where $k_{ox} = k_{ox}^{\circ} \exp(fE)$. At steady state, $d\theta/dt = 0$. We can graphically show the steady-state solutions by letting

$$\Gamma_1 = (k_{ox}/k_{dis}^{\circ})(1 - \theta_s) \equiv \gamma(1 - \theta_s) \quad [16]$$

$$\Gamma_2 = \theta_s \exp(-\beta\theta_s) \quad [17]$$

where the intersections of the curves Γ_1 and Γ_2 are the steady states. This is illustrated in Fig. 1 for several values of β . The necessary and sufficient conditions for MSS are found by evaluating

$$\left. \frac{\delta\Omega}{\delta\theta} \right|_s = 0 \quad [18]$$

and knowing $\Omega = 0$ at steady state, which indicate the points of stability change. This gives the following expression in terms of θ_s

$$\theta_s^2 - \theta_s + 1/\beta = 0 \quad [19]$$

Fig. 1. Steady-state functions Γ_1 and Γ_2 from Eq. [16] and [17]. Intersections of Γ_1 and Γ_2 are the steady-state values. The following parameters were used: (a) $\beta = 6$, $\gamma = 0.06$; (b) $\beta = 2$; $\gamma = 0.06$.

Solving for θ_s yields

$$\theta_s = 0.5 \pm 0.5[1 - 4/\beta]^{1/2} \quad [20]$$

Real roots exist for $\beta \geq 4$. Therefore, the bifurcation point is $\beta = 4$ ($\theta_s = 0.5$) and MSS occur for $\beta > 4$. Also from Eq. [18]

$$\gamma = (\beta\theta_s - 1) \exp(-\beta\theta_s) \quad [21]$$

and at the bifurcation point $\beta = 4$, $\gamma = 0.135$. Therefore, another condition for MSS is that $\gamma < 0.135$ calculated from Eq. [21]. Figure 2 shows the bifurcation set of γ vs. β .

The stability of solutions of Eq. [15] can be determined from the sign of the eigenvalue, which is $\delta\Omega/\delta\theta$ evaluated at the steady state. When three steady states exist, the middle solution is unstable and the outer two are stable. This also can be checked by evaluating the trajectory $d\theta/dt$; the trajectory always moves away from the central steady state. In Fig. 3, the regions of stability are shown for θ_s vs. β at constant γ and θ_s vs. γ at constant β . This one-dimensional model cannot give oscillations, since a pair of purely imaginary eigenvalues is required. In other words, the model must be at least two dimensional for periodic solutions. In Griffin's analysis, the current density-potential curves were calculated for an electrode potential range of about -1230 to -1250 mV for MSS for the fixed parameters: $k_{dis}^{\circ} = 1300$ mA/cm², $k_{ox}^{\circ} = 8 \times 10^{32}$ mA/cm², and $f = 57.6$ V⁻¹. Using these parameters, $\gamma = 6.15 \times 10^{28} \exp(57.6E)$. From bifurcation analysis for $\beta = 6$, $0.0529 < \gamma < 0.0754$ or $-1250 < E < -1235$ mV, which is in agreement with Griffin's results.

The requirement for β for MSS was determined by Griffin for one particular set of rate constant values by solving Eq. [14], and our results agree with those of Griffin. However, our analysis gives much more information. As shown in Fig. 2, the region of multiplicity in parameter space is evaluated; that is, $\gamma = k_{ox}/k_{dis}^{\circ} < 0.135$ and $\beta > 4$. From our analysis, we can determine the range of all parameter values that are important for this model to predict the active-passive transition feature of the polarization curve.

Case II — Analysis of the Franck and Fitzhugh Model

Franck and Fitzhugh (10) formulated a mathematical model of iron polarized at a constant potential and found oscillatory solutions of the two system variables, surface coverage and an overpotential, $E = E_p - E_r$, where E_p is the constant applied potential and E_r is the Flade potential. The Flade potential is defined by them as the electrode potential at which the transition from the active to passive state takes place. The mechanism which was modeled is

Fig. 2. Bifurcation diagram showing regions of one and three steady states in the parameter space of β vs. γ .

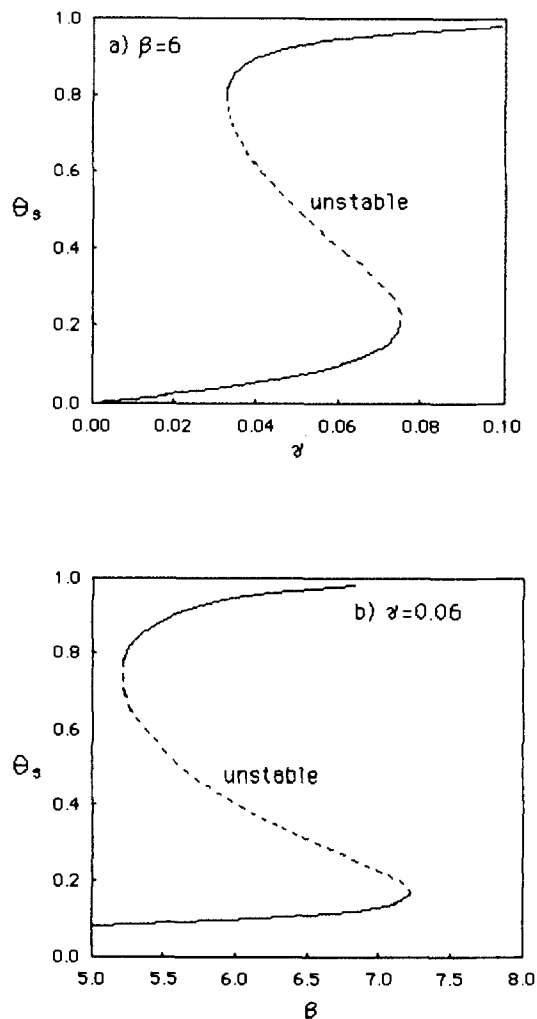

Fig. 3. Stability diagrams for multiple steady states of surface coverage θ_s for (a) γ at $\beta = 6$ and (b) β at $\gamma = 0.06$. Unstable region denoted by a dotted line.

Qualitatively, the model describes the following sequential steps as iron is anodically polarized in H_2SO_4 . First, the iron electrode is in an active state with a local current density of ~ 10 A/cm². Because of the presence of Fe^{2+} , hydrogen ions electromigrate away from the electrode, consequently reducing the H^+ concentration at the electrode. The Flade potential depends upon the H^+ concentration, and it is shifted negatively as the H^+ concentration decreases. The overpotential therefore increases, causing passivation to occur and the current density to decrease to a few microamperes per square centimeter. However, the back-diffusion flux of H^+ is increased, eventually increasing the H^+ concentration at the electrode. Hence, the overpotential decreases and the electrode becomes active again. This cycle of events is said to produce the observed electrochemical oscillations.

The basic features of the model are the assumptions of a discontinuity in the kinetics at the Flade potential ($E = 0$) and the dependence of the Flade potential on H^+ concentration. The model is simplified by linearizing (i) the current-potential curve, (ii) the dependence of Flade potential on the concentration of H^+ , and (iii) the concentration profiles in the electrode diffusion layer. The oxide film is formed on the electrode when $E > 0$ and dissolves when $E < 0$. The rate of film dissolution is proportional to coverage θ , and the rate of film formation is proportional to the active electrode area ($1 - \theta$). At the active sites, metallic dissolution occurs when $E < 0$. The sum of the partial currents of both reactions (Eq. [22] and [23]), each of which depends linearly on potential, may be written as

$$I_p = k_i(1 - \theta) + k_g E \theta^* \quad [24]$$

where

$$\theta^* = \theta \quad \text{for } E < 0$$

$$\theta^* = 1 - \theta \quad \text{for } E > 0$$

k_i is the current density of metallic dissolution (Eq. [22]) at E_p , and k_g is the gradient of the linearized polarization curve for the passivation reaction (Eq. [23]). By linearizing the Nernst equation, an expression for E as a function of H^+ concentration is given by

$$E = k_c(h_0 - h) - (E_i^0 - E_p) \quad [25]$$

where h_0 is the H^+ concentration at a constant standard potential of a given electrolyte, h is the H^+ concentration at the electrode surface, E_i^0 is the Flade potential at h_0 , and $k_c = RT/F$. It is assumed that only the H^+ ions are charge carriers in the electrolyte and that the flux of H^+ is equal to the sum of the diffusional and electromigrational terms. Writing the change of H^+ concentration from the flux equation yields

$$\frac{dh}{dt} = k_d(h_0 - h) - k_m I_p \quad [26]$$

where $k_d = 2D/\delta^2$, $k_m = 2/F\delta$, D is the diffusion coefficient for H^+ , and δ is the diffusion-layer thickness. By differentiating Eq. [25] and then by substitution of Eq. [24] and [26], the result is

$$\frac{dE}{dt} = K_1 - K_2 E - K_3 \theta + K_4 E \theta^* \quad [27]$$

where

$$K_1 = k_d(E_p - E_i^0) + k_m k_c k_i$$

$$K_2 = k_d$$

$$K_3 = k_m k_c k_i$$

$$K_4 = k_m k_c k_g$$

The change in coverage is given by

$$\frac{d\theta}{dt} = K_5 E \theta^* \quad [28]$$

where

$$K_5 = k_r k_g$$

and k_r is equal to the passive layer area, square centimeters per coulomb.

The system of equations (Eq. [27] and [28]) is nonlinear due to the $E\theta$ terms. By means of an analog computer, these equations were integrated by Franck and Fitzhugh and a combination of the five K parameters (or eight individual constants) was found, evidently by a considerable searching effort, to give sinusoidal periodic solutions. A phase-plane portrait was drawn of the solutions for the set of differential equations for three cases: $E > 0$, $E < 0$, and for the discontinuous case of all E not equal to zero. The trajectories indicated an unstable focus for the cases of $E > 0$ and $E < 0$, but a stable limit cycle was found for the discontinuous case for the following set of parameter values: $K_1 = 1250$ mV s⁻¹; $K_2 = 2$ s⁻¹; $K_3 = 2000$ mV s⁻¹; $K_4 = 20$ s⁻¹; and $K_5 = 1$ mV⁻¹ s. Therefore, it was concluded that the discontinuity in E was essential for periodic solutions. Additionally, it was inferred that the assumed linearizations in the model caused it to be invalid, since initial values of E and θ far outside the limit cycle resulted in trajectories tracing toward infinity.

The authors were able to improve their model by assuming a logarithmic dependence of Flade potential on H^+ concentration and including a function for charge transport of SO_4^{-2} and Fe^{2+} ions. However, the charge-transport function was given only graphically and the new parameter values, which resulted in relaxation oscillations, were not stated explicitly. Therefore, this improved model will not be used in the present analysis.

Table I. The determinant and trace of the linearized Jacobian evolved at the steady states of Eq. [27] and [28]

Steady state (E_s, θ_s)	det J	tr J
$E < 0$ ($0, K_1/K_3$) ($K_1/K_2, 0$)	$K_1 K_5$ $-K_1 K_5$	$-K_2 + (K_1 K_4 / K_3)$ $-K_2 + (K_5 K_1 / K_2)$
$E > 0$ ($0, K_1/K_3$) ($[K_1 - K_3]/K_2, 1$)	$K_5(K_3 - K_1)$ $-K_5(K_3 - K_1)$	$-K_2 + K_4 - (K_1 K_4 / K_3)$ $-K_2 + (K_5 / K_2)(K_1 - K_3)$

By applying linear stability and bifurcation analysis to the model of Franck and Fitzhugh, we can gain much information about the steady states and conditions for periodic solutions. By setting both dE/dt and $d\theta/dt$ (Eq. [27] and [28]) equal to zero, the following steady states are determined

$$(E_s, \theta_s) = \{(0, K_1/K_3), (K_1/K_2, 0)\} \quad \text{for } E < 0$$

$$(E_s, \theta_s) = \{(0, K_1/K_3), ([K_1 - K_3]/K_2, 1)\} \quad \text{for } E > 0$$

The model equations may be linearized about the steady state and the determinant and trace of the linearized Jacobian may be evaluated, as shown in Table I, to determine the stability of the steady states and the conditions for bifurcation. Although K_2 through K_5 are always positive, considering the definitions in Eq [27] and [28], K_1 can be positive if $E^{\circ}_i - E_p < K_3/K_2$ or negative if $E^{\circ}_i - E_p > K_3/K_2$. However, since $0 \leq \theta \leq 1$ and $(0, K_1/K_3)$ is a common steady state in both cases of $E \geq 0$, K_1 must be greater than zero.

Franck and Fitzhugh concluded in their paper (10) that a discontinuity in E is necessary for oscillations of the model variables E and θ . However, from our analysis, the steady state $(0, K_1/K_3)$ is a Hopf bifurcation point for the following conditions

$$\text{for } E < 0 \quad K_1 > 0, K_4 = K_2 K_3 / K_1$$

$$\text{for } E > 0 \quad K_3 > K_1, K_4 = K_2 K_3 / (K_3 - K_1) \quad [29]$$

Notice that the conditions are different for the two cases and coincide only when $K_1 = 0.5K_3$. This corresponds to a steady state of $(0, 0.5)$ and a bifurcation parameter $K_4 = 2K_2$ for $E \geq 0$. If we inspect the parameter values found by Franck and Fitzhugh to produce oscillations and thought by them to correspond to a stable limit cycle, we find that a limit cycle occurs not when $K_1/K_3 = 0.5$, but when $K_1/K_3 = 0.625$. The steady state where Hopf bifurcation can occur is at the discontinuity $E = 0$, which is not defined in the model differential equations (Eq. [27] and [28]). This is a weak point of this model.

