD⁺), the ratio $D(\text{neutral})/D(\text{charged})$ ranges from 1.3 to 1.9 in acetone, according to the supporting electrolyte concentration. The above-mentioned results concerning S_8 and S_8^{2-} yield the ratios $D_1/D_2 = 1.4 \pm 0.07$ (for $n = 2$) and $D_1'/D_2 = 0.9 \pm 0.04$ (for $n = 8/3$). The diffusion coefficients of S_8 and S_8^{2-} may be affected by the shape of the species (ring or chain). The comparison between several mono- or tetra-alkylammonium ions (chains or spheroids with the same molecular weight) shows that the ionic mobility of the spheroid is a few percent larger. The "two-electron" hypothesis then appears more likely than the "8/3-electron" one.

A final piece of evidence in favor of the two-electron process is obtained through the analysis of the variations of the second wave amplitude during electrolysis at -0.9 V. Provided that the concentrations and diffusivities of various species are known, the second wave current i_2 can be derived as a function of the number of F, f , in the various reaction schemes. Regardless of the scheme, the respective concentrations C_1 , C_2 , and C_3 of S_8 , S_8^{2-} , and S_6^{2-} may be derived at any stage of the electrolysis

$$C_1 = C_0 i_1/i_0$$

$$C_2 = 4(C_0(1 - 3f/8) - C_1)$$

$$C_3 = 2(C_0(f - 2) + 2C_1)$$

Reactions [3] and [6] are slow.—The dismutation reactions [3] and [6] take place only in the bulk of the solution. The first stage is then reaction [1], while the second wave involves reactions [1] + [2] and [5]. The limiting currents are derived by use of coefficients D_1 and D_2 and of proper electron numbers. In this first case the ratio i_1/i_0 is

$$Y_1 = \frac{i_2}{i_0} = \frac{i_1}{i_0} + \frac{1}{2} \left(\frac{D_2}{D_1} \right)^{2/3} f = \frac{i_1}{i_0} + 0.40f$$

Reaction [3] is fast and [6] is slow.—Reaction [3] now occurs inside the diffusion layer; the first voltammetric wave then corresponds to the formation of S_6^{2-} (Eq. [4]). In the bulk of the solution, S_6^{2-} is partly reconverted into S_8^{2-} as long as S_8 is present; this process takes place outside the diffusion layer and thus does not affect the first wave. Derivation of the second wave current in this case is more complicated. The reduction of S_8^{2-} proceeds through evolution of S_8 and S_6^{2-} , which are reduced into S_3^{2-} . The molecular sulfur S_8 (present in the bulk or evolved inside the diffusion layer) is indeed not reduced into S_4^{2-} , such a process not being consistent with two waves of equal amplitudes for S_8 reduction. The correct assumption here is reduction of S_8 into S_3^{2-} via a 16/3 electron process. The complete set of equations for the second wave is then

The ratio i_2/i_0 in this second case is

$$\begin{aligned} Y_2 &= \frac{i_1}{i_0} + 2 \left(\frac{D_2}{D_1'} \right)^{2/3} \left(1 - \frac{i_1}{i_0} - \frac{3}{16} f \right) \\ &= \frac{i_1}{i_0} + 2.66 \left(1 - \frac{i_1}{i_0} - \frac{3}{16} f \right) \end{aligned}$$

(note the use of coefficient D_1' for S_8).

Reaction [3] is slow and [6] is fast.—Reaction [6] now takes place inside the diffusion layer; reduction of S_6^{2-} thus yields S_4^{2-} (reaction [7]). The remainder of the process is the same as in the first case. The result is then

$$\begin{aligned} Y_3 &= \frac{i_1}{i_0} + 2 \left(\frac{D_2}{D_1} \right)^{2/3} \left(1 - \frac{i_1}{i_0} - \frac{1}{4} f \right) \\ &= \frac{i_1}{i_0} + 1.58 \left(1 - \frac{i_1}{i_0} - \frac{1}{4} f \right) \end{aligned}$$

The values Y_1 , Y_2 , and Y_3 of the ratio i_2/i_0 are plotted against f together with the experimental values in Fig. 4. It is clear from this plot that the first hypothesis is in quite good agreement with experiments, while calculated variations Y_2 and Y_3 bear no relation to them.

This last result supports the simplest model for S_8 reduction at a rotating electrode, i.e., two electrochemical steps involving two-electron transfers according to reactions [1] and [2].

Reactions Between Polysulfide Ions and Cd^{2+}

Discoloration of polysulfide solutions.—A solution containing S_8^{2-} and S_6^{2-} shows a deep blue color; when a solution containing Cd^{2+} [as $Cd(NO_3)_2$, for instance] is gradually added to the polysulfide solution, the blue color vanishes and turns to light yellow. When the initial content of the polysulfide solution is mainly S_4^{2-} , the initial color is yellow-green; again, it turns to light yellow upon Cd^{2+} addition. The discoloration is sharp enough to allow an accurate determination of the corresponding quantity of Cd^{2+} ions. Figure 5 shows a plot of this Cd^{2+} quantity against the total polysulfide content of the solution. The same linear variation is observed, irrespective of the reduction state of the polysulfide ions. The abscissa then can be either the mole number of S_x^{2-} or the number f of F/mol S_8 when the polysulfide solution is obtained by means of S_8 reduction. This implies that Cd^{2+} reacts in the same manner with S_8^{2-} , S_6^{2-} , and S_4^{2-} . The $S_x^{2-}: Cd^{2+}$ ratio at discoloration is ≈ 2.1 , thus we consider the formation of cadmium-polysulfide complexes with the formula

The difference between the stoichiometric ratio 2 in the formula and the experimental value 2.1 can be ascribed to

Fig. 5. Plot of the Cd^{2+} quantity required for discoloration of a polysulfide ion solution against the total polysulfide content. 60°C; initial sulfur content, 5×10^{-5} mol.

various causes, such as a systematic misinterpretation of the discoloration point or influence of oxygen introduced by the Cd^{2+} solution. The nonquantitative formation of S_4^{2-} leads to some deviation from the linear variation when f is close to 4 F/mol S_8 .

Fig. 6. Absorption spectra of a polysulfide solution containing S_8^{2-} ($\approx 2 \times 10^{-5}$ mol) and S_6^{2-} ($\approx 4 \times 10^{-5}$ mol) ($v = 20$ ml) before and during Cd^{2+} addition: 1, before addition; 2, $+10^{-5}$ mol Cd^{2+} ; 3, $+2 \times 10^{-5}$ mol Cd^{2+} ; 4, $+4 \times 10^{-5}$ mol Cd^{2+} (1 mm cell).

Polysulfide complex formation reactions.—The formation of cadmium dipolysulfide complexes and their behavior may be studied by means of spectroscopy and voltammetry. Figure 6 shows the absorption spectra of a solution containing S_8^{2-} and S_6^{2-} (obtained by electrolysis of S_8 with $f = 2.4$). According to Ref. (14) and (15), band B (490 nm) is due to S_8^{2-} , whereas band A (618 nm) is assigned to the radical $S_3^{\cdot-}$, issued from S_6^{2-} dissociation. Band D, at 355 nm, was also assigned to S_8^{2-} (15); however, we observed a strong absorption at this wavelength, even when S_8^{2-} was completely reduced into S_6^{2-} and S_4^{2-} . This observation can be compared to the absorption data concerning sulfanes H_nS_n . The first allowed transition wavelength of these compounds shows little dependence upon the chain length n (for $4 \leq n \leq 8$) and lies in the same domain (17). When Cd^{2+} is added to the polysulfide solution, the absorbance of bands A and B decreases and vanishes when discoloration is obtained; it should be pointed out that band D does not vanish (Fig. 6). The absorbance of band B is a linear function of S_8^{2-} concentration, whereas, owing to the dissociation of S_6^{2-} into $S_3^{\cdot-}$, the absorbance of band A is related to the square root of S_6^{2-} concentration (15). The variations of S_8^{2-} and S_6^{2-} concentrations upon Cd^{2+} addition can then be derived from the spectra of Fig. 6; they are plotted in Fig. 7. It is clear that S_6^{2-} concentration decreases much faster than S_8^{2-} concentration at the beginning of Cd^{2+} addition: this means that the complex $[Cd(S_6)_2]^{2-}$ is more stable than $[Cd(S_8)_2]^{2-}$.

A similar result is obtained with a solution containing S_6^{2-} and S_4^{2-} . The initial spectrum displays bands A, D, and C (430 nm), which is assigned to S_4^{2-} (15) (Fig. 8). There is a sharp decrease of band C upon a first addition of Cd^{2+} solution, while band A remains unaffected; S_4^{2-} thus reacts with Cd^{2+} prior to S_6^{2-} . When more Cd^{2+} is added, band A decreases in turn; in the same time, band C is altered as its maximum moves towards 490 nm, which is the position of band B (S_8^{2-}).

This stability difference is also displayed through voltammetric plots (Fig. 9). Solutions containing S_8^{2-} and S_6^{2-} (Fig. 9a) or S_6^{2-} alone (Fig. 9b) were prepared by electrolysis. In both cases, the limiting current of the first reduction wave increases when Cd^{2+} is added up to discoloration, the half-wave potential not being altered. This behavior is explained in terms of S_8 regeneration and implies the reactions

Fig. 8. Absorption spectra of a polysulfide solution containing S_6^{2-} and S_4^{2-} ($\approx 4 \cdot 10^{-5}$ mol each in 20 ml) before and during Cd^{2+} addition: 1, before addition; 2, $+10^{-5}$ mol Cd^{2+} ; 3, $+2 \times 10^{-5}$ mol Cd^{2+} ; 4, $+3 \times 10^{-5}$ mol Cd^{2+} . Discoloration takes place for 3.8×10^{-5} mol Cd^{2+} . (1 mm cell).

oration, the half-wave potential not being altered. This behavior is explained in terms of S_8 regeneration and implies the reactions

The shift of band C toward the position of band B in the spectra of Fig. 8 is consistent with reaction [9]: as $[Cd(S_6)_2]^{2-}$ is converted into $[Cd(S_4)_2]^{2-}$, the evolved sulfur S_8 reacts with S_6^{2-} to yield S_8^{2-} through dismutation reaction [3]. As S_8^{2-} in turn reacts with Cd^{2+} when discoloration takes place, the whole process can be described by the dismutation reaction

Fig. 7. Variation of S_8^{2-} and S_6^{2-} concentrations during Cd^{2+} addition (derived from the spectra of Fig. 6).

Fig. 9. Observation of the first wave limiting current increase when Cd^{2+} is added up to discoloration to a polysulfide solution. (a) After electrolysis until $f = 1$. (b) After electrolysis until $f = 8/3$ (same conditions as Fig. 1).

Complex formation with Cd²⁺ generated in situ.—Direct generation of Cd²⁺ ions inside the solution is achieved during S₈ electrolysis by oxidation of cadmium metal. For this purpose, the current is shared between two auxiliary electrodes: one is a cadmium wire set into the solution, the second is platinum foil with a junction bridge (Fig. 10). The cadmium oxidation current is set by means of a current splitter (two variable resistors) in order to obtain 1 mol Cd²⁺ for 2 mol S₈²⁻ or another ratio. The ratio is precisely monitored by means of two current integrators. This method rules out possible troubles arising from the oxygen or water content of the cadmium salt solution; in addition, it allows the precise monitoring of small Cd²⁺ quantities.

When the electrolysis is performed with a S₈²⁻: Cd²⁺ ratio of 2, the solution gradually turns yellow and the absorption spectra shows only one band at 340-350 nm. The distinctive colorations of polysulfide ions soon appear if the S₈²⁻: Cd²⁺ ratio is increased to a slight extent. This result confirms the exact value of the stoichiometric ratio in the formula of the complex.

The concentration of unreduced sulfur is again monitored by voltammetry during electrolysis at -0.9V. Figure 11 must be compared to Fig. 2. The slope of the S₈ concentration variation remains the same from $f = 0$ to $f \approx 8/3$, indicating transfer of 8/3 electrons. The reduction process is then

The complex $[Cd(S_8)_2]^{2-}$ thus does not appear, even at the beginning of the electrolysis ($f < 1$). Because there is no excess Cd²⁺ ions in the solution, the electrochemical stage remains S₈ reduction into S₈²⁻. When $f \leq 1$, the dismutation of S₈²⁻ into S₈ and S₆²⁻ is weak; the 8/3 electron

Fig. 10. Experimental setup for Cd²⁺ generation during S₈ reduction: (T) working electrode; (R) SCE reference electrode; (A) auxiliary electrodes circuit; (ce) platinum counterelectrode; (Cd) cadmium wire.

Fig. 11. Variation of the unreduced sulfur concentration during electrolysis at -0.9V with Cd²⁺ generation (S₈²⁻:Cd²⁺ ratio = 2).

number then results from the complete conversion of $[Cd(S_8)_2]^{2-}$ into $[Cd(S_6)_2]^{2-}$ according to reaction [8]. When f reaches 8/3 F/mol S₈, the first wave does not disappear; however, the electrolysis current is small and vanishes when f is about 3. This indicates a moderate conversion of $[Cd(S_8)_2]^{2-}$ into $[Cd(S_4)_2]^{2-}$ through reaction [9].

In order to complete the reduction and reach $f = 4$, the electrolysis potential must be raised to ca. -1.4V. The polysulfide complex $[Cd(S_4)_2]^{2-}$ is then obtained through reduction of $[Cd(S_6)_2]^{2-}$, which rids the process of the nonquantitative reduction of S₈ (or S₈²⁻) into S₄²⁻. This reduction is again studied by means of voltammetry and spectroscopy. The limiting current of the second wave shows a linear dependence against f , with an abrupt change of the slope at $f \approx 8/3$. Spectrophotometry yields additional information about the absorption band located around 340-350 nm, which is observed in both complex and polysulfide solutions (band D). The absorbance increases in a linear fashion as $[Cd(S_8)_2]^{2-}$ is evolved during electrolysis until $f = 8/3$ (Fig. 12). The molar absorptivity of $[Cd(S_8)_2]^{2-}$ is derived from this part of the curve: $\epsilon \approx 5200$ at 340 nm. When $f > 8/3$, $[Cd(S_8)_2]^{2-}$ is reduced into $[Cd(S_4)_2]^{2-}$; the absorption decrease implies that the absorptivity of the latter complex is smaller than the former. The linear variation of the absorbance as a function of f

Fig. 12. Variation of the absorbance at 340 nm during electrolysis of a S₈ solution ($C_0 = 2.5 \times 10^{-3}$ mol/liter⁻¹) with Cd²⁺ generation (S₈²⁻:Cd²⁺ ratio = 2; 1 mm cell).

indicates that this reduction is quantitative. The molar absorptivity of $[\text{Cd}(\text{S}_x)_2]^{2-}$ can then be derived: $\epsilon' \approx 1200$ at 340 nm.

Conclusion

A full set of consistent electrochemical evidence supports the "two-electron" model for sulfur reduction at a rotating electrode in DMSO. The two voltammetric waves of same amplitude are thus assigned to the simple electrochemical reactions [1] and [2]. The chemical reactions which are likely to alter the electron number, *i.e.*, dismutation reactions [3] and [6], are slow and occur only in the bulk of the solution.

The addition of a cadmium salt to a solution of polysulfide ions leads to the formation of soluble and stable polysulfide-cadmium complexes. Their general formula is $\text{Cd}(\text{S}_x)_2^{2-}$, with $x = 8, 6,$ and 4 . The complex stability increases as the polysulfide chain length x decreases from 8 to 4, which leads to several reactions between complexes, polysulfide ions, and sulfur. These chemical reactions are similar to those involving polysulfide ions themselves. However, the trend towards short chain polysulfide-cadmium complex formation is more pronounced than for free polysulfide ions. For instance, there is a moderate conversion of $[\text{Cd}(\text{S}_6)_2]^{2-}$ into $[\text{Cd}(\text{S}_4)_2]^{2-}$ and S_8 , while the corresponding conversion of S_6^{2-} into S_4^{2-} is not observed. We are not aware of any other description of similar polysulfide-metallic ion complexes.

The behavior of polysulfide ions and polysulfide-cadmium complexes in presence of excess Cd^{2+} ions and the formation of other polysulfide-cadmium compounds will be examined in our next paper.

Time-Dependent Energy Efficiency Losses at Nickel Cathodes in Alkaline Water Electrolysis Systems

H. E. G. Rommal^{*,1} and P. J. Moran^{**}

Department of Materials Science and Engineering, The Johns Hopkins University, Baltimore, Maryland 21218

ABSTRACT

Water electrolysis in alkaline solutions is an important hydrogen production method. One difficulty encountered in systems employing nickel electrodes in KOH electrolytes is the continual decrease in operating efficiency with time. The major component of this decrease is the rise in cathodic overpotential at constant cell current. It was found that the kinetic parameters of Tafel slope and exchange current density increase markedly with the decline of efficiency. Four mechanisms have previously been postulated as being responsible for this phenomenon. In the present work, it was found that the loss of efficiency can be completely recovered; and an examination of the recovery mechanism supports the theory of hydrogen absorption's being responsible for the efficiency decline.

Hydrogen is an important raw material for many industries and is regarded as a viable replacement for petroleum products as the world's primary future fuel (1-3). One method used to produce hydrogen is water electrolysis. Many commercial electrolysis systems employ nickel anodes and cathodes in aqueous potassium hydroxide electrolyte. Efficiencies of these systems have been improved substantially in the last five years (4) with the development of advanced high surface area nickel electrodes and modification of cell designs to minimize resistive losses.

One of the most persistent and least well-understood problems plaguing those systems is the continual decrease in energy efficiency with time during operation.

¹Present address: Department of Metallurgy and Materials Engineering, Lehigh University, Bethlehem, Pennsylvania 18015.

The energy efficiency E_o can be written (5)

$$E_o = E_{\max} E_v E_l$$

where E_{\max} is the maximum intrinsic efficiency of the reaction(s) in question derived from the thermodynamic considerations, E_v is the voltage efficiency, and E_l is the current efficiency. Current efficiencies in unipolar water electrolyzers are close to 100% since no side reactions occur (6). Since E_{\max} is a thermodynamic property which is nearly invariant at the temperatures of interest and E_l is close to unity, the only term which could be significantly degraded with time is E_v . Typical values of full cell voltage efficiencies, referenced to the 1.23V reversible full cell potential, in industrial alkaline systems are about 70%, and decline to approximately 60% after only 200h of operation (7). Voltage efficiency can be improved by reducing the magnitude of either cathodic or anodic overpotential or the resistive losses in the electrolyte.

Electrolyte conductivity was found to be invariant with time by other investigators (8). While both η_A and η_c increase with time, the rise in the magnitude of the cathodic overpotential is reputed to be more severe for nonactivated flat-plate electrodes (9), and reportedly represents the major component of the degradation of E_0 with time (henceforth referred to as cathodic time effects). The phenomenon of cathode voltage increase with time at constant current and temperature has, therefore, been pursued in this research.

Apparatus and Experimental Conditions

An electrochemical cell for investigation of cathodic voltage-time behavior was constructed of polypropylene and high density polyethylene and is illustrated in Fig. 1. A 10 cm² Ni 200 screen counterelectrode was surrounded by a woven polyethylene membrane to minimize gaseous oxygen transfer from anolyte to catholyte during electrolysis. Also, the catholyte was purged with prepurified nitrogen for 1h prior to and throughout each test to displace any dissolved oxygen present. These measures minimized the possibility of oxygen depolarization at the cathode. The electrolyte used was a 30 weight percent (w/o) aqueous KOH solution prepared from Baker Reagent Pellets or Hooker Chemical 45 w/o solution diluted with deionized or distilled water, and cleaned by pre-electrolysis. Reference electrodes were of the saturated calomel (SCE) type and were coated with Teflon, except at the frit, to minimize electrolyte contamination by dissolution of the glass body. To insure proper functioning, SCE's were checked against another SCE reference electrode in KCl solution before and after each test. The electrolyte temperature was maintained at 37° ± 1°C by placing the cell in a controlled-temperature bath. This temperature simulates commercial operation. A Teflon-coated thermometer was used to monitor electrolyte temperature.

Working electrodes (cathodes) were fashioned from 1.0 cm² square sections cut from 0.125 in. thick Ni 200 plate. These sections were metallographically mounted in an inert polymer resin and mechanically polished to expose a planar 1.0 cm² apparent geometric surface area. Mounted and polished electrodes were cleansed thoroughly in each of a series of solvents (ethanol, acetone, ethanol, distilled water) and dried in a stream of nitrogen.

Galvanostatic control was maintained with a Princeton Applied Research (PAR) Model 173 Potentiostat/Galvano-

stat or a Kepco Model CK 36-1.5 Regulated Power Supply. Controlled potential experiments were conducted using the PAR Model 173 Potentiostat and a PAR Model 175 Programmer. Unless otherwise indicated, data were corrected for IR drop in the electrolyte by a current interruption technique (10). Typical ohmic half-cell resistance values were 0.6-0.7Ω. Voltage or current vs. time data were averaged at logarithmically spaced time intervals.

Galvanostatic Experiments

Initial investigations of the increase of η_c with time were made galvanostatically. Cells were operated for a period of 6h, and the increases in the cathodic half-cell potential (cathode vs. SCE) were monitored. Tests were conducted at six apparent current densities ranging from 2.5 to 500 mA/cm².

Previous investigators have reported a linear behavior of cathode half-cell potential with log time with a slope of 100 mV/decade time (9). Tests made in this study at lower current densities, 2.5-25 mA/cm², typically showed this linear behavior with a slope of 90 mV/decade time. However, at higher current densities, 100-500 mA/cm², sharp increases in the cathode potentials occurred between 10³ and 10⁴s (16.67 min and 2.78h, respectively) with slopes of approximately 450mV/decade time. In the regions preceding and following this sharp increase, the potential was linear with log time with slope 90 mV/decade. A plot of average cathodic half-cell potential vs. log time for all current densities tested appears in Fig. 2. It can be seen that this sharp increase in the higher current density experiments (henceforth called the "jump") is responsible for approximately 50% of the total increase in cathode potential over 6h in each case. No data were recorded during the first minute of operation to allow for system stabilization. It can be seen that the magnitude of this increase is much larger for the 100 and 200 mA/cm² tests than for the experiments at lower current densities. It can also be seen, however, that the total increase in η_c is less for the runs at 500 mA/cm² than for the 100 and 200 mA/cm² tests.

The cathodes operated at 500 mA/cm² for 6h were covered with a black deposit. Energy dispersive x-ray microanalysis of this deposit with a Tracor Northern TN-2000 Energy Dispersive X-ray Analysis System mounted on an ISI-60A scanning electron microscope showed the deposit to be predominantly iron. Fe is a common trace impurity in all available forms of KOH and most deionized and distilled water. All four combinations of Baker KOH, Hooker KOH, deionized H₂O, and distilled H₂O were prepared in an attempt to identify the major source of the Fe. Cathodes were run at 500 mA/cm² for 6h in each electrolyte, and the surface examined afterward via scanning electron microscopy for extent of Fe deposition. These tests clearly indicated that the deposition was much greater from the Baker KOH than from the Hooker, with the choice between distilled or deionized water used for dilution being unimportant. Fe is roughly as electrocatalytic for the production of hydrogen as Ni (11), and the deposition of a rough layer of Fe onto a smooth Ni surface increased the active surface area, decreasing the true cur-

Fig. 1. Schematic of cell used for efficiency loss studies

Fig. 2. Nickel cathode potential behavior with time under galvanostatic control as a function of current density in 30 w/o KOH at 37°C.

rent density (and, hence, η_c) and working against the time effects. This deposition is strongly dependent on current density, as expected, and, hence, had little effect on the tests made at 200 mA/cm² and below. Optical and scanning electron microscopy revealed no detectable deposits on all but the 500 mA/cm² cathodes. All subsequent tests were performed using Hooker 45 w/o KOH solution diluted with deionized H₂O, which was cleaned by pre-electrolysis using 50 cm² Ni 200 electrodes and a current of 10 mA for 24h. Electrolytes were checked for Fe content by a visible spectrophotometric technique. It was found that appreciable Fe did not accumulate and that the jump was fairly reproducible for solutions with Fe concentrations below 0.03 ppm. The location of the jump in time was found not to be readily correlated to current density, and its onset did not occur at a specific overpotential.

Potentiostatic Experiments

One would expect analogous behavior if similar tests were performed potentiostatically. Cathodes were held at a constant potential of $-2.00V$ vs. SCE (non-IR corrected) for 6h, and the decrease in cell current was recorded. The current shows a steady decay for the first 10^3 - 10^4 s, and then there is a sharp drop, which corresponds to the jump observed in galvanostatic tests. In these potentiostatic experiments, the cells lost, on the average, 90% of the initial current over 6h. Typical behavior of a potentiostatic test is shown in Fig. 3. In order to determine if the kinetic parameters of Tafel slope b and exchange current density i_0 , for the hydrogen evolution reaction are affected by the efficiency loss, average cathode overpotentials obtained from the preceding galvanostatic tests at various times were plotted vs. log current density. Values were taken from the first (1 min) and last (6h) data points and times just before (10^3 s) and just after (10^4 s) the jump for each current. Values for b and i_0 obtained from these plots are given in Table I. It can be seen that both b and i_0 increase dramatically with the advancement of time effects. Also, since the values are similar for 1 min and 10^3 s, and for 6h and 10^4 s, it is the jump which causes nearly all of this change in b and i_0 .

To further substantiate these findings, a set of Tafel experiments was devised. Cathode potential measurements were made at nine different current densities ranging from 10^{-3} to 0.6 A/cm². The potential was allowed to stabilize for only 2s at each current density before the value was recorded; thus, a Tafel plot was generated in approximately 20s. This short period allowed for almost no time effects to occur. The cathodes were then operated at 100 mA/cm² for 6h, allowing the jump to occur, and the fast Tafel experiment repeated without allowing hydrogen evolution to cease at the cathodes. The average data for these tests yielded values of $b = 125$ mV/decade and $i_0 = 1.9 \times 10^{-6}$ A/cm² before the jump and $b = 310$ mV/decade and $i_0 = 0.9 \times 10^{-4}$ A/cm² after the jump. Those values are nearly identical to those obtained from the previous galvanostatic tests. In addition, the IR drop in the cell was

Fig. 3. Nickel cathode current density behavior with time for potentiostatic control at $-2.00V$ vs. SCE in 30 w/o KOH at 37°C.

Table I. Hydrogen evolution parameters for nickel cathodes at various times during cathode voltage increase with time

TIME	b (mV/decade)	i_0 (A/cm ²)
60 sec (1 min)	100	2×10^{-6}
10^3 sec	125	3×10^{-6}
10^4 sec	300	10^{-4}
2.16×10^4 sec (6hrs)	300	10^{-4}

checked both before each initial and after each final Tafel plot, and was found to be constant. This indicates that there is neither electrolyte resistivity component in the cathode voltage increases, nor resistive deposit accumulated on the electrode.