As shown from the present analysis, conditions for Hopf bifurcation to periodic solutions do exist for the two separate sets of model equations. If we can neglect the development of the model which includes the reasoning for the discontinuity at $E = 0$, then both sets of equations can produce oscillatory behavior for certain parameter values. By using the parameter values given by Franck and Fitzhugh, except for the bifurcation parameter K_4 , which is calculated from Eq. [29], a stable limit cycle is determined around the steady state $(0, 0.625)$ for both sets of model equations with $\theta^* = \theta$ or $\theta^* = 1 - \theta$. In Fig. 4, a stable limit cycle and oscillations are shown for $\theta^* = \theta$ and $K_4 = 3.2$. The frequency of the oscillations is 5.6 Hz, with very small amplitudes of E and θ of 0.88 mV and 0.0016, respectively. Figure 5 shows a stable limit cycle and periodic solution transients for $\theta^* = 1 - \theta$ and $K_4 = 5.33$. The frequency is 4.4 Hz, and the amplitudes of E and θ are somewhat larger than in Fig. 4, 1.68 mV and 0.022, respectively. Thus, both sets of differential equations from Eq. [27] and [28] can give limit cycles and sinusoidal oscillations of E and θ . However, the model development must be reconsidered to give a basis for these equations to represent the active-passive transition region.

Fig. 4. Limit cycle of E vs. θ around the steady state $(E_s, \theta_s) = (0, 0.625)$ and trajectories of E and θ for the following parameter values: $K_1 = 1250 \text{ mV s}^{-1}$; $K_2 = 2 \text{ s}^{-1}$; $K_3 = 2000 \text{ mV s}^{-1}$; $K_4 = 3.2 \text{ s}^{-1}$; and $K_5 = 1 \text{ mV}^{-1} \text{ s}$.

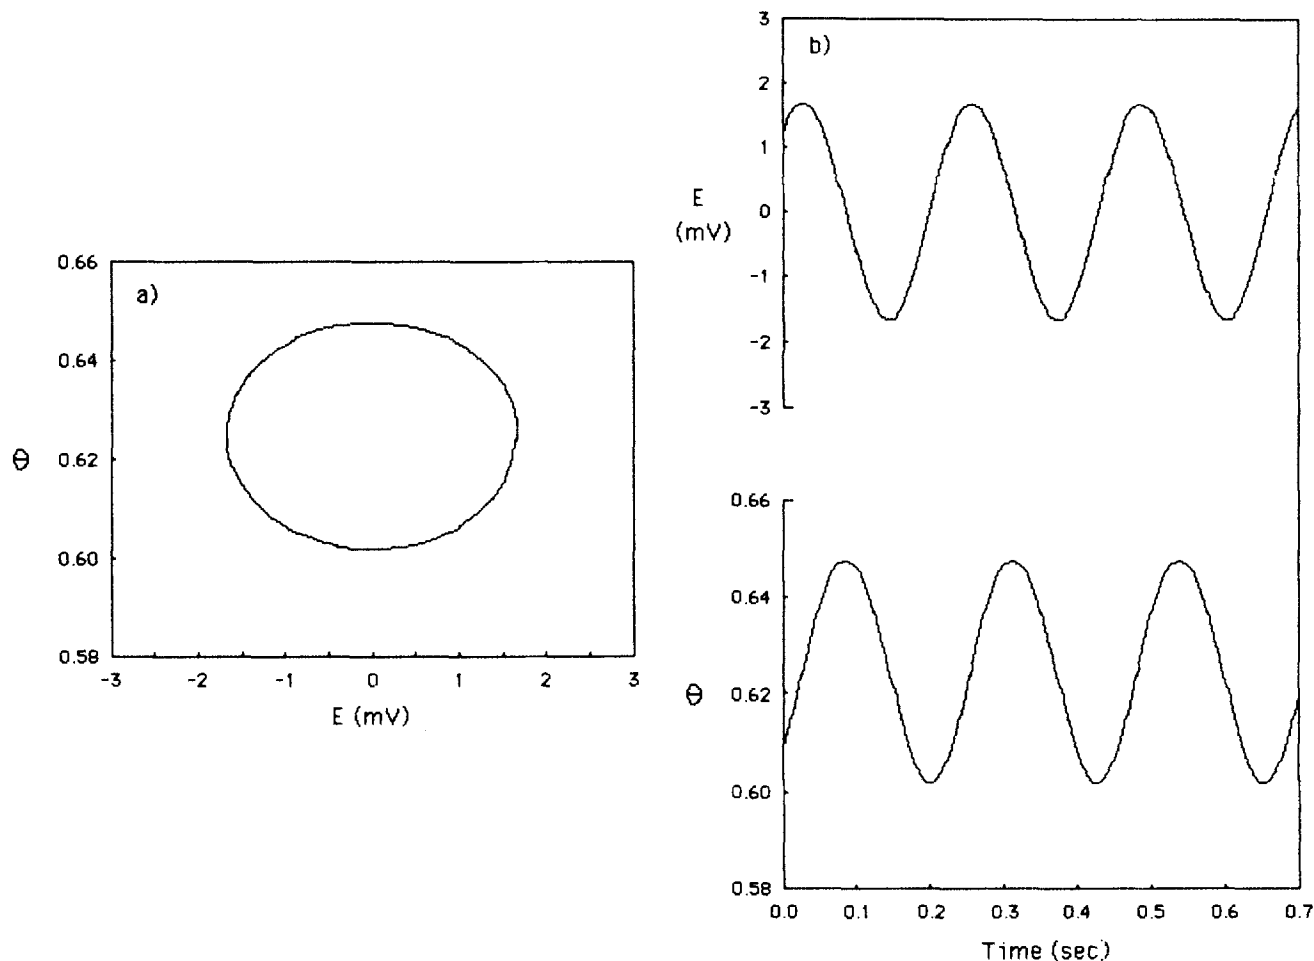

Fig. 5. Limit cycle of E vs. θ around the steady state $(E_s, \theta_s) = (0, 0.625)$ and trajectories of E and θ for the following parameter values: $K_1 = 1250 \text{ mV s}^{-1}$; $K_2 = 2 \text{ s}^{-1}$; $K_3 = 2000 \text{ mV s}^{-1}$; $K_4 = 5.33 \text{ s}^{-1}$; and $K_5 = 1 \text{ mV}^{-1} \text{ s}$.

Another conclusion drawn by Franck and Fitzhugh (10) was that the model did not represent the real system far outside the limit cycle. This is incorrect, for at initial conditions far from the limit cycle trajectories would approach the other steady state. The other steady state in each case is an unstable saddle point, since $\det J < 0$, as displayed in Table I. Actually, these saddle points are each out of the region of consideration of the model. But as a saddle point, the trajectories near them would eventually wind back to the stable steady state.

Summary

The application of stability and bifurcation analysis to two models of passivation from the literature shows the strength of these relatively new mathematical tools. For the one-dimensional model of Griffin (4), the conditions for a static bifurcation to MSS were determined. The two-dimensional model of Franck and Fitzhugh (10) was analyzed for a Hopf bifurcation to periodic solutions. Obviously, MSS does not necessarily imply oscillatory solutions. Indeed, a system of equations of at least two dimensions is required for oscillations to exist. This type of analysis, together with the inherent physical constraints, such as possible positive-valued constants and $0 \leq \theta \leq 1$, for example, gives limits and sometimes exact values of the system parameters for MSS and periodic behavior. Therefore, the search for a set of physically reasonable parameter values which give the desired system dynamics, particularly if there are numerous parameters that could be varied, can be immensely aided by these techniques of analysis. In some cases, the necessary conditions imposed upon the model may prove not to be physically realistic; such an outcome would cast serious doubt on the physical reasonableness of the mechanism itself.

Digital Impedance for Faradaic Analysis

I. Introduction to Digital Signal Analysis and Impedance Measurements for Electrochemical and Corrosion Systems

William H. Smyrl^{*1}

Sandia National Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

The faradaic impedance for single reactions on electrodes and for multiple parallel reactions (*e.g.*, corrosion) is discussed for both voltage and concentration perturbations. Concentration perturbations in the presence of convective flow are discussed for the rotating disk. The measurement of impedance by the techniques of digital signal analysis is briefly discussed, and instrumentation to perform the measurements is described.

Previous reports (1, 2) have described preliminary work on the application of digital signal analysis to impedance measurements on corroding systems. The technique of digital impedance for faradaic analysis (DIFA) is to be more fully discussed here. In the following papers, application of DIFA to copper electrodisolution and to copper corrosion in HCl will be discussed in turn. In other papers in the series, DIFA studies of copper corrosion in H₂SO₄ will be described.

An electrochemical cell with two electrodes is characterized by the impedance contributions as shown in Fig. 1. The electrolytic solution has an impedance, Z_s , due only to the resistivity of the solution, except at high frequencies, where the Debye-Falkenhagen effect becomes important (4). Ionic conduction in the solution is transformed to electronic conduction in the metal phase by charge transfer at the interface, which leads to an interfacial impedance Z_i at each electrode. Z_i is composed of a capacitance arising from the departure of the composition from electroneutrality (electrical double layer) and a faradaic impedance associated with the charge-transfer reaction.² In the simplest case of a single electrode reaction on an electrode, the interfacial impedance is a parallel combination of the double-layer capacitance, Z_c , and the faradaic impedance, Z_f , *i.e.*

$$\frac{1}{Z_i} = \frac{1}{Z_c} + \frac{1}{Z_f} \quad [1]$$

The faradaic impedance is determined by the kinetics of the charge-transfer reaction.

The current for a single electrode reaction may be expanded in a Taylor series about steady-state conditions, *i.e.*

$$i = \bar{i} + \left(\frac{\partial i}{\partial V} \right)_{\bar{C}_o} \tilde{V} + \left(\frac{\partial i}{\partial C} \right)_{\bar{V}} \tilde{C}_o \quad [2]$$

The Taylor expansion of the current in Eq. [2] is for small perturbations of the voltage and concentration

$$\begin{aligned} V &= \bar{V} + \tilde{V} \\ C &= \bar{C} + \tilde{C} \end{aligned} \quad [3]$$

where \bar{V} and \bar{C} are steady-state terms and the time varying voltage and concentration are \tilde{V} and \tilde{C} , respectively.

^{*}Electrochemical Society Active Member.

¹Present address: Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, Minnesota 55455.

²A *priori* separation of double-layer impedance and faradaic impedance is assumed here.

The subscript on the concentration in Eq. [2] denotes interfacial conditions. The derivatives in Eq. [2] are determined at steady state, *i.e.*, $V = \bar{V}$, $C = \bar{C}$. With more than one reaction, as in corrosion, a similar expansion may be made for each reaction. Coupling them appropriately will yield the total current as a function of all the perturbations.

Impedance with No Concentration Perturbations

The Butler-Volmer relationship for the current and voltage of a single anodic dissolution reaction is

$$\frac{i}{nF} = k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} - k_c C_o \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \quad [4]$$

where k_a and k_c are heterogeneous rate constants and α_a and α_c are transfer coefficients. V is the voltage with respect to an arbitrary reference electrode, and both k_a and k_c depend on that choice of reference electrode. C_o is the concentration of the metal product ion at the surface. For negligible concentration fluctuations, Eq. [4] and [2] yield a relationship for the faradaic impedance. Since

$$Z_f = \frac{\tilde{V}}{\tilde{i}A} = 1 / \left(\frac{\partial i}{\partial V} \right)_{\bar{C}_o} A \quad [5]$$

the faradaic impedance at zero current density is

$$Z_f = \frac{RT}{i_o n (\alpha_a + \alpha_c) A F} \quad (\text{at } i \rightarrow 0) \quad [6]$$

Fig. 1. Equivalent circuit for a simple electrochemical cell consisting of an interfacial impedance on each electrode and a resistor for the electrolytic solution separating the two.

where A is the area of the electrode. The exchange current density for the reaction is related to the heterogeneous rate constants by

$$i_0 = [(k_a^{\alpha_c})(k_c C_0)^{\alpha_a}]^{1/(\alpha_a + \alpha_c)}$$

At large anodic or cathodic current densities, the impedance depends on the current density. In the Tafel limit of large anodic current densities, from Eq. [4] and [2]

$$Z_f = \frac{RT}{\bar{i} \alpha_a A F} \quad [7]$$

A similar expression holds for the cathodic Tafel region.

For situations such as corrosion where several parallel reactions occur simultaneously, the development above may be generalized to

$$\frac{\bar{i}_T}{\bar{V}} = \sum_{\text{anodic}} \left(\frac{\partial i_a}{\partial V} \right) + \sum_{\text{cathodic}} \left(\frac{\partial i_c}{\partial V} \right) \quad [8]$$

or

$$\frac{1}{Z_{f,T}} = \sum_{\text{anodic}} \frac{1}{Z_{f,a}} + \sum_{\text{cathodic}} \frac{1}{Z_{f,c}} \quad [9]$$

The faradaic impedance for a corrosion couple (single anodic reaction 1, single cathodic reaction 2) at the corrosion potential, i.e., $i_T = 0$, is given by

$$Z_{f,T} = \frac{RT}{i_{\text{corr}}(\alpha_{a1} + \alpha_{c2})AF} \quad [10]$$

The corrosion current density is

$$i_{\text{corr}} = \bar{i}_{a1} = -\bar{i}_{c2} \quad [11]$$

The faradaic impedance in Eq. [10] has also been called the linear polarization resistance in the corrosion literature (5).