Recovery of Lost Efficiency

Since the cathodic overpotential increases occur during vigorous hydrogen evolution, it seems reasonable to infer that a cathodic reaction (or reactions) is responsible for the time effects. Given this, it also follows that a corresponding anodic reaction or reactions might reverse the process. Recovery of lost efficiency has, in fact, been observed. In commercial cells, a complete recovery of full cell voltage increases incurred during hundreds of hours of operation can be accomplished by simply removing the applied current for a period as short as 0.2h (7). Also, the increase in the cathodic overpotential seen after many hours of operation can be completely recovered by removal of the polarizing current for a period of one or two days or by shorting the anode to the cathode for a substantially shorter period, on the order of several minutes (9). Similar behavior has been observed qualitatively by the authors. It is presumed that, during open- or short-circuit decay, an anodic reaction (or reactions) is occurring at the cathode, undoing or reversing the mechanism responsible for time effects. Examinations of the recovery mechanism(s) were made in conjunction with tests similar to the 6h potentiostatic experiments described earlier. Cathodes were held at $-2.00V$ vs. SCE (non-IR corrected) for a period of 3h, allowing the jump to occur, and the drop in cell current recorded. The decrease in current ranged from 33% to a more typical 90%, as shown in Fig. 3. Shorting the anode to cathode for a period of 10 min and resuming the polarization to $-2.00V$ vs. SCE produced typically 95% recovery of the lost current.

In order to study the reaction(s) occurring during recovery, a set of cyclic voltammetric tests was devised. Electrodes were potentiodynamically swept from -2.00 to $-0.50V$ vs. SCE (non-IR corrected) and back at a scan rate of 1.0 mV/s and the cell current recorded. The electrodes (cathodes) were then held at $-2.00V$ vs. SCE (well into H₂ evolution) for 3h, and the cell current decay was observed. The sweep from -2.00 to 0.50V vs. SCE and back was then repeated. It was found that this sweep typically produced a recovery of 80-90% of the current lost during the previous 3h decay period. Figure 4 shows a plot of typical current behavior in the potential region anodic to reversible hydrogen potential ($-1.094V$ vs. SCE for 30 w/o KOH, pH 14.7) during the two potentiodynamic sweeps.

Several things can be observed in Fig. 4. First, the overall anodic activity is much greater in the postdecay sweeps than in the sweeps made before the 3h current decay. Second, in both cases there are two (potential-defined) regions of activity: one between the reversible hydrogen potential and $-0.8V$ vs. SCE, and other between $-0.8V$ and $-0.5V$ vs. SCE. Third, it is the first region, negative to $-0.8V$ vs. SCE, that shows the greatest increase in activity from pre- to postdecay sweeps. To test the initial hypothesis that it is indeed anodic activity which is responsible for the recovery of time effects, these same experiments were repeated, but the upper sweep limit was changed from $-0.5V$ vs. SCE to $-1.10V$

Fig. 4. Anodic portions of single-cycle voltammograms for nickel before and after decay of current density at -2.00V vs. SCE in 30 w/o KOH at 37°C .

vs. SCE (just cathodic to reversible hydrogen and before the occurrence of anodic current). These cathodic-only sweeps produced no current recovery whatsoever.

A reaction or reactions occurring in some or all of the potential region anodic to reversible hydrogen potential is therefore responsible for recovery. To determine which portion of the anodic region causes recovery, a slightly different set of controlled potential experiments was devised. Cathodes were held at -2.00V vs. SCE (non-IR corrected) for 3h, allowing the cell current to decay as before. Potentiodynamic sweeps were then performed from -2.00V vs. SCE to successively more anodic potentials, and back. These upper sweep limits varied from -1.20V vs. SCE to -0.50V vs. SCE in 100 mV increments. The scan rate used was 100 mV/s . The amount of anodic charge passed during each sweep was measured using a PAR Model 379 Coulometer or an Electroynthesis Corporation Model 640 Coulometer. The cathodic cell currents at -2.00V vs. SCE after each sweep (a measure of recovery) were also recorded. Figure 5 contains a plot of both the anodic coulombs contained in, and the cell current of -2.00V vs. SCE after each sweep vs. the upper sweep limit. 90% of the recovery typically occurred in the region between the reversible hydrogen potential and -0.80V vs. SCE , further indicating that it is this region which is primarily responsible for the recovery. However, the task of attempting to identify the mechanisms operating in the two regions of anodic activity still remained.

Proposed Efficiency Loss Mechanisms

Four possible mechanisms have been postulated by previous investigators as being responsible for the increase in cathodic overpotential with time.

1. Increases in η_c are caused by a loss of electrocatalytically active material from the cathode (12, 13).
2. Increases in η_c are caused by slow reduction of nickel hydroxide to nickel, which may be a poorer evolver of hydrogen (14).
3. Increases in η_c are caused by deposition of impurities from the electrolyte onto the cathode (7).
4. Increases in η_c are caused by the absorption of atomic hydrogen into the lattice of the nickel cathode (9, 15).

The first hypothesis was easily tested. Cathodes were examined by scanning electron microscopy; their surfaces were found to be unchanged during 6h of operation at 100 mA/cm^2 . In addition, this mechanism is usually common only in systems employing activated cathodes. Those in this study were flat-plate, unactivated Ni.

If second hypothesis were true, it would follow that the anodic activity responsible for recovery would correspond to reformation of $\text{Ni}(\text{OH})_2$ from nickel. To test this theory, an experiment was devised to yield the nickel hy-

Fig. 5. Current recovered and associated anodic charge detected for successive single-cycle voltammetric sweeps from and after 3h at -2.00V vs. SCE for nickel in 30 w/o KOH at 37°C .

droxide formation peak alone. A piece of nickel used as a dummy electrode was held at -1.050V vs. SCE (slightly anodic to the reversible hydrogen potential). The working nickel electrode was electrically connected parallel with the dummy but not introduced into the cell yet. The working electrode was then abraded with dry 600 grit polishing paper to expose a fresh nickel surface. The grit was blown from the electrode surface with nitrogen, and it was inserted into solution under potentiostatic control at -1.050V vs. SCE . The dummy electrode was then disconnected and removed from solution. Since the working electrode was never polarized cathodically, no time effects occurred. Also, it is assumed that inserting a relatively oxide- and hydroxide-free nickel surface into solution under potentiostatic control preserved the nickel surface. The working electrode was then swept at 1.0 mV/s to -0.50V vs. SCE and back. Since no time effects have occurred, no recovery peak should appear. In fact, only one peak at approximately -0.70V vs. SCE was observed, and its position is in good agreement with potentials reported for nickel hydroxide formation peaks (16). This indicates that the anodic peak in the region between -0.80V vs. SCE and -0.50V vs. SCE (centered around -0.70V vs. SCE) in Fig. 3 corresponds to the formation of nickel hydroxide. No appreciable activity was observed in the potential region from reversible hydrogen potential to -0.80V vs. SCE responsible for recovery. This indicates that nickel hydroxide formation is not responsible for recovery, and, hence, that reduction of nickel hydroxide is probably not the mechanism responsible for time effects.

The hypothesis of impurity deposition was examined in the following way. If impurity deposition from solution is responsible for time effects, then the anodic activity negative to -0.80V vs. SCE (the "recovery peak") responsible for recovery should correspond to oxidation or dissolution of the deposited impurity. An examination of the coulombs contained in the recovery peaks yields an average value of $4 \times 10^{-2}\text{ C/cm}^2$. If it is assumed that the impurity is a metallic ion (such as Fe), a calculation of the amount dissolved during recovery and hence this amount deposited during decay can be made. If the atomic weight, valence, and density of Fe are used in this calculation, the result yields an estimated 300 \AA thick layer of deposit which would be present after 3h of evolution at 100 mA/cm^2 . This is more than enough to be easily detectable by scanning electron microscopy and energy dispersive x-ray microanalysis (EDS). The conventional detector utilized is capable of detecting all elements heavier than fluorine in the part per ten thousand range, and, as mentioned previously, the only element detected on any cathode surface (other than Ni) was Fe, which has been shown

to improve, not degrade, catalytic performance (17). In addition, these recovery identification experiments were performed using KOH solutions containing less than 0.03 ppm Fe, virtually eliminating its deposition. Although it is possible that non-EDS detectable monolayer impurities were present on the electrode surface, it should be realized that care was taken to construct the cell and components of inert materials and that the electrolytes were purified by pre-electrolysis.

The fourth proposed mechanism, hydrogen absorption, is supported by this research because the potential region where the anodic recovery reaction is observed is consistent with hydrogen oxidation potentials. The increase in both the Tafel slope and exchange current density is peculiar, as one would expect an increase in b but a decrease in i_0 to accompany a degradation of catalytic properties. If the mechanism is indeed hydrogen absorption, then perhaps this process itself influences the E vs. $\log i$ behavior of the cathode. It may even take the form of a competing electrochemical reaction, as proposed by Conway *et al.* (18), and it has been demonstrated (19) that even a small (current-wise) competing reaction can have a major influence on experimentally observed Tafel parameters.

Conclusions

Cathodic voltage-time effects on nickel in KOH are manifested as increases in cathodic overpotential at constant current or decreases in cell current at constant cathode half-cell potential. For galvanostatic tests at low current densities, η_c increases linearly with \log time. However, at higher current densities, there is a relatively rapid increase in η_c following an incubation period. This rapid increase was found to drastically increase the values of b and i_0 for the hydrogen evolution reaction. Four mechanisms to explain cathodic time effects have been previously proposed. They are (i) loss of catalyst, (ii) impurity deposition, (iii) reduction of $\text{Ni}(\text{OH})_2$, and (iv) absorption of atomic hydrogen by the cathode. Time effects are completely recoverable, and an investigation of the recovery mechanism has yielded evidence to contradict mechanisms (i), (ii), and (iii) and support the hydrogen absorption mechanism. A thorough investigation of hydrogen absorption and its relation to time effects will appear in a later paper.

ESCA and Photoelectrochemical Studies of p-n Junction Silicon Electrodes Protected by Platinum Deposition for Use in Solar Energy Conversion

Yoshihiro Nakato, Masahiro Hiramato, Yasushi Iwakabe, and Hiroshi Tsubomura

Laboratory for Chemical Conversion of Solar Energy and Department of Chemistry, Osaka University, Toyonaka, Osaka 560, Japan

ABSTRACT

Layers of mixed platinum and silicon were formed on p⁺-n junction silicon single crystal wafers (hereafter abbreviated as p⁺-n-Si) by depositing Pt on the p⁺-Si surface, followed by heating at 320°-350°C. ESCA studies showed that Pt silicide (PtSi, or in some cases a mixture of PtSi and Pt₂Si) was formed when a 3-5 nm-thick Pt layer on Si was heated, whereas a nonstoichiometric, Si-rich Pt-Si intermixed layer was formed when an ultrathin Pt layer (1.0 nm thick) on Si was heated. It was also confirmed that, in the former case, a majority of the deposited Pt remained in the form of pure metal when Pt-deposited silicon was exposed to air for ca. one day before heating. The p⁺-n-Si photoanode covered with Pt silicide gave photocurrent-voltage characteristics nearly the same as the previously reported Pt-coated p⁺-n-Si photoanode in a hydrogen iodide/iodine solution, indicating that Pt silicide formation does not affect the photovoltage at the p⁺-n junction. The photocurrent of ca. 14 mAcm⁻² at the maximum power point was maintained for 400h under continued illumination and only slightly reduced after 4500h (~6.3 months). The p⁺-n-Si electrode covered with the Pt-Si intermixed layer gave a short-circuit photocurrent higher than that covered with Pt silicide by virtue of the higher light transmittance in the layer, but was somewhat inferior in photocurrent stability. ESCA studies of the electrodes after long-term stability tests revealed that some platinum was lost in the outermost layer, suggesting that the decay of the fill factor is mainly due to the chemical change at the top surface in both the case of Pt silicide and of the Pt-Si intermixed layer.

Many studies have been made on semiconductor photoelectrochemical (PEC) cells in view of the direct conversion of solar energy into storable chemical energy. It has become clear that the main difficulty in this method lies in the fact that all known semiconductor electrodes having suitable bandgaps are unstable in electrolyte solutions. Various attempts have been made to stabilize such semiconductor electrodes. A method applicable to chemical conversion is coating the electrodes with thin layers of protective materials such as noble metals (1), metal oxides (2, 3), metal silicides (4), organic materials (5-7), and boron phosphide (8). Some coating materials also act as catalysts for photoelectrode reactions (9-12).

We reported previously (13) that a p⁺-n-Si photoanode coated with 2-3 nm-thick Pd or Pt metal photoelectrolyzes hydrogen iodide into hydrogen and iodine without external bias, with a high solar-to-chemical conversion efficiency of ca. 8%. The photocurrent was stable for 500h in the case of Pt coating. Nearly the same results were obtained with n⁺-p-Si photocathodes (14). In the course of the work, we found that Pd atoms penetrate into Si during Pd deposition, resulting in a Pd-Si intermixed layer (13b, 14). The layer was electrochemically much more stable than the deposited Pd metal. Although these Pd layers were much less stable than the deposited Pt layers, this result suggested that Pt silicide might be much more stable than the deposited Pt metal layer.

It has been well known that metals deposited on Si react with it at relatively low temperatures such as from 100° to 700°C, forming metal silicides (15). Such silicides have good conductivity and adhesivity to the Si substrate and are promising as a protective layer for the Si electrodes. Noble or near-noble metal silicides have been well studied. According to recent literature, Pt₂Si grows first at temperatures above 200°C until entire Pt is consumed, and then PtSi starts to grow under ultrahigh vacuum conditions (16). The growth mechanism is strongly affected by the presence of oxygen in the ambient, and PtSi often grows rather predominantly under low vacuum (10⁻⁷ to 10⁻⁶ torr) (16, 17). PtSi on Si is stable at temperatures below 700°C (18). The formation of a Pt-Si intermixed layer in nonannealed samples is also reported (19).

Little work has been done on electrochemical properties of metal silicides in relation with their composition or structure. Recently, Bard *et al.* reported that an n-Si electrode covered with Pt silicide shows photocurrent stable for 8 or 185h for oxidation of bromide or ferrous ions, re-

spectively (4). They interpreted the AES and XPS results as showing the presence of PtSi intergrown with Si (4b, 20). They also reported (4b) that Ir silicide-covered or RuO₂-modified Ir silicide-covered n-Si electrodes are more stable.

In this paper we will report on the photoelectrochemical properties of Pt silicide and Pt-Si intermixed layers, thermally grown on p⁺-n-Si photoanodes. The latter are newly found in the present work and are interesting photoelectrochemically because they are formed from an ultrathin Pt layer deposited on Si, causing little attenuation of the incident light. ESCA studies and electrochemical measurements were made for investigating the surface mechanisms of the electrode degradation.

Experimental

Single crystal wafers of p⁺-n-Si, prepared by an ion implantation method, were obtained from Mitsubishi Electric Corporation. The concentration of doped boron was ca. 2 × 10²⁰ cm⁻³ and the p-n junction depth was 0.6-0.9 μm. Other details were described elsewhere (13b).

Pt was deposited on the p⁺-Si [100] side of the wafer at an average rate of 0.5 nm/min under 1-2 × 10⁻⁶ torr by electron beam evaporation. The p⁺-n-Si wafer was etched in a 46% HF solution for 2 min, quickly washed, dried, and put in the vacuum within 10 min after the etching. The average thickness of the deposited Pt was monitored with a quartz crystal oscillator. The temperature of the sample was monitored with a Chromel-Alumel thermocouple in contact with the sample holder. It did not exceed 90°C during the Pt evaporation.

Heating of the Pt deposited p⁺-n-Si wafer was performed by using a radiation heater in the electron beam evaporation chamber under 1-3 × 10⁻⁶ torr. In most cases, the Si wafer was heated immediately after the Pt evaporation without exposing it to air. In other cases, it was exposed to air for a while and then heated under vacuum. The temperature of wafer rose to 300-400°C within 6 min. The heated sample was removed from the evaporation chamber after it cooled to 50°C.

ESCA spectra were obtained with a Shimadzu ESCA 750 spectrometer (13b). The binding energies were corrected by using the C1s peak of contaminant carbon as a standard. The relative atomic concentrations were calculated from the integrated peak intensities corrected for the relative ionization cross sections. The depth profile was obtained from ESCA measurements combined with

the Ar⁺ ion sputtering technique. The sputter rates for Si and Pt in our apparatus were estimated to be ca. 0.04 and 0.09 nm/s, respectively, from reported sputtering yields (21) by the 2.0 keV Ar⁺-ion beam. The depth profiles in the present work are not corrected for the differences in the sputter rates.

The electrodes were prepared by making an ohmic contact on n-Si with indium-gallium alloy. A tungsten-halogen lamp or a Wacom Solar Simulator (AM1) was used as the light source (14). The cells were cooled by circulating water around them in cases where long-term stability tests were made. Further experimental details were described elsewhere (13b, 14).

Results

ESCA studies of p⁺n-Si coated with Pt and heated at 320°-350°C.—We reported previously (13b) that most of the Pt deposited on Si was in the form of pure metal after heating at 400°C for 10 min, contrary to the previous reports demanding platinum silicide formation (15). Therefore, we have investigated the detailed experimental conditions for the silicide formation.

Figure 1 shows Si2p and Pt4f ESCA spectra for a p⁺n-Si wafer which was coated with 5.0 nm-thick Pt and heated in vacuum at 350°C for 5 min. The spin-orbit splitting for the Si2p peak was too small to be resolved, contrary to that for the Pt4f. The Si2p peak observed with a short Ar⁺-ion etching time was somewhat broad (curves 1 and 2). It shifted toward lower binding energies with increase in etching time, finally approaching that of pure Si. The two Pt4f peaks also shifted in parallel to each other with increasing etching time.

Figure 2(A) shows relative atomic concentrations for the same electrode as in Fig. 1, as a function of the Ar⁺-ion etching time. The contribution of the contaminating carbon is not included in the figure. The oxygen concentration was kept at ca. 12%, even with long etching time, indicating that it is also due to the sample contamination. One can see from Fig. 2(A) that Si and Pt are present with an atomic ratio of nearly 1:1 in a region of the etching time from 0 to 100s, showing the formation of Pt silicide with a stoichiometry of PtSi. In this region, the Pt4f_{7/2} peak lies at 72.0 eV, ca. 0.7 eV higher than that for the Pt metal, and the Si2p peak lies between 100.2 and 100.3 eV, ca. 0.8 eV higher than that for elemental Si, as seen in Fig. 2(B).

The oxygen concentration is relatively high from 0 to 40s [Fig. 2(A)]. The Si2p peak shifted toward higher energies in this region [Fig. 2(B)]. The Pt4f_{7/2} peak also shifted toward higher energies at the surface [Fig. 2(B)]. It is also noted that the Si2p peak for a short etching time shows a broad swelling at the higher energy side, as seen in curve 1 of Fig. 1. All these results suggest that PtSi is covered with a thin oxide layer.

Fig. 1. ESCA spectra of p⁺n-Si coated by 5.0 nm-thick Pt and heated at 350°C for 5 min (curve 1) and of those after subsequent Ar⁺ ion etching, 20s (curve 2), 60s (curve 3), and 150s (curve 4).

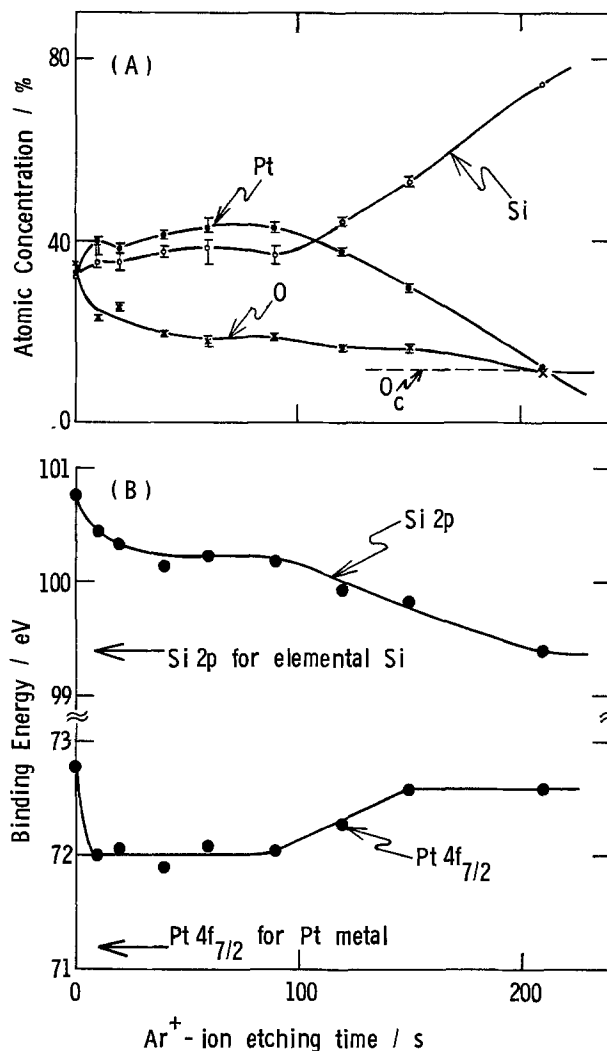

Fig. 2. Relative atomic concentrations (A) and binding energies (B) for the same p⁺n-Si as in Fig. 1, as a function of the Ar⁺ ion etching time. O_c in (A) refers to the oxygen concentration attributable to the contamination.

When Si was coated with Pt 3-5 nm thick and heated at 300°-350°C, the Pt silicide formed was in most cases PtSi. In some cases, however, the Pt to Si atomic ratio in the silicide region increased to 1.5. This indicates the formation of a mixture of PtSi and Pt₃Si (16, 17). The Pt4f_{7/2} peak for the Pt silicide layer with the Pt/Si ratio of 1.5 lay at 71.8 eV, ca. 0.2 eV lower than that for PtSi, being indicative of the Pt4f_{7/2} peak for Pt₃Si lying rather close to that for the Pt metal.

Figure 3 shows the results of ESCA studies for a p⁺n-Si wafer which was coated with 5.0 nm-thick Pt, exposed to air for one day, and then heated at 350°C for 5 min. In this case, the deposited Pt was in the form of pure metal, because the binding energy for the Pt4f_{7/2} peak for the Ar⁺-ion etching time from 0 to 50s agreed with that of the Pt metal [Fig. 3(B)]. A similar result was reported in our previous paper (13b), where Pt was evaporated at a high rate of 0.1 to 1.0 nm/s by using an electrically heated tungsten boat under 2 × 10⁻⁵ torr.

It is to be noted in Fig. 3(A) that the oxygen concentration increases at the interface between Si and Pt. The Si2p peak also exhibited a broad swelling at the higher energy side at this interface. These results indicate that a thin silicon oxide (SiO_x) layer is formed at the interface while Pt-deposited p⁺n-Si is exposed to air, and the oxide layer acts as a diffusion barrier to prevent the silicide formation. This explanation is supported by the fact that the less silicide formed, the longer the air-exposure time. ESCA studies also showed that both the oxygen concentration at the Si-Pt interface and the swelling at the higher energy side of the Si2p peak increased with longer

Fig. 3. Relative atomic concentrations (A) and binding energies (B) for p⁺n-Si which was coated with 5.0 nm-thick Pt, exposed to air for one day, and heated at 350°C for 5 min, as a function of the Ar⁺ ion etching time.

air-exposure. The interfacial SiO_x layer grew faster when Pt was deposited at a high evaporation rate. Goodnick *et al.* reported (17) that no PtSi was formed, even by heating at 400°C for 1h in a case where Pt was deposited on Si having a thermally grown, 3.0 nm-thick SiO₂ surface layer.

Figure 4(A) shows the depth profile for a p⁺n-Si wafer which was coated with an ultrathin Pt layer (ca. 1.0 nm thick) and heated immediately at 320°C for 5 min. The deposited Pt diffused into Si, but the Pt/Si atomic ratio was much less than unity, changing with the Ar⁺-ion etching time, in contradiction to the case of Fig. 2. This suggests that a nonstoichiometric, Si-rich Pt-Si intermixed layer was formed at the surface. The binding energy for the Pt4f_{7/2} peak was nearly constant, irrespective of the Pt/Si ratio, lying at 72.7 eV [Fig. 4(B)], ca. 0.7 eV higher than that for PtSi [Fig. 2(B)]. The Si2p peak, on the other hand, shifted little from that for elemental Si.

ESCA studies of a p⁺n-Si wafer coated with 1.0 nm-thick Pt, but not heated, showed a monotonic decrease of the Pt concentration from the surface into the interior, contrary to Fig. 4(A). The Pt4f_{7/2} peak in this case lay at 72.0 eV just at the surface (*i.e.*, in case of no Ar⁺-ion etching) and at ca. 72.7 eV in a region of the etching time longer than 10s, similar to that in Fig. 4(B). This suggests that all Pt intermixes with Si during the Pt deposition when the Pt layer is ultrathin.

Photoelectrochemical behavior of p⁺n-Si photoanodes covered with Pt silicide or Si-rich Pt-Si intermixed layers in hydrogen iodide/iodine solutions.—Figure 5 shows current density(*j*)-potential(*U*) curves for various p⁺n-Si photoanodes. Curve a is one of the best results for p⁺n-Si electrodes coated with 5.0 nm-thick Pt and heated at 350°C for 5 min. The depth profile of this electrode was similar to that of Fig. 2(A), except that the Pt/Si atomic ratio was about 1.5 in the silicide region. The electrode gave a reasonable open-circuit photovoltage (*V*_{oc} ~ 0.55V) but a small fill factor.

Fig. 4. Relative atomic concentrations (A) and binding energies (B) for p⁺n-Si coated with 1.0 nm-thick Pt and heated at 320°C for 5 min, as a function of the Ar⁺ ion etching time.

The fill factor was improved by etching the electrode in a 10% HF solution for 10s, as shown by curve b. The dark cathodic current also increased by the etching. No detectable changes, however, were observed in the depth profile and the binding energy for the Pt4f_{7/2} peak. It is to be noted here that the *j*-*U* curve for the etched electrode (curve b) nearly agreed with that for a p⁺n-Si electrode coated with 5 nm-thick Pt but not heated (curve c). The fill factor was generally small for electrodes prepared by heating at high temperatures (400°-500°C) for a long time (20-40 min) and was not sufficiently improved by HF etching in such cases.

Curve d in Fig. 5 shows the *j*-*U* curve for a p⁺n-Si electrode coated with 1.0 nm-thick Pt and heated at 320°C for 5 min, thus having a Si-rich Pt-Si intermixed layer as shown in Fig. 4. The electrode was etched in a 10% HF solution for 10s before measurements. The short-circuit current (*j*_{sc}) was higher than the cases of curves b and c, due to the thinner Pt layer, and the *V*_{oc} and the fill factor were nearly the same.

Figure 6 shows the results of photocurrent stability tests. The photocurrent was measured under continuous illumination in a PEC cell containing a 7.6M HI/0.2M I₂ stirred solution, with the Si electrode connected through an external 150Ω resistor to a Pt counterelectrode. The 150Ω resistor was employed to obtain the photocurrent at the maximum power point. Curve a stands for the Pt silicide-covered p⁺n-Si electrode, which gave curve b in Fig. 5. The photocurrent was quite stable for 400h, and

Fig. 5. Photocurrent density (j)-potential (U) curves: (curve a) for a p^+n -Si electrode covered with an as-formed Pt silicide layer; (curve b) for the same electrode as curve a, except that it was etched in a 10% HF solution for 10s; (curve c) for a p^+n -Si electrode coated with Pt, but not heated; and (curve d) for that covered with a Si-rich Pt-Si intermixed layer, after being etched in a 10% HF solution for 10s. Curves a', b', c', and d' are for the dark currents. The light source is a Wacom Solar Simulator (AM1 100 mWcm⁻²). The electrolyte is a 7.6M HI/0.05M I₂ stirred solution.

the j - U curve observed after the stability test agreed with the initial curve. ESCA measurements performed after this test, however, showed a decrease of the outermost Pt, as shown in Fig. 7.

Curve b in Fig. 6 is for another electrode which was prepared simultaneously under the same condition as that of the electrode which gave curve a. The photocurrent was maintained rather well during a very prolonged period of 4500h. No change was observed for the V_{oc} and j_{sc} .

Figure 8 shows the results of stability tests for electrodes covered with a Si-rich Pt-Si intermixed layer corresponding to Fig. 4. Experiments were made in the same way as in Fig. 6, except that a 100Ω external resistor was used instead of a 150Ω one by taking account of the higher j_{sc} in this case. Curve a is for the electrode which gave the j - U curve d in Fig. 5. No change in V_{oc} and j_{sc} was observed again in this case. ESCA studies of the degraded electrodes showed a decrease of Pt only at the surface, with little growth of silicon oxide at the surface, in the same way as indicated in Fig. 7. Curve b is for another electrode which was prepared under the same conditions as the electrode giving curve a. The fill factor of this electrode was somewhat small at the beginning, compared with that for the electrode of curve a, but the photocur-

Fig. 6. Photocurrent density (j) vs. time for two Pt silicide covered p^+n -Si electrodes, prepared simultaneously under the same conditions. They were etched in a 10% HF solution for 10s before experiments. The light source is a tungsten-halogen lamp.

Fig. 7. Atomic concentrations of O and Pt for the Pt silicide-covered p^+n -Si electrode as a function of the Ar⁺ ion etching time, observed before (—○—) and after (—●—) the 400h photocurrent stability test shown in curve a of Fig. 6.

rent decayed rather gradually. The p^+n -Si electrode, coated with 1.0 nm-thick Pt and not heated, showed the j - U curve nearly the same as the heated one (curve d of Fig. 5), but the fill factor decreased faster during the stability tests.

Discussion

We have concluded that PtSi or a mixture of PtSi and Pt₂Si was grown in the case where a relatively thick (3-5 nm) Pt layer was deposited on p^+n -Si and heated, whereas a nonstoichiometric, Si-rich Pt-Si intermixed layer was grown in the case where an ultrathin (1.0 nm) Pt layer was deposited on p^+n -Si and heated. McGuire *et al.* (22) reported that the Pt4f_{7/2} peak for PtSi lies 0.4 eV higher than that for Pt metal, in relatively good agreement with the present result.

Some investigations have been made on the formation of thin nonstoichiometric intermixed layers at the metal/silicon or silicide/silicon interfaces (15, 19, 23), for the purpose of understanding the mechanism of silicide formation or its effect on the Schottky barrier height. Abbati *et al.* reported (19) that a Pt-Si intermixed layer with a concentration gradient was formed when 2-10 monolayers of Pt were deposited on clean Si at room temperature. A similar result was obtained in the present work. The result in Fig. 4 is the first to show that a nonstoichiometric Pt-Si intermixed layer exists even after heating the sample at 320°C. It seems reasonable that

Fig. 8. Photocurrent density (j) vs. time for two p^+n -Si electrodes covered with the Si-rich Pt-Si intermixed layer, prepared under the same conditions. They were etched in a 10% HF solution for 10s before experiments.

such a layer is formed, even in heated samples when the amount of the Pt deposited is too small to form the silicide.

Figures 2 and 3 suggest that the Pt-Si intermixed layer similar to the case of Fig. 4 is also present at both the PtSi/Si and Pt/Si interfaces, as seen from the chemical shift of the Pt $4f_{7/2}$ peak to 72.7 eV. The presence of similar interfacial layers with graded concentrations was reported at Ni/Ni $_2$ Si and Ni $_2$ Si/Si interfaces (23). It is also noted that the Pt $4f_{7/2}$ peak at 72.7 eV in the present work is very similar to that reported by Bard *et al.* (20), though they interpreted it as due to PtSi.

It was reported by several workers (15a, 17, 20) that PtSi is covered with a thin oxide layer when it is formed under $\sim 10^{-6}$ torr, as observed in the present work (Fig. 2). The improvement of the fill factor of the Pt silicide-covered electrode by HF etching (curves a and b in Fig. 5) indicates that this oxide layer is responsible for the small fill factor. Since the ESCA analysis showed no detectable change in the surface chemical composition by the etching, it seems likely that the reaction kinetics are improved by the HF etching, which removes very thin oxide layers covering the Pt atoms at the top surface in contact with the electrolyte solution.

As mentioned in the preceding section, the ESCA studies of the p-n-Si electrodes covered with Pt silicide after long-term stability tests showed a loss of the outermost Pt (Fig. 7), even for the case where the photocurrent had been unchanged. A similar loss of the outermost Pt atoms was observed for electrodes covered with the Si-rich Pt-Si intermixed layer. It is reasonable that by such a change, the electrochemical active sites are decreased, thus increasing the overpotential for electrochemical reactions and decreasing the fill factor. The inferiority of the photocurrent stability for the electrode covered with the Si-rich Pt-Si intermixed layer, as compared with the electrode covered with Pt silicide, can be explained by assuming that the above effect of the decrease of the surface Pt atoms becomes more prominent as the Pt/Si atomic ratio at the surface becomes smaller.

As can be seen from Fig. 6, the p-n-Si electrode covered with Pt silicide has shown a good stability under illumination over a period of 4500h. However, further investigations should be necessary to decide whether the coating of this type is superior to the previously reported, Pt-coated electrodes.

Acknowledgment

The authors wish to express their thanks to Mitsubishi Electric Corporation for kindly offering p-n junction Si single crystal wafers.

The Chemistry of Li/SOCl₂ Cells

An ESR Study of Carbon Electrodes

S. S. Kim, Boyd J. Carter, and F. D. Tsay

Jet Propulsion Laboratory, Applied Mechanics Division, California Institute of Technology, Pasadena, California 91109

ABSTRACT

Carbon electrodes from Li/SOCl₂ cells were studied by electron spin resonance after various stages of discharge. Different behavior was observed in the temperature-dependent part of the ESR linewidth, defined as "intrinsic linewidth," ΔH_{int} , when two different electrolytes were used. With one electrolyte, 1.5M LiAlCl₄/SOCl₂, the ΔH_{int} value stayed constant or slightly decreased whereas with another electrolyte, 1.0M LiAlCl₄/14% BrCl in SOCl₂, the value increased as discharge progressed. The carbon electrodes are modified differently during discharge with these two electrolytes, and it is speculated that this may be due to changes in the carbon matrix functional groups. This difference in the carbon electrodes may explain the claimed differences in safety performance of the cells.

The lithium (Li)-thionyl chloride (SOCl₂) cell system has been of great interest for many applications because of its high specific energy and high discharge rates. However, there have been safety problems with these cells, since the cells have been found on occasion to vent (expel internal liquids and gases) or explode (1). It is of major importance to resolve these safety problems to provide safe cells. Previously, we have studied the cell chemistry during discharge to +0.5V (2). With the establishment of a mechanism for the reduction of SOCl₂ during discharge to +0.5V at 25°-30°C, we have eliminated the concern of a cell explosion due to buildup, and then rapid decomposition of a chemical intermediate formed during discharge. The research mentioned above only studied discharge to +0.5V, and did not address the hazardous conditions of voltage reversal of Li-SOCl₂ cells. Voltage reversal can occur in a battery if one cell in a series connected stacks of cells has less capacity than the other cells. During discharge, the cell with less capacity is fully discharged, but current continues to flow through the cell in the same direction, driven by the other cells in the stack. The voltage of this particular cell drops below 0 V, and new reactions occur in the cell. As an example, carbon-limited voltage reversal occurs when a cell has excess Li and electrolyte, and the cell is limited by the carbon electrode capacity. In this case, the carbon electrode is reported to be plugged with LiCl (3) and possibly S, products of the reduction of SOCl₂ which limit the ability of the electrode to reduce SOCl₂ at the rates required to support the discharge currents. When the cell voltage drops below 0 V, it is then possible for new reactions such as LiCl or LiAlCl₄ reduction to form Li metal to occur. These reduction reactions are reasonable based upon the cell voltage holding at -0.1 to -0.20V at 10 mA/cm².

Carbon-limited voltage reversal has been found to be a hazardous discharge condition for Li-SOCl₂ cells. A possible explanation for the observed ventings and explosion of carbon-limited cells during reversal is the exothermic reaction observed by Kilroy *et al.* (4) in their calorimetry research. Recently, a catalytic effect of carbon black on the reactivity of lithium with SOCl₂ electrolytes has also been reported (5). At low temperatures (<100°C), it was found that lithium-carbon samples would exhibit large exotherms when in contact with cell electrolytes. Thus it was suggested that during carbon-limited voltage reversal, when LiCl could be reduced to Li metal, the lithium-carbon/electrolyte reaction could occur raising the temperature in the cell, leading to thermal runaway.

The reaction between sulfur and Li metal was also found to be an exothermic reaction, initiating at ~130°C. This reaction could also account for the safety hazard, or react in addition to the lithium-carbon/electrolyte reaction. Liang *et al.* (6) have reported that adding BrCl to neutral LiAlCl₄/SOCl₂ electrolyte improves the safety performance of the cell. It was postulated that the BrCl can react with sulfur deposited on the carbon during reduction of SOCl₂, dissolving the sulfur. Thus, the sulfur is not

present during reversal to react with Li metal and possibly lead to thermal runaway.

In order to understand the changes occurring in the carbon electrode during discharge and their implication to cell safety, we have initiated ESR studies of the carbon electrode. Many researchers studied carbon crystals (7), polycrystalline carbon (8), ultrafine graphite particles (9), and metal-carbon intercalation compounds (10) by ESR. It was found that ESR linewidth is very sensitive to the variation of spin lattice relaxation processes of the charge carriers in the carbon samples. In this respect, it was of interest to use ESR spectroscopy as a unique tool to determine the changes in the carbon, as the discharge proceeds. By employing both 1.5M LiAlCl₄/SOCl₂ (A) and 1.0M LiAlCl₄/14% BrCl in SOCl₂ (B) as electrolytes, it should also be possible to better understand the safety hazards due to changes in the carbon electrode during reversal and, in particular, elucidate the manner in which BrCl possibly improves the safety of the cell.

Experimental

All cell components were handled under an argon atmosphere in a Vacuum Atmospheres Dry Box (<10 ppm O₂ and H₂O). Thionyl chloride (SOCl₂) was obtained from Aldrich and purified by vacuum distillation from triphenylphosphite. Lithium tetrachloroaluminate (LiAlCl₄) was obtained from Lithium Corporation of America and bromine chloride (BrCl) was obtained from Dow Chemical Company. Both were used without further purification.

1.5M LiAlCl₄/SOCl₂ electrolyte (A) was prepared by adding the necessary LiAlCl₄ to purified SOCl₂. Undissolved solids (LiCl) were separated by decanting the solution. 1.0M LiAlCl₄/14% BrCl in SOCl₂ (B) was prepared by adding a known amount of BrCl to purified SOCl₂, followed by addition of the necessary amount of LiAlCl₄. Again, separation of undissolved solids (LiCl) was effected by decanting.

Two different sets of carbon electrodes, commercial and JPL, were studied. The commercial carbon electrodes were purchased from Power Conversion, Incorporated (Mount Vernon, New York) and used without modification. The JPL carbon electrodes were prepared by applying a 10% Teflon-Shawinigan acetylene black mixture onto expanded nickel metal, rolling, drying, and finally sintering the electrode at 280°C for 1h. The Shawinigan acetylene black (average particle size ~42.5 nm) was purchased from Gulf Oil and Chemical Company (Englewood Cliffs, New Jersey).

Carbon electrodes for analysis were prepared by discharging carbons in a one-compartment cell shown in Fig. 1. Two lithium electrodes were used for each carbon electrode, and they were separated by Mead Glass Paper 935-BJH. Measured amounts of electrolyte (~1.4 ml) were added to the assembly, which was then sealed in a plastic bag to prevent electrolyte evaporation. Cells were discharged at constant current (10 mA/cm² of carbon) using

Fig. 1. One-compartment cell assembly

an Electronic Measurements Model C629 Constant Current Power Supply. A Fluke 8021 B multimeter was used to follow the current, and a Hewlett-Packard 7132 A recorder was used to follow voltage and time. Typical voltage vs. time plot during discharge is shown in Fig. 2.

All carbon electrodes sampled at different stages of discharge were dried at room temperature *in vacuo* for 2h or more in the antichamber of the dry box. Samples were collected by scraping carbon flakes off the dried electrodes. The carbon flakes showed different degrees of agglomeration. The flakes were ground slightly inside the dry box with a mortar and pestle to ensure homogeneous sampling. ESR spectra of these samples showed symmetrical lineshapes (C_2 symmetry with respect to the center of each spectrum), very close to Lorentzian (see Fig. 3). The symmetric lineshape ensured the carbon samples of particle size smaller than the microwave skin depth. The carbon samples (~20 mg) were transferred to ESR tubes (3 mm od, 2 mm id) equipped with ground joints. The tubes were sealed under argon with Apiezon N grease in the dry box.

An ESR spectrometer (Varian E-line Century Series) operating at X band (9.2 GHz) was used with 100 kHz field modulation. For most of the samples, ESR scans were made at two temperatures, at 77 and 294 K (room temperature). Some of the samples were also measured at 192 K. The intermediate temperature, 192 K, was obtained by blowing cold N_2 gas through a Dewar insert inside a microwave cavity.

Results and Discussion

The carbon samples show ESR lineshapes close to Lorentzian (see Fig. 3). All the observed spectra gave $g = 2.0032$. They are assigned as from charge carriers in carbon as reported earlier by several authors (7-9). The Lorentzian lineshape of the observed spectra shows that the major contribution to the linewidth is from the spin relaxation processes, the linewidth being inversely proportional to T_1 and T_2 , spin-lattice relaxation time and spin-spin relaxation time, respectively. In conductors (11, 12), the two processes are no longer distinguishable and can be regarded as $T_1 = T_2$. The relaxation times are affected by temperature, presence of impurities in the matrix, and also by particle size due to spin flipping at

Fig. 2. A typical plot of voltage vs. Ah during discharge. In this case, current was kept at 80.7 mA (10 mA/cm²).

Fig. 3. ESR spectra of a carbon sample at 294 and 77 K. The carbon sample was collected from a cell containing electrolyte B discharged to 0.208 Ah. The observed spectra are compared with simulations of Lorentzian and Gaussian lineshape.

particle surfaces. The surface contribution to linewidth becomes more important with smaller particles. The observed ESR linewidth are thus a reflection of all these relaxation processes.

Each set of carbon electrodes, commercial or JPL, were prepared from one lot of carbon. Thus, one can assume a uniform distribution of particle size for each set of electrodes. However, after discharging processes, the carbon flakes from the electrodes showed different degrees of agglomeration, which effects the particle size of the sample. In order to filter out the effects of particle size on the observed linewidths and study the changes in the carbon matrices, we used the approach of Watts and Cousins (13). They proposed that the observed linewidth, ΔH_{obs} , can be broken down into three separate contributions

$$\Delta H_{\text{obs}} = \Delta H_{\text{int}} + \Delta H_s + \Delta H_c \quad [1]$$

or expressed in corresponding relaxation times

$$\frac{1}{T_2} = \frac{1}{T_{\text{int}}} + \frac{1}{T_s} + \frac{1}{T_c} \quad [1']$$

in which ΔH_{int} is the "intrinsic linewidth," (or T_{int} , the "intrinsic relaxation time") contribution from phonon modulated spin-orbit coupling mechanism. It is believed (14, 15) that this is the main interaction responsible for relaxation processes in carbon lattices intercalated with heavy atoms (*e.g.*, Br, Cl). The second term, ΔH_s (or T_s), is related to the spin flipping at the particle surface and is a function of particle size. The third term, ΔH_c (or T_c), is a temperature-independent term which may arise from crystalline defect centers or from impurities in the sample.

In Fig. 4, the observed linewidths are plotted as a function of temperature. The relationship is quite linear, within experimental error, for the temperature ranges studied. With the support of theoretical studies (16-18), one can regard the ΔH_{int} as proportional to temperature

$$\Delta H_{\text{int}} = k_1 T \quad [2]$$

The rest of terms will be regarded as constant in temperature

$$\Delta H_s + \Delta H_c = \text{const.} \quad [3]$$

It should be noted that the case discussed by Watts and Cousins (13), where ΔH_s was treated as inversely propor-

Fig. 4. Variation of ESR linewidth, ΔH , of carbon samples as a function of temperature. With A electrolyte, O = carbon-limited voltage reversal (CLVR), and Δ = normal discharge (ND). \square = Carbon wetted with electrolyte and dried (CW). With B electrolyte, \bullet = CLVR, \blacktriangle = ND, \blacksquare = CW.

tional to temperature, does not fit our observed linewidth data.

From relations [1]-[3], the ΔH_{int} values are calculated by Eq. [4]

$$\Delta H_{\text{int}} = \frac{\Delta H^{294} - \Delta H^{77}}{294 - 77} \times T, \quad 77 \leq T \leq 294 \quad [4]$$

in which ΔH^{294} and ΔH^{77} denote the observed derivative ESR linewidths (peak to valley) at 294 and 77 K.

Examples of observed ESR linewidth data and calculated ΔH_{int} values are listed in Table I. The carbon sample at 0.0 Ah was prepared by wetting the fresh electrode with corresponding electrolyte and dried under vacuum. These carbon samples showed larger ΔH_{int} value than fresh carbons. However, samples from carbon electrode wetted only by SOCl₂ showed ΔH_{int} value similar to the fresh carbons. It appears the difference is caused by the adsorption (deposition) of the solute material, LiAlCl₄, on the pores of carbon electrode. After pumping under vacuum in the process of drying, the solvent SOCl₂ evapo-

rated, but the solute material did not. The solute material with Al and Cl atoms then shortens the relaxation time through spin-orbit coupling, and broader ΔH_{int} values are observed. However, when another set of carbon samples is studied as a function of wetting time (up to 2.5h) without any electrical discharge, the samples did not show any change in ΔH_{obs} or ΔH_{int} value within experimental error.

If we now define

$$\Delta(\Delta H) = \Delta H^{294} - \Delta H^{77}$$

then, at a given temperature, T

$$\Delta H_{\text{int}} \propto \Delta(\Delta H) \quad [5]$$

Since they are proportional to each other, one can simply compare $\Delta(\Delta H)$ in place of ΔH_{int} . In Fig. 5, the $\Delta(\Delta H)$ values are plotted as a function of the total amount of charges passed in the units of ampere hours. For each set of discharged carbons, commercial and JPL carbon, a similar tendency was observed; the carbons discharged with A electrolyte tend to give narrower (or constant) ΔH_{int} [and $\Delta(\Delta H)$] value with discharge, and the carbons with B electrolyte give broader ΔH_{int} values with discharge.

The spin-orbit coupling is very weak in Li (13, 17, 18), and changes in Li concentration in the carbon matrix should not affect ΔH_{int} value significantly. Thus, the observation of slight decrease (or constant) in ΔH_{int} value with electrolyte A does not contradict the generally accepted discharge mechanism in which LiCl is deposited (or intercalated) in the carbon electrode during discharge, and later reduced to Li metal during voltage reversal.

Liang *et al.* (6) have speculated that sulfur may also be deposited in the carbon electrode during discharge with electrolyte A, and this sulfur may be the source for the safety hazard during voltage reversal of cells with electrolyte A. They also reported that cells with electrolyte B may be safer because the presence of BrCl in SOCl₂ may help dissolve sulfur in the carbon electrode. If the deposition of sulfur is in the form of intercalation through the carbon matrices, the observed ΔH_{int} value for the case of A electrolyte should increase with discharge because the intercalation would shorten the spin lattice relaxation time by spin orbit coupling mechanism. In case of B electrolyte, the ΔH_{int} linewidth should be narrower than the corresponding A electrolyte case because of less amount of sulfur deposition on the carbon electrode during discharge. Our results do not agree with this picture. However, if the deposition of sulfur is only an agglomeration on the carbon surface and segregated from the carbon matrix, the deposition should not affect the ESR linewidth significantly. Some heavy atoms must be electronically interacting with the carbon electrode, thus

Table I. The ESR linewidths (G) of carbon samples after discharge

Fig. 5. A plot of $\Delta(\Delta H) = \Delta H^{294} - \Delta H^{77}$ vs. amount of discharge (Ah) for commercial and JPL carbon electrodes in two different electrolytes, A and B. Typically normal discharge is in the range of 0 ~ 0.11 Ah, voltage reversal from ~ 0.11 Ah.

broadening the ΔH_{int} linewidth with discharge when using electrolyte B. One possible explanation of the data appears to be an interaction between BrCl and the carbon electrode. As the discharge progresses, BrCl interacts with the carbon, possibly forming C—Br and/or C—Cl bonds. This interaction of carbon lattice with heavy elements will shorten the spin-lattice relaxation time (T_{int}) through stronger spin-orbit coupling and results in broader ΔH_{int} values. It seems that the possibly improved safety of cells with electrolyte B probably arises because of the change in the characteristics of the carbon (e.g., carbon functional groups) and the influence of these changes on the cell chemistry.

As suggested above, ESR is very sensitive to subtle changes in the carbon electrode. Indeed, the ESR method can be employed to study oxidation of carbon surfaces after prolonged (1 day) exposure to air. It was found in our laboratory that fresh carbon particles (Shawinigan acetylene black) give narrower ESR linewidth upon cooling from 294 to 77 K, i.e., $\Delta(\Delta H) > 0$, however, after prolonged exposure to air, the trend is reversed, i.e., the linewidth becomes broader upon cooling to 77 K, $\Delta(\Delta H) < 0$. This observation can be explained by oxidation of the carbon surfaces after exposure to air, as in the case of metal oxide particles studied by Bowring and Cousins (19). This result is important, since it points out the need to carefully control the handling of the carbon used in preparing electrodes to achieve reproducible cells. This result also shows the ESR as a valuable "quality control" tool to identify unknown causes for irreproducible results and performance of carbon electrodes.

In summary, it has been demonstrated that ESR spectroscopy is a valuable tool for investigating the chemistry in Li/SOCl₂ cells. Changes in characteristics of the carbon, due to exposure to oxygen or BrCl, have been identified. Moreover, changes in carbon functional groups will almost certainly impact the chemistry, safety, and performance of Li/SOCl₂ cells. In particular, the reported improved safety of Li/SOCl₂ cells with the BrCl additive is best explained by the changes in the characteristics of the carbon electrode because of reaction with BrCl.

Acknowledgments

The authors would like to thank other members of our battery research team, Roger Williams and Maggie Evans, for many helpful discussions. This research represents one phase of research performed at the Jet Propulsion Laboratory, California Institute of Technology, sponsored by the National Aeronautics and Space Administration under Contract NAS7-918.

ABSTRACT

Single-crystal silicon solar cells having efficiencies within 1% of those prepared in semiconductor-grade silicon have been fabricated in twice-recrystallized, high purity metallurgical silicon. Produced in a 100 kW experimental arc furnace by carbothermic reduction of pure silica with pelletized carbon black, the best "solar-grade" silicon contained 50-100 ppmw Al, 50-100 ppmw Fe, 10 ppmw Ti, 1.8 ppma B, and 2.1 ppma P. Following two Czochralski (Cz) recrystallizations, the metal impurity levels in the final ingot were indistinguishable from those in once Cz-recrystallized semiconductor-grade silicon, while the boron and phosphorus contents were 1.5 ppma and 0.6 ppma, respectively. The average efficiency of 4 cm² test solar cells prepared in twice-recrystallized "solar-grade" materials was 13.7%, compared to 14.4% for semiconductor-grade controls. The average efficiency of unencapsulated, production-type 100 mm diam solar cells made in this material was 11.8%. Compared with earlier experiments, this represents a nearly 2% improvement in efficiency, which is attributed largely to the factor of two lower boron content in the starting silicon.

Since 1976, the average price of photovoltaic modules fabricated from crystalline silicon solar cells has decreased from about \$40/W_{pk} (1980 dollars) to about \$8.50/W_{pk} (1980 dollars). However, substantial reductions in module manufacturing cost and price are believed necessary to provide impetus for any major potential market expansion. Since the cost of silicon wafers is a major ingredient in module cost, a joint research program to explore the feasibility of one promising route to low cost crystalline silicon for high efficiency solar cells was undertaken jointly by Exxon and Elkem, AG.

The generic sequence of manufacturing steps selected for evaluation consists of: (i) preparation of pure C and SiO₂ feedstocks, (ii) arc furnace reduction of the feedstocks to pure metallurgical silicon (PMS), (iii) metallurgical purification of PMS to solar-grade polysilicon (SGP), at a price goal of \$14/kg in 1980 dollars (1), (iv) crystal growth of silicon ingot from SGP, (v) slicing of silicon wafers from the silicon ingot, and (vi) processing of the wafers into solar cells.

Similar research and development efforts, starting with pure feedstocks (2-5), and related efforts, starting with conventional metallurgical silicon (6-7), have been reported, with the common objective to reduce solar cell cost. This paper describes recent advances made in feedstock selection and arc furnace operation which result in lowered boron concentration in the silicon and in improved efficiency in solar cells made from it.