As an aside, two assumptions were made in developing Eq. [8] and [9]. The first assumption is the principle of superposition of several parallel reactions (6-8). This supposes that each reaction makes an independent contribution (except for electrical coupling) to the total faradaic process. The second assumption is really an approximation that the faradaic process may be treated as a linear system. Electrode processes are inherently nonlinear (see Eq. [4]), but for small perturbations in voltage or concentration, the response may be linear in the limit. This is implied in the use of the Taylor expansions in Eq. [2]. Armstrong *et al.* (9) have also used Taylor expansions for the treatment of impedance of electrochemical systems.

The interfacial impedance for the systems described by Eq. [6]-[10], coupled with the double-layer capacitance, has the well-known semicircular behavior in the complex plane as shown in Fig. 2. The low frequency intercept on the real axis gives the faradaic impedance Z_f . A resistance characterizing the solution resistivity would act in series with the interfacial impedance to shift the entire semicircle in Fig. 2 along the real axis. The low frequency intercept would then be the sum of the faradaic impedance and the solution series resistance. The high frequency intercept on the real axis would be the solution series resistance. Sluyters *et al.* (4, 10) give a complete description of the analysis. More will be said below about the application to the copper corrosion system.

Impedance with both Voltage and Concentration Perturbations

In the presence of concentration effects, the last term of the Taylor expansion in Eq. [3] must be included in the impedance analysis. It is useful to introduce the concentration term for a particular problem, and we choose mass transfer at the rotating disk for further discussion. The classical Warburg treatment (3) of the impedance of diffusion is valid for situations with no convection, and has received adequate treatment in the literature. The impedance for diffusion with superimposed convective flow

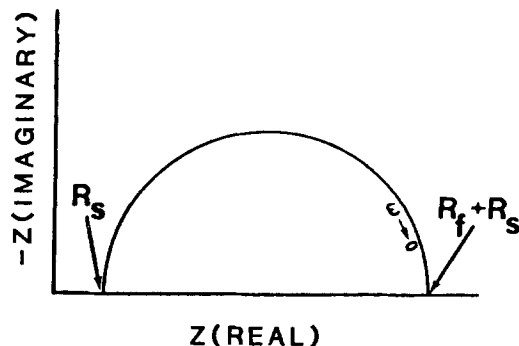

Fig. 2. Complex plane impedance plot of interfacial impedance of an electrode.

has only recently received attention, and will be described here for the purposes of this paper and the succeeding two papers. The concentration of a reactive species C , in the presence of a large excess of supporting electrolyte, obeys the equation

$$\frac{\partial^2 C}{\partial \xi^2} + 3\xi^2 \frac{\partial C}{\partial \xi} - \frac{\partial C}{\partial t^*} = 0 \quad [12]$$

The dimensionless distance normal to the disk surface is

$$\xi = z \left(\frac{\alpha \nu}{3D} \right)^{1/3} \left(\frac{\Omega}{\nu} \right)^{1/2} \quad [13]$$

and the dimensionless time t^* is defined by

$$t^* = t \left(\frac{\alpha \nu}{3D} \right)^{2/3} \left(\frac{\Omega D}{\nu} \right) \quad [14]$$

In the above equations, z is the distance normal to the electrode, α is a constant ($=0.51023$), ν is the kinetic viscosity, D is the diffusion coefficient, and Ω is the rate of rotation of the rotating disk. Homay and Newman (11) and Tribollet and Newman (12) described the concentration fluctuations caused by sinusoidal signal superimposed on a steady-state signal at the limiting current. The time varying current, \bar{i} , and surface concentration, \bar{C}_0 , are related by

$$\frac{\bar{i}}{nF} = -D \left. \frac{\partial C}{\partial y} \right|_{y=0} \quad [15]$$

or

$$\frac{\bar{i}}{nF} = \frac{-D \bar{C}_0}{\delta} \left. \frac{d\theta}{d\xi} \right|_{\xi=0} \quad [16]$$

The last equation was derived by recognizing that C would be given by a separation of variables

$$\bar{C} = B (\exp iKt^*) \theta \quad [17]$$

for a sinusoidal current of frequency ω . The parameter K is a dimensionless frequency given by

$$K = \omega \left(\frac{3D}{\alpha \nu} \right)^{2/3} \left(\frac{\nu}{\Omega D} \right) \quad [18]$$

δ is the steady-state diffusion layer thickness on the rotating disk, i.e.

$$\delta = \left(\frac{3D}{\alpha \nu} \right)^{1/3} \left(\frac{\nu}{\Omega} \right)^{1/2} \Gamma(4/3) \quad [19]$$

The variable θ obeys the equation

$$\frac{d^2 \theta}{d\xi^2} + 3\xi^2 \frac{d\theta}{d\xi} - jK\theta = 0 \quad [20]$$

where $j = \sqrt{-1}$, subject to the boundary conditions

$$\begin{aligned} \theta &= 1 \text{ at } \xi = 0 \\ \theta &= 0 \text{ as } \xi \rightarrow \infty \end{aligned}$$

Tribollet and Newman (12) have solved Eq. [19] for both low and high frequencies, and Levart and Schuhman (13, 14) treated the problem earlier. Analytic results were also obtained for

$$\left. \frac{d\theta}{d\xi} \right|_{\xi=0} = \theta'(0)$$

which is the surface flux and is important for impedance calculations through Eq. [16].

The Taylor expansion, Eq. [3], may now be written

$$\bar{i} = \left(\frac{\partial i}{\partial V} \right)_{\bar{c}_o} \bar{V} + \left(\frac{\partial i}{\partial C_o} \right)_{\bar{V}} \left[- \frac{\bar{i}\delta}{nFD\theta'(0)} \right] \quad [21]$$

or

$$\bar{i} = \left[\left(\frac{\partial i}{\partial V} \right)_{\bar{c}_o} \bar{V} \right] / \left[1 + \frac{\left(\frac{\partial i}{\partial C_o} \right)_{\bar{V}} \delta}{nFD\theta'(0)} \right] \quad [22]$$

The faradaic impedance is given by the formal equation

$$Z_f = \frac{\bar{V}}{\bar{i}A} = \left[1 - \left(\frac{\partial i}{\partial C_o} \right)_{\bar{V}} \left(\frac{\delta}{nFD} \right) \left(- \frac{1}{\theta'(0)} \right) \right] / A \left(\frac{\partial i}{\partial V} \right)_{\bar{c}_o} \quad [23]$$

The concentration-dependent term is the Warburg impedance in the presence of convective flow. The Warburg impedance is dependent on the frequency of the perturbation, becoming negligible at high frequencies, but with a finite value at low frequencies. The latter property should be contrasted with the classical Warburg impedance (no convective flow), which approaches an infinite value as the frequency decreases to zero. Equation [23] will be used in succeeding papers in the analysis of copper dissolution kinetics in HCl, and further discussion will be presented there.

To summarize this section, the departure from steady-state current due to small perturbations of voltage and concentration may be treated by a Taylor series expansion. Equations [6] and [7] give the faradaic impedance for single reactions, and Eq. [8] and [10] give the impedance for coupled, parallel reactions—all in the absence of concentration perturbations. For the reaction of a minor component in an excess of supporting electrolyte, concentration effects lead to a faradaic impedance which is given by Eq. [23] for a rotating disk system.

Digital Impedance for Faradaic Analysis

In the previous section, the relation between the total impedance and the faradaic impedance was briefly described for simple systems. Several equations for the faradaic impedance were developed which gave the dependence on reaction parameters for single and multiple reactions. These results will be used in the following papers for analysis of the impedance of copper dissolution and corrosion in order to determine the kinetics of the reactions. The purpose of the present section is to describe the measurement of the overall interfacial and cell impedance by digital acquisition and processing of voltage and current signals.

Studies of the impedance of electrochemical cells have been carried out for many years for the purpose of determining the kinetics of faradaic processes. Reviews are available on the classical techniques of measurement (4, 10, 15), and in the analysis of results (4), and for corrosion systems as well (16). The present paper will describe the technique of digital impedance for faradaic analysis (DIFA), which was first described elsewhere (1, 2). This represents the first application of fast Fourier transform (FFT) processing of multiple-frequency signals for corrosion studies. It is similar to the studies of Smith *et al.* (17-23) on electroanalytical applications, and Epelboin *et al.* (24) have used similar ideas for frequency-by-frequency impedance analysis in corrosion systems.

Fig. 3. Continuous signal and the equal interval samples over one period.

The basic ideas of digital signal analysis (1, 25) may be developed by considering the signal in Fig. 3. The signal $f(t)$ is sampled at regular intervals Δt to produce a set (not a series) of samples, $[f_n(t)]$. The total sampling interval is $T = n\Delta t$. The sample $f_n(t)$ is presumed to be the value of the continuous function $f(t)$ at the sampling point. The discrete Fourier transform (DFT) of the sample set is defined by (25)

$$\hat{F}(j\omega) = \sum_{n=-\infty}^{\infty} f_n(t) e^{-jn\omega\Delta t} \quad [24]$$

\hat{F} has both real and imaginary parts, and is periodic over ω with period $2\pi/\Delta t$. In actual practice, one samples over a finite period T , so that Eq. [24] becomes

$$\hat{F}(j\omega) = \sum_{n=0}^{N-1} f_n(t) e^{-jn\omega\Delta t} \quad [25]$$

where there are a total of N samples which begin at $t = 0$. Since there are only N independent samples, there are N independent parts of \hat{F} , to be computed over one of its periods, say $\omega\Delta t = 0$ to 2π . Let

$$\omega = \frac{2\pi m}{N\Delta t} \quad m = 0, 1, \dots, N-1 \quad [26]$$

and Eq. [25] becomes

$$\hat{F}_m = \sum_{n=0}^{N-1} f_n(t) e^{-j(2\pi mn/N)} \quad m = 0, 1, \dots, N-1 \quad [27]$$

Of the $2N$ parts (real and imaginary) of F_m in Eq. [26], only the values from $m = 0$ to $N/2$ need to be computed since

$$\hat{F}_m = \hat{F}_{N-m}^* \quad [28]$$

and the asterisk denotes complex conjugate. We complete the definitions by noting that the inverse DFT is

$$f_n(t) = \frac{1}{N} \sum_{m=0}^{N-1} \hat{F}_m e^{j(2\pi mn/N)} \quad n = 0, 1, \dots, N-1 \quad [29]$$

For each set of samples in the time domain $[f_n(t)]$, there is a set of values in the frequency domain (F_m), and the two sets are related by Eq. [27] and [29]. The frequency ω of an individual member of $[F_m]$ is given by Eq. [26].

For a sinusoidal signal such as in Fig. 3

$$f(t) = \bar{A} e^{j\omega_0 t} \quad f_n(t) = \bar{A} e^{jn\omega_0 \Delta t} \quad [30]$$

all the spectral content is concentrated at ω_0 . Using Eq. [24]

$$\hat{F}(j\omega) = \bar{A} (1 - e^{jN(\omega_0 - \omega)\Delta t}) (1 - e^{j(\omega_0 - \omega)\Delta t}) \quad [31]$$

As $\omega \rightarrow \omega_0$, one obtains

$$\hat{F}(j\omega_0) = \bar{A}N \quad [32]$$

and at multiples of ω_0 , i.e., $\omega = m\omega_0$

$$\hat{F}(j\omega) = 0 \quad [33]$$

This means that at harmonics of the input signal of frequency (ω_0), the DFT gives the correct spectrum if the frequency of a member of the set $[F_m]$ matches ω_0 , i.e.

$$\omega_m = \frac{2\pi m}{N\Delta t} = \omega_0 \quad [34]$$

All other members of the set $[F_m]$ are zero. For specifics, we choose $m = 1$, and see that the product $(N\Delta t)$ must be chosen such that Eq. [34] is obeyed. This constitutes "matching" the frequency of the DFT to that of the input signal to obtain accurate results. Stated another way, the input spectrum should be sampled over an integral number of periods. Failure to do this leads to a "leakage" error, which is discussed elsewhere (25).

The results may be generalized as follows. For an input spectrum which consists of superimposed sinusoids such that the higher frequency members are harmonics of the lowest frequency ω_0 , the DFT gives a spectrum set $[F_m]$ which is accurate at ω_0 and each of the higher harmonics, provided that sampling is over exactly an integral number of periods of the lowest frequency. This requirement automatically ensures that the higher frequency harmonics are sampled over an integral number of periods as well. One other restriction concerns the highest frequency that may be included in the spectrum. For a given sample interval, Δt , the highest frequency that may be accurately sampled is given by the relation

$$\omega_{HI} \leq \frac{1}{2\Delta t} \quad [35]$$

otherwise, "aliasing" will occur (25). Thus, it is seen that the full power of DFT processing is utilized by multiple frequency signals subject to the restrictions of periodicity and aliasing. The use of such an excitation signal (1) is described further below. Smith *et al.* (17-23) and de Levie (26) have used multiple frequency signals for impedance determinations in other applications.

Performing the discrete Fourier transform on a computer is done by the fast Fourier transform (FFT) algorithm (25). The operation gives the spectral content of the processed signal in terms of a set (not a series) of values $[F_m]$. This has a close similarity to the classical method of approximating an arbitrary function by the superposition of sinusoids, i.e., a Fourier series. The set $[F_m]$ has a close correspondence to the coefficients of the Fourier series representation. In the present application, the input signal is not arbitrary, but has known frequency content, which is chosen to match the requirements of the FFT, as discussed above.

The ratio of the voltage excitation spectra $[V_m]$ to the current response $[I_m]$, at each frequency, is the impedance for a linear system, i.e.

$$Z_m = \frac{\hat{V}_m}{\hat{I}_m} \quad [36]$$

The subscript m identifies the frequency of the respective functions, as given in Eq. [26]. The requirement of linearity is met for electrochemical systems for voltage perturbations of < 5 mV as a general rule, and means that the impedance at one frequency is independent of that at other frequencies. A more detailed discussion of the impedance transfer function for linear electrical circuits and networks is given by Stearns (25). As a closing comment, it should be noted that Eq. [36] is valid at the frequency ω_m (see Eq. [26]), independent of the form of the input. Several different voltage excitation signals could be used, but, compared at the same frequency, all would give identical values of the impedance.