Experimental

SiO₂ and C feedstocks.—Impurity analyses of the principal SiO₂ and C feedstocks evaluated in this work are shown in Tables I and II, respectively. The methodology of feedstock selection and the methods for cleaning the quartz and the pelletization of SiO₂ and carbon black powders are described elsewhere (3, 8, 9). Two sources of lump quartz and two sources of granular quartz were evaluated. The lump quartz sources from British Columbia and Arkansas, which were previously analyzed (3) with results similar to those shown in Table I, are of equivalent purity and moderate projected cost (\$0.25-\$0.50/kg). The type-"A" granular quartz, is a relatively high cost (\$2.00/kg) material upgraded to high purity from pegmatite, whereas the type-"B" granular quartz is low cost (\$0.10/kg) commercial-type feedstock from quartz rock.

*Electrochemical Society Active Member.

For the overall arc furnace reaction

cleaned lump quartz or silica/sucrose pellets was used together with C-black/sucrose or C-black/sucrose/silica pellets. Granular quartz was further ground and pelletized either with C-black and sucrose, or with sucrose alone. The particular combination of SiO₂ and C feedstocks is identified for each test reported in Table III.

Two carbon blacks, type I, a thermal black from natural gas, and type II, a furnace black from residual oils, were selected for evaluation. Since in pelletized form both ma-

materials behaved similarly in arc furnace operation, most of the tests, including all those reported here in Table III, were conducted using type I. The carbon black powder was converted into 1-2 cm size pellets using water-sucrose solutions in a pilot-size, 1m diam disk pelletizer. The purchased carbon electrodes were used without further treatment.

Submerged-arc-reduction furnace operation.—The selected C and SiO₂ feedstocks, described above, were converted into PMS in two different single-phase, laboratory-size, one-electrode arc furnaces of split-body design having nominal 50 and 100 kW power ratings, respectively. The construction of the smaller furnace is similar to one of fixed-body design previously described (9), but incorporates the split-body design in addition. The larger furnace incorporates the split-body design (10), as shown in Fig. 1. The tests in the 50 kW furnace were designed to establish suitable smelting conditions and to develop the appropriate materials of construction for subsequent use in the 100 kW, split-body furnace under the purest operating conditions. For simplicity, the graphite electrode, which is positioned vertically and centered in the 100 cm id cavity, is omitted from the drawing. Likewise, the graphite tapping spout has been omitted for clarity. A feedback loop on the 100 kW furnace allowed for automatic position adjustment of the electrode in order to maintain constant electrical load to the furnace. The duration of the smelting tests varied from about 1 to 2.5 days, with PMS production rates of about 1.5 kg/h in the 50 kW furnace and of about 5 kg/h in the 100 kW furnace.

Fig. 1. Schematic illustration of experimental 100 kW arc furnace. The sketch is simplified, and not to scale.

Metallurgical purification of PMS to SGP.—From previous work on metallurgical-grade silicon (MG-Si) (6, 7, 11) and on pure metallurgical grade silicon (PMS) (3), we concluded that there was little hope of obtaining high efficiency solar cells on any silicon material taken directly from an arc furnace and then recrystallized once. The silicon from an arc furnace, even under the best possible operating conditions, contains too much silicon carbide and metal impurities. Accordingly, an intermediate low cost metallurgical or hydrometallurgical step is needed to convert high purity arc-furnace silicon (PMS) into solar-grade polysilicon (SGP) ready for final recrystallization. One aim of this program was to explore intermediate purification steps which could meet the overall cost goal of \$14/kg (1980 dollars) and still provide the requisite purity (13) so that high efficiency solar cells could be obtained.

As an initial standard for comparison, we have employed Czochralski recrystallization for conversion of arc-furnace silicon to solar-grade polysilicon ready for final recrystallization. At the same time, we conducted a separate investigation of alternative approaches to upgrading arc-furnace silicon which would meet cost and purity goals.

Drawing on the experience of Hunt (3) and Secco d'Aragona (11), we adopted the following procedure. Each PMS batch was given a two-step etch, first in aqueous HF and then in an HNO₃-HF-HOAc(acetic) acid mixture to remove oxide, slag, and extraneous iron particles introduced during crushing of the silicon. About 15 kg of the etched PMS was charged into a standard quartz crucible in the growth chamber of a commercial crystal puller. After melting, the silicon was observed to be covered with a thick layer of silicon oxide and silicon carbide slag. The oxide slag was removed by reducing the Ar pressure in the chamber to less than 1 torr and increasing the melt temperature, to "boil" the melt. The "boiling" action occurs because of the rapid evolution of SiO gas.

To remove most of the remaining SiC slag, silicon seeds were introduced and crowns were grown to occlude the SiC floating on the surface. However, because of SiC dislodged from the walls during growth, only polycrystalline ingots could be grown. The typical growth rate employed for ~11 cm diam ingots was 6.4 cm/h, with 15 rpm seed rotation and 8 rpm crucible counter-rotation. The polycrystalline ingot was cylindrically ground to remove about 3 mm from its outer surface, and cropped at the seed and the tang. After being etched in a mixture of hydrofluoric, nitric, and acetic acids, the resulting rod served as prototype SGP for crystal growth into the final silicon ingot.

Table IV. Metal impurity content in Czochralski once-recrystallized ingots^a (spark-source mass spectroscopy)

PMS-7	SPC-13	Seed Tang	2 (3) 100	20 (4 × 10 ⁻³) 100	< 1 (2 × 10 ⁻⁴) 100

^a The numbers in parenthesis = $k_{eff} \times [\text{metal}]$ in the arc-furnace run. $K_{eff} = 0.01$ (Al); 10^{-5} (Fe); 10^{-6} (Ti).

^b Seed at 0.1 of melt pulled; tang at 0.7 of melt pulled.

Impurity analyses from the seed and tang of several of the once-recrystallized polycrystalline ingots are shown in Table IV. The numbers in parentheses indicate the product of distribution coefficient of the metal impurity and the metal impurity content in the PMS melt, at the seed of the ingot. The analysis for Al suggests that quite large Al concentrations can be incorporated due to the relatively large distribution coefficient. The analyses for Fe at the seed suggest that constitutional supercooling may already be occurring for this impurity. As indicated, small Ti concentrations were measured at the seed. A pronounced increase in the concentrations of Al, Fe, and Ti is noted at the tang of the ingots due to constitutional supercooling. The plot of the metal impurity concentrations in the PMS melt in Fig. 2, together with a theoretical curve similar to that of Hopkins *et al.* (12) for the onset of constitutional supercooling as a function of crystal growth rate, substantiates the expectation that supercooling and a strong increase in impurity content of the ingot would occur at or near the seed of the ingot. Once this behavior was understood, the attempt was made to grow ~11 cm diam polycrystalline Czochralski ingots at lower growth rates in order to eliminate the occurrence of constitutional supercooling. However all attempts were unsuccessful owing to the difficulty in maintaining diameter control at low growth rates in the commercial Czochralski furnace under normal operating conditions

Fig. 2. Metal impurity concentrations in the PMS melt

without extensive improvement in the feedback and control systems. Thus, in all the work reported here, a growth rate of about 6.4 cm/h was employed.

Growth of silicon ingot from SGP.— In principle, conversion of low cost SGP to low cost silicon wafers might be carried out by any one of several crystal growth methods, including Czochralski, Bridgman, float zone, and ribbon techniques. For the purpose of evaluating the feedstock preparation, arc furnace operation, and solar cell processing steps in the overall manufacturing sequence, in the present paper we focus on the Czochralski single-crystal growth method in order to make possible the simplest and most direct correlation with current production technology for single-crystal solar cells employed by much of the terrestrial photovoltaic industry.

Most of the Czochralski ingots for this study were ~11 cm diam boules grown in a commercial crystal growth apparatus under standard conditions for operation of this type equipment. No significant differences in Czochralski growth were observed from SGP compared to growth from semiconductor silicon.

Solar cell processing.—Solar cells of the production design and size shown in Fig. 3a were fabricated in 100 mm diam, 500 μm thick wafers sliced from the single-crystal ingots grown from arc-furnace silicon. In addition, a few Czochralski and float zone wafers, prepared from semiconductor silicon either in house or by outside vendors, were fabricated into 100 mm diam solar cells to provide a comparison. Junction formation was performed in the p-type wafers by the well-known POCl_3 process (14), followed by low cost Ni/solder metallization and AR coating. Hence, the results reported for 100 mm diam wafers provide a good indication of what may be expected in factory production without optimization.

In order to gain some indication of the solar cell performance which might be expected with further solar cell optimization, small test cells 2 × 2 cm size (see Fig. 3b) were fabricated.¹

¹Cells were fabricated by Applied Solar Energy Corporation, City of Industry, California 91749.

Fig. 3. a: A cell produced in 100 mm diam 500 μm thick wafers sliced from single-crystal ingots grown from arc-furnace silicon. b: 2 × 2 cm test cell.

The solar cell efficiency was measured with a Spectrolab XT-10 Type 1 simulator. Light intensity was 100 mW/cm² (AM1) calibrated with a test cell. The simulator uses an arc lamp with a water filter to cut off the long wavelengths, and chuck temperature is kept at 28°C.

Results and Discussion

Impurity levels in PMS from arc-furnace tests.—General considerations from this and previous work (3-5, 9) suggest that there are probably three main contributions to impurities in the PMS. The first contribution is contamination from the materials of construction of the arc furnace and from the stoking and tapping operations. The second is extraneous contamination during handling and preparation of the feedstocks. The third is the base level of impurities in the raw feedstocks, shown in Tables I and II. For the 50 kW furnace tests, a combination of the first two factors appears to determine the impurity levels in the final PMS, as indicated by the analytical data in Table III. One exception to this trend is run no. PMS-9, for which additional boron and aluminum appear to have been incorporated from the type-B granular quartz. This run, however, did exhibit exceptionally low energy consumption. For this reason, most of the runs in the 100 kW furnace were conducted using mixed C/SiO₂ pellets, which appear to offer a reactivity advantage over pellets made from carbon black alone.

The first run in the 100 kW arc furnace, PMS-15, appears to suffer the same contamination problems experienced in the 50 kW furnace tests. The other four runs, however, probably reflect a residual contribution of impurities from the furnace itself, which is difficult to quantify, plus a contribution from the raw material feedstocks. No measurable difference in B, P, Al, Fe, or Ti can be attributed to the use of Malvern as compared to Mt. Rose lump quartz. However, the use of type-A granular

quartz as the sole source of SiO₂ appears to have been the major factor contributing to the two-fold reduction in these impurities in PMS-20. The method in which we have the best confidence for determining the impurity contribution from feedstocks is to convert them to PMS in an arc furnace of the purest construction possible and then to measure the B and P in the PMS by an analysis of Hall measurements along silicon ingots (15).

At this time, we cannot give a firm answer as to the availability of low cost granular silica sources which could be substituted for the relatively high cost type-A granular quartz. Nor can we determine whether still further reductions in B content of PMS would be possible either by feedstock selection, improvement in feedstock preparation, or in the purity and size of the arc furnace. But it is clear that the results achieved in this work with granular quartz represent a factor of two improvement over the best previously reported arc-furnace silicon from pure feedstocks, as reported by Hunt and Dosaj (3): B, 4.7 ppma; P, <1 ppma. As discussed in the next sections, this factor of two reduction in B content leads directly to an approximate 2% improvement in solar cell efficiency.

Solar cell performance as function of B and P level in arc-furnace silicon and semiconductor silicon.—Figure 4 shows the dependence of short-circuit current density upon B concentration over a three orders of magnitude range of boron concentration. This dependence of short-circuit current, with a change in slope at the 1-2 ppma boron concentration level, results in a similar variation in solar cell efficiency with boron concentration. For all except the two lowest data points for twice Cz recrystallized PMS, there is little or no difference between the behavior of ingots from PMS or semiconductor-grade silicon. For these two ingots, a third recrystallization, as indicated by the arrows in the figure, raised the short-circuit current to the range observed for semiconductor-grade ingots.

Fig. 4. Short-circuit current density dependency on B concentration

Hence, it appears that for these two cases, the first Cz purification of the PMS was not sufficiently effective in removing metal impurities or carbon. As also indicated in Fig. 4, a similar improvement was generally noted in short-circuit current density when once recrystallized PMS was given a second recrystallization to a Cz single crystal.

Table V shows the best solar cell performance obtained in production-size 100 mm diam solar cells of the construction shown in Fig. 3a. These results indicate strong correlation with B level, and weak or no correlation with P level. For B levels exceeding 4 ppma (average) in the twice recrystallized Czochralski ingot, the best efficiency achieved was 9.5%. For B levels in the range 2.4-3.3 ppma, it was possible to achieve about 10.5% efficiency. When the B level was reduced to 1.5 ppma, as described above using type-A granular quartz, efficiency of 12.5% was achieved, representing an absolute increase of 2% efficiency in these production-size cells.

The data on production-size solar cells in Table VI provide further confirmation that short-circuit current and hence efficiency depend strongly on boron concentration in solar cells derived both from semiconductor-grade silicon and from solar-grade silicon. Hence we conclude that, after appropriate upgrading, residual metal impurity concentrations in single-crystal Czochralski ingots are due to the crystal-growth operations (16) rather than the original arc-furnace silicon. While impurities and/or structural defects may be directly responsible for the observed degradation of performance with increasing boron content, we conclude that the boron is directly involved in their formation. They might be due, for instance, to complexes or precipitates of boron oxide, boron nitride, or metallic borides.

Solar cell performance as a function of diffusion length in arc furnace and semiconductor silicon.—Although the decrease of solar cell efficiency at high B levels, corresponding to electrical resistivity levels lower than

0.1 Ω -cm, has long been recognized (17), the experimental data in Fig. 4 show a threshold behavior at much lower B levels ($\sim 5 \times 10^{16} \text{ cm}^{-3}$ on 1 ppma) than would be calculated assuming classical Auger recombination ($\sim 10^{18} \text{ cm}^{-3}$ or 20 ppma) as the limiting degradation mechanism (18, 19). Hence, to investigate this effect further, we have prepared a number of Cz ingots from semiconductor-grade silicon, with different B levels, and measured their diffusion length and solar cell performance compared to that of Cz ingots twice recrystallized from PMS. Figure 5 shows a plot of short-circuit current as a function of diffusion length, obtained on wafers prior to solar cell processing by the measurement of capacitively coupled, charge carrier lifetime (20). The solid curve is calculated for 450 μm thick solar cells according to the methodology of Amick and Ghosh (21). The experimental points appear well fitted by a curve representing a 20% loss for reflection and shadowing. Thus, it is apparent that semiconductor-grade silicon wafers and arc-furnace silicon wafers show a similar increase in short-circuit current with increasing diffusion length (*i.e.*, decreasing B concentration). Suitably recrystallized arc-furnace silicon behaves identically to semiconductor-grade silicon. The occurrence of the threshold behavior in Fig. 4 at lower B levels than expected for Auger recombination is, therefore, probably related to as-yet uncharacterized effects of residual metal impurities (16, 22) from the crystal-growth apparatus, to carbon or oxygen contamination (23), to point defects, or to complexes or precipitates of these entities with boron.

Performance of production-size solar cells in single-crystal Czochralski ingots from the highest purity PMS.—As discussed above, production-size solar cells from ingots SPC-76, SPC-77, and SPC-83, prepared by two recrystallizations of PMS-20, showed the best efficiency of all the arc-furnace tests. The correlation of the improved efficiency with decreased boron concentration appears well founded.

Fig. 5. Short-circuit current as a function of diffusion length

The best individual cell fabricated had an efficiency of 12.9%, as indicated in Table V. To gain some indication of the distribution of efficiency, which can be expected in production, we fabricated a total of 99 solar cells using procedures similar to those employed in production. The three ingots evaluated had seed-to-tang resistivities that collectively ranged from 0.53 to 0.76 Ω -cm. In analyzing the results, we were interested in evaluating two factors. The first was the overall distribution of efficiencies. The second was the variation of efficiency along the length of the Czochralski ingot, since any metallic impurities or carbon, possibly carried over from the PMS to the SGP, might be expected to raise the levels of these impurities towards the tang of the ingot.

The distribution of efficiencies of the 99 cells is shown in Fig. 6. Two-thirds of the cells fall in the efficiency range between 11.5% and 12.5%. Three-eighths of the cells have solar cell efficiencies \geq 12%. Only one-twelfth of the cells have efficiencies below 10%. The principal reason for the low efficiency tail is low fill factor, which was discussed above. Hence, improvement in fill factor should be a key objective of further development work on solar-grade silicon ingots such as those investigated here.

Cell parameters for ingot SPC-77 are shown in Fig. 7 as a function of the fraction of the melt pulled. The decrease in cell efficiency and diffusion length for fractions of the melt pulled greater than 0.5 is attributed to the disloca-

Fig. 6. Distribution of efficiencies of the 99 cells

Fig. 7. Cell parameters for ingot SPC-77 as a function of the fraction of the melt pulled.

tion density, which increased from zero to about 10,000/cm² at the tang. The cause of the high dislocation density appears related to the thermal history of this ingot, rather than due to impurities, since a relatively small 10 kg charge was used, resulting in poor growth control toward the tang. Another ingot, SPC-83, was essentially dislocation free from seed to tang, and exhibited relatively constant efficiency along the length of the ingot.

Solar cell performance in laboratory-scale 4 cm² test cells in ingot from highest purity PMS.—Table VII shows the comparison of performance, including average, maximum, and minimum values for 4 cm² test cells fabricated by Applied Solar Energy Corporation from semiconductor Cz ingot and from ingot SPC-83 derived from the best arc-furnace silicon reported here, PMS-20. The principal reason for a difference in the average efficiency in SPC-83, 13.7%, and that in SPC-B, 14.4%, is the low fill factor of the one low value cell.

The average test cell efficiency on 4 cm² cells (13.7%) exceeds that obtained on production-size 78 cm² cells (11.8%) for three reasons. The first is lower reflection due to a two-layer AR coating. The second is lower shadowing (~7%) as compared to the production-size cells (~15%). The third factor is a statistical effect in the material or the processing of larger area cells. The results on small area cells do suggest, however, that it should be possible to produce production-size cells with efficiencies of about 14% from twice-recrystallized PMS.

Conclusions

The technical feasibility of reacting pelletized granular quartz and carbon black in a specially constructed 100 kW arc-furnace, to produce purified metallurgical silicon (PMS) having 1.8 ppma B has been demonstrated. This is a factor of 2.5 lower B concentration than previously reported for PMS. The production of this quality of PMS at low cost appears feasible since MG-Si is produced commercially in large submerged arc reduction furnaces. Increasing the size of the arc furnace should, if anything, improve the purity of PMS silicon.

Comparison of solar cell performance in once- and twice-recrystallized PMS ingots confirms our initial working hypothesis that for high efficiency solar cells, an intermediate upgrading step is necessary to convert PMS to a solar-grade polysilicon (SGP) feedstock suitable for final recrystallization into ingot. The successful use of the Czochralski process for this intermediate purification demonstrates the feasibility of directional solidification as a generic metallurgical upgrading step. However, to accomplish this economically will require development and scale-up of alternative, *e.g.*, Bridgman, processes, since Czochralski upgrading does not appear economical at any scale for producing \$14/kg SGP.

Table VII. Comparison of the performance of laboratory-size test solar cells^a with silicon source used for growth of Czochralski ingot

Silicon sources	Cz ingot	[B] (ppma)	[C] (ppma)	ρ (Ω -cm)	Number of solar cells	Efficiency (%)	J_{sc} (mA/cm ²)	FF	V_{oc} (V)
Semiconductor	SPC-B ^b	0.1	<1	2	8 Average	14.4	31.5	0.780	0.589
					Maximum	14.7	31.5	0.800	0.588
					Minimum	14.2	31.5	0.750	0.588
PMS-20	SPC-83 ^c	1.5	1-3	0.6	12 Average	13.7	30.3	0.754	0.597
					Maximum	14.8	31.3	0.790	0.600
					Minimum	9.3	29.5	0.530	0.597

^a 2 × 2 cm area, fabricated by ASEC.

^b One Czochralski recrystallization.

^c Two Czochralski recrystallizations.

We have shown that the efficiency of crystalline-silicon solar cells depends critically upon boron concentration. The lowered boron content in the present PMS results in a net 2% improvement in solar cell efficiency compared to previous work on solar cells derived from PMS.

The Current-Voltage Characteristics of a Photoelectrochemical Cell Using p-Type Porous Si

Nobuyoshi Koshida, Masahiro Nagasu, Takashi Sakusabe, and Yuji Kiuchi

Department of Electronic Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184, Japan

ABSTRACT

Fundamental characteristics of a photoelectrochemical cell using p-type porous-Si layer (PSL) as a semiconductor photoelectrode were measured. The PSL electrode exhibited stable photodiode characteristics. The increase in the PSL thickness was very useful in suppressing the dark current, although it resulted somewhat in reducing the photosensitivity, due to the increase in surface recombination losses of photogenerated carriers.

The surface of n-type semiconductors with small bandgaps suitable for solar energy conversion is unfortunately unstable in photoelectrochemical cell. For example, a n-type Si electrode operated in aqueous electrolytes is rapidly passivated under illumination (1). In order to suppress photoanodic surface corrosion of n-type semiconductors and to stabilize the operation, several attempts based upon thin film coating (2-8) and chemical derivatization (9) have been made.

The porous-Si layer (PSL) applied here was found in the 1950s by Uhlir (10) and Turner (11) in the course of the anodization studies of Si in HF solution. Recently, the formation mechanism of PSL and its structure were studied by Unagami (12, 13) in detail. According to those results, PSL is formed by local dissolution during anodization in HF solution. It consists of many micropores formed uniformly in the thickness direction. The diameter of micropores ranges from about 50 to 300Å, depending on the resistivity of Si substrate and the condition of anodic reaction. This PSL, which can be oxidized easily by thermal process (14, 15), has been applied to the isolation technique in integrated circuits (16).

The PSL can be obtained in either n-type or p-type Si substrate. In n-type Si, however, the anodic reaction needs to be carried out under illumination to generate holes which are necessary for the formation of PSL. In this paper, we report the application of PSL as a photoelectrode of a photoelectrochemical cell using p-type Si substrates.

Experimental

Formation of PSL electrodes.—Silicon wafers used in this experiment were (111) p-type single crystals (0.3-0.5 Ω cm) with a mirror surface. Prior to anodization, the wafers were cleaned, a thin Al film was deposited on the back side, and they were alloyed to form an ohmic contact. Nonanodized parts of the wafers were then covered with acidproof wax. Anodization was done in 50 weight percent (w/o) HF solution under a constant current density. The current densities i_A were adjusted to the values below those used for electropolishing. After rinsing the anodized wafers in deionized water and removing the wax, the HF solution left in PSL was released by heat-treatment at 100°-150°C in vacuum. The thickness of PSL was measured separately by microscopic observation of level lapped surfaces.

Measurements of the characteristics of PSL electrodes.—The wafers were covered again with the wax and then used as photoelectrodes of the cell with Pt counterelectrode and SCE reference. The electrolyte was 0.005M Na_2HPO_4 (pH = 7.8). The light source was a 150W tungsten lamp; the maximum exposure intensity was 60 mW/cm² (in 0.4-0.9 μm wavelength range). The current-voltage curves of PSL photoelectrodes were measured under different light intensities. N_2 bubbling was done throughout the measurements in order to prevent the sticking of the H_2 bubbles at the PSL surface. Quantum efficiencies were measured using He-Ne laser of 6328Å wavelength and 1 mW power. The stability of PSL elec-

trodes was also evaluated by the change in the dark current with passed charge during the continuous photo-cathodic operation.

Results and Discussion

PSL thickness.—Figure 1 shows the thickness of PSL formed under various conditions as a function of the anodic reaction time t_A . The PSL thickness d , which is larger for higher current density of anodization and for lower resistivity of the Si substrate, increases nearly in proportion to t_A . These results are consistent with those reported previously (12).

The local-dissolution of Si resulting in PSL is ensured by the steady hole supply from the substrate. The formation of PSL, therefore, proceeds more easily for lower-resistivity substrates. In fact, PSL formed in the low-resistivity substrate becomes deeper than that in the high-resistivity one, even if anodization was done at the same current density and reaction time, as shown in Fig. 1. This means that the porosity of PSL is decreased as the resistivity of the substrate is lowered. Under the experimental conditions in Fig. 1, the porosity of PSL ranges between 40% and 50% (12).

The scanning electron micrograph of cleaved cross section of PSL is shown in Fig. 2. A uniform PSL is formed in the thickness direction. The porosity appears to be independent of the PSL thickness.

Current-voltage curves.—A typical example of photo-current-voltage characteristics under bias obtained from the PSL photoelectrode is shown in Fig. 3. The PSL in this case was formed under the conditions of $i_A = 50$ mA/cm², $t_A = 20$ min, and $d = 57$ μm . In the backward (cathodic) bias region, photocurrent behaves in a way similar to that of a normal photodiode. These curves were stable and reproducible. The rising voltage of photocurrent was -0.75V (vs. SCE) and open-circuit photovoltage was

Fig. 1. Thickness of PSL formed at different current densities as a function of anodic reaction time. The result obtained from a high-resistivity (3-5 Ω cm) substrate is also shown by the dotted line.

Fig. 2. Scanning electron micrograph of cleaved cross section of anodized PSL.

0.50V. Reversible hydrogen and oxygen evolution potentials in this cell are -0.70 and 0.53V (vs. SCE), respectively. Under photocathodic operation, H₂ and O₂ evolutions were observed at PSL and Pt electrodes, respectively. Similar results were obtained from the photoelectrodes with different PSL thickness.

Sensitivity.—Figure 4 shows the saturated photocurrent i_s of some PSL electrodes as a function of the light intensity. The linearity between i_s and the light intensity is consistently maintained over a wide illumination range. The sample of $d = 0$ represented in Fig. 4 is the naked Si electrode prepared only by a conventional chemical etching process. As the PSL thickness was increased, photosensitivity, S , defined as the ratio of i_s to the light intensity, was reduced. Figure 5 shows the change in S obtained from Fig. 4 with the PSL thickness. Quantum efficiencies η are also shown in Fig. 5. It should be noted that both S and η become almost constant in the region of the PSL thickness beyond 30 μm . The final values of S and η correspond to the intrinsic values of PSL. This is

Fig. 3. Current-voltage curves of a p-type PSL photoelectrode

Fig. 5. Photosensitivity and quantum efficiency as a function of the PSL thickness.

reasonable, considering that single or polycrystalline structure remains in PSL (13) and that the absorption coefficient of single-crystal Si for visible light is 10^3 - 10^5 cm^{-1} (17).

At the surface of PSL, thin surface porous film (SPF) is formed at the early stage of anodization (12). The local dissolution of Si resulting in PSL is initiated by this SPF. The SPF can easily be etched by HNO₃ + HF solution. In order to investigate the influence of SPF, photocurrent-voltage curves of the SPF etched sample were also measured. The results were similar to those shown in Fig. 3-5.

Fig. 6. Normalized spectral response of photosensitivity for three different PSL electrodes.

Fig. 7. Suppressing effect of PSL on the dark current

Fig. 8. Scanning electron micrograph of cleaved cross section of PSL after photocathodic operation.

Therefore, SPF itself has no significant effects on the photoelectronic process.

Spectral response.—Figure 6 shows the spectral response of some PSL electrodes. It can be seen that as the PSL thickness is increased, the sensitivity in the short-wavelength region is reduced. This suggests that the increase in the PSL thickness results in higher surface recombination rate of photogenerated carriers. The reduction in photosensitivity with increasing PSL thickness shown in Fig. 5 can thus be explained from this result.

Stability.—The most important characteristic of the PSL electrode was the stability of operation. Figure 7 compares the dark current of PSL with that of the naked Si substrate as a function of passed charge of electricity through the sample at an average current density of 2 mA/cm² under illumination. These dark currents were measured at a terminal voltage of 5V between PSL and Pt electrodes. It is apparent from Fig. 7 that the formation of a thick PSL produces a pronounced suppressing effect on the dark current.

Figure 8 shows a cross-sectional view of PSL after a long-time photocathodic operation. A certain degree of dissolution of PSL can be seen. Further operation resulted in the development of dissolution toward the substrate and the subsequent increase in the dark current. The final current-voltage curves are shown in Fig. 9. Although the dark current is considerably increased, both the stability and the net photocurrent are comparable with those at the initial stage shown in Fig. 3.

During the formation of PSL, the working face of local dissolution was the bottom of the micropores (12). Similarly, the dark current controlled by the majority carrier

Fig. 9. Current-voltage curves of the PSL photoelectrode at the final stage of operation. The sample is the same as the one shown in Fig. 3.

holes is thought to be governed by the rear surface of PSL. While PSL remains thick enough, the interfacial charge transfer occurs only near the surface of PSL. At that time, the dark current is negligible. As the dissolution of PSL due to the out diffusion of holes proceeds under illumination, the PSL thickness is gradually decreased. As the consequence of this, the dark current is increased. Finally, it reaches the original value of the naked Si substrate. If the initial PSL is thick enough, the dark current will be suppressed successfully over a long period of time because of the requirement of a large amount of charges for dissolution. This picture explains the result of Fig. 7 qualitatively.

Conclusion

Fundamental characteristics of PSL photoelectrodes have been shown. The formation of a porous structure at the p-type Si surface is very useful in suppressing the dark current of the photoelectrochemical cell. The PSL electrode can provide a basis in the understanding of the photoelectrolysis at semiconductor-liquid interfaces, although p-type PSL itself does not show net energy conversion of light. Further studies concerning the interfacial charge transfer process in PSL and the application of PSL to n-type Si substrates are in progress.

Maximum Power Spectroscopy of n-Type a-Si:H, c-Si, CdSe, and InP in Nonaqueous Photoelectrochemical Cells

J. M. Rosamilia and B. Miller*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Amorphous silicon photoanodes in a nonaqueous photoelectrochemical cell show wavelength dependence of their power outputs. This behavior has been studied by maximum power spectroscopy (MPS) and compared to similar experiments with conventional short-circuit spectroscopy. The derivative maximum power output under constant chopped input power (MPS) shows dependence on the wavelength distribution in superimposed fixed beams, whereas the conventional short-circuit measurements do not. Single-crystal substrates of n-Si, n-CdSe, and n-InP do not show any differences between the spectroscopies. Rotating ring-disk electrode studies confirm the regenerative behavior of the n-CdSe and n-InP electrodes with the $\text{Fe}(\text{HOCH}_2\text{Cp})_2 - \text{Fe}(\text{HOCH}_2\text{Cp})_2^+$ couple in $\text{LiClO}_4/\text{methanol}$ solution. [$\text{Fe}(\text{HOCH}_2\text{Cp})_2$ = hydroxymethyl ferrocene.]

Photoelectrochemical cells (PEC's) with semiconductor-electrolyte junctions have attracted much attention as candidate systems for the conversion of solar energy into electricity. The spectral response of these systems is a fundamental characterization usually taken as the set of monochromatic quantum efficiencies under short-circuit photocurrent (I_{sc}) collection. We have elsewhere (1) discussed an alternative approach called maximum power spectroscopy (MPS), which measures the derivative maximum power output response to a selected spectral intensity distribution of a scanned monochromatic chopped beam superimposed on one from a fixed source.

PEC's are sensitive in light to electricity conversion to many factors (*viz.*, electrode kinetics, recombination of photogenerated hole-electron pairs, counterelectrode behavior, internal resistances, solution absorbance, and surface reflectivity). The last two of this list will directly influence spectral response at zero power (short circuit), as may significant recombination effects. All, however, will affect the maximum power output.

In the introduction of MPS (1), we studied a p-n Si diode, using added series resistance to simulate these advantages of response realizable in maximum power efficiency spectra. We wish to devote our attention here to photoelectrochemical cells having a common nonaqueous electrolyte phase (20 mM $\text{Fe}(\text{HOCH}_2\text{Cp})_2/1.0\text{M}$ $\text{LiClO}_4/\text{CH}_3\text{OH}$) (2, 3) and four different n-type doped semiconductor photoelectrodes, amorphous hydrogenated silicon (a-Si:H), crystalline silicon (c-Si), CdSe, and InP. Silicon electrodes of both forms have been stabilized to a considerable degree in nonaqueous solvents (2-7), and developments following the introduction of ethanolic ferrocene/ferrocenium solutions by Legg *et al.* (4) have been especially promising.

Recent investigations indicate that the a-Si:H junctions exhibit wavelength-dependent fill factors (2), and this behavior would be particularly interesting to study by MPS.

Both crystalline and amorphous silicon photoanodes in 1.5M LiClO_4 -methanol solution with 0.02-0.20M ferrocene or hydroxymethyl ferrocene/0.5 mM oxidized form are capable of significant solar power conversion efficiencies of 10.1% (3) and 2.7-3.3% (2), respectively.

For further comparison, we chose also to study a semiconductor (CdSe) of bandgap similar to that of a-Si:H and one (InP) whose surface properties in this system would be of additional interest from the viewpoint of stability. For these latter two materials, we felt it necessary to document independently the nature of the reactions proceeding under illumination. Therefore, rotating ring-disk electrode (RRDE) studies were applied to examine whether the photogenerated holes at n-CdSe and n-InP react efficiently to oxidize solution redox species of the ferrocene type.

The MPS technique measures the modulated maximum power output response, ΔP_o , of the photovoltaic system to a chopped monochromatic power input, ΔP_i , superimposed on a steady input power, P_s . The P_s source gives flexibility to the choice of operating levels and allows probing of nonlinearity and saturation effects as a function of intensity. In the present case, the spectral content of P_s would also be significant. In all situations, we compare MPS results to those of short-circuit current spectroscopy under the same conditions.

Experimental

Electrodes.—0.5-0.6 μm thick films of a-Si:H deposited on stainless steel substrates and doped n-type were made available to us as epoxy-mounted electrodes by N. S. Lewis of Stanford University. Their preparation has been previously described (2). The photoelectrode area exposed to the electrolyte was ~ 0.3 cm². Electrodes of single-crystal n-type silicon (c-Si) were prepared from polished wafers of 1-10 Ω -cm resistivity. The a-Si:H and c-Si photoanodes were etched in 5% aqueous HF for 10s, followed by a methanol rinse immediately before use. n-Type CdSe (Cleveland Crystals, Incorporated) 1.8 Ω -cm,

* Electrochemical Society Active Member.

(0001)-face photoanodes were etched for 30s in 4-1 HCl:HNO₃, then rinsed in distilled water. Next they were immersed for 30s in a 10% aqueous KCN solution (to dissolve any selenium that may have been present following oxidation by the aqua regia), with final rinse in methanol. n-InP (Czochralski-grown, kindly supplied by W. A. Bonner) photoanodes were etched in concentrated HCl for 10s, then rinsed with methanol just prior to use.

Reagents.—Anhydrous methanol (0.007% H₂O) was obtained from J. T. Baker, and hydroxymethylferrocene was obtained from Strem Chemical, Incorporated Reagent grade LiClO₄ (Aldrich Chemical Company, Incorporated) and the hydromethylferrocene were used without further purification. All solutions were stored over activated Linde 3A molecular sieves.

Spectroscopy.—The circuitry and instrumentation for obtaining maximum power spectral response were as recently described (1, 8). The input light consisted of a 5 Hz chopped monochromatic beam of power P_i superimposed on a constant beam of power P_s . The bandpass averaged 10 nm (50% of intensity) over the spectrum. The level of P_i was kept constant, independent of wavelength (12 μ W). A 50W tungsten-halogen lamp equipped either with a 600 nm longwave transmitting filter for $\lambda > 600$ nm or a 500 nm shortwave transmitting filter for $\lambda < 500$ nm was the P_s source. The transmitting filters were interference types from Melles Griot. The optical path length through the solution was ~ 5 mm, and no corrections were made for solution absorbance. The cell was operated in a 3-electrode configuration, using graphite rods for both counter and reference electrodes. The reference zero is therefore the solution redox level. The cell solution contained 20 mM Fe(HOCH₂Cp)₂/1.0M LiClO₄/CH₃OH, unless otherwise indicated, and the redox level was established by oxidation of some Fe(HOCH₂Cp)₂ to Fe(HOCH₂Cp)₂⁺ prior to measurement. Solutions were stirred using a magnetic spin bar. Input power regulation, spectral scanning, and data acquisition and plotting were performed under Apple IIe computer control in conjunction with the necessary servo instrumentation (1).

Because inputs are controlled for constant power, spectra of short-circuit current (ΔI_{sc}) have to be corrected for the number of photons (multiplied by photon energy) to be quantum efficiency displays. When there are no wavelength dependent internal losses to cause a normalized difference between ΔI_{sc} and ΔP_o spectra, these spectra also are the same, in spite of different units (current vs. power), because the voltage effect of each absorbed photon is the same, as earlier seen (1).

RRDE.—Rotating ring-disk electrode (RRDE) experiments employed a Pine Instrument Model RDE3 bipotentiostat with graphite rods both as reference and counter-electrodes. n-CdSe and n-InP disks were provided with a Au ring by means of epoxy seals. The areas of the n-CdSe and n-InP disks were 0.175 cm². The geometric collection efficiency, N , of each electrode (9) was determined experimentally by controlling the current at the disk for Fe(HOCH₂Cp)₂ reduction (forward diode direction, dark reaction) and by measuring the disk shielding of the limiting cathodic current at the ring. The cells were equipped with an optical flat bottom to permit illumination of the disk with a 100W tungsten-halogen lamp. A rotation speed of 1600 rpm and a scan rate of 10 mV/s were maintained in all such experiments.

Results

a-Si:H.—Shown in Fig. 1 are the current-voltage and the corresponding $V \times I$ (power) curves for a-Si:H in 20 mM Fe(HOCH₂Cp)₂ for shortwave ($\lambda < 500$ nm) and longwave ($\lambda > 600$ nm) irradiation. Intensities are adjusted to provide identical short-circuit currents in each case.

Fill factors (ff) and maximum power outputs are summarized in Table I. For such experiments, these quantities are 20% greater for lower wavelength irradiation. These data are consistent with those of Gronet *et al.* (2). Displayed in Fig. 2 are plots of I_{sc} vs. P_o for different levels

Table I.

P_s λ , nm	I_{sc} mA	ff	P_o mW
>600	0.68	0.47	0.24
<500	0.68	0.56	0.29

of irradiation at $\lambda > 600$ nm and $\lambda < 500$ nm. P_o is a linear function of I_{sc} over the input power range examined for long and short excitation wavelengths, but the slope, dP_o/dI_{sc} , is steeper under shorter wavelength irradiation. Total internal losses are a function of incident wavelength (2). This factor is emphasized in maximum power output, as opposed to short-circuit (I_{sc}) measurements, because of the role of photoconductivity in the response of this material.

Observing these trends with a-Si:H prompted us to examine the wavelength effect in more detail with maximum power spectra (ΔP_o vs. λ). The spectral cutoffs of the P_s beams were the same in these experiments as those in Fig. 1 and 2. Again these intensities were adjusted to provide the same short-circuit photocurrent density for $\lambda > 600$ nm and $\lambda < 500$ nm sources. The level of I_{sc} was that indicated by the arrow on the abscissa of Fig. 2. It is clear

Fig. 1. Current-voltage (---) and power-voltage curves (—) for irradiation of $\lambda < 500$ nm and $\lambda > 600$ nm, a-Si:H cell.

Fig. 2. Plot of P_o vs. I_{sc} for irradiation of $\lambda < 500$ nm (Δ) and $\lambda > 600$ nm (\circ), a-Si:H cell. The arrow indicates the level of P_s employed in Fig. 3.

that the choice of I_{sc} will modify the modulated spectra, depending on the nature of internal voltage losses, as shown for our earlier model experiments (1).

Figure 3A, curve I, shows the modulated power spectrum ΔP_o vs. λ for a-Si:H using $\lambda < 500$ nm for P_s . ΔP_o declines below 530 nm because of solution absorption (λ maximum for $Fe(HOCH_2Cp)_2$ absorption is 435 nm), whereas the longer wavelength limit is that expected from the 1.7 eV bandgap of a-Si:H. Curve II in Fig. 3A is that for P_s at $\lambda > 600$ nm, and it shows a reduced ΔP_o response relative to curve I at wavelengths between 540 nm and the bandgap edge. The ΔP_o responses for both P_s beams are much closer at $\lambda < 530$ nm. The integrated spectral responses are consistent with the wavelength-dependent fill factors for a-Si:H semiconductor liquid junctions given in Fig. 1 and 2. Modulated short-circuit (ΔI_{sc}) spectra employing P_s of $\lambda > 600$ nm and $\lambda < 500$ nm for constant total dc short-circuit current are shown in Fig. 3B. There is no significant effect traceable to the spectral distribution of P_s intensity.

n-Si.—When the experiments of Fig. 3A and 3B are repeated with n-Si and are normalized to the peak value, a single curve is found within experimental resolution for the combinations of $P_s > 600$ nm and $P_s < 500$ nm with ΔP_o and ΔI_{sc} , as illustrated in Fig. 4A and 4B. There is no P_s source wavelength effect with the n-Si single crystal, in contrast to that with the a-Si:H substrate.

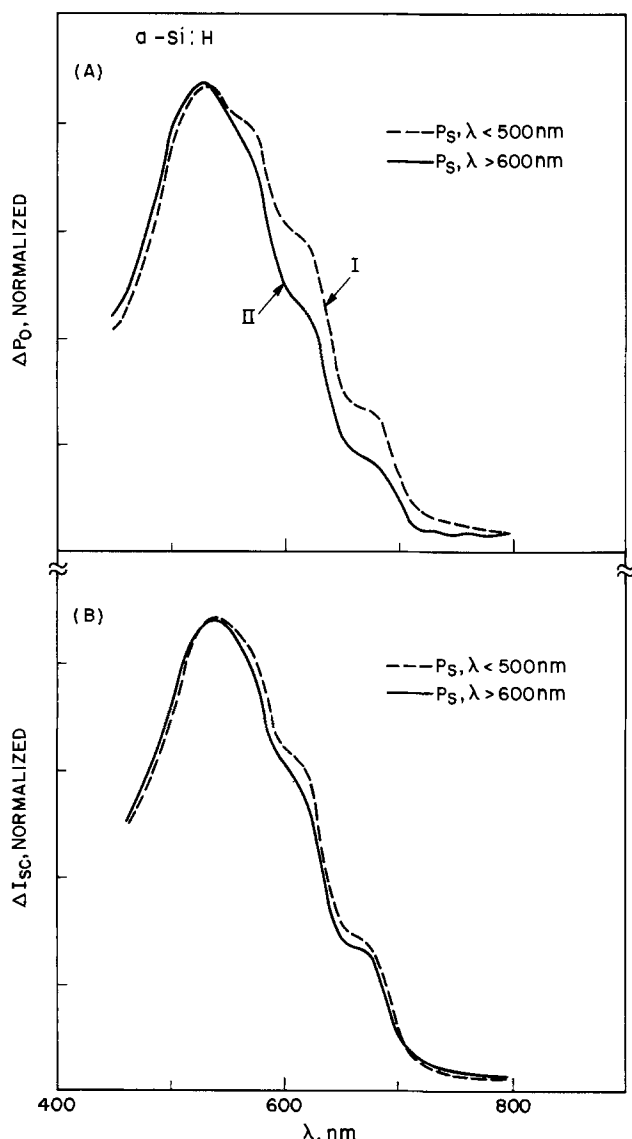

Fig. 3. Modulated spectra (A) ΔP_o vs. λ and (B) ΔI_{sc} vs. λ for a-Si:H employing P_s $\lambda < 500$ nm (---), and P_s $\lambda > 600$ nm (—).

Fig. 4. Modulated spectra (A) ΔP_o vs. λ and (B) ΔI_{sc} vs. λ for n-Si employing P_s $\lambda < 500$ nm (---), and P_s $\lambda > 600$ nm (—).

n-CdSe.—RRDE experiments were first performed to establish if the photogenerated holes produced at a n-CdSe photoanode interface are consumed by hydroxymethylferrocene in 1.0M $LiClO_4/CH_3OH$ solution, rather than by photocorrosion of the semiconductor itself. Figure 5 shows i_D-E_D and the corresponding i_R-E_D curves for a n-CdSe/Au RRDE in 20 mM $Fe(HOCH_2Cp)_2$ under photon flux limited conditions. The ring is controlled at a potential to collect $Fe(HOCH_2Cp)_2^+$ generated at the semiconductor disk. The i_R-i_D relation from this data is shown as the lower line in the insert. The shielding technique for calibration of the collection efficiency (N) at the ring is shown as the dashed line in the insert (note that the current scales are different but proportional). The plot of ring reduction current vs. controlled disk currents under illumination (lower trace) has a slope of 0.342, in agreement with the experimental N of 0.352 for the dark shielding data (dashed trace). These results indicate that, within experimental accuracy, the photogenerated holes react to oxidize the ferrocene derivative at the n-CdSe surface un-

Fig. 5. i_D-E_D and i_R-E_D curves for an illuminated n-CdSe disk-Au ring electrode in 20 mM $Fe(HOCH_2Cp)_2$. E_D scan at 10 mV/s, $E_R = -0.2$ V, $\omega = 1600$ rpm. The insert is the i_R-i_D curve (—) for the potential scan under $h\nu$ conditions. The dotted trace is i_R-i_D for ring shielding in the dark under controlled i_D .

der these illumination conditions. The cell thus operates in a nominally regenerative manner. The stabilization of the surface against corrosion is further evidenced by reproducible cycling behavior between open and short circuit over the short term (hours) tested.

The maximum power spectrum was recorded for n-CdSe under conditions as described for a-Si:H to compare the behavior of a single-crystal semiconductor of virtually the same direct bandgap as a-Si:H. ΔP_0 vs. λ for n-CdSe under the two incident wavelengths of P_s conditions is shown in Fig. 6. The steep edge at the n-CdSe bandgap of 1.7 eV and the solution absorption determine the spectral shape. There is no difference in results for P_s , $\lambda > 600$ nm and $\lambda < 500$ nm. n-CdSe in this medium exhibits no wavelength dependence of fill factors. The Δi_{sc} vs. λ spectra on normalization were identical to the maximum power spectra, as was the case with c-Si, and they are not shown here.

During our investigation, we observed spectral effects due to excess Se on the surface of a freshly oxidatively etched electrode. In Fig. 6 (dotted-dash trace) is the maximum power spectrum of such an electrode if the described KCN solution treatment is not applied. Before immersion in KCN, there is a decrease in the spectral response below 600 nm attributable to the red film of excess Se formed on the surface by aqua regia. The KCN dip has also been used previously for the semiconductor electrode in the n-CdSe/Na₂S-S-NaOH/C solar cell to yield a more reproducible initial electrode state (10).

n-InP.—Parallel studies to those on n-CdSe were performed with n-InP. The equivalent study to that in Fig. 5, but for an n-InP disk with Au ring, is displayed in Fig. 7. A collection efficiency of 0.312 is obtained for the plot of i_R vs. controlled photoanodic values of i_D from the insert of Fig. 5. This corresponds adequately to the N value of 0.329 calculated from the shown dark reaction ring shielding. Further confirmation that charge is being efficiently transferred to the redox system was obtained from a plot of i_R vs. i_D while controlling E_D , as in the Fig. 7 scan ($N = 0.308$).

Photogenerated holes thus oxidize the solution species ($\text{Fe}(\text{HOCH}_2\text{Cp})_2$) under these circumstances, within ring detectability. Maximum power stability for n-InP photoanodes at suitable P_s levels is sufficient for the periods necessary to obtain spectra. The presence of water in the methanol solution significantly contributes to surface oxidation and early cell degradation. Thus, the oxidation wave in this system usually corresponds to a higher fill

Fig. 6. Modulated power spectra ΔP_0 vs. λ of n-CdSe. The solid line shows the spectra under low energy excitation; the dashed line, under high energy excitation. The dash-dotted line is a spectrum obtained before KCN treatment.

Fig. 7. i_D - E_D and i_R - E_D curves for an illuminated n-InP disk-Au ring electrode in 20 mM $\text{Fe}(\text{HOCH}_2\text{Cp})_2$. E_D scan at 10 mV/s, $E_R = -0.2$ V, $\omega = 1600$ rpm. The insert is an i_R - i_D (—) plot for an illuminated disk at controlled i_D . The i_R - i_D (---) plot was obtained by controlling cathodic disk currents in the dark and measuring the ring shield currents.

factor at a freshly etched disk and decreases slowly on cycling. Efficient collection of $\text{Fe}(\text{HOCH}_2\text{Cp})_2^+$ at the ring (constant i_R/i_D ratio) is retained while i_D declines. More careful drying with molecular sieves and the use of drier methanol sources promote stability. Competitive oxide film formation at the disk eventually leads to passivating thickness which inhibit the oxidation of $\text{Fe}(\text{HOCH}_2\text{Cp})_2$. The occurrence of parallel processes in which the surface oxidation of n-InP cannot be initially suppressed, but which subsequently promote the tunneling transfer of charge to the redox system, have been discussed elsewhere (11, 12). When the film thickness increases, this transfer is inhibited and passivity is observed. The potential scan in Fig. 7 is of a surface on which a thin oxide film initially exists because the electrode was previously cycled. When higher light intensities are applied, degradation is much faster. These effects are shown in Fig. 8 for potential scan and constant potential conditions. The parallel process of surface oxidation is slow in drier solutions. The degradation (oxide) component of disk current is, however, then too low to alter the collection efficiency for the disk $\text{Fe}(\text{HOCH}_2\text{Cp})_2^+$ product within ring accuracy.

Fig. 8. i_D and i_R vs. E_D (—) and i_D and i_R vs. time (---) curves for an illuminated n-InP disk-Au ring electrode in 20 mM $\text{Fe}(\text{HOCH}_2\text{Cp})_2$. All conditions are the same as in Fig. 7, except for the more intense irradiance. The insert is collection efficiency N vs. E_D or time Δ obtained from i_R - i_D vs. E_D and the respective i_D - i_R vs. time curves.

Fig. 9. Modulated power spectra ΔP_0 vs. λ of n-InP. The solid line shows the spectra under low energy excitation; the dash line, under high energy excitation.

Thus, the current efficiency for surface oxidation is indicated to be less than a few percent.

Maximum power spectra for n-InP in this system, shown in Fig. 9, were analogous to those for n-CdSe and c-Si, except for the bandgap (1.35 eV). P_s beams with either short or long wavelength photons in equal numbers have no differentiating effect on the ΔP_0 response. All three examples of crystalline semiconductors studied here were thus parallel in this regard. This would be the classical expectation: all photons of greater than bandgap energy produce the same output and thus show no excitation wavelength differentiation.

Conclusions

The recently introduced method of maximum power spectroscopy has been used to characterize amorphous silicon and three n-type crystalline Si, CdSe, and InP semiconductor photoelectrodes. With a superimposed beam of either short or long wavelength excitation, the thin film of a-Si:H was the only material to exhibit a

wavelength dependent effect in the differential power output spectrum. However, under the same conditions, the differential short-circuit quantum efficiency spectrum displays no dependence on the wavelength distribution of the steady beam when it is normalized to constant dc cell output.

RRDE studies evidence that n-CdSe and n-InP photoanodes in this methanolic medium operate in a regenerative manner. Photocorrosion and/or photopassivation processes at these electrodes are largely circumvented under these operating conditions. The stability of n-InP is more sensitive to light intensity and electrolyte purity and decreases on extended potential cycling.

Polymer Films on Electrodes.

XVI. *In Situ* Ellipsometric Measurements of Polybipyrazine, Polyaniline, and Polyvinylferrocene Films

Clifford M. Carlin, Larry J. Kepley, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Ellipsometry was used to study the electrodeposition of polymer films formed by oxidation of bipyrazine, polyvinylferrocene, and aniline. For polymeric films of limited thickness displaying good optical characteristics (*i.e.*, high reflectivity, uniform coverage, and homogeneity), the film refractive index and thickness were determined. Nonideal ellipsometric behavior was observed when film morphology varied with film growth. Polyvinylferrocene films in 0.1M TBABF₄/acetonitrile were shown to be 15% thicker in the oxidized form than in the reduced form.

Polymer-modified electrodes are prepared by coating thin (100Å-2 μm) films of polymers on conductive substrates (1, 2). These polymers can be electronically conductive ones (*e.g.*, polypyrrole or polyaniline) or those that contain electroactive centers (*e.g.*, polyvinylferrocene or doped Nafion).

The electrochemical investigation and characterization of electron and mass-transport processes in polymer-

*Electrochemical Society Active Member.

coated electrodes has suffered from the lack of a simple and accurate technique for the determination of the polymer film thickness, *d*. Although the thickness of films in solution can be estimated from mechanical stylus profilometer (*e.g.*, Dektak) measurements of dry film thicknesses or from integrated voltammetric currents and assumed densities, uncertainties in the estimated film density, swelling factors, coulometric efficiency for film deposition, and redox processes lead to a low degree of

confidence in the values of d obtained. Recently, *in situ* profilometer measurements of the change in thickness upon reduction of a film have been reported (3). The development of a generally applicable optical technique to determine d would be desirable, since optical methods are inherently precise and often suitable for measurements *in situ*.