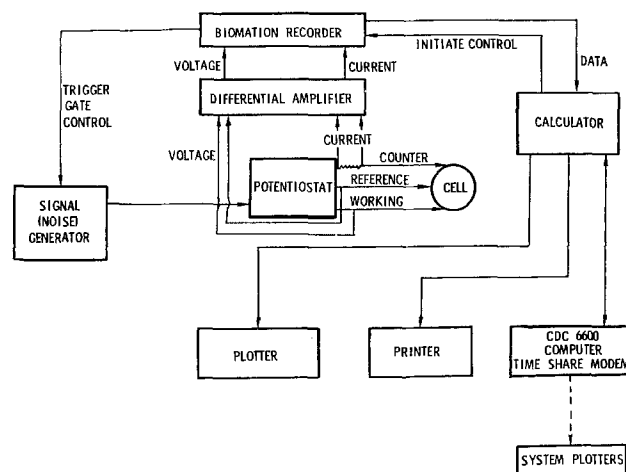

Fig. 4. Block diagram of system used for digital impedance for faradaic analysis measurements.

Measurement System Description

The measurement of impedance by DIFA is reported here and following with a system (1, 2, 27) which consisted of four elements.

1. The first component was the multiple frequency signal generator (Hewlett-Packard Noise Generator) which provided a signal of known frequency content. It consisted of several (in our case, either 51 or 101) sinusoids superimposed to produce the final signal. The lowest frequency of the set was ω_0 , and the higher members were harmonics (both odd and even) up to the cutoff frequency.

2. The second component was the digitizer (Biomation Waveform Recorder Model 1015) and low-pass filter and amplifier (Preston Scientific). The filter eliminated high frequency noise to prevent aliasing. The digitizer had a 1024 word memory per channel, so that a total of 511 frequencies would be analyzed simultaneously. The signal generator cannot be matched with the digitizer for more than 101 frequencies and still avoid leakage and/or aliasing, and the results described below typically used 51 frequencies in the input signal. The digitizer was synchronized exactly with the signal generator so that the total sampling period is equal to the generating sequence period.

3. The third member of the system was the calculator-controller (Hewlett-Packard 9830), which initiated the measurement cycle and stored the data received from the digitizer. Repetitive cycles could be run for time domain averaging of data. No FFT processing was done with the calculator. The data were transmitted via phone line to a large-scale computer (CDC 6600) for FFT processing and plotting. Impedance data could be transmitted back to the calculator for mass storage, but were stored on magnetic tape in the 6600 system more typically.

4. The electrochemical cell and control potentiostat constituted the fourth element of the system. The voltage excitation signal was superimposed on the steady-state control voltage at the input to the potentiostat and was a small perturbation to the control voltage, typically 3-5 mV peak to peak. The data described below were taken at 500 Hz and below, which was quite adequate for analysis of the copper dissolution and corrosion system. The voltage signal between the working electrode and the reference electrode was measured at the electrochemical cell by a voltage follower, and the signal was filtered and input to one channel of the digitizer. Simultaneously, the current response signal was measured as a voltage drop across a precision resistor in series with the electrochemical cell. The current signal was filtered in a duplicate filter and input to a second channel of the digitizer. In this way, the impedance data corresponded to the interfacial impedance plus a solution ohmic drop for that part of

the electrolytic solution between the reference electrode and the working electrode.

The system is capable of application over a wide range of frequencies. The signal generator can generate spectra between 1.5×10^{-4} Hz and 50 kHz. The digitizer can sample signals between 2×10^{-5} Hz and 50 kHz, and the low-pass filters may be used to 100 kHz. The system has been used successfully over the frequency range 10^{-4} to 50,000 Hz with no difficulty. The precision of the results has been limited by the Biomation digitizer which stored the data as 10 bit words, *i.e.*, the precision as 1 part in 1024. Noise pickup over some frequency ranges limited the precision for single runs to about 1%, but multiple run averages significantly improved the results. Typical precision has been found to be 0.5-1%. The accuracy of the system checked with precision resistor-capacitor networks approached 0.1%.

A final word may be said about convenience of DIFA as compared to frequency-by-frequency techniques. At high frequencies, the two are rather comparable in the time involved for data collection. DIFA offers significant savings of time at lower frequency ranges where the data are collected at the higher harmonics in the frequency band at the same time that the fundamental frequency is sampled. The time savings may be crucial for electrochemical systems that change with time, such as corrosion.

Summary

The impedance of several electrochemical processes have been reviewed in general, with use of a Taylor expansion for small amplitude voltage and concentration perturbations. Special attention was given to the Warburg impedance in the presence of convective flow for a rotating disk electrode. The principles of digital signal analysis have been reviewed briefly, and an experimental apparatus for conducting FFT electrochemistry has been described.

Digital Impedance for Faradaic Analysis

II. Electrodeposition of Cu in HCl

William H. Smyrl^{*1}

Sandia National Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

The electrodeposition of Cu was studied experimentally by both steady-state and impedance (DIFA) techniques on a rotating disk. The anodic dissolution was found to be largely mass-transfer controlled, but a kinetic contribution could be identified at high rotation rates. The steady-state behavior was satisfactorily modeled, and kinetic parameters α_a , α_c and the exchange current density were determined. The impedance of the system was also modeled; experimental results confirmed the steady-state kinetic parameters and the mass-transfer-kinetic model at all frequencies.

Copper anodically dissolves in acidic chloride solution to form CuCl_2^- (1-14) at low current densities and Cl^- concentrations less than $\sim 1\text{M}$. Higher complexes are formed at other current densities and concentrations (11). The dissolution to form CuCl_2^- has been found to follow Tafel-like behavior with a slope of 60 mV/decade at 25°C (1-14). The current at any potential has been found to be

strongly dependent on stirring conditions, and the dependence is roughly the square root of rotation speed for a rotating disk (7, 8, 10-13). The purpose of the present paper is to extend these measurements on electrodeposition, and to give a more complete analysis for both steady-state and impedance determinations.

Kinetics of Electrodeposition

Copper anodically dissolves in acidic chlorides by the one-electron reaction

^{*}Electrochemical Society Active Member.

¹Present address: Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, Minnesota 55455.

The cuprous species also participates in a complexation reaction, which has the equilibrium constant (15)

$$K_c = \frac{[\text{CuCl}_2^-]}{[\text{Cu}^+][\text{Cl}^-]^2} = 6.96 \times 10^4 \quad [2]$$

The current density for copper dissolution is then (16)

$$\frac{i}{F} = k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} - k_c (C_{\text{Cu}^+}^0) \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \quad [3]$$

or, with Eq. [2]

$$\frac{i}{F} = k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} - k_c \frac{C_1}{K_c (C_2^0)^2} \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \quad [4]$$

In these equations, the first term is the anodic term, the second is cathodic, and both reactions are taken to be fast, *i.e.*, both k_a and k_c , the heterogeneous rate constants, are large. The superscripts on the concentrations in the cathodic term indicate interfacial conditions ($z = 0$). C_1 is the surface concentration of CuCl_2^- , and C_2^0 that for Cl^- . α_a and α_c are the kinetic transfer coefficients for the forward and backward reactions, respectively, and are shown below to be equal to 0.5. F , R , and T have their usual significance. The potential V is the potential of the electrode with respect to the saturated calomel electrode, unless otherwise noted. This choice of a reference of potential is arbitrary, but convenient for electrodisolution measurements in solutions containing none of the product metal ion.

For zero bulk solution concentration of CuCl_2^- , and a large excess of Cl^- in solution, Eq. [4] becomes

$$\frac{i}{F} = k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} - \frac{k_c C_1^0}{K_c C_2^2} \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \quad [5]$$

The surface concentration C_1^0 at steady state is determined by the kinetics of the reactions, subtracting that which is transported into the solution by diffusion and convection. The rotating disk electrode system was chosen for the studies in this and the following paper because the mass transport can be characterized quantitatively under both steady-state and time varying conditions at the surface (17-19).

The steady flux of CuCl_2^- at the surface may be shown to be (for zero CuCl_2^- concentration in the bulk)

$$N_1 = \frac{D_1 C_1^0}{\delta} \quad [6]$$

Equation [6], along with

$$N_1 = \frac{i}{F} \quad [7]$$

may be used to eliminate C_1^0 in Eq. [5], to yield

$$\frac{i}{F} = \frac{k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\}}{\left[1 + \frac{\bar{k}}{C_2^2 \Omega^{1/2}} \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \right]} \quad [8]$$

The diffusion-layer thickness for the rotating disk, δ , in Eq. [6] is given by the relationship (17, 18)

$$\delta = 1.6117 D_1^{1/3} \nu^{1/6} \Omega^{-1/2} \quad [9]$$

where ν is the kinematic viscosity of solution, D_1 is the diffusion coefficient of CuCl_2^- , and Ω is the disk rotation rate. In Eq. [8], \bar{k} is

$$\bar{k} = \frac{k_c}{K_c} (1.6117 D_1^{-2/3} \nu^{1/6}) \quad [10]$$

Equation [8] describes the general current-voltage behavior expected for electrodisolution of copper in HCl. In the limit that the second term in the denominator of

Eq. [8] is much larger than the first

$$\frac{i}{F} = \frac{k_a C_2^2 \Omega^{1/2}}{\bar{k}} \exp \left\{ \frac{(\alpha_a + \alpha_c) F}{RT} V \right\} \quad [11]$$

The slope

$$\frac{dV}{d(\log i)} = \frac{2.303 RT}{(\alpha_a + \alpha_c) F} \quad (\text{constant rotation rate}) \quad [12]$$

is 59 mV/decade at 25°C when

$$(\alpha_a + \alpha_c) = 1 \quad [13]$$

The slope given by Eq. [12] and [13] is that found experimentally in all laboratories (1-14), including our own (to be reported below). The slope $dV/d(\log i)$ expected for the general Eq. [8] is a complex function which approaches Eq. [12] as a limiting case.

Equation [11] describes the limiting behavior when the dissolution rate is controlled by the rate at which the product species is removed from the surface by convection and diffusion. The limiting case would be expected for fast kinetics (specifically fast cathodic kinetics) and slow rates of mass transfer. Conversely, as the rotation rate of a rotating disk is increased, the dissolution rate should deviate from Eq. [11] and should follow the more general Eq. [8], where there is mixed mass-transfer-kinetic control. The mixed mass-transfer-kinetic regime for electrodisolution of Cu was investigated in this laboratory, and the results are described further below.

Bockris and Despic (20) were apparently the first to develop a relationship similar to Eq. [8], but not for a rotating disk. The same equation was derived again later (6), for discussion of the electrodisolution of Cu and Cu-Ni alloys, but it was never used. Instead, an equation similar to Eq. [11] was used under conditions of modest rates of mass transfer. Kiss *et al.* (7-8) developed Eq. [11], and, for general complexation reactions, for Cu dissolution studies on a rotating disk. Equation [11] (or an equivalent) for the rotating disk was used by all other investigators for Cu electrodisolution in chloride solutions. No one has previously investigated the mixed mass-transfer-kinetic regime for Cu dissolution.

Nobe *et al.* (11) found the dissolution current density to be proportional to the square of the chloride concentration, in agreement with Eq. [11]. At higher current densities and chloride concentrations, some deviations were observed, but these were found to be due to the formation of higher cuprous complexes or to precipitation of chloride films.

Kiss *et al.* (7, 8), Bonfiglio *et al.* (14), Nobe *et al.* (11), and Moreau (10) all found the Cu dissolution rate to be a function of rotation rate for a rotating disk. The current density was shown to be a linear function of $\Omega^{1/2}$, with $i \rightarrow 0$ as $\Omega^{1/2} \rightarrow 0$, as given by Eq. [11]. In all these studies, the mass-transfer rates were either modest (low rotation rates) or the chloride concentration was high and Eq. [11] would be expected to be a suitable approximation for mass transfer controlled dissolution.

Riddiford (21) has suggested the use of the rotating disk for the study of fast electrode reactions under mixed mass-transfer-kinetic control, but it has not been used for the study of anodic dissolution reactions. For anodic dissolution, a desirable procedure would be to use high rotation rates and zero solution concentration of the product ion. Inverting Eq. [8], one obtains

$$\frac{F}{i} = \frac{1}{k_a} \exp \left\{ \frac{-\alpha_a F}{RT} V \right\} + \frac{\bar{k}}{k_a C_2^2 \Omega^{1/2}} \exp \left\{ \frac{-(\alpha_a + \alpha_c) F}{RT} V \right\} \quad [14]$$

The reciprocal of the current density should be a linear function of $\Omega^{-1/2}$, with a finite intercept at $\Omega \rightarrow \infty$. The intercept is just the anodic contribution to the current density, evaluated in the absence of mass-transfer effects, *i.e.*

$$\lim_{\Omega \rightarrow \infty} \left(\frac{F}{i} \right) = \left(\frac{1}{k_a} \right) \exp \left\{ \frac{-\alpha_a F}{RT} V \right\} \quad [15]$$

and the slope at constant potential is

$$\frac{\partial \left(\frac{F}{i} \right)}{\partial (\Omega^{-1/2})} = \frac{\bar{k}}{k_a C_2^2} \exp \left\{ \frac{-(\alpha_a + \alpha_c) F}{RT} V \right\} \quad [16]$$

The two heterogeneous rate constants

$$k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\}$$

and

$$k_c \exp \left\{ \frac{-\alpha_c F}{RT} V \right\}$$

may be determined from Eq. [15] and [16]. The present investigation used this analysis technique with high rotation rates and low chloride concentration to enhance the influence of kinetics on the dissolution process. It should be noted that the behavior described in Eq. [15] and [16] is general and should be approached by all "mass-transport-controlled" dissolution reactions as the rotation rate is increased. In this sense, the technique of determining the rate constants by extrapolating to $\Omega \rightarrow \infty$ is general and may be applied to other situations as well. Aside from aqueous systems, the dissolution of Cr in molten $\text{AlCl}_3\text{-NaCl}$ also appears to be described by the formalism given above (22).