Of the optical methods available for making thin film measurements, perhaps the most attractive for this purpose is ellipsometry (4). It has several advantages over other optical techniques: (i) it has already been successfully applied in the study of passivating and adsorbed layers in various electrochemical systems (4-8) [e.g., in the anodic growth of passivating oxide layers on metal electrodes (8)], as well as in the study of electroinactive polymers on semiconductors (9, 10); (ii) it does not require a transparent electrode, only an optically smooth electrode surface; (iii) it does not require the determination of absolute light intensities; and (iv) it can be used to determine the thicknesses of layers much less than the wavelength of visible light. Although ellipsometry has been applied to the study of a wide variety of surfaces under various experimental conditions, it has not been used to characterize polymer-modified electrodes. In this paper, we describe *in situ* ellipsometric measurements on a series of polymer-modified electrodes and gauge its utility and limitations for several types of conductive and electroactive polymer coatings.

Experimental

Instrumentation.—Ellipsometry measurements were obtained on a modified O. C. Rudolph and Sons, Incorporated, Model 437 research ellipsometer [PSCA optical arrangement (4)]. The source was a tungsten/iodine lamp, and wavelengths suitable for the quarter-wave plates available were isolated with interference bandpass filters. Detection was accomplished with a Hamamatsu R928 photomultiplier tube by passing the output photocurrent through a variable resistance box and measuring the resulting voltage with a digital voltmeter. Measurements were made for a range of compensator/analyzer settings around the null-point, which, by interpolation, could generally be determined to within 0.3° for either the compensator or analyzer azimuth. Inaccuracies due to optical components' nonideality and improper alignment were somewhat larger than this and were functions of the reflection polarizations. These errors could be largely eliminated by averaging the calculated optical parameters obtained with the two unique compensator positions which allowed the reflection to be extinguished (*i.e.*, fast axis along the major or minor ellipse of polarization). The procedure was generally not applied, however, because it required doubling of an already lengthy (approximately 10 min per point) data collection time and because the corrections had little effect on the estimated film thickness or morphology.

The cell used during the ellipsometry measurements is shown in Fig. 1. The cell top and base were constructed of either stainless steel or Plexiglas. The window openings are 1/8 in. holes positioned so that incident light can strike the electrode at 45° , 60° , or 75° angles. The cell tops were machined so that glass windows could be cemented in place perpendicular to the direction of propagation of the incident or reflected radiation. Glass or Plexiglas side plates were also cemented in place. The electrode was a 0.5 cm diam piece of glassy carbon attached with conductive epoxy cement to the end of a brass rod. This assembly was inserted into a heat-softened Teflon tube which was cooled and threaded. The electrode surface was polished with increasingly finer diamond paste and alumina, ending with $0.05 \mu\text{m}$ alumina. Electrodes were sonicated for at least 10 min in deionized water before use.

Materials.—Acetonitrile, MeCN (Fisher Scientific), was dried with 0.4 nm molecular sieves (M-512, Fisher Scientific). Tetrabutylammonium tetrafluoroborate, TBABF₄ (Southwestern Analytical Chemicals), and methylene

Fig. 1. Ellipsometer cell. Indicated are the cell top (T) and base (B), windows (W), sides (S), electrode (E), and mounting hole (M) and access ports (A) through which pass the counter and reference electrodes.

chloride, CH₂Cl₂ (Fisher Scientific), were used as received. Aniline (MCB) was distilled once from calcium hydride under nitrogen. Bipyrazine, bpz, was used as received from Professor A. B. P. Lever (York University). Polyvinylferrocene, PVF, was prepared and characterized (MW = 15,700; degree of polymerization = 74) by T. W. Smith *et al.* (11). Copolymers of vinylferrocene and vinylcyclopentadienylmanganeses tricarbonyl, VF-VCM (80/20 and 22/78 mole percent [m/o] ratio), were prepared and characterized by Dr. C. U. Pittman, Jr., *et al.* (12).

Film deposition.—Bipyrazine was electrochemically polymerized onto glassy carbon (13) from 3 mM bpz/10% aqueous H₂SO₄ by cycling the electrode potential at 500 mV/s between 1.5 and 2.1V *vs.* a saturated calomel electrode (SCE). The potential for bipyrazine oxidation is close to that of water, so a clearly defined wave for bpz oxidation cannot be resolved in the cyclic voltammograms and bpz oxidation currents cannot be monitored. Ellipsometry measurements were made both on the dry electrode and *in situ* with the potential held at 1.5V *vs.* SCE. For the former experiments, the polymer was deposited outside of the ellipsometer cell and the electrode was rinsed with deionized water and dried with a stream of nitrogen gas.

Polyaniline films (14) were deposited by electrochemical oxidation of aniline from 100 mM aniline/1M aqueous H₂SO₄ solutions either potentiostatically (at 0.8V *vs.* SCE) or by cycling the applied potential between -0.2 and 0.8V *vs.* SCE. Ellipsometry measurements were made *in situ* with the potential held at -0.2 V *vs.* SCE.

Polyvinylferrocene and the VF-VCM copolymers were anodically precipitated from 0.1M TBABF₄/CH₂Cl₂ containing 0.2 mg of polymer per ml of solution (15). Deposition potentials were generally 200 mV positive of the PVF redox potential, *i.e.*, about 0.7V *vs.* a silver wire reference electrode. Ellipsometry measurements were made with the electrode in either the deposition solution or a 0.1M TBABF₄/MeCN solution. For the latter method, optically higher quality films were obtained by dipping the film-coated electrode once into each of the following rinses: 0.1M TBABF₄/MeCN, 0.05M TBABF₄/MeCN, and neat MeCN.

Analysis.—The optical constants of the polymer films generated by the above techniques were obtained by simulating a series of ellipsometry curves (ψ vs. Δ) and visually choosing the best fit of the experimental ψ and Δ . In general, there are four constants (the refractive indexes of the solution or gas phase contacting the film, N_0 , and of the substrate, N_2 ; the angle of incidence, ϕ ; the wavelength, λ), one variable (thickness, d), and one parameter (film refractive index, N_1) necessary in generating a particular curve. In all cases, N_0 was determined independently with an Abbe refractometer and ϕ and λ set to values appropriate to the experiment. The assignment of N_2 was made by determining ψ and Δ for the bare electrode and calculating a bulk refractive index. For this study, it was assumed that displacement of any adsorbate or chemical modification of the electrode surface upon polymer deposition caused no significant change in N_2 . Ignoring the correction procedure described above did not have a significant effect on the choice of N_1 (and, therefore, the calculated d), but did lead to a small, finite deviation of the experimental data from ideal behavior for films of high optical quality. For the films described below as being nonideal (i.e., inhomogeneous or nonuniform), this instrumental error can be considered insignificant.

Results

Polybipyrazine.—Electrochemical formation and deposition of a polymer film on an electrode is especially convenient because the ellipsometric parameters can be determined as the film grows. For a film of uniform density, refractive index, and thickness (d), the expected ψ vs. Δ plot would be periodic with one complete cycle occurring when d equals about one-half the wavelength of the incident light wave. Typical data obtained for the *in situ* deposition of polybipyrazine are shown in Fig. 2. The refractive index of the deposition solution was 1.387, and the calculated N_2 for the glassy carbon electrode immersed in that solution was $1.82-i0.67$. The experimental data shown in Fig. 2 do not follow the expected ideal behavior for a nonabsorbing film because the points are not exactly periodic as the film thickness approaches 250 nm. The particular values of N_1 for the simulations in Fig. 2 were chosen by fixing the real part and determining the imaginary part that provided the best fit of the data in the first cycle of the polarization curve. It was difficult to determine the exact precision in N_1 (and d), but based on a series of simulations that provide a reasonably good fit to the experimental data, d is probably known to within $\pm 10\%$ for the thinnest (<50 nm) films and within $\pm 3\%$ for the thicker films. The two best fits, for $N_1 = 1.63-i0.022$ and $1.64-i0.017$, are those shown in Fig. 2. There is an obvious deviation of the experimental from the simulated curves for the thickest films. Such behavior is characteristic of a nonuniform or variable thickness film (see "Discussion" section), and in general the

Fig. 2. *In situ* experimental (●) and simulated (—) data for reduced (1.5V vs. SCE) polybipyrazine deposited from 3 mM bipyrazine in 10% aqueous H_2SO_4 ($N_0 = 1.387$). The simulations consist of line segments connecting calculated points for films in 3 nm increments. The complex refractive indexes are (A) $1.63-i0.022$ and (B) $1.64-i0.017$. Indicated d are in nm.

Fig. 3. Experimental (●) and simulated (---) data for dry polybipyrazine films. The simulation is for $N_1 = 1.64-i0.035$. Indicated d are in nm.

bipyrazine films grown in the ellipsometer cell were often visibly nonuniform. Since similar data for thicker polymer films is consistent with an imaginary component of N_1 of about 0.025, curve A ($N_1 = 1.63-i0.022$) probably represents the best fit of the data in Fig. 2. The results for dry polybipyrazine appear in Fig. 3. The dotted line demonstrates the excellent fit of the data to the simulated curve for $N_1 = 1.64-i0.035$ ($N_2 = 1.84-i0.70$).

Figure 4 contains plots of estimated thickness of wet and dry polybipyrazine layers as a function of number of deposition cycles. In general, it was difficult to control the deposition rate of these films from day to day. The bipyrazine oxidation wave is buried under that of the solvent, so small relative changes in deposition potential (due, perhaps, to electrode pretreatment) or in the reference electrode potential could lead to significant changes in deposition rate. Measurements on a particular film in both the wet and dry states indicate that polybipyrazine exhibits very little swelling, so that most of the difference in the observed deposition rates in Fig. 4 can be attributed to variations in experimental parameters or deposition technique. Figure 4 contains two notable features: a wide linear growth region and an initial stage of apparently more rapid deposition. The significance of these characteristics is discussed below.

Polyaniline.—All attempts to obtain ideal plots of ψ vs. Δ for the polyaniline deposition were unsuccessful. Figure 5 contains the best set of results for the reduced polymer which was obtained for films deposited by cycling the working electrode potential between -0.2 and $0.8V$ vs. SCE. A good fit, dashed line, of the early data (to a half-cycle) was obtained for $N_0 = 1.346$ and $N_1 = 1.60$. The spi-

Fig. 4. Growth curves for reduced *in situ* (●) and dry (○) polybipyrazine films. Films were grown under different conditions (see text).

Fig. 5. Reduced (-0.2V vs. SCE) polyaniline which was deposited from 100 mM solutions in $1\text{M H}_2\text{SO}_4$ by cycling the electrode potential between -0.2 and 0.8V vs. SCE . The curve (---) is that predicted for $N_1 = 1.61$. Indicated d are in nm.

raling inward of the ψ vs. Δ data after a half-cycle was accompanied by a marked decrease in the absolute reflectivity and the increasingly hazy appearance of the electrode surface. Potentiostatically growing the polymer produced a coating with obviously poorer optical properties.

Polyvinylferrocene and VF-VCM copolymers.—Attempts to monitor film deposition of PVF in $0.1\text{M TBABF}_4/\text{CH}_2\text{Cl}_2$ solution were unsuccessful. Although a steady increase of oxidized polymer on the electrode surface could be verified by cyclic voltammetry and typical surface waves were observed, there were only very small changes in the reflection polarization of 546 nm light. Oxidation for several hours resulted in the appearance of a blue-green flocculent material on the electrode surface and a decrease in absolute reflectivity, but little change in the reflection polarization. These results suggest that PVF deposits as a highly solvated layer on the electrode surface.

Ellipsometric measurements on films deposited in $0.1\text{M TBABF}_4/\text{CH}_2\text{Cl}_2$ and transferred with rinsing to $0.1\text{M TBABF}_4/\text{MeCN}$ for measurement produced plots of ψ vs. Δ from which d could be determined. Rapid growth ($5\text{--}10\text{ nm/min}$) was apparent from both electrochemical and optical measurements. Figure 6 contains results for an accumulative deposition in which the electrode was repeatedly transferred between deposition and observation solutions. Starting with the bare electrode and proceeding around the dashed curves, each point represents the reflection polarization observed for a film grown thicker between points. The circular and triangular points correspond to the film in the oxidized and reduced (neutral) states, respectively. Simulations are shown by solid lines

connecting points calculated for 10 nm film thickness increments. Each simulated curve represents a fit of the first five data points for each oxidation state with $N_0 = 1.347$ (measured) and $N_2 = 1.81 \pm 0.66$ (calculated). These data indicate that the oxidized form of the polymer film has a lower refractive index (1.48 vs. 1.53) and is 15% thicker than the reduced form (Fig. 7). The experimental ψ vs. Δ plots in Fig. 6 are clearly aperiodic and spiral inward in a fashion similar to that of polyaniline.

Figure 8 is a plot of measured thickness vs. integrated reduction current for a reduced PVF film that displayed good optical properties up to a thickness of 325 nm . This film was grown and studied in the same manner as the film discussed above, except that it was not allowed to dry during the rinsing and transferring procedure. In addition to having reflection polarizations which were close to the ideal behavior for $N_1 = 1.51$, it exhibited, for a scan rate of 10 mV/s , thin-layer cyclic voltammetric waves from which integrated reduction currents were obtained. The plot is fairly linear, as would be expected for a film depositing with uniform density and electroactivity.

Unlike the homopolymer, the deposition of the copolymers could be monitored directly in the deposition solution. Very slow deposition (several hours being required to obtain the data shown) of the 22% ferrocene VF-VCM yielded a reasonable plot of ψ vs. Δ to about 150 nm (Fig. 9). The refractive index of the film was about 1.52 , and N_0 was 1.424 . Also shown in Fig. 9 is a plot of thickness vs. integrated reduction current. The deposition of optically detectable polymer film becomes very inefficient at a thickness of about 150 nm . The surface became noticeably hazy when growth of thicker films was attempted. A spiraling inward of the ellipsometry plot may be occurring, but scattering caused the loss of so much signal that additional data could not be obtained. If the electrodes were washed in acetonitrile, however, a partial restoration of surface reflectivity was observed, without removal of all of the polymer layer. Similar behavior was observed with $80\%/22\%$ VF-VCM.

Discussion

Polybipyrazine.—Of the films studied, polybipyrazine exhibited the best optical characteristics. The deviation of the experimental data in Fig. 2 from that expected for a single layer of refractive index 1.63 ± 0.022 is most likely due to a nonuniform film thickness across the electrode surface. Because of instrumental limitations, a relatively large area, 0.1 cm^2 , or approximately 50% , of the electrode surface had to be included in any optical measurement. If this film is not passivating (as Fig. 4 suggests), non-uniform deposition due to, for example, edge effects, may

Fig. 6. Experimental and simulated polarizations for PVF films deposited from methylene chloride and transferred to acetonitrile. The simulations are the best fits of the first five points for each oxidation state. Tic marks are placed every 10 nm . The dashed lines are included only for clarity.

Fig. 7. Reduced (d_r) vs. oxidized (d_o) PVF polymer film thicknesses from data and simulations in Fig. 6.

lead to a relative variation in film depth, d , which is independent of the effective mean thickness. The theoretical plots of ψ vs. Δ shown in Fig. 2 were made by drawing straight lines between calculated points every 3 nm; the effects of nonuniformity would be expected to be most apparent in the regions of these curves where both ψ and Δ are strongly dependent on thickness. In Fig. 2, this occurs when ψ is close to its maximum for a particular cycle. In this region, a spread of reflection polarizations (i.e., depolarization) would lead to an observed ψ which is lower than expected for a uniform film. The effect is much more noticeable in the second cycle because the absolute variation in film thickness could be considerably greater (because the film is three times thicker) and, for absorbing films, the dependence of ψ and Δ on d is somewhat greater. Instrumental designs (14) which permit higher spatial resolution would be required to study thicker films, because this type of variability in d will eventually lead to depolarization sufficient to render thickness information unobtainable. Alternatively, the use of a profiling ellipsometer system (17) could provide coverage information for the entire electrode surface.

The data for the dry polybipyrazine film (Fig. 3) is interesting, because its refractive index is very similar to that of the wet film (i.e., the real part of N_1 equal to 1.64 vs. 1.63 for the wet polymer). Since little swelling was observed between the wet and dry polymer, this behavior suggests either that solvent is mostly excluded from the reduced polymer layer, as might be expected for a neutral

Fig. 8. Thickness vs. integrated reduction currents for PVF

Fig. 9. Data for the *in situ* deposition of 22/78 PVF/VF-VCM in methylene chloride. The top curve represents an attempted fit with $N_1 = 1.52$. The bottom curve is a plot of estimated thickness vs. total deposition charge passed.

organic film, or that the air-dried film retained a significant amount of solvent. The former seems unlikely because rapid diffusion of hydroquinone through the reduced polymer has been observed (13).

Another interesting result of the polybipyrazine experiments is contained in Fig. 4. A plot of the ellipsometrically determined coating thickness vs. the number of deposition cycles clearly indicates that the polymer layer is not passivating toward continued deposition for layers of up to 325 nm. This implies that electron transport is rapid within the oxidized film (and the film is capable of oxidizing the monomer) and/or that mass transport of the monomer to the electrode surface (through the film) is not significantly limited by the presence of the polymer layer. These results are consistent with the electrochemical findings (13). Although, taken alone, these ellipsometry data cannot be used to deduce the mechanism of film deposition for polybipyrazine, they do show that ellipsometry may provide supportive evidence about the nature of the film in such an investigation. For example, the initial deposition rate for films <70 nm thick is twice that of the limiting rate (see Fig. 4).

Polyaniline.—Although ellipsometry does not yield useful thickness measurements for $d > 150$ nm, the polyaniline results are significant in that they demonstrate the sensitivity of the ellipsometric technique to film morphology. For the data presented in Fig. 5, reasonably precise film thicknesses can be obtained during the early stages of film growth. Optically, this film behaves well to about 150 nm, as is evident by the good fit of the data to a curve for $N_1 = 1.60$ and by the fact that macroscopic examination of the electrode surface showed a highly reflective surface. For thicker films, the optical characteristics of the polyaniline layer changed, as is evident from the inward spiral of the ellipsometry data. Simulations using various combinations of real and imaginary components for N_1 confirm that the unusual behavior of the measured ψ and Δ in Fig. 5 cannot be described by ellipsometry theory for homogeneous films, so effects of inhomogeneity and/or surface roughness must be considered. The theory for inhomogeneous coatings has been developed (4), but in general, closed-form solutions for the ellipsometry equation cannot be obtained, even if a functional description of the depth-dependent refractive index is available (18). Calculations may be made if the film is approximated by a series of discrete homogeneous layers. If the refractive index of these layers is assumed to decrease with distance from the substrate/film interface, the simulated curves spiral inward in a fashion similar to the observed polyaniline curves. However, optical and electron microscopy (not shown) indicate that

the deposition of a relatively dense polymer layer up to 150 nm is followed by the growth of loosely packed fiberlike structures which have diameters of about 200 nm. Fibrous structures of this size cause roughness effects that would preclude the use of a multiple layer (microscopic) approach to the simulation of the ellipsometry data and would force the use of theories for the treatment of gross roughness (19). Additional data, such as multiple angle measurements, will be required to determine whether a particular model is valid.

The optical properties of the polyaniline films depend on the deposition technique. The data in Fig. 5 are for a film deposited by cycling the electrode potential as described in the experimental section, while potentiostatically-grown films exhibited much poorer optical characteristics. The fiberlike structures found in the thicker films are clearly electronically conductive, since microscopic examination of the film during oxidation and reduction shows rapid changes in the color of the fibers during electrochemical cycling. Growth of these fibers may be analogous to the growth of needlelike crystals of conductive tetrathiafulvalenium bromide in Nafion films (20, 21). These results suggest a changing mechanism for film deposition. The initially deposited film is much more dense, because the possibility of monomer oxidation directly at the electrode is high. As it becomes increasingly difficult for monomer to reach the electrode surface, oxidation at the termini of the conductive aniline chains becomes the dominant Faradaic process, leading to fiber production. Attempts have been made to improve the homogeneity of the aniline polymers by using different potential pulse or controlled current deposition programs, but little improvement in the optical characteristics of the films above 150 nm has been realized.

Polyvinylferrocene and VF-VCM copolymers.—PVF films produced by prolonged oxidation in methylene chloride could not be detected *in situ*, indicating that PVF deposits as a very diffuse, highly solvated layer. A film was obviously being formed, because the blue-green flocculent material was observed on the electrode, and large cyclic voltammetric surface-waves resulted when the applied potential was scanned negatively. The lack of change in the reflection polarization indicates, however, that the oxidized film had a refractive index that was not significantly different than that of the deposition solution.

The copolymers deposited more densely than PVF in methylene chloride, and it was possible to monitor their growth *in situ* up to thicknesses of 150 nm (see Fig. 9). At this point, deposition either effectively ceased or the density of newly deposited film became too low to be optically detected. These films grew much more slowly (about 50 nm/h) than PVF, which may have enhanced their ability to pack more densely, thus permitting one to monitor their growth in the deposition solution. The limiting factor in measuring the thickness of these films appears to be their inherent nature to grow inhomogeneously.

Films grown in methylene chloride and directly transferred into acetonitrile without rinsing resulted in ψ vs. Δ curves which spiraled quickly inward and cyclic voltammetric waves that showed diffusional tailing. This kind of ellipsometric behavior would be expected, as discussed above, of a film whose refractive index (and, therefore, density) decreases with distance from the electrode or whose surface is becoming increasingly rough. A precise description of the inhomogeneity would be important to know if one expects to model the electrochemical behavior of this redox polymer successfully.

The sensitivity of ellipsometry to roughness and/or inhomogeneity dictated that procedures be found to improve the quality of PVF films. Variability of film quality was a persistent problem, and ellipsometric characterization proved a useful diagnostic tool for ascertaining if a film was depositing uniformly. Nonideal growth could be observed early, long before the appearance of any light

scattering or tailing cyclic voltammetric waves. Since PVF is slightly soluble in neat MeCN, but insoluble in 0.1M TBABF₄/MeCN, the films were rinsed as described in the "Deposition" section. The films were ellipsometrically observed to become thinner by this procedure. MeCN probably dissolves any loosely-bound outer layer and also solvates the film, thus improving its homogeneity. Films of improved optical and electrochemical quality could be grown to 300 nm by rinsing the electrode between depositions in this fashion, and ellipsometry curves (not shown) spiraled inward less dramatically. High surface reflectivity could generally be restored by this procedure with minimal concurrent loss of polymer.

Although homogeneous and uniform films were difficult to grow, Fig. 7 and 8 indicate that useful information could be obtained over a limited range of d . Figure 7 is especially interesting in that it represents the first reliable measurement of an oxidation/reduction swelling coefficient for an electroactive polymer. The observed decrease in film refractive index and increase in thickness that occurs upon oxidation of the polymer suggests that PVF is swelled by the uptake of counterions and attendant solvent molecules. The measured swelling coefficient (determined from the slope of the line in Fig. 7) is 1.15. Although allowance for film absorptivity has not been made, it is believed that this would be small, because the films in Fig. 7 are rather thin, and measurements on thicker (though somewhat inhomogeneous) films do not indicate that absorption is a problem.

The data in Fig. 8 allow comparison to be made between PVF film thicknesses determined ellipsometrically and by a nonoptical technique. The slope of the line in Fig. 8 provides a thickness/charge relationship given by

$$d = (1.9 \times 10^{-3} \text{ cm}^3 \text{ C}^{-1}) Q/A \quad [1]$$

where d is the thickness, in cm, Q is the charge passed to reduce the totally oxidized film, in coulombs, and A is the electrode area, in cm². This finding is consistent with previously published results (22) for thicker PVF polymer films. The concentration of electroactive redox centers, C , is approximated (assuming $n = 1$) by

$$C = Q/dAF \quad [2]$$

where F is Faraday's constant. From the experimental expression for d , one obtains

$$C = (F \times 1.9 \times 10^{-3} \text{ cm}^3 \text{ C}^{-1})^{-1} \approx 5M \quad [3]$$

which is consistent with a reasonably densely packed array ($\sim 1.1 \text{ g/cm}^3$) of ferrocene moieties.

Conclusion

It has been shown that the ellipsometric technique can be applied successfully to the *in situ* study of electroactive polymer-modified electrodes. Data have been presented on three classes of electroactive polymer materials.

The conductive polymer, polyaniline, exhibits a very inhomogeneous morphology and at best displays ideal optical properties only up to 150 nm. Thickness and structural information for polyaniline films with a thickness greater than this will require multiple angle studies in order to apply microscopic or gross roughness theories to this system. Ellipsometry may prove to be useful in attempts to monitor and control the morphology of conductive films.

In situ measurements for the electroprecipitated redox polymers (PVF and the copolymers) have proven to be capable of providing redox site concentrations (necessary for electrochemical studies), as well as information on morphological changes that occur upon oxidation or reduction of these films. Detailed ellipsometric studies will eventually assist in the understanding of the mechanisms of charge transport in this important class of compounds.

Electropolymerized bipyrazine yielded the best films for the ellipsometric determination of thickness. Al-

though instrumental and sample problems limited our ability to make precise measurements for thicknesses beyond about 400 nm, analysis of much thicker layers is well within reach.

As a general tool for the study of polymer modified electrodes, ellipsometry will eventually be limited by effects of gross roughness and film nonuniformity. Implementation of improved cell designs and more complex theoretical considerations may improve its utility in this field. Data acquisition with an automatic ellipsometer and at multiple wavelengths should also aid in the elucidation of the structure and behavior of polymer films on electrodes.

Electrocatalytic Oxidation of As(III)

II. Kinetic Studies at Pt Electrodes

Tim D. Cabelka,¹ Deborah S. Austin, and Dennis C. Johnson*

Department of Chemistry and Ames Laboratory,² Iowa State University, Ames, Iowa 50011

ABSTRACT

The empirical rate law for the electrocatalyzed oxidation of As(III) at a Pt RDE in acidic media was determined from potentiostatic measurements to be

$$k = k_0(t/t_0)^{-b} \exp \{-E/E_0\}$$

where $t_0 = 1.0$ s and $E_0 = 0.161$ V vs. SCE. For an electrode surface covered with less than the equivalent of a monolayer of PtO (*i.e.*, $Q_{ox}/Q_H < ca. 2$), $b = 0.30$, whereas for an extended oxide coverage (*i.e.*, $Q_{ox}/Q_H > 2$), $b = 0.5$. The coefficient k_0 is independent of time (t) and electrode potential (E), but decreases as a function of the log of As(III) flux, *i.e.*, $\omega^{1/2}C^b_{As(III)}$. It is PtOH and not PtO that is the active agent for oxygen-atom transfer in the electrocatalytic mechanism. The finite rate of oxidation of As(III) observed for $Q_{ox}/Q_H \gg 2$ is concluded to result from $\cdot OH$ generated as the first step in the mechanism for continued oxide growth. It is concluded also that the generation of $\cdot OH$ at a highly oxidized Pt surface occurs at a rate independent of applied potential.