The exchange current density for the Cu/CuCl_2^- system is related to the heterogeneous rate constants by

$$\frac{i_0}{F(C_{\text{Cu}^+})^{\alpha_a/(\alpha_a+\alpha_c)}} = (k_a)^{\alpha_c/(\alpha_a+\alpha_c)} (k_c)^{\alpha_a/(\alpha_a+\alpha_c)} \quad [17]$$

Thus, one may obtain the quantities

$$k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} \quad \text{and} \quad k_c \exp \left\{ \frac{-\alpha_c F}{RT} V \right\}$$

as described above at any measured potential. The exchange current density, given in Eq. [17], is independent of the choice of the reference electrode, since

$$\left[k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} \right]^{\alpha_c/(\alpha_a+\alpha_c)} \times \left[k_c \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \right]^{\alpha_a/(\alpha_a+\alpha_c)} = k_a^{\alpha_c/(\alpha_a+\alpha_c)} k_c^{\alpha_a/(\alpha_a+\alpha_c)} \quad [18]$$

The measurements to be described below were analyzed to yield the exchange current density for Cu/CuCl_2^- , a fundamental kinetic parameter for the system. A procedure described earlier (6) to determine the exchange current density involved Eq. [11], and this appears to be inappropriate.

DIFA Measurements in Electrodeposition

Time varying measurements on electrodeposition supplemented the steady-state investigations. The digital impedance for faradaic analysis (DIFA) technique was described in the first paper of this series (23) and was used here for the kinetic investigation. The rotating disk was used for the impedance studies, and the time varying current (\bar{i}) and concentration gradient at the electrode surface are related by

$$\frac{\bar{i}}{F} = -D_1 \frac{\partial \bar{C}_1}{\partial z} \Big|_{z=0} \quad [19]$$

As in the previous paper, the concentration of CuCl_2^- has a steady part and a time varying component

$$C_1 = \bar{C}_1 + \tilde{C}_1 \quad [20]$$

where \tilde{C}_1 is of the form [cf. Ref. (19) and (24)]

$$\tilde{C}_1 = B \theta \exp(jt\omega) \quad [21]$$

where B is a constant, $j = \sqrt{-1}$, ω is the excitation frequency, and the function θ contains the spatial dependence of \tilde{C}_1 . Equation [19] becomes

$$\frac{\bar{i}}{F} = \frac{-D_1 \bar{C}_1}{\delta} \frac{\partial \theta}{\partial \xi} \Big|_{\xi=0} \quad [22]$$

the variable ξ is

$$\xi = z\Gamma(4/3)/\delta \quad [23]$$

and δ is given by Eq. [9]. Γ is the gamma function (31).

The faradaic impedance was given formally in the preceding paper, i.e.

$$Z_f = \left[1 + \frac{\left(\frac{\partial i}{\partial \bar{C}_1} \right) \delta}{FD_1 \theta'(0)} \right] / \left(\frac{\partial i}{\partial \bar{V}} \right)_{\bar{C}_1} \quad [24]$$

and

$$\theta'(0) = \frac{\partial \theta}{\partial \xi} \Big|_{\xi=0} \quad [25]$$

The time varying voltage and concentration are small perturbations about steady state, and the derivatives may be evaluated from the previous section. From Eq. [5]

$$\left(\frac{\partial i}{\partial \bar{C}_1} \right)_{\bar{V}} = \frac{k_c F}{K_c C_2^2} \exp \left\{ \frac{-\alpha_c F}{RT} \bar{V} \right\} \quad [26]$$

$$\left(\frac{\partial i}{\partial \bar{V}^c} \right)_{\bar{C}_1} = \frac{F^2 (\alpha_a + \alpha_c) k_a}{RT} \exp \left\{ \frac{\alpha_a F}{RT} \bar{V} \right\} - \frac{\alpha_c F^2}{RT} \left(\frac{\bar{i}}{F} \right) \quad [27]$$

where \bar{V} , \bar{C}_1 , and \bar{i} are steady-state quantities. With Eq. [26] and [27], the equation for the faradaic impedance of copper electrodisolution becomes

$$Z_f = \frac{\left[M \left\{ 1 - \frac{1}{\Gamma(4/3)(-\theta'(0))} \right\} + \frac{1}{\Gamma(4/3)(-\theta'(0))} \right]}{\frac{iA(\alpha_a + \alpha_c)F}{RT} \left[1 - \frac{\alpha_c}{(\alpha_a + \alpha_c)} M \right]} \quad [28]$$

The quantity M is the ratio

$$M = \frac{(\bar{i}/F)}{k_a \exp \left\{ \frac{\alpha_a F}{RT} \bar{V} \right\}} \quad [29]$$

which measures the steady-state current density relative to the current density extrapolated to $\Omega \rightarrow \infty$ (see Eq. [15]), and A is the area of the electrode.

The complex function $\{-1/\theta'(0)\}$ has all the frequency dependence of Z_f . This function has been discussed previously for another impedance situation (17, 24), and has the properties

$$\left. \begin{aligned} \text{Re} \left(-\frac{1}{\theta'(0)} \right) &\rightarrow \Gamma(4/3) \\ \text{Im} \left(-\frac{1}{\theta'(0)} \right) &\rightarrow 0 \end{aligned} \right\} \omega \rightarrow 0 \quad [30]$$

and

$$\left. \begin{aligned} \text{Re} \left(-\frac{1}{\theta'(0)} \right) &\rightarrow 0 \\ \text{Im} \left(-\frac{1}{\theta'(0)} \right) &\rightarrow 0 \end{aligned} \right\} \omega \rightarrow \infty \quad [31]$$

In Eq. [30] and [31], the limits are given for the real and imaginary parts, respectively. Therefore, the impedance from Eq. [28] has the limits

$$Z_f \Big|_{\omega \rightarrow 0} = \frac{RT}{\bar{i}A(\alpha_a + \alpha_c)F} \left[\frac{1}{1 - \frac{\alpha_c}{\alpha_a + \alpha_c} M} \right] \quad [32]$$

$$Z_f \Big|_{\omega \rightarrow \infty} = \frac{RT}{\bar{i}A(\alpha_a + \alpha_c)F} \left[\frac{M}{1 - \frac{\alpha_c}{\alpha_a + \alpha_c} M} \right] \quad [33]$$

In the limit of mass-transfer control, $M \rightarrow 0$, and

$$Z_f = \left(\frac{RT}{\bar{i}A(\alpha_a + \alpha_c)F} \left[\frac{1}{\Gamma(4/3)[- \theta'(0)]} \right] \right)_{M=0} \quad [34]$$

with the limits

$$Z_f \Big|_{\omega \rightarrow 0} = \left(\frac{RT}{\bar{i}A(\alpha_a + \alpha_c)F} \right)_{M=0} \quad [35]$$

$$Z_f \Big|_{\omega \rightarrow \infty} = 0 \quad (M = 0) \quad [36]$$

It will be shown below that Eq. [35] and [36] are good approximations for copper electrodisolution impedance because M is small.

The faradaic impedance of copper electrodisolution should be a function of the level of current, \bar{i} , and the ratio M , both of which are obtained from steady-state measurements. Determinations of the impedance and the steady-state quantities provide an independent check on the consistency of the measurements. The frequency dependence of the faradaic impedance is given by the convective Warburg function $\{-1/\theta'(0)\}$ discussed by Newman *et al.* (17, 24), and arises from the transport of CuCl_2^- away from the surface. At high excitation frequency ω , the magnitude of the real and imaginary parts of $\{-1/\theta'(0)\}$ are equal, in agreement with classical Warburg impedance behavior for diffusion with no convection. Convection becomes important at low excitation frequency, however, and there is deviation from the classical semi-infinite Warburg impedance to give a finite value for the real part of the impedance and zero for the imaginary part at zero frequency (see Eq. [30]). In other words, there is a steady-state flux of the diffusing species with convection because there is a steady diffusion-layer thickness. Without convection, there is no steady-state flux into an infinite medium and the diffusion boundary layer grows as \sqrt{t} .

Experimental

Both steady-state and impedance measurements of Cu electrodisolution were made. The steady measurements were more extensive, and the impedance provided an indication of consistency for the mass-transport-kinetic model derived above.

A rotating disk electrode system was used for all the determinations. The disk assembly was constructed so that the disk could be attached to the rotating shaft by a threaded mount. The shaft and attached disk had an eccentricity that was less than 0.1% of the disk diameter (19). Electrical contact to the rotating shaft was made by a silver ring-silver graphite brush assembly (Graphite Metallizing Corporation). Rotation of the shaft was controlled by a dc servo motor, and the speed was calibrated with a stroboscope. The copper rotating disk was fabricated by attaching a copper button onto a brass rod and inserting the lower end into a Teflon body with a tight press fit. The upper end of the brass shaft was threaded to mount on the rotating shaft. The lower part of the assembled electrode was immersed in the solution through a matched hole in the Teflon cover of a glass vessel in which the experiments were conducted. A Pt mesh counterelectrode was mounted in the bottom of the vessel, facing the Cu rotating disk. A reference electrode capillary was inserted through the cover and positioned just outside (5 mm) the outer Teflon edge of the rotating disk, and in the plane of the disk. Nitrogen gas was

sparged continuously through the solution during the course of the measurements.

Surface preparation of the Cu rotating disk consisted of polishing on a metallography wheel with 0.05 μm alumina in deionized water. The polishing cloth used on the wheel was extensively washed with deionized water before use, and the cloth was replaced after 3-4 h of use. The polished specimen was rinsed in deionized water and soaked in 0.1N HCl for 1-2 min, mounted on the rotating disk shaft, and immersed in the solution for measurement. The preparation technique produced a surface that gave highly reproducible results. Light etching of the Cu with dilute HNO_3 in an ultrasonic bath gave identical electrochemical behavior if the specimen was rinsed carefully in water and HCl after the etch step. Electrode area, A , equals 0.695 cm^2 .

Copper for the rotating disk electrode was OFHC rod of 99.99% purity. HCl solutions (0.1N) were prepared from ampuls available commercially for analytical standards (Baker Analyzed) and diluted to volume with freshly prepared deionized water. The water was 20 M Ω quality produced by cascaded ion-exchange beds in series with activated charcoal. The nitrogen gas used was Ultra High Purity Grade (99.999%) from Matheson.

Steady-state electrochemical measurements were performed under potentiostatic control. Current to the rotating disk was measured after steady state was achieved at each potential (~ 5 min), and the potential was changed in increments of 5 mV between measurements. Current was measured as the potential drop across a precision 10 Ω resistor in series with the electrochemical cell.

Impedance measurements were made as described in the preceding paper and as demonstrated in an earlier paper (26). A multiple frequency voltage signal from a signal generator (Hewlett-Packard 3722A Noise Generator) was superimposed on a constant control voltage at the input of the control amplifier of the potentiostat. The maximum amplitude of the voltage perturbation was 3-5 mV peak to peak, independent of the frequency range used. Each frequency range contained 51 superposed sinusoids consisting of a fundamental frequency and the next 50 harmonics (both even and odd). The voltage signal was measured between the working and reference electrode leads at the cell with a voltage follower, amplified and filtered by a differential amplifier with a low-pass filter, and digitized on one channel of a Biomation Waveform Recorder (Model 1015). The current signal was measured as the voltage drop across a precision resistor in series with the cell. The signal was also passed through a differential amplifier with a low-pass filter, and recorded on a second channel of the digitizer. The voltage and current signals were recorded simultaneously and strobed out of the waveform recorder buffer memory into the calculator-controller (Hewlett-Packard 9830B). The data were stored on a floppy disk for subsequent treatment and analysis. The data were digitized over two periods of the lowest frequency in the spectra. The higher frequencies were also periodic in this sequence length, and the sampling rate was always greater than five times the highest frequency to avoid "aliasing" (26). The total time for data taking was two times the period of fundamental frequency summed over the number of frequency ranges sampled. This was approximately 22s for the data described here. Additional time was required for manually setting up the instrumentation for each frequency range, initiating the data acquisition through software control, and strobing out the data. The total elapsed time for data acquisition was typically 1-2 min for the total of three frequency ranges (153 frequencies). The DIFA apparatus could be used for time domain averaging of multiple determinations (26), but the data reported here were from single runs.

The stored data were transmitted to a CDC 6600 computer for analysis. A fast Fourier transform (FFT) was performed on the voltage and current. The ratio of the voltage to the current at each frequency yielded the dimensionless impedance at that frequency, *i.e.*

$$\bar{Z} = \frac{\bar{V}}{I} \quad [37]$$

The dimensional impedance was calculated by the procedure introduced by Smith (28). This consists of making measurements on a "dummy cell" of precision resistors and capacitors that closely approximate values for the electrochemical cell. All amplifier gains and other instrumentation settings are then identical for the two determinations. From the known values of the "dummy cell," the theoretical impedance at each of the measured frequencies is calculated and compared to the measured dimensionless impedance of the dummy cell, *i.e.*

$$Z_{RD} = Z_{TD}/Z_D \quad [38]$$

The application of Z_{RD} to the dimensionless impedance of the electrochemical system then yields the impedance at each frequency, *i.e.*

$$Z = (\bar{Z}) Z_{RD} \quad [39]$$

The procedure amounts to a calibration of the measurement system at the measured frequencies and automatically corrects for instrumentation gain and phase-shift errors.

Results and Discussion

Results of the steady-state investigation of electrodis-solution of Cu from a rotating disk are given in Fig. 1. Also plotted therein are cathodic H_2 evolution results on the Cu electrode. Identical results in both regions were obtained with either H_2 or N_2 as the cover gas. The Tafel slope for hydrogen evolution was 110 mV/decade, in good agreement with the investigation by Bockris and Pentland (29). At cathodic current densities greater than 10 mA/cm², deviation from Tafel behavior, in large part due to ohmic drop in the solution, was observed.

Anodic current curves are shown for two rotation rates, and additional data were obtained at 2000 rpm. The Tafel-like slope was 60 mV/decade at all three rotation rates, in agreement with Eq. [12] and [13] and earlier results (1-14). This result implies that the anodic dissolution is largely mass-transport controlled at these rotation rates and $(\alpha_a + \alpha_c) = 1$. At higher current densities, ohmic drop caused deviations from the Tafel-like behavior.

To determine the influence of kinetics, the data were plotted as a function of rotation rate, as shown in Fig. 2. The data follow Eq. [14] for mass-transport-kinetic control with a finite intercept on the current axis as $\Omega \rightarrow \infty$. The same behavior was observed over the entire potential range investigated, up to current densities where ohmic drop became significant. The finite intercept in Fig. 2 provides a measurement of the anodic kinetic rate constant according to Eq. [15], and the slope is identified in Eq. [16]. The anodic term determined from the intercept

Fig. 1. Electrodissolution kinetics of a copper rotating disk in oxygen-free 0.1N HCl at 25°C.

Fig. 2. Reciprocal current density as a function of disk rotation rate

was found to be a function of potential as demonstrated in Fig. 3, where the function

$$\log \left[k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} \right]$$

is plotted *vs.* V . The straight line has a slope of 120 mV/decade, and, therefore, $\alpha_a = 0.5$. This leads to the conclusion that $\alpha_c = 0.5$ as well. The quantity $[\partial(F/i)/\partial\Omega^{-1/2}]$ in Eq. [16] was found to be a function of potential, and the data are shown in Fig. 4. The straight line has a slope of 60 mV/decade, in agreement with the finding above that $(\alpha_a + \alpha_c) = 1$.

The anodic and cathodic rate constants

Fig. 3. Anodic and cathodic rate constants as a function of applied potential.

Fig. 4. Dependence of (current-rotation rate) function on applied potential.

$$k_a \exp \left\{ \frac{\alpha_a F}{RT} V \right\} \quad \text{and} \quad k_c \exp \left\{ \frac{-\alpha_c F}{RT} V \right\}$$

respectively, were determined at several potentials from the data above and plotted in Fig. 3. The constants in \bar{k} (see Eq. [10]) were assigned the values

$$\nu = 0.89 \times 10^{-2} \text{ cm}^2/\text{s} \quad [30]$$

$$D_1 = 5.68 \times 10^{-6} \text{ cm}^2/\text{s}$$

$$K_c = 6.96 \times 10^4 \quad [15]$$

$$\Gamma(4/3) = 0.89298 \quad [31]$$

The diffusion coefficient, D_1 , was evaluated from the impedance measurements described below.

The exchange current density divided by the CuCl_2^- concentration, i.e., $i_0/C_1^{1/2}$, was calculated from Eq. [17], [18], and [2]

$$\left(\frac{i_0}{C_1^{1/2}} \right) = \frac{F k_a^{1/2} k_c^{1/2}}{K_c^{1/2} C_2} \quad [40]$$

The quantity $[i_0/C_1^{1/2}]$ was found to be independent of potential, as shown in Table I.

The results reported here are in substantial agreement with previous studies. The major contribution of the present study has been the determination of the kinetic parameters of the dissolution reaction enabled by the use of lower Cl^- concentration and higher rotation rates than used previously. The kinetic contribution, though measurable, was found to be small in the voltage ranges studied here. A measure of the kinetic contribution is given by the ratio M (see Eq. [32]). For complete control by mass transfer, $M = 0$, and departures from this limit increase as kinetics become important for anodic dissolution. The kinetic contribution is dominant as $M = 1$. In the limit of small M , the "Tafel" slope was found to be 60 mV/decade, in agreement with literature values. Even at -150 mV, where M was found to be substantially different from zero (see Table II), the Tafel slope was almost unaffected. Using Eq. [8] and the M values from Table II, the Tafel slope at -150 mV was calculated to be 66 mV/decade. One

		2000 rpm
0.130		3000 rpm

would expect to achieve full kinetic control at $M = 1$, which is equivalent to the condition

$$\left[\frac{\bar{k}}{C_2^2 \Omega^{1/2}} \right] \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \ll 1 \quad [41]$$

$$\left(\frac{k_c}{2.33} \right) \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} \ll 1 \quad [42]$$

for 1000 rpm. From Fig. 3, it can be seen that the equality

$$\left(\frac{k_c}{2.33} \right) \exp \left\{ \frac{-\alpha_c F}{RT} V \right\} = 1 \quad [43]$$

should be obeyed at about -65 mV. The inequality would then be observed at potentials more positive than approximately $+45$ mV, where the current density would be approximately 19 mA/cm^2 . The dissolution current density would be independent of rotation rate, and the Tafel slope would be 120 mV/decade. Verification of the prediction was outside the scope of the present study, but it is of interest for future study in this laboratory.

Impedance Results

The digital impedance results were found to confirm the description given above for electrodisolution of copper. The complex impedance at -205 mV is given in Fig. 5 both as a function of frequency and rotation speed. An important quantity to be derived from these measurements is the impedance at zero frequency, Z_f^0 , where the imaginary part goes to zero (Eq. [30]) and the real part becomes proportional to the steady-state dissolution current (see Eq. [32] and [35]).

The determination of the faradaic impedance was accomplished by the following procedure.

1. The ohmic solution concentration, R_s , was determined as the high frequency intercept on the real impedance axis, since R_s acts in series with the interfacial impedance. For the current voltage range studied, R_s was found to be 15Ω , and this agrees with the ohmic drop calculated for the position of the reference electrode and the solution resistivity (24).

2. R_s was vectorially subtracted from the total impedance, and the admittance/frequency, Y/ω , was calculated.

Fig. 5. Impedance of Cu electrodisolution

A plot of $Y(\text{imag.})/\omega$ vs. $Y(\text{real.})/\omega$ yielded the double-layer capacitance, CA , as the intercept on the $Y(\text{imag.})/\omega$ axis as $\omega \rightarrow \infty$. The double-layer capacitance C was calculated from the result by dividing by the area of the disk electrode. C was found to be $40\text{--}46 \times 10^{-6}$ F/cm² for all the tests.

3. Vectorial subtraction of CA from the interfacial impedance yielded the faradaic impedance for the system.

The faradaic impedance calculated as described above is plotted in Fig. 6 as $Z_f(\text{real.})$ vs. $-\omega Z_f(\text{imag.})$. A straight line was fitted to the low frequency data, and extrapolation to zero frequency gave $Z_f(\text{real.})$. The imaginary part of Z_f should be zero at zero frequency (Eq. [30]), and the real part can be related to the steady-state current density by Eq. [32] or [35], depending on the value of M . M was calculated from Eq. [32], and is given in Table III at two potentials and three rotation rates. The results compare favorably with M values determined in the steady-state measurements (Table II).

The experimental faradaic impedance was made dimensionless according to Eq. [28] with the experimental values of the current density and M . The result should be identical to the theoretical convective Warburg function $\{-1/\theta'(0)\}$. The two are compared in Fig. 7. The two agree very well. This was found to be true at all rotation rates and potentials used in the study. The agreement confirms that the faradaic impedance for Cu dissolution in HCl is given by Eq. [28].

It is noted that Eq. [28] gives the general behavior of the faradaic impedance where there is mixed kinetic and mass-transfer control of dissolution. In the limit of mass-transfer control, $M = 0$, the impedance is given by Eq. [34] with the limits given by Eq. [35] and [36]. For $M = 1$, i.e.,

kinetic control of anodic dissolution, from Ref. (28)

$$Z_f = \frac{RT}{iA\alpha_a F} \quad [44]$$

as expected.

Finally, a new technique was discovered for determination of the diffusion coefficient of CuCl_2^- from the impedance measurements. The technique involves calculation of the diffusion coefficient from the slope of the linear relationship observed between $Z_f(\text{real.})$ and $[-\omega Z_f(\text{imag.})]$ at low excitation frequencies (see Fig. 6). The linear behavior is expected from the properties of the function $\{-1/\theta'(0)\}$. Theoretical values of the real and imaginary parts of this function taken from the literature (19, 31) yield the relationship valid for Schmidt number $(\nu/D_1) \rightarrow \infty$

$$\frac{d\left[\text{Re}\left\{-\frac{1}{\theta'(0)}\right\}\right]}{d\left[\text{KIm}\left\{-\frac{1}{\theta'(0)}\right\}\right]} = -0.373 \quad [45]$$

where (23)

$$K = \omega\nu\left(\frac{3D_1}{a\nu}\right)^{2/3} (\Omega D_1)^{-1} \quad [46]$$

and a has the value 0.51023 (17, 18, 21). The experimental slope, S , is defined as

$$\frac{dZ_f(\text{real.})}{d[\omega Z_f(\text{imag.})]} = S = -0.373\left(\frac{dK}{d\omega}\right) \quad [47]$$

or

$$D_1^{1/3} = -0.373\left(\frac{3}{a}\right)^{2/3} \nu^{1/3}(S\Omega)^{-1} \quad [48]$$

Equation [48] for the diffusion coefficient is general for $(\nu/D_1) \rightarrow \infty$, and does not require knowledge of the solution

Fig. 7. Dimensionless convective Warburg impedance function compared to experimental data for Cu dissolution.

concentration C° , or the electrode area for calculation of the diffusion coefficient. For finite values of the Schmidt number, Sc , the limiting slope at low frequency is a function of Sc , and may be calculated from the results given in Ref. (19) and elsewhere (33). For example, for $Sc = 1500$, the functional relationship is obeyed

$$\frac{d \left[\operatorname{Re} \left\{ -\frac{1}{\theta'(0)} \right\} \right]}{d \left[\operatorname{KIm} \left\{ -\frac{1}{\theta'(0)} \right\} \right]} = -0.400 \quad [49]$$

Equation [48] for the diffusion coefficient becomes

$$D_1^{1/3} = -0.400(3/\alpha)^{2/3} \nu^{1/3} (S\Omega)^{-1} \quad [50]$$

for $Sc = 1500$.

D_1 was determined for several rotations rates and steady-state currents, and was found to $5.68 \times 10^{-6} \text{ cm}^2/\text{s}$. This compares favorably with values quoted in the literature (3), which were $6.2\text{--}6.6 \times 10^{-6} \text{ cm}^2/\text{s}$. It should be noted again that the calculation of the diffusion coefficient from the low frequency impedance measurements is independent of solution concentration and electrode area. The calculation is based solely on the experimental faradaic impedance and the properties of the convective Warburg impedance function $\{-1/\theta'(0)\}$ which are described in the literature. Further discussion is outside the scope of this paper, but a more detailed description of this technique for diffusion coefficient measurements will be published shortly. Some results have been discussed previously (35).

Conclusions

A theoretical model was developed for electrodisolution of Cu in 0.1N HCl solutions which were copper free. The mass-transfer-kinetic model agreed with steady-state measurements on a rotating disk. The kinetic parameters α_a , α_c , and the product $(k_a^{1/2}k_c^{1/2})$ were determined from the experimental data. The faradaic impedance for the electrodisolution was also developed for the mass-transport-kinetic model. Experimental results agreed with the theoretical development here as well, and gave confirmation to the steady-state model. The experimental impedance results, made dimensionless in an appropriate way, match the theoretical function $\{-1/\theta'(0)\}$, in agreement with the development given in the section on DIFA measurements in electrodisolution. A new technique for determination of diffusion coefficients from impedance measurements at low frequency was used to evaluate the diffusion coefficient of CuCl_2^- . The value was $5.68 \times 10^{-6} \text{ cm}^2/\text{s}$, which compares favorably with literature results.

Digital Impedance for Faradaic Analysis

III. Copper Corrosion in Oxygenated 0.1N HCl

William H. Smyrl* and Larry L. Stephenson

Sandia National Laboratories, Division 1841, Albuquerque, New Mexico 87185

ABSTRACT

Impedance measurements have been made on copper rotating disks corroding in oxygenated 0.1N HCl. A model is developed here for the first time for the faradaic impedance of a corrosion couple consisting of an anodic dissolution reaction dominated by convective diffusion and a cathodic reaction under kinetic control. The model was found to be obeyed for all values of disk rotation rate, oxygen concentration, and voltage excitation frequency. The corrosion rate was found to depend on oxygen concentration to the 2/3 power, and on rotation rate to the 1/6 power.

The corrosion of copper in aqueous acid solutions occurs on an oxide-free surface that makes it an attractive metal for generic studies. Copper corrodes slowly in acids free of oxidizing agents (1, 2), but in the presence of dissolved oxygen or other reactants the corrosion rate increases substantially, depending on the oxidation potential of the reactant, its concentration, and rate of supply to the copper surface (2-4). The acid participates in the process by stabilizing either the cuprous [Cu(I)] or cupric [Cu(II)] product ion.