A brief review of the electrochemical literature for As(III) was presented in part I of this work (1), together with our results of voltammetric studies at Pt rotating disk and ring-disk electrodes. The irreversible oxidation of As(OH)₃ at Pt electrodes in acidic media is electrocatalyzed dramatically by the anodic discharge of adsorbed $\cdot OH$ (*i.e.*, PtOH) as the first step in (i) the production of surface oxide (*i.e.*, PtO) and (ii) the evolution of O₂(g) at an oxide-covered Pt surface. The rate of oxidation of As(III) is substantially lower at a surface covered by a well-developed layer of PtO with a rate constant (k), mea-

sured during the negative potential scan, which is independent of potential in the range $0.9 \leq E \leq 1.2$ V vs. SCE. Hence, for a fixed quantity of surface oxide, the rate-determining step (rds) is not a charge-transfer step. The value of k measured at 1.0V on the negative potential scan for an oxide covered electrode decreases with increasing value of the anodic scan limit (E_a) for the preceding positive scan as described by

$$k = M \cdot \exp \{-E_a/E_0\} \quad [1]$$

where M and E_0 are constants; the value of M was not studied for time dependence in part I (1). The charge corresponding to the total surface oxide (Q_{ox}) formed during a cyclic potential scan for $E_a \geq 1.0$ V in the presence of As(III) is approximately the same as for the absence of As(III). Since Q_{ox} is a linear function of E_a (2), Eq. [1] can

*Electrochemical Society Active Member.

²Operated for the U.S. Department of Energy by Iowa State University under Contract no. W-7405-ENG-82.

be rewritten as

$$k = N \cdot \exp \{-Q_{ox}/Q_0\} \quad [2]$$

where N and Q_0 are constants under the conditions of measurement.

Gilroy (2) has reviewed the literature pertaining to the kinetics of oxide growth at Pt electrodes and provided additional data to demonstrate the time dependence of Q_{ox} as described by

$$Q_{ox} = a\eta \ln(t/t_0) \quad [3]$$

where a and t_0 are constants, and η is the applied overpotential for oxide formation. Combining Eq. [2] and [3] to eliminate Q_{ox} gives the anticipated dependence of k on t following a potential step to a fixed value of η

$$\ln k = \ln N - (a\eta/Q_0) \ln(t/t_0) \quad [4]$$

Here, we report the results of a kinetic study of the electrocatalyzed oxidation of As(III) in acidic media to test the validity of Eq. [4].

Experimental

Instrumentation and chemicals.—Most conditions and devices described in Ref. (1) apply. The electrode was Model AFMD/8 Pt RDE ($A_d = 0.166 \text{ cm}^2$) in conjunction with the MSR rotator (Pine Instrument Company). In some experiments, speed control was by an analog signal from a linear ramp generator; in others, control was by a Model 6800 Southwest Technical Products Corporation computer (Pine Instrument Company) using a 12-bit D/A converter.

All chemicals were analytical reagent grade and solutions were prepared from triply distilled water. The NaClO_4 used to regulate ionic strength was recrystallized twice from distilled water to minimize the level of trace Cl^- .

Procedures.—The reproducibility of the electrode surface activity was insured for potentiostatic i - t studies by the customary voltammetric pretreatment under a triangular-sweep potential waveform applied 10-20 times or until the i - E curves were reproducible. Conditions for the pretreatment were: $E_p = 1.2$ - 1.3 V , $E_c = 0.1$ - 0.2 V , $\phi = 3$ - 6 V/min ; ω and C^b were the values to be applied in the subsequent potentiostatic study. A value of E_c less than 0.1 V was not chosen to avoid electrodeposition of bulk As⁰. The pretreatment was terminated on the negative scan at $E = E_c$; then, E was stepped immediately to the potentiostatic value of interest and the i - t curve recorded.

The faradaic response was modeled after the treatment of coupled kinetics (3) as given by

$$i = \frac{nFADC^b}{\delta + D/k} \quad [5]$$

where $\delta = 1.61D^{1/3}\nu^{1/6}\omega^{-1/2}$ and all terms have their customary electrochemical significance for the RDE. The constant k is taken to be a generalized rate constant and was determined to be a function of t , E , C^b and $\omega^{1/2}$. Two specific applications of Eq. [5] were used for calculating k as a function of t .

Method A.—The value of i was recorded as a continuous function of t and k was calculated for selected values of t using

$$k = \frac{1}{nFAC^b(1/i - 1/i_{lim})} \quad [6]$$

where i_{lim} corresponds to the calculated transport-limited current for the RDE. As will be demonstrated, large error in k can result at small t , *i.e.*, when $i \approx i_{lim}$, due to a small error in the estimation of i_{lim} .

Method B.—For some kinetic studies of long duration (*i.e.*, $t > \text{ca. } 500 \text{ s}$), k was calculated from the intercept of the $i^{-1}\omega^{-1/2}$ plot made according to

$$i^{-1} = \frac{\omega^{-1/2}}{0.62nFAD^{2/3}\nu^{-1/6}C^b} + \frac{1}{knFAC^b} \quad [7]$$

from the i - ω curve recorded at selected values of t . The time to sweep the range of ω (*i.e.*, 30 - 525 rad/s) was *ca.* 45 s , which was small in comparison to the large values of t involved in these i - t studies. Hence, the quantity of surface oxide was estimated to be constant during the course of each ω scan. Twelve specific values of i^{-1} were plotted *vs.* $\omega^{-1/2}$ from each i - ω curve for eight values of t , and the slopes and intercepts were obtained by linear regression.

The Pt RDE electrode was polished with $1.0 \mu\text{m}$ alumina for all experiments. The average roughness factor was determined to be 2.0 , based on measurements of the charge for hydrogen adsorption (Q_H).

Results and Discussion

Dependence of k on t .—Representative current-time (i - t) curves for 2.00 mM As(III) are shown in Fig. 1 for E in the region of electrocatalysis (see Fig. 1 and 7, part I). The calculated i_{lim} is shown for comparison (*i.e.*, $465 \mu\text{A}$). Of the numerous plotting methods tested, the best linear plots were obtained for $\log k$ *vs.* $\log t$, as illustrated in Fig. 2 for Method A with $t = 10$ - $10,000 \text{ s}$. The plots are adequately approximated by a linear correspondence for the regions of $t < \text{ca. } 200 \text{ s}$ (slope = *ca.* -0.3) and $t > \text{ca. } 500 \text{ s}$ (slope = *ca.* -0.5).

Method B was applied to the evaluation of k in the range 360 - 7200 s and plots of i^{-1} *vs.* $\omega^{-1/2}$ are shown in Fig. 3. The fact that these plots are parallel with that for i_{lim}^{-1} *vs.* $\omega^{-1/2}$ supports the choice of D for calculating i_{lim} . The plot of $\log k$ *vs.* $\log t$ for eight values of t was linear with a slope of -0.49 , in agreement with Method A for $t > \text{ca. } 500 \text{ s}$ (Fig. 2).

Consideration of error.—Values of k calculated from i at small t (Method A) can have large error when $i \approx i_{lim}$ (see Eq. [6]). Since i_{lim} cannot be measured directly using the Pt RDE, it was calculated based on the value of D ($1.026 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ for $0.5 \text{ M H}_2\text{SO}_4$) from measurements of i_{lim} at a Au RDE, where the oxidation of As(III) is transport limited. Consider the plots of $\log k$ *vs.* $\log t$ in Fig. 2 for $E = 1.0$ and 1.2 V which are redrawn in Fig. 4. Also shown in Fig. 4 are the plots for k calculated using i_{lim} estimated to be *ca.* 6% lower than the "correct" value used for Fig. 2. The shaded area between the two curves illustrates the extent of uncertainty in $\log k$; *i.e.*, the 6% decrease in i_{lim} produces an increase of k of $\geq 50\%$ for $t < \text{ca. } 20 \text{ s}$ at $E = 1.0 \text{ V}$. The error in k for small t is much less at larger E because i decreases more rapidly from i_{lim} (see Fig. 1).

Dependence of k on E .—Of greatest consequence in electroanalysis is the rapid decrease in response at relatively short times (*i.e.*, $t < 100 \text{ s}$). Representative plots of $\log k$ *vs.* $\log t$ are shown in Fig. 5 for E increased by 50 mV increments in the range 0.90 - 1.25 V for $\omega^{1/2} = 10.23 \text{ rad}^{1/2} \text{ s}^{-1/2}$; the statistics for such plots are given in Table I for two values of ω . The slopes exhibit negligible dependence on

Fig. 1. Current-time (i - t) curves for As(III) at E (V vs. SCE): a = 1.00 , b = 1.10 , c = 1.20 , and d = 1.30 . Conditions: $C^b = 2.00 \text{ mM As(III)}$ in $0.50 \text{ H}_2\text{SO}_4$, $\omega^{1/2} = 10.23 \text{ rad}^{1/2} \text{ s}^{-1/2}$.

Fig. 2. Plots of $\log k$ vs. $\log t$ for $t = 10-10,000s$ (Method A). E (V vs. SCE): a = 1.00, b = 1.10, and c = 1.20. Conditions: $C^b = 2.00$ mM As(III) in $0.50M$ H_2SO_4 , $\omega^{1/2} = 10.23$ $rad^{1/2} s^{-1/2}$.

E , and the average value is -0.30 . The intercepts (I) of $\log k$ - $\log t$ plots (i.e., $\log k$ for $t = 1s$) are linearly dependent on E (Fig. 6, curves A and B). Because of the large uncertainty of the intercept calculated from $\log k$ - $\log t$ plots, for

Fig. 3. Plot of i^{-1} vs. $\omega^{-1/2}$ (Method B). t (min): a = 6, b = 24, c = 60, and d = 120; e = theoretical for $D/k = 0$. Conditions: $C^b = 0.515$ mM As(III) in $0.50M$ $HClO_4$; $\omega^{1/2} = 5.60$ $rad^{1/2} s^{-1/2}$ between values of t ; $E = 1.10V$ vs. SCE.

Fig. 4. Plots of $\log k$ vs. $\log t$ and consideration of error. Conditions: $C^b = 2.00$ mM As(III) in $0.50M$ H_2SO_4 , $\omega^{1/2} = 10.23$ $rad^{1/2} s^{-1/2}$; E (V vs. SCE): A = 1.00; B = 1.20; i_{lim} (μA): A1, B1 = $465 \mu A$ (as shown in Fig. 2) A2, B2 = $427 \mu A$.

which all data is taken for $t \geq 10s$, values of $\log k$ at $t = 100s$ for these same experiments are plotted also in Fig. 6 (curves C and D). The slopes of the plots in Fig. 6 are: -2.34 (A), -3.09 (B), -2.71 (C), and -2.74 (D); the average is -2.7 ± 0.3 .

The dependence of k on E and t for $t < 100s$ is described by

$$k = k_0(t/t_0)^{-b} \exp \{-E/E_0\} \quad [8]$$

where $t_0 = 1.0s$, $b = 0.30$, and $E_0 = (1/2.7) \ln 10 = 0.161V$. This value of E_0 is in satisfactory agreement with the value $0.177V$ reported for Eq. [6] of Ref. (1). This agreement may seem surprising at first thought because of the differences in the two experimental techniques. In Ref. (1), k was found to be virtually independent of E in the range $1.2-0.9V$ during the negative scan of E . This results because Q_{ox} is established by the value of E_a for the posi-

* Conditions: 2.00 mM As(III) in 0.50M H_2SO_4 .

negative scan and remains virtually constant during the negative scan within the potential range specified. The dependence of k on E from potentiostatic experiments reported here ($t < 100\text{s}$) is virtually identical to that from cyclic voltammetry (1), and we conclude that Q_{ox} controls the value of k for both experiments.

The value of k_0 in Eq. [8] was calculated from the data for 2.00 mM As(III) (Table I), and the results are shown in Table II; \bar{k}_0 represents the average of k_0 for nine values of t in the range 10-100s. The values of k_0 at $E = 0.90$ and 1.25V differ significantly from the values for $E = 0.95$ -1.20V and are ignored in computing the grand average of \bar{k}_0 . The value of k_0 at $E = 1.25\text{V}$ deviated from \bar{k}_0 because of the significant rate of $\text{O}_2(\text{g})$ evolution for $E > 1.20\text{V}$ and the concomitant catalysis of As(III) oxidation [see Fig. 7 of Ref. (1)]. Justification for ignoring the value of k_0 at $E = 0.90\text{V}$ is nonexistent at this time, as this potential seems well within the range for the electrocatalyzed reaction.

Dependence of k_0 on C^b and $\omega^{1/2}$.—Although b in Eq. [8] was found to be independent of C^b and $\omega^{1/2}$, k_0 decreased with increased flux of As(III) for all values t and E . Representative $\log k$ - $\log t$ plots are shown in Fig. 7 as a function of $\omega^{1/2}$ for 2.0 mM As(OH)₃. The value of k_0 is adequately given by

$$k_0 = -d - e \log (\omega^{1/2} C^b / M \text{ rad}^{1/2} \text{ s}^{-1/2})$$

* $C^b = 2.0 \text{ mM As(III)}$ in $0.5\text{M H}_2\text{SO}_4$.

where $d = 110 \pm 10 \text{ cm s}^{-1}$ and $e = 38 \pm 6 \text{ cm s}^{-1}$. The large uncertainties in d and e are the result of difficulty in reproducing results from run to run as C^b was varied. This could be the consequence of an impurity problem. An additional consideration of the uncertainty is the fact the convenient variation of flux was limited approximately to only one decade.

The fundamental cause of the decreasing value of k with increasing flux of As(III) is not clear. Perhaps the product As(V) is adsorbed on and/or occluded in the rapidly growing oxide. As a result, the accessibility of As(OH)_3 for the adsorbed $\cdot\text{OH}$ might be decreased substantially. We note again that the rate of oxide growth is virtually unaffected by the presence of As(III) in solution and, therefore, the presence of As(V) in the diffusion layer.

Dependence of b on Q_{ox} .—From square-wave modulated voltammetry [Fig. 7 of Ref. (1)], it was concluded that the maximum rate for the surface-controlled oxygen-transfer reaction between the surface "oxide" and As(OH)_3 corresponds to a surface with adsorbed $\cdot\text{OH}$ as the predominate form of "oxide" at a coverage less than the equivalent of one monolayer (*i.e.*, $Q_{\text{ox}}/Q_{\text{H}} < 1$). Since As(OH)_3 is readily adsorbed at oxide-free Pt sites, the most favorable reaction mechanism is concluded to involve co-adsorbed $\cdot\text{OH}$ and As(OH)_3 . Hence, it was suspected that the transition of the slope of $\log k$ - $\log t$ plots from -0.30 to -0.50 might correspond to a change in the predominate reac-

Fig. 7. Plots of $\log k$ vs. $\log t$ for $t = 10$ -100s as a function of $\omega^{1/2}$. $\omega^{1/2}$ ($\text{rad}^{1/2} \text{ s}^{-1/2}$): a = 10.23, b = 14.47, c = 20.47, and d = 25.07. Conditions: $C^b = 2.0 \text{ mM As(III)}$, $E = 1.10\text{V}$.

tion mechanism as a consequence of the growth of surface oxide beyond the equivalent of a monolayer of PtOH (i.e., $Q_{ox}/Q_H > 1$) when the number of available Pt sites for adsorption of As(OH)₃ is minimal and the oxygen transfer reaction is between PtOH and As(OH)₃ in the outer Helmholtz plane, as suggested pictorially in Ref. (1).

Values of i as a function of Q_{ox} from the voltammetric experiments of Ref. (1) are replotted in Fig. 8. Recall that the corresponding plot of $\log k$ vs. Q_{ox} is linear [Fig. 8 of Ref. (1)]. The values of Q_{ox} corresponding to the equivalent of a monolayer of PtOH (i.e., $Q_{ox}/Q_H = 1$) and a monolayer of PtO (i.e., $Q_{ox}/Q_H = 2$) are indicated in Fig. 8. Clearly, $i = i_{lim}$ for $Q_{ox}/Q_H \leq 1$. Furthermore, $i < 0.5 i_{lim}$ for $Q_{ox}/Q_H > 2.0$ and the corresponding values of $\log k \ll -1.5$ [see Fig. 8 of Ref. (1)]. From Fig. 2, $b = 0.50$ when $\log k \ll -1.5$, and the transition in the value of b corresponds apparently to an extent of surface oxide substantially beyond the equivalent of a monolayer of PtO. We note that the concept of a perfect monolayer for a polycrystalline surface having a substantial degree of surface roughness undoubtedly is imaginary, at best. But, insofar as mechanistic proposals have validity for practical electrode surfaces, we conclude that $b = 0.30$ for $0 < \theta_{PtOH} < 1.0$ and $b = 0.50$ for an extended surface oxide ($\theta_{PtO} \gg 1.0$) such that $\theta_{PtOH} \rightarrow 0$. Based on the conclusion that the extended growth of oxide for $Q_{ox}/Q_H > 2$ continues to involve generation of adsorbed $\cdot OH$, these sites of greatest reactivity are undoubtedly widely dispersed on the surface and the electrode can be characterized as not being uniformly accessible.

Consideration of nonuniform accessibility for the electrode.—The observation of a linear plot of i^{-1} vs. $\omega^{-1/2}$ having a nonzero intercept (I) is diagnostic evidence of "mixed control" of the faradaic process at a RDE (see Eq. [5]). For an electrode surface with uniform activity, mass transport within the diffusion layer is solely in a direction normal to the surface and a nonzero intercept (I) in Fig. 3 is representative of slow coupled chemical or electrochemical processes. For a partially blocked electrode surface, the electrode is not uniformly accessible, and appreciable curvilinear diffusional transport occurs to active surface sites. For this case, $I > 0$, even for rapid reaction kinetics at the reactive sites and I is a function of the geometry and spacing of the active surface sites. Landsberg *et al.* (4-6) characterized the $i-\omega^{1/2}$ response for partially blocked RDE surfaces based on a theory of curvilinear diffusion by Smythe (7) and noted (6) that diagnostic evidence for curvilinear diffusion is the constancy of the product DI for a given anolyte. Experimental verification was achieved for alteration of D by changing the viscosity of the media. The product $D_{As(III)}I$ (Method B) was examined for As(III) in 0.50M HClO₄ as a function of added NaClO₄; the data are summarized in Table III. The product $D_{As(III)}I$ increased by more than 60% in going from $\mu =$

Fig. 8. Plot of i vs. Q_{ox} . $C^b = 1.11$ mM As(III) in 0.50M H₂SO₄, $\omega^{1/2} = 10.23$ rad^{1/2} s^{-1/2}, $Q_H = 200$ μC .

^d $D_{As(III)} = 0.66 \times 10^{-5}$ cm² s⁻¹.

0.5-5.0M. We conclude that curvilinear diffusion is not responsible exclusively for the nonzero intercepts of the $i^{-1}-\omega^{-1/2}$ plots, although its contribution cannot be excluded totally.

Possibility of oxygen abstraction from PtO.—It was estimated from cyclic voltammetry (1) that Q_{ox} is relatively unaffected by the presence of As(III) for $E_a > 1.0V$. A Pt flow-through detector was applied in a rigorous test of this conclusion. With a stream of 2.0 mM As(III) in 0.5M H₂SO₄ flowing through the detector at 0.5 ml min⁻¹, the value of E was scanned from $E_c = 0.0V$ to $E_a = 1.3V$ at 3.0V min⁻¹ and then to 1.0V, at which the negative scan was interrupted for $t = 10$ min. After the delay, the stream was switched to pure 0.5M H₂SO₄ and E was scanned to 0.0 V while recording the cathodic $i-E$ curve; the experiment was repeated in the absence of As(III). The areas of the two oxide reduction peaks were virtually identical ($\pm 1\%$). Hence, it is verified that the presence of As(III) does not alter Q_{ox} . Furthermore, it is demonstrated by this experiment that abstraction of O atoms by As(OH)₃ from PtO is negligible. If abstraction had occurred during the 10 min delay, the value of Q_{ox} would have steadily decreased in the presence of As(OH)₃ to the value corresponding to a scan to $E_a = 1.0V$. Additional evidence for this came from cyclic voltammetry: when the negative potential scan was halted at $E = 1.0V$ in cyclic voltammetry at the RDE, there was no increase in i with time beyond that value observed for the uninterrupted scan.

Diffusion of As(OH)₃ through the oxide film.—The potential-independent rate of As(III) oxidation observed on the negative scan in cyclic voltammetry [Fig. 7 of Ref. (1)] reflects the absence of an electron transfer in the rate-determining step. The possibility of slow molecular diffusion through the oxide film was considered. For such a mechanism, D/k in Eq. [5] would be replaced by the thickness of the oxide, which is proportional to Q_{ox} for $Q_{ox}/Q_H > 1$. If such is the controlling mechanism, linear plots would be obtained for $\log k$ vs. $\log Q_{ox}$.

Summary and Conclusion

The formation of chemisorbed $\cdot OH$ (i.e., PtOH), as the first step in production of surface oxide at Pt electrodes, is a reversible process (8, 9). The reversibly adsorbed $\cdot OH$ can be stabilized by place exchange with surface atoms of Pt, to give a species designated as OHPt, and ultimately oxidized further at high E to yield PtO. The kinetic results reported here are consistent with the conclusion that PtOH, but not OHPt nor PtO, is active as the O transfer agent in the electrocatalytic oxidation of As(OH)₃ to OAs(OH)₃. The dependence of k on E given here from potentiostatic measurements is virtually the same as for k on E_a from voltammetric studies (1), even though k in Ref. (1) was measured during the negative scan at $E < E_a$. In the voltammetric case, k is independent of E on the negative scan (1.1-0.9V) for $E_a > ca. 1.1V$ because Q_{ox} is fixed by E_a and remains virtually constant during the negative scan on the time scale of the voltammetric experiment.

Clearly, the time dependence of k from the potentiostatic measurements (Eq. [8]) is not consistent with that

predicted (Eq. [4]) on the basis of the observed $k - Q_{ox}$ dependence in Ref. (1) (Eq. [2]) and the known $Q_{ox} = t$ behavior (Eq. [3]). We had predicted that the $\ln k - \ln t$ slope would be a linear function of E and independent of t ; however, we observed the slope of $\ln k - \ln t$ plots to be independent of E and to undergo a transition (-0.30 to -0.50) in the region $t = 400$ - 600 s (see Fig. 2, 5). The explanation of this apparent conflict is that Q_{ox} represents the total charge for the three forms of surface oxygen, i.e., $Q_{ox} = Q_{PtOH} + Q_{OHPl} + Q_{PtO}$, and not just the active form, Q_{PtOH} . Furthermore, the $Q_{ox} - t$ behavior (Eq. [3]) does not correspond to the $Q_{PtOH} - t$ behavior, since the ratio Q_{PtOH}/Q_{ox} is not constant with time. The reaction between PtOH and adsorbed $As(OH)_3$ is very fast and $i \approx i_{lim}$ for small t when $Q_{PtOH} \approx Q_{ox}$ and $Q_{ox} < 1$, i.e., there are numerous adsorption sites available for $As(OH)_3$. But even in this case for $Q_{ox}/Q_H < 1$, Q_{PtOH} steadily decreases with time because of place exchange; hence, i decreases with time and we observe a $\ln k - \ln t$ slope of -0.30 . For large E where $Q_{OH}/Q_H \gg 1$, Q_{PtOH} is still significant at short t but O transfer is concluded now to occur by a slower reaction to $As(OH)_3$ in the outer Helmholtz plane, possibly by the mechanism suggested pictorially in Ref. (1). With increasing t , i decreases significantly below i_{lim} , and we observe a $\ln k - \ln t$ slope of -0.50 . We recall again from Ref. (1) that for E in the region of O_2 evolution, the surface coverage by adsorbed $\cdot OH$ is increased greatly and k increases accordingly; we observed signals for $As(OH)_3$ by hydrodynamically modulated voltammetry, in excess of $0.8 i_{lim}$ at heavily anodized electrodes, for which $i < 0.1 i_{lim}$ in the absence of O_2 evolution.

The electrocatalytic oxidation with O transfer for $As(OH)_3$ bears striking resemblance to the electrocatalytic production of IO_3^- from I^- at Pt in acidic media (10). In that case, production of IO_3^- occurs nearly at a mass-transport-limited rate simultaneously with oxidation of adsorbed iodine to IO_3^- during the rapid formation of surface oxide on the positive voltammetric scan; also, production of IO_3^- is at a transport-limited rate when O_2 is being evolved. In contrast to $As(OH)_3$, production of IO_3^- is negligible for $Q_{ox}/Q_H > 2$ in the absence of O_2 evolution and when $dQ_{ox}/dt \approx 0$, i.e., the negative voltammetric scan. We interpret this to reflect a very low rate of O transfer to I^- in the outer Helmholtz plane.

Experimental results from variation of solution viscosity do not confirm the possibility that the low reactivity of an oxide-covered electrode at large time can be characterized exclusively as conforming to the model of a non-uniformly accessible surface. We conclude that, even though Q_{PtOH} is small, $Q_{PtOH} \neq 0$, and it is the slow rate at which adsorbed $\cdot OH$ is regenerated on the oxide-covered surface after O transfer which is rate determining. If so, the $k - E - t$ dependencies are descriptive of the oxide-growth rate for $Q_{ox}/Q_H \gg 2$. But if this is true, we must conclude also that for an electrode with Q_{ox} fixed by application of $E > 1.1V$, the rate of oxide growth is independent of E for subsequent kinetic measurements at $0.9 < E < 1.1V$. The oxide growth mechanism could be controlled by the place-exchange reaction at the Pt-PtO interface (11) and the oxidation of $As(OH)_3$ may serve as a useful probe for further studies of oxide growth kinetics. We continue to investigate this possibility.

How to Reduce the Cointercalation of Propylene Carbonate in Li_xZrS_2 and Other Layered Compounds

W. R. McKinnon and J. R. Dahn

National Research Council of Canada, Division of Chemistry, Solid State Chemistry, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

Cointercalation of propylene carbonate (PC) into layered materials intercalated with lithium can be reduced with concentrated electrolytes. We show electrochemical and x-ray diffraction evidence for this reduction in Li/ZrS_2 cells with $LiAsF_6/PC$ electrolyte.

When Li intercalates into a host solid in an electrochemical cell, it sometimes carries with it molecules of the solvent from the electrolyte (1, 2). Such cointercalation of the solvent interferes with studies of intercalation of unsolvated Li. Moreover, if cointercalation occurs but is not recognized, experiments can be misinterpreted; in fact, cointercalation might be responsible for many of the discrepancies between reports of the electrochemical behavior of intercalation electrodes. Cointercalation is also a problem in commercial applications of intercalation batteries, because the large expansion of the lattice by the solvent degrades the host electrode. Propylene carbonate (PC) is an attractive solvent because it has a low vapor pressure and is easy to purify, but it cointercalates with

Li in layered compounds such as $TiS_2(1, 3)$. Many replacements for PC are volatile and sometimes explosive when combined with lithium salts in batteries.