In HCl solutions, the CuCl_2^- species is dominant at low concentrations of Cl^- (5), with other chloro complexes becoming important at higher chloride concentrations. Miller and Bellavance (6) investigated the corrosion of copper in oxygenated acid chloride solutions by a rotating ring-disk technique. CuCl_2^- was produced at the disk electrode and detected at the outer ring electrode. The corrosion rate was found to depend weakly on the rotation speed (see below), and was controlled by the rate of reduction of dissolved oxygen at only 5-10% of the diffusion limiting current of O_2 . These studies established that the corrosion process obeyed the principle of superposition (7, 8) for the metal dissolution and O_2 reduction. The present investigation confirmed that the system obeys the superposition principle, as described below.

The faradaic impedance of the parallel simultaneous reactions is (9)

$$\frac{1}{Z_{f,T}} = \frac{1}{Z_{f,a}} + \frac{1}{Z_{f,c}} \quad [1]$$

The reduction of oxygen has complex kinetics, and proceeds by an overall two-electron reaction to produce peroxide (10, 11) in chloride solutions. Subsequent reduction of peroxide to hydroxide or water is not important for this discussion [see Miller *et al.* (6)]. The faradaic impedance of the oxygen reduction is assumed to be given by (see below)

$$Z_{f,c} = \frac{-RT}{i_c \alpha_{oc} \text{FA}} \quad [2]$$

The impedance of the Cu dissolution reaction was shown in the preceding paper (5) to be given by

$$Z_{f,a} = \frac{\left[M \left\{ 1 - \frac{1}{\Gamma(4/3)[- \theta'(0)]} \right\} + \frac{1}{\Gamma(4/3)[- \theta'(0)]} \right]}{\frac{i_a(\alpha_{aa} + \alpha_{ac})\text{FA}}{RT} \left[1 - \frac{\alpha_{ac}}{(\alpha_{ac} + \alpha_{cc})} M \right]} \quad [3]$$

where M is the quantity (5)

$$M = \frac{\left(\frac{\bar{i}_a}{\bar{F}} \right)}{k_{aa} \exp \left\{ \frac{\alpha_{aa} \text{F} \bar{V}}{RT} \right\}} \quad [4]$$

From Eq. [1]-[3], one obtains for the corrosion couple

*Electrochemical Society Active Member.

$$\frac{1}{Z_{f,t}} = \frac{i_{\text{corr}} \text{FA}}{RT} \times \left\{ \alpha_{cc} + \frac{(\alpha_{aa} + \alpha_{ac}) \left[1 - \frac{\alpha_{ac} M}{(\alpha_{aa} + \alpha_{ac})} \right]}{\left[M \left\{ 1 - \frac{1}{\Gamma(4/3)[- \theta'(0)]} \right\} + \frac{1}{\Gamma(4/3)[- \theta'(0)]} \right]} \right\} \quad [5]$$

where

$$i_{\text{corr}} = i_a = -i_c \quad [6]$$

when the anodic dissolution reaction is completely mass-transfer controlled (5)

$$M = 0 \quad [7]$$

and Eq. [5] becomes

$$\frac{1}{Z_{f,t}} = \frac{i_{\text{corr}} \text{FA}}{RT} \{ \alpha_{cc} + (\alpha_{aa} + \alpha_{ac}) \Gamma(4/3)[- \theta'(0)] \} \quad [8]$$

Equations [5] and [8] are the fundamental relationships between copper corrosion current density and measured impedance. The oxygen concentration in solution and the copper disk rotation rate influence the corrosion rate and will be discussed below. It should be emphasized that Eq. [5] and [8] are specific to an anodic reaction which is influenced by mass-transport coupled to a cathodic reaction which is kinetically controlled. The treatment here is the first for a corrosion system of this type, but other systems may exhibit the behavior described here as well. One might expect, for example, that the behavior shown here will be obeyed for molten salt systems where many anodic dissolution reactions are known to be mass-transfer-kinetic controlled.

It will be demonstrated in this paper that the corrosion rates measured by weight loss, by prediction from deaerated solution currents at the same potential, and by direct impedance measurement agree very well. The corrosion rate will also be reported as a function of dissolved oxygen concentration and rotation rate of the corroding copper disk. It will be shown that this agrees with the behavior predicted from the kinetics of the reactions. Both steady-state and impedance results will be reported. Preliminary results were published earlier (8, 12).

Experimental

Copper for the rotating disk electrodes was OFHC rod, of 99.99% purity. Copper foil for the weight loss experiments was 99.999% purity. HCl solutions (0.1N) were prepared from ampuls available commercially for analytical standards (Baker Analyzed) and diluted to volume with freshly prepared deionized water. The water was 18-20 MΩ quality produced by cascaded ion exchange beds in series with activated charcoal. Gases used were Ultra High Purity Grade (99.999%) from Matheson.

The analysis of dissolved oxygen concentration was done by a specific oxygen electrode assembly. O_2 concentrations obtained by analysis were in excellent agree-

ment with those calculated from the gaseous O₂ partial pressure with Henry's law (13). Copper concentration in solution from the foil corrosion tests was determined with a specific copper electrode and confirmed by emission spectroscopy.

The rotating disk assembly was described in the preceding paper (5). As before, gas was sparged continuously through the solution during the course of the measurements. The copper disk was prepared as before (5).

Weight loss measurements were conducted on copper foils of 100 cm² surface area. Experiments were performed either at constant-potential (no O₂ in solution) or at open-circuit corrosion conditions (with dissolved O₂). The constant-potential measurements were made at the same potentials as were observed for the corrosion tests. The rectangular-shaped Cu foil was surrounded on both sides with a Pt screen, with a Teflon screen separating the two. Gas was sparged through the solution during the measurements. The experimental arrangement made it possible to conduct the dissolution and corrosion tests under identical conditions of dissolution distribution and solution convection. The solution volume was 295 ml.

The foils were degreased with methyl ethyl ketone and acetone, lightly etched in air-saturated HCl in an ultrasonic bath, rinsed in deionized water and acetone sequentially in the ultrasonic bath, and air dried to constant weight (~10 min). After a dissolution of corrosion experiment, the foil was again rinsed in water and acetone and air dried. Repeated measurements showed the weights to be good to $\pm 1 \times 10^{-3}$ g.

Impedance measurements were made with the apparatus described earlier (5, 9), over the frequency range 0.1-500 Hz. The measurements were performed under potentiostatic conditions at the corrosion potential. The copper disk was immersed in the solution after polishing. The measurements after 10 and 30 min were identical to the 2 min measurements. One set of data in each frequency range (*i.e.*, 0.1-5, 1-50, and 10-500 Hz) was taken in approximately 1 min elapsed time. The actual data collection required 12s, with the remaining time being required to change manual settings on amplifiers, signal generator, and digitizer.

Results and Discussions

The results of the Cu foil experiments are summarized in Table I. The agreement is excellent between the weight loss and solution analysis in O₂-saturated 0.1N HCl, on one hand, and the current density measured in deaerated solution, on the other hand. This agreement confirms that superposition is obeyed for the Cu/O₂ corrosion system in HCl. The rate of corrosion was found to be at ~10% of the O₂ diffusion-limited current density, so we assume that O₂ reduction was under kinetic control. The reduction, when coupled with Cu dissolution, gave a corrosion system which was used as a model for impedance studies.

The impedance measurements on the Cu rotating disk were made in the frequency range 10⁻¹-500 Hz, at disk rotation rates of 700, 1000, 2000, and 3000 rpm, respectively,

Table I. Results of the Cu foil experiments

	Calculated rate Cu dissolution (g/s-cm ²)	Calculated current density (A/cm ²)
100% O ₂ -saturated 0.1N HCl		
Weight loss	$2.29 (\pm 0.04) \times 10^{-7}$	3.49×10^{-4}
Solution analysis	$2.37 (\pm 0.16) \times 10^{-7}$	3.60×10^{-4}
	Potential (vs. SCE) (mV)	Measured current density (A/cm ²)
Deaerated 0.1N HCl	-54	3.5×10^{-4}
	-58	3.1×10^{-4}

and for dissolved oxygen concentrations of from 3.2 to 33.5 ppm. All measurements were made under potentiostatic control at the corrosion potential.

In Fig. 1 are plotted the results of impedance measurements at three different rotation rates and an oxygen concentration of 33.5 ppm. The results at other oxygen concentrations were similar. At low excitation frequencies, the impedance was found to depend strongly on rotation rate as shown, but at high frequency the curves coincide, as expected for a diffusion-dominated process (Cu dissolution). That is, for values of $(\omega/\Omega) > 0.6$, the real and imaginary parts of the impedance are of equal magnitude (this is strictly true only for the convective Warburg part of the interfacial impedance).

The impedance data at each rotation rate and oxygen concentration were analyzed to determine the corrosion rate. As shown above, it is necessary to extrapolate the measured impedance to zero frequency to determine the steady-state corrosion rate. For the present system, the extrapolation was straightforward and unequivocal because the reactions (kinetics) and processes (mass transfer) were successfully modeled and obeyed Eq. [5] (see also Eq. [8]). Accounting for all reactions and processes was necessary before the extrapolation could be performed with any confidence. For systems more complex than copper corrosion in oxygenated solutions, the reactions modeling may not be unequivocal and the impedance information will not give a unique determination of rate parameters. The data treatment is described further below, and will be the subject of work to be reported elsewhere.

In the limit of zero frequency, Eq. [5] yields

$$\frac{1}{Z_{f,t}} \Big|_{\omega \rightarrow 0} = \frac{i_{\text{corr}}FA}{RT} \left\{ \alpha_{\text{cc}} + (\alpha_{\text{aa}} + \alpha_{\text{ac}}) \left[1 - \frac{\alpha_{\text{ac}}M}{(\alpha_{\text{aa}} + \alpha_{\text{ac}})} \right] \right\} \quad [9]$$

For the additional condition, $M = 0$ (see Eq. [8])

$$\frac{1}{Z_{f,t}} \Big|_{\substack{\omega \rightarrow 0 \\ M \rightarrow 0}} = \frac{i_{\text{corr}}FA}{RT} (\alpha_{\text{aa}} + \alpha_{\text{ac}} + \alpha_{\text{cc}}) \quad [10]$$

Thus, some knowledge of the magnitude of M and the values of the kinetic transfer coefficients α_{aa} , α_{ac} , α_{cc} is required in order to determine the corrosion rate from the limiting impedance. For the copper dissolution reaction studies in the previous paper (5), α_{aa} and α_{ac} are both equal to 0.5. For the present paper, the cathodic transfer coefficient for oxygen reduction, α_{cc} , is assumed to be 0.5. It will be shown below that the data are satisfactorily represented by Eq. [10], where $M = 0$.

The extrapolation to zero frequency is performed as in the previous paper (5), *i.e.*, by noting that the total impedance obeys the empirical relationship

$$\frac{dZ_{\tau}(\text{real})}{-d[\omega Z_{\tau}(\text{imag.})]} \Big|_{\omega \rightarrow 0} = \text{const.} \quad [11]$$

Fig. 1. Impedance of copper rotating disk at three rotation rates and 33.5 ppm dissolved oxygen.

The linear behavior is shown in Fig. 2 for one particular rotation rate and oxygen concentration. A linear relationship would yield

$$\frac{dZ_T(\text{real})}{-d[\omega Z_T(\text{imag.})]} = \frac{dZ_{i,T}(\text{real})}{-d[\omega Z_{i,T}(\text{imag.})]} \quad [12]$$

and the total impedance and the interfacial impedance would be identical except for the (constant) solution resistance, i.e.

$$Z_T = Z_s + Z_{i,T} \quad [13]$$

Further, we have assumed that the interfacial impedance is composed of a double-layer capacitance (CA) in parallel with the faradaic impedance given by Eq. [5] or [8]. Therefore

$$A_{i,T}(\text{real}) = Z'_{i,T} = \frac{([Z_{i,T}(\text{real})]^2 + [Z_{i,T}(\text{imag.})]^2) Z_{i,T}(\text{real})}{[Z_{i,T}(\text{real})]^2 + \{\omega CA([Z_{i,T}(\text{real})]^2 + [Z_{i,T}(\text{imag.})]^2) - Z_{i,T}(\text{imag.})\}^2} \quad [14]$$

$$Z_{i,T}(\text{imag.}) = Z''_{i,T} = \frac{-j[\omega CA\{[Z_{i,T}(\text{real})]^2 + [Z_{i,T}(\text{imag.})]^2\} - Z_{i,T}(\text{imag.})]}{[Z_{i,T}(\text{real})]^2 + \{\omega CA([Z_{i,T}(\text{real})]^2 + [Z_{i,T}(\text{imag.})]^2) - Z_{i,T}(\text{imag.})\}^2} \quad [15]$$

and as $\omega \rightarrow 0$

$$|\omega CA([Z_{i,T}(\text{real})]^2 + [Z_{i,T}(\text{imag.})]^2)| \ll |Z_{i,T}(\text{imag.})| \quad [16]$$

so that

$$\left. \frac{dZ'}{-d(\omega Z'')} \right|_{\omega \rightarrow 0} = \left. \frac{dZ_{i,T}(\text{real})}{-d[\omega Z_{i,T}(\text{imag.})]} \right|_{\omega \rightarrow 0} \quad [17]$$

It may be shown

$$\left. \frac{dZ_{i,T}(\text{real})}{-d[\omega Z_{i,T}(\text{imag.})]} \right|_{\omega \rightarrow 0} = \frac{d\text{Re} \left[-\frac{1}{\theta'(0)} \right]}{-d \left[\omega I_m \left(-\frac{1}{\theta'(0)} \right) \right]} + 0(\omega) \quad [18]$$

and this is the basis for the linear behavior in Fig. 2 at low frequencies. The last term in Eq. [18] denotes the order of magnitude of terms which are negligible compared to the first term at low frequencies. Further discussions of the linear behavior at low frequencies will be given elsewhere.