The amount of host cointercalated with PC is reduced if high currents are used to discharge the cell initially (4). Apparently, unsolvated Li diffuses into the host more quickly than solvated Li, and PC will not enter a layer that contains enough unsolvated Li. Thus PC can still be used in experimental cells if the first discharge is done quickly; if too much Li is removed on subsequent charges, however, PC may cointercalate.

We have discovered that, in some cases, cointercalation of PC is nearly eliminated with a saturated solution of $LiAsF_6$ in PC. To illustrate this here, we compare

Li/Li_rZrS₂ cells made with 1M and saturated solutions of LiAsF₆ in PC. We have measured the voltage V vs. x in Li_rZrS₂, as well as the structure of the ZrS₂ host in these cells. At low currents, little PC cointercalates in cells made with the saturated solution, whereas PC cointercalates into almost all of the ZrS₂ in the 1M solution. We discuss these differences in terms of the chemical potential of PC in the electrolyte.

Experimental Procedure

Powdered ZrS₂ was made by reacting Zr and excess S at 900°C, then quenching. The particle size was less than 1 μm. Electrochemical cells with Li and ZrS₂ electrodes were prepared as described in Ref. (5), except that the electrolyte was either a 1M or a saturated solution of LiAsF₆ (used as received from U.S. Steel Agri-Chemicals) in PC (obtained from J. T. Baker then vacuum distilled). We also prepared cells with beryllium x-ray windows (4) to study changes in the structure of the ZrS₂ host *in-situ* in both 1M and saturated solutions.

A saturated solution of LiAsF₆ in PC has a lower conductivity than a 1M solution, so we could not use ZrS₂ electrodes flattened with rollers, as we did in our earlier work on TaS₂ (6). With the fine ZrS₂ powder used here, the pores of rolled electrodes are so small that cells made with these electrodes have very poor kinetics. In ZrS₂ electrodes that were not rolled, up to 60% of the host did not make good electrical contact to the electrode and so did not intercalate.

Experimental Results

The ZrS₂ powder used here gives results similar to those reported earlier for coarser powder (6). Figure 1 shows $-\partial x/\partial V$ vs. x for the third charge and fourth discharge of a Li/Li_rZrS₂ cell made with a saturated electrolyte. (The data have been normalized to a change $\Delta x = 1$ for the voltage range shown.) The peaks in Fig. 1 near 1.9V are broader than in our earlier results. This broadening is due to the smaller particles, not to the higher currents. The width of the peaks increases by only a few percent if the current is doubled. We chose the finer powder for this work because PC cointercalates into it more rapidly. The peaks in Fig. 1 are caused by the change in structure of ZrS₂ from the 1T polytype at $x = 0$ to the 3R polytype at $x = 0.23$ (6).

When PC is cointercalated, V vs. x is different than the behavior shown in Fig. 1. Figure 2 shows V vs. x for the first discharge of three Li/Li_rZrS₂ cells, two made with a saturated solution of LiAsF₆ in PC, and one with a 1M solution. The values of x in Fig. 2-5 have not been renormalized, but rather are calculated only from the current and the mass of ZrS₂ in each cell. We call this the "apparent" value of x , to stress that it measures only the average Li content of the entire electrode and so does not distinguish

Fig. 1. $-\Delta x/\Delta V$ vs. voltage V for the third charge and fourth discharge of a Li/Li_rZrS₂ cell with saturated LiAsF₆/PC as electrolyte. The curves have been normalized so $\Delta x = 1$ over the range of voltage shown. For the currents used, the charge and discharge each took about 17h.

Fig. 2. Cell voltage V vs. the apparent value of x in Li_rZrS₂ for the first discharge of Li/Li_rZrS₂ cells. (····): 1M LiAsF₆/PC electrolyte, 25h rate. (—): Saturated LiAsF₆/PC electrolyte, 50h rate. (---): Saturated LiAsF₆/PC electrolyte, 18h rate. The apparent value of x was calculated only from the current and the mass of ZrS₂. The rate quoted corresponds to the time to change the apparent x by $\Delta x = 1$.

Li_rZrS₂ without PC, cointercalated ZrS₂, and unintercalated ZrS₂. For the cell made with 1M solution, the voltage rises with x between $x = 0.4$ and 0.6 , then remains constant well beyond $x = 1$. As we show below, cointercalation of PC begins at 1.9V in Fig. 1; the plateau at 1.75V in the cell with 1M electrolyte corresponds to a further reaction of the cointercalated material with lithium. Cointercalation of PC and lithium is much slower than intercalation of lithium alone, so the voltage in Fig. 1 probably does not measure the free energy of the cointercalation reaction, as we discuss below.

Figure 3 shows $-\partial x/\partial V$ vs. V for the same cells as in Fig. 2. For the cell with 1M solution, $-\partial x/\partial V$ diverges near 1.7V, corresponding to the rise in voltage near $x = 0.4$ in Fig. 2. ($-\partial x/\partial V$ for $x > 0.4$ has not been plotted for this cell.) The cells with saturated solution were run at 25 and 50h rates. (These rates correspond to the time to change the apparent x by $\Delta x = 1$.) Both these cells show peaks near 1.6V, not present in Fig. 1, which presumably correspond to the plateau at 1.8V in the cell with 1M solution. Hence, some of the ZrS₂ is being cointercalated with PC in the cells with saturated electrolyte. The peaks at the 50h rate are higher, implying that more of the host has been cointercalated at the slower rate.

We studied the degree of cointercalation using *in situ* x-ray diffraction. Figures 4 and 5 compare the changes in the x-ray diffraction spectra of Li_rZrS₂ for cells with saturated and 1M solutions, respectively. These spectra were taken on the first discharging at constant current. Figure 4 is similar to the results of Ref. (6). As x increases, Bragg

Fig. 3. $-\Delta x/\Delta V$ vs. cell voltage V for the curves in Fig. 2.

Fig. 4. X-ray diffraction spectra for ZrS_2 during the first discharge in a $Li/Li_{1-x}Zr_xS_2$ cell with saturated $LiAsF_6/PC$ electrolyte. The cell was discharged at constant current at a 25h rate. The apparent x for the scans, starting from the front, is 0.03, 0.12, 0.21, 0.29, 0.38, and 0.47. The 101 peaks from 1T- ZrS_2 and the 104 peak of 3R- ZrS_2 are shown, together with a peak from some component of the cell (*).

Fig. 5. As in Fig. 4, except for cells with 1M $LiAsF_6/PC$ electrolyte at a 40h rate (The last scan is from a different cell than the other eight). Starting from the front, the apparent x is 0.07, 0.12, 0.18, 0.24, 0.30, 0.35, 0.41, 0.51, 2.04. In addition to the peaks in Fig. 4 are peaks from cointercalated ZrS_2 (labeled as C).

peaks from the original 1T structure of ZrS_2 shrink, and those from the 3R structure grow. The remaining peaks in the 1T structure for $x > 0.2$ are from ZrS_2 that did not make good electrical contact to the electrode. There are no extra peaks in Fig. 4 from ZrS_2 cointercalated with PC. In contrast, Fig. 5 does show extra peaks from cointercalated ZrS_2 . These peaks grow until $x \approx 0.3$, then shrink again when the voltage reaches the plateau at 1.75V (Fig. 2). In the last curve in Fig. 5, which corresponds to an apparent x of 2.0, the peaks from cointercalated Li_xZrS_2 have completely disappeared. (We do not know what happened to this material during the plateau at 1.75V. If it decomposed, the decomposition products are not crystalline enough to give Bragg peaks). Note that the peaks for the cointercalated material are broad, so a small amount of cointercalation would not be seen in Fig. 4. The causes of the long plateau in $V(x)$ in Fig. 2 have not been studied.

Discussion

Our x-ray results show that less PC is cointercalated from a saturated solution of $LiAsF_6$ in PC than from a 1M solution. The electrochemical behavior in Fig. 2 and 3 is consistent with this reduction, for the features in $-dx/dV$ associated with the cointercalation are reduced in a saturated solution. The interpretation of Fig. 2 and 3, however, is complicated by kinetics. PC can be kept out of the host even in a 1M solution of $LiAsF_6/PC$ if the first discharge is done at high currents (4), indicating that cointercalation of Li and PC is slower than intercalation

of Li alone. Thus, when cointercalation of Li and PC is occurring in parallel with intercalation of Li alone, the measured voltage V corresponds to V_1 , the voltage of the intercalation reaction, and not to V_c , the voltage of the cointercalation reaction. This is probably why the voltages for the cells in Fig. 2 are similar at low x : intercalation of Li alone is almost at equilibrium, but cointercalation is far from equilibrium. Moreover, this argument implies that the rate of cointercalation will decrease as the difference $V_c - V_1$ decreases. This difference will decrease with increasing concentration of the electrolyte, as we now show.

For simplicity, suppose lithium in the host is either free of PC or solvated by n atoms of PC, so we only need to consider two types of guest: Li and $Li(PC)_n$. The voltage of intercalation of Li is related to the difference in μ and μ_0 , the chemical potentials of lithium in the host and in lithium metal, respectively, by (8)

$$V_1 = -(\mu - \mu_0)/e \quad [1]$$

where e is the magnitude of the electronic charge. For cointercalation of Li and PC, each atom of Li that enters the host carries with it n molecules of PC, so the voltage is

$$V_c = -[(\mu + n\omega) - (\mu_0 - n\omega_0)]/e \quad [2]$$

where ω and ω_0 are the chemical potentials of PC in the host and in the solution, respectively. The difference in potential of the two reactions is

$$V_c - V_1 = n(\omega_0 - \omega)/e \quad [3]$$

Since the chemical potential of any molecule decreases with the number of those molecules (9, 10), ω_0 should be lower in a saturated electrolyte solution than in a 1M solution, so $V_c - V_1$ should be smaller and cointercalation should be slower.

A complication in our experiments is that there are similar amounts of ZrS_2 and PC in our cells, so the concentration of the electrolyte increases as PC cointercalates (ω_0 decreases). Further work is needed to determine the ranges of stability of the various phases, and to study the kinetics of intercalation and cointercalation.

In conclusion, we have shown that less PC cointercalates into Li_xZrS_2 from a saturated solution of $LiAsF_6$ in PC than from a 1M solution. We have found similar reductions in cointercalation with Li_xZrSe_2 and Li_xTaS_2 . The use of concentrated solutions should extend the usefulness of PC as a solvent in experimental cells used in the study of intercalation, and possibly in cells for commercial applications.

In Situ Production of Ozone in Water Using a Membrane Electrolyzer

S. Stucki, G. Theis,¹ R. Kötzi, H. Devantay, and H. J. Christen

Brown Boveri Research Center, CH-5405 Baden, Switzerland

ABSTRACT

The application of solid polymer electrolyte or Membrel water electrolysis cells with PbO_2 anodes for anodic generation of ozone in electrolyte-free water is reported. Maximum yields were obtained at a temperature of 25°-30°C and a current density of 1.0-1.3 Acm^{-2} . The current efficiency was not found to depend on ozone concentration in the feed water. Both, the perfluorinated membrane and the anode do not show any degradation of performance after 2500h of operation. The excellent stability and performance of the cell are correlated with properties of the membrane and its interface with the anode: exclusive transference of electric current by protons; absence of convection in the electrolyte; high oxygen oversaturation in the vicinity of the electrode.

Ozone is playing an increasingly important role as an environmentally clean oxidant in water treatment and several new processes in chemical and pulp industries. The application of ozone—unlike that of chlorine—does not leave harmful residues such as haloforms, etc., after reaction. The environmental advantages of ozone over chlorine justify its higher cost of generation for an increasing number of applications. Because ozone is highly reactive and cannot be stored over an extended period of time, it has to be generated on site. The usual technique is by silent electrical discharge in an ozonizer using dry air or pure oxygen as a medium. The specific energy consumption of classical ozonizers has been improved recently (1) to values of 14 Wh g^{-1} for air and 6 Wh g^{-1} for oxygen feed.

The literature on electrolytic ozone production was reviewed by Foller and Tobias (2). In terms of efficiency, the anodic formation of O_3 does not seem to be able to beat the classical gas-phase process; the best results have been obtained at technically impractically low temperatures, and these just about reach the efficiency of a modern air-driven ozonizer. Still, electrolytic ozone generation offers a couple of features that are not realized in the classical method and which make it an interesting alternative for various small-scale applications of ozone: investment costs for an electrolyzer (per unity mass of produced O_3) are expected to be considerably lower than for conventional equipment. The concentrations of O_3 in the product gas that can be achieved are higher for electrolytic systems. This reduces the gas volumes involved in ozone treatment or opens applications where high concentrations are a prerequisite.

The solid polymer electrolyte or Membrel cell design is a particularly interesting design for an electrolytic ozone generator, since it can be operated in electrolyte-free water and hence allows *in situ* ozonation in water streams.

Solid polymer electrolyte cells have been shown to offer a conceptually attractive approach to new or established electrochemical processes (3). In water electrolyzers, the ion conducting membrane electrolyte is in its H^+ form and is hence a strong acid. It was shown by Foller and Tobias (2) that electrolyte properties correlate strongly with the ozone yield and that the Lewis acidity of the electrolyte anion, in particular, correlates with current efficiency. The terminal $-\text{SO}_3\text{H}$ groups of the perfluorinated side chains of the Nafion membrane material seem to fit the electrolyte requirements of a good ozone generating cell. In the following, we report results obtained with a Membrel water electrolysis cell modified with a high overpotential anode.

Experimental

The cell used for these studies consisted of a membrane and electrode assembly known from Membrel water electrolyzer designs (4). The cathode consisted of a Pt catalyst deposited with a proprietary method onto the surface of a Nafion 120 membrane and contacted by a

porous graphite current collector. The membrane was allowed to swell in water at 130°C corresponding to a water uptake of ~30 weight percent (w/o). The anode was formed by a porous titanium sintered material covered with a PbO_2 layer and pressed onto the surface of the membrane. The complete membrane and electrode assembly had an area of 30 cm^2 and was contained in a monopolar circular cell housing made of titanium and stainless steel. Figure 1 shows a diagram of the cell used. Care was taken to provide sufficient volume of the housing to allow thermostating of the assembly. The cell was mounted in an all-glass and Teflon water circulating system. The same water was used for both feed and cooling agent.

Figure 2 shows the flow system of the experimental set up. Water was circulated in a closed anode loop by a PTFE circulation pump. A constant circulation flow was maintained throughout all experiments at ~50 $\text{liter}\cdot\text{h}^{-1}$. The loop was fed with demineralized water. The feed water flux (j_w) was adjusted by a metering valve between 5 and 60 $\text{liter}\cdot\text{h}^{-1}$. An overflow maintained a constant water volume in the anode loop. A small fraction of water (~0.1 $\text{liter}\cdot\text{h}^{-1}$ at the rated currents) was transported by electro-osmosis through the membrane to the cathode compartment and discarded. Circulation of water in the cathode loop was maintained by gas lift pumping only, which was sufficient for reasonable thermostating of the entire cell body.

Current efficiencies of ozone production were determined by measuring the ozone concentrations in the produced oxygen gas and in the water overflow from the anode loop. Concentration measurements were performed using a UV-vis spectral photometer (Shimadzu UV-120-02) with separate flow-through absorption cuvettes for the liquid and the gaseous phases. Concentra-

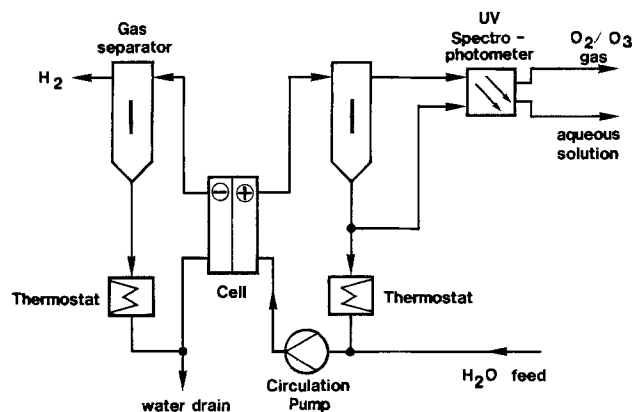

Fig. 2. Flow scheme of experimental rig

tion (gm^{-3}) was calculated from the measured extinction data using the coefficients from literature: $3024 \text{ cm}^{-1} \text{ mol}^{-1} \text{ liter}$ at 253.7 nm for the gas (5) and $2900 \text{ cm}^{-1} \text{ mol}^{-1} \text{ liter}$ at 258 nm for the aqueous solution (6). The PbO_2 electrode was characterized before and after service in the cell by x-ray diffraction at glancing incidence (2°) and scanning electron microscopy.

The feed water was demineralized by passing through a mixed bed ion exchange column. Conductivity was in the range of $1.2 \mu\text{S cm}^{-2}$.

Results

Ozone yield.—The current efficiency of the Membrel ozone generator was determined as a function of the process variables: current, temperature, and feed-water flow. All data are reported for one specific anode structure. The influence of the structural parameters of the anode such as porosity and thickness will be discussed in a later publication (7). The behavior of the generator (discussed here as a function of the above-mentioned process parameters) is qualitatively not affected by the anode geometry. The current efficiency η_i was calculated from the concentration data measured in the gas phase and in the aqueous phase after production had reached steady state, which happened after $\sim 100\text{h}$ of operation. The current efficiency is defined as

$$\eta_i = (j_w C^w + j_g C^g) z F i^{-1} \cdot 100\%$$

where j_w and j_g are the flow rates of water and anode gas, respectively, C^w and C^g the corresponding concentrations of ozone, i the current, F the Faraday constant, and z the number of electrons necessary for the formation of 1 mol of O_3 ($z = 6$).

In Fig. 3, current efficiency is plotted in percents against temperature. The current efficiency shows a maximum of $\sim 15\%$ at a temperature of $25^\circ\text{--}30^\circ\text{C}$. This temperature and its peak value are rather unexpectedly high. Efficiency maxima have been reported at much lower temperatures in concentrated solutions of oxyacids, *i.e.*, at -40°C in H_2SO_4 (2), -10°C in H_3PO_4 (2), and -30°C in HClO_4 (8). No explanation for these maxima has yet been found.

The dependence of the relevant data for O_3 formation on current density is shown in Fig. 4. The current efficiency (Fig. 4b) increases with increasing current density and levels off above $\sim 1.3 \text{ kAm}^{-2}$, reaching a saturation value. Qualitatively, the curve shape resembles the corresponding curves reported by Foller and Tobias (2) for sulfuric acid at 0°C . The specific power consumption P of the process expressed in watt-hours (dc power) per gram of produced ozone is calculated from the current efficiency η_i and the corresponding cell voltage U

$$P = \frac{UzF}{M\eta_i}$$

where M is the molecular weight of ozone, F the Faraday constant, and z the number of electrons transferred in forming O_3 .

Fig. 3. Current efficiency as a function of temperature. Current density: $i = 1 \text{ Acm}^{-2}$; feed water: $j_w = 5 \text{ liter}\cdot\text{h}^{-1}$.

Combining the data of Fig. 4b with the current-voltage characteristics of the cell (Fig. 4c) yields the plot of P vs. current density (Fig. 4a), which shows a minimum around 1 A/cm^2 .

The concentrations of ozone that correspond to the efficiency data reported above are in the order of $150\text{--}180 \text{ gm}^{-3}$ in the gas phase and $20\text{--}30 \text{ gm}^{-3}$ in water. These concentrations depend, of course, on the amount of water that is fed to the system per unit time (j_w). At constant temperature (18°C) and current (30A), the water flux (j_w) was varied between 5 and $60 \text{ liter}\cdot\text{h}^{-1}$. The ratio of the concentrations of ozone in gas and in water (which, in the limiting case of $j_w = 0$ is ~ 5) increases with water flux. This indicates that, in the flow system used, an equilibrium partition of ozone between gas and liquid is only attained at very small fluxes. This is illustrated in Fig. 5a, which is a graph of the apparent Henry constant defined as

$$H_{\text{app}} = (C^g)(C^w)^{-1}$$

where C^g and C^w are both measured in grams per cubic meter of gas or liquid, respectively. The concentration of ozone in water in this experiment varied between 25 and 4 ppm (Fig. 5b). The total quantity of ozone produced per unit time (j_{O_3}), however, is independent of the water flux, as can be seen from the top curve of Fig. 5c. The other two curves of Fig. 5c show the fractions of the total ozone production: first, that which leaves the system as aqueous solution and, second, that which leaves in the gas phase. The independence of ozone yield from feed-water flux means that current efficiency is not influenced by the degree of saturation with ozone of the water passing through the cell.

Stability.—One problem generally encountered with ozone generating cells is the long-term stability of electrode materials and cell equipment. Nafion membranes are well known for their extraordinary stability against oxidants (9). The excellent oxidation stability is confirmed by our long-term testing of cells. No degradation of the membrane was detected after $>2000\text{h}$ of operation under a constant load of 1.3 Acm^{-2} . During operation, the effluent water was checked for fluoride ions. The levels measured with an ion-selective electrode were only just within its detection limit and were not indicative of significant decomposition.

Lead dioxide is known to undergo corrosion in liquid acids under conditions of high anodic currents (10, 11). Long-term experiments with Membrel cells were performed in order to assess the corrosion behavior of PbO_2 deposited on titanium. For this purpose, an experiment was run over a period of 2500h under a load of 1.3 Acm^{-2} . The water from the anode loop was checked for lead ions by inverse voltammetry.² The lead level found did not differ significantly from the level of the deionized feed

² Analysis of Pb content in water were kindly performed by Dr. H. Siegenthaler of the Institut für anorgan. Chemie, Universität Bern, Switzerland.

Influence of feed water flux on cell performance data at $T = 30^\circ\text{C}$ and $i = 1 \text{ Acm}^{-2}$. a: Apparent Henry constant, expressed as the ratio of concentrations of ozone in the gas phase and in the water $H_c^{\text{app}} = (C_g/C_l)$. b: Concentration (ppm) of ozone in the anode water loop, analyzed by UV absorption at 258 nm. c: Ozone production rate in grams per hour, leaving the apparatus in \square : the aqueous phase ($j_{\text{O}_3}^w$), \triangle the gas phase ($j_{\text{O}_3}^g$) and \circ : overall ($j_{\text{O}_3} = j_{\text{O}_3}^w + j_{\text{O}_3}^g$).

water (feed water: 0.35 ppb; anode loop: 0.38 ppb). The cell voltage was stable within $3.45 \pm 0.1 \text{ V}$ at 30°C throughout the experiment.

After disassembling the cell, the PbO_2 layer was inspected using scanning electron microscopy. The micrograph of Fig. 6a shows the back of the electrode which was not in direct contact with the membrane, and Fig. 6b shows the electrode surface facing the membrane. The differences between the back and the front are evident. The crystallite morphology of PbO_2 is partly destroyed in the contact areas where the electrode reaction took place

Fig. 6. Scanning electron micrographs of the PbO_2 layer of a Membrel anode after 2500h of service. a(left): Back of the electrode, not electrochemically active. b(right): Front of the electrode with areas of intimate contact with the membrane.

at a high rate. The estimated current density at the points of contact with the membrane (destroyed crystal morphology) was about 2.5 Acm^{-2} . The crystallography of the PbO_2 layer was studied by x-ray diffraction at glancing incidence ($\sim 2^\circ$), which samples a layer depth of $\sim 0.1 \mu\text{m}$. The diffractograms of Fig. 7 show the lines observed for both sides of the electrode after use in the cell. The rear surface consists of a mixture of $\beta\text{-PbO}_2$ and $\alpha\text{-PbO}_2$ due to the deposition process chosen. The lines originating from the $\alpha\text{-PbO}_2$ structure are strongly diminished on the front surface which was electrochemically active. It is known from the literature (10) that α - and $\beta\text{-PbO}_2$ usually corrode at the same rate, so preferential corrosion of $\alpha\text{-PbO}_2$ can be excluded. More likely is a transformation of $\alpha\text{-PbO}_2$ into $\beta\text{-PbO}_2$ via a solute species (discussed below).

Discussion

Comparing the results that were obtained using the Membrel water electrolyzer as an ozone generator with published work on comparable systems, one finds two features which are strikingly different. First, the PbO_2 coating in contact with Nafion seems to be more stable (by several orders of magnitude) than in liquid electro-

Fig. 7. X-ray diffraction at glancing incidence of the same electrode as Fig. 6. a: Expected lines for $\alpha\text{-PbO}_2$ (17). b: Diffractogram of the back of the electrode. c: Diffractogram of the front part of the electrode. d: Expected lines for $\beta\text{-PbO}_2$ (17).

lytes. Second, the system shows a distinct yield maximum at a comparably high temperature of $25^\circ\text{--}30^\circ\text{C}$. Both properties of the system are important for its technical application and must be deduced from specific properties of the ion exchange membrane used as an electrolyte and its interface to the PbO_2 anode. It is generally assumed that perfluorinated ionomer materials in contact with water segregate into one hydrophilic and into one (possibly two) hydrophobic phases (12). The hydrophilic phase contains the ionic groups and most of the water and forms a percolating network within the membrane. The electrolytic properties of Nafion membranes are given by this aqueous phase, formed by fixed anions, mobile cations (hydronium ions in the case of water electrolysis), and water. In many respects, Nafion does behave like an "ordinary" aqueous electrolyte: *i.e.*, cyclic voltammetry of Pt electrodes in contact with Nafion in pure water gives all the features that are well known in acidic liquid electrolytes (13).

With respect to the corrosion stability of lead dioxide, two properties of the membrane electrolyte seem to be decisive. The electrolyte is convection free and prevents mechanical wear of the electrode coating. The proton transference number in this application is 1.0, and, therefore, no concentration gradients of electrolyte species by transference will occur, even at extremely high current densities. The corrosion resistance can be rationalized assuming the validity of the model for PbO_2 corrosion in liquid acids proposed by Foller and Tobias (10). They assume chemical dissolution of PbO_2 as Pb^{2+} in a layer with very high proton activity near the anode (due to transference) and reformation of $\beta\text{-PbO}_2$ in the bulk of the electrolyte where pH is higher. Support for this model was deduced from the observed transformation of $\alpha\text{-PbO}_2$ as an electrode coating into $\beta\text{-PbO}_2$ as a corrosion product. Our results fit very well into that model. The absence of concentration gradients at the anode surface reduces drastically the chemical dissolution of PbO_2 . The little PbO_2 that does dissolve is redeposited immediately onto the surface because of unfavorable transport conditions for its removal from the electrode (absence of convection).