Both Eq. [9] and [1] were used to determine the corrosion rate from the measured impedance. For the corrosion potentials observed here, the value of $M(5)$ was always of the order of 0.1 or less. The maximum contribution from the last term in Eq. [9] was thus less than or equal to 5% of the dominant contribution, and Eq. [10] was then used to analyze the data since the experimental uncertainty was larger than this.

Table II contains the results of several determinations of the corrosion rate at 1000 rpm and 33.5 ppm O_2 . Also

Fig. 2. Faradaic impedance plotted to display the linear behavior low frequency.

Table II. Corrosion rate from DIFA measurement compared to dissolution rate in deaerated 0.1M HCl solutions. 1000 rpm, 33.5 ppm O_2 (100%)

Corrosion potential (mV vs. SCE)	Corrosion rate from DIFA (A/cm ²)	Current density deaerated solution (A/cm ²)
-190	1.64	1.8
-195	1.45-1.48 × 10 ⁻⁵	1.5-1.52 × 10 ⁻⁵
-200	1.39-1.43	1.24-1.25
Avg.	1.45 (±0.06) × 10 ⁻⁵	1.394 (±0.16) × 10 ⁻⁵

given are the corrosion potential of each run and the corrosion current calculated from this potential and the results from the previous paper for deaerated solutions. The corrosion currents show satisfactory agreement, confirming that superposition was obeyed for the kinetics. Results at other oxygen concentrations and rotation rates are plotted in Fig. 3 and 4. The uncertainty bars shown in the figures are the result of different corrosion rates for different runs, even though the rotation rate and oxygen concentration were closely controlled at the values shown. The corrosion potential also varied, but the corrosion current always agreed closely with the deaerated solution results. We conclude that most of the data scatter in Fig. 3 and 4 was caused by variations of the oxygen re-

Fig. 3. Corrosion current density of copper in oxygenated 0.1N HCl at several rotation rates, 25°C.

Fig. 4. Corrosion current density of copper in oxygenated 0.1N HCl as a function of disk rotation rate.

duction reaction rate. It was outside the scope of the investigation to pursue the matter further.

In Fig. 3, $\log i_{\text{corr}}$ vs. \log oxygen concentration, C_o^∞ , have a slope of 2/3 for the 1000 and 3000 rpm data, respectively. These curves reflect the assumptions already described above. That is, when oxygen reduction kinetics are irreversible, and first order in oxygen concentration, one has the relationship for the cathodic current

$$\frac{i_{\text{cc}}}{2F} = -k_{\text{cc}}C_o^\infty \exp\left[\frac{-\alpha_{\text{cc}}F}{RT}V\right] \quad [19]$$

Here, C_o^∞ is the dissolved oxygen concentration and k_{cc} is the rate constant for the reduction of oxygen. This may be an oversimplification of the oxygen reduction reaction [see, for example, Ref. (8, 9)], but the data were satisfactorily represented with this assumption. Therefore, Eq. [19] will be adopted for the remainder of the discussion. Equation [19] yields then the expression for the corrosion current density (5)

$$i_{\text{corr}} = \left(\frac{k_{\text{aa}}K_c}{k_{\text{ac}}}\right)\left(\frac{D_1C_{\text{Cl}^{-2}}}{\delta}\right)^{\frac{(\alpha_{\text{aa}} + \alpha_{\text{ac}})}{(\alpha_{\text{aa}} + \alpha_{\text{ac}} + \alpha_{\text{cc}})}} \left\{\frac{2k_{\text{ac}}k_{\text{cc}}C_o^\infty}{k_{\text{aa}}}\left(\frac{\delta}{D_1K_cC_{\text{Cl}^{-2}}}\right)\right\} \quad [20]$$

Since

$$\alpha_{\text{aa}} = \alpha_{\text{ac}} = \alpha_{\text{cc}} = 0.5 \quad [21]$$

i_{corr} is proportional to $(C_o^\infty)^{2/3}$, as is shown by the data in Fig. 3. It is clear that this relationship provides a satisfactory fit to the experimental data. Other powers of C_o^∞ would also fit the data, within some narrow limits, but the simple model adopted above has been preferred here.

Equation [20] was also used to fit the data in Fig. 4 for the dependence of the corrosion current on disk rotation rate. The dependence is quite weak, as was noted earlier by Miller and Bellavance (6). For the assumptions in Eq. [21] and the definition for the diffusion layer thickness from the previous paper (5)

$$i_{\text{corr}} \text{ proportional to } (\Omega)^{1/6} \quad [22]$$

The lines in Fig. 4 were drawn to obey this relationship. Again, the fit to the experimental data is satisfactory. As a final note, it was found that expression [22] also fits the earlier data of the Miller and Bellavance (6) satisfactorily.

One may derive the corrosion potential of the couple as a function of oxygen concentration and disk rotation rate as well. From Eq. [12] of the previous paper (5) and Eq. [20] above (both for $M = 0$), it may be shown that the corrosion potential V^* is given by

$$V^* = \frac{RT}{(\alpha_{\text{aa}} + \alpha_{\text{ac}} + \alpha_{\text{cc}})F} \ln \left\{ \left(\frac{3.2234k_{\text{ac}}k_{\text{cc}}}{k_{\text{aa}}K_c} \right) \left(\frac{C_o^\infty}{\Omega^{1/2}} \right) D^{-2/3}\nu^{1/6}C_{\text{Cl}^{-2}} \right\} \quad [23]$$

In Fig. 5, the quantity $C_o^\infty/\Omega^{1/2}$ is plotted vs. V^* in a semi-logarithmic fashion. The line has a slope of 39.4 mV/decade, i.e.

$$\frac{RT(2.303)}{(\alpha_{\text{aa}} + \alpha_{\text{ac}} + \alpha_{\text{cc}})F} = 39.4 \text{ mV} \quad [24]$$

for 25°C and the α values from Eq. [21]. The line fits the experimental data for all values of C_o^∞ and Ω . C_o^∞ represents the contribution from the dissolved oxygen concentration, and $\Omega^{-1/2}$ comes from the copper dissolution rate dependence on the disk-rotation rate.

Conclusions

It is concluded that impedance measurements by DIFA gave excellent results for the corrosion rates of copper in oxygenated 0.1N HCl. The steady-state corrosion rates were calculated from the straightforward zero frequency

Fig. 5. Dependence of corrosion potential on dissolved oxygen concentration and disk rotation rate.

extrapolation of the impedance, a procedure which was justified by modeling the coupled kinetic processes. The experimental corrosion rate results were consistent with the model, and were found to depend on oxygen concentration and rotation rate as $(C_o^\infty)^{2/3}$ and $(\Omega)^{1/6}$. The observed corrosion potential was also derived and was found to depend on these variables as $\ln C_o^\infty/\Omega^{1/2}$. The model of an anodic dissolution reaction, dominated by convective diffusion, and coupled with a kinetically controlled cathodic reaction, may also be applicable to a wide range of metals in molten salt corrosion systems. The analysis of the impedance will largely follow that described here for the first time, and DIFA measurements will be very useful for these systems as well.

From Eq. [8] and [10]

$$\frac{Z_{f,T}}{\bar{Z}_{f,T}} \left[\frac{\alpha_{\text{aa}} + \alpha_{\text{ac}}}{\alpha_{\text{aa}} + \alpha_{\text{ac}} + \alpha_{\text{cc}}} \right] = \frac{1}{1 - \frac{Z_{f,T}}{\bar{Z}_{f,T}} \left[\frac{\alpha_{\text{cc}}}{\alpha_{\text{aa}} + \alpha_{\text{ac}} + \alpha_{\text{cc}}} \right]} = \frac{1}{\Gamma(4/3)[- \theta'(0)]} \quad [25]$$

where

$$\bar{Z}_{f,T} = Z_{f,t} \Big|_{\substack{\omega \rightarrow 0 \\ M \rightarrow 0}} \quad [26]$$

Thus, the faradaic impedance of the corrosion system when made dimensionless at each frequency by dividing by $\bar{Z}_{f,T}$, and arranged as in Eq. [25], should be identical to the convective Warburg impedance function (5). Further, one single curve, the convection Warburg impedance function curve, should fit the data for all rotation rates and oxygen concentrations. As in the previous paper (5), the solution resistance and double-layer capacitance were subtracted vectorially from the total impedance to yield the faradaic impedance for the corrosion couple. Figure 6 verifies Eq. [25] for the faradaic impedance at one of the rotation rates shown in Fig. 1. All other data were found to fall on the same curve as well at all voltage excitation frequencies. The double-layer capacitance used to fit the data at all frequencies was found to be 40-42 $\mu\text{F}/\text{cm}^2$, as found in the previous paper (5).

The general use of impedance measurements in corrosion systems will be most productive for those cases which resemble the simple system studied here and for the study of transient corrosion processes. In the first case, the ability to extrapolate to zero frequency with confidence and to fit the impedance data at all frequencies enables one to determine all the system properties that are important. The multiple-frequency determination of system properties will be greatly facilitated by experimental equipment such as the array-processor-enhanced DIFA system developed at our laboratory (14). Multiple-frequency modeling by digital signal analysis adaptive

Fig. 6. Impedance of copper rotating disk at three rotation rates and 33.5 ppm dissolved oxygen.

filter procedures have been described in the literature (15, 16) for electrical engineering applications. This procedure improves on the use of "limiting behavior" for characterizing system properties, and gives the best fit to the data at all frequencies.

Crystalline Anodic Oxide Growth on Aluminum Foil in an Aqueous Ammonium Dihydrogen Phosphate Anodization Electrolyte

C. T. Chen* and G. A. Hutchins

Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

The parameters affecting the growth of small crystallites within the anodic oxide film formed on aluminum during anodization in an 85°C aqueous ammonium dihydrogen phosphate electrolyte have been investigated. The degree of crystallinity of the anodic oxide was observed to increase with decreasing anodization current density and increasing voltage. The more crystalline films had a higher capacitance, were thinner, and contained less phosphorus than largely amorphous films anodized to the same voltage. A short thermal treatment of the aluminum foil at 600°C produced tiny platelets of γ - Al_2O_3 , which acted as effective nucleation sites for the growth of crystalline anodic oxide. Nucleation of crystalline anodic oxide also occurred on electropolished foil; however, the deposition of a thin amorphous oxide film on the electropolished aluminum prevented crystal growth during subsequent anodization. The crystalline anodic oxide has the γ - Al_2O_3 crystal structure and shows a strong preferred orientation related to the orientation of the aluminum substrate. A much smaller number of crystal growth sites was observed in the anodic oxide grown on (100) aluminum grains than in the oxide grown on any other substrate orientation.

The growth of crystalline aluminum oxide on aluminum foil during anodization has been discussed in numerous technical papers. In one commercial process, the aluminum foil is reacted with hot water for several minutes to form a layer of pseudoboehmite (γ' - $\text{Al}(\text{OH})_3$) containing excess water (1, 2). The barrier oxide formed during subsequent anodization is mostly crystalline γ' - Al_2O_3 and results in part from field-assisted dehydration of the hydrous oxide (2-5). The capacitance of the crystalline barrier oxide formed after hydration is greater than that of a largely amorphous oxide formed at the same anodization voltage without the hydration layer. The capacitance increase has been attributed to the greater density and field strength of the crystalline oxide (3, 6), and the practical advantage was recognized long before the structure

of the oxide was fully analyzed (7, 8). The crystalline composite oxide grown by this method exhibits an electrical instability which has been related to the presence of voids (6, 9, 10) and/or trapped oxygen (5, 11). This instability may be corrected by a relaxation or depolarization step followed by reanodization (3, 10).

Since the hydration in hot water smooths the etch structure of capacitor foil, and since the hydrous oxide remaining after anodization has a tendency to plug fine pores, the process described above is suitable only for high voltage foil with a coarse etch structure. It has recently been discovered that an increase in capacitance may also be achieved by a short thermal oxidation prior to anodization (12), and that this capacitance increase is due to the growth of crystalline anodic oxide (13-15). The thermal oxide developed can be very thin (< 10 nm) and

* Electrochemical Society Active Member.

still be effective; this treatment is therefore preferable for low voltage foil with a fine etch structure.

It has been suspected that tiny crystallites of thermal oxide formed during heat-treatment provide effective nucleation sites for crystalline anodic oxide growth (14). The existence of crystalline nuclei in thin thermal films is shown in this paper (Fig. 4); however, it is also found that nucleation of crystalline anodic oxide can occur on electropolished foil without thermal treatment (16). Growth of crystalline anodic oxide on foils with or without thermal treatment occurs most easily in aqueous solutions of organic acids or their salts such as ammonium citrate (15), ammonium pentaborate (13), or boric acid (17). In a phosphate electrolyte, crystalline anodic oxide growth is considerably more sluggish, possibly because the presence of incorporated phosphate inhibits crystallization (15).

We have observed that crystalline oxide grows slowly on electropolished foil and somewhat more rapidly on electropolished foil with thermal treatment during anodization at 85°C in an aqueous electrolyte containing 1 g/liter ammonium dihydrogen phosphate (ADP). Our primary interest has been to investigate the dynamics of crystal growth in anodic oxide. We report here on some of the parameters that effect the extent of crystal growth during anodization in an aqueous phosphate electrolyte. The relationships between degree of crystallinity, capacitance, field strength, oxide uniformity, and phosphate concentration are also explored.

Experimental Procedure

Specimens 100 cm² in area were cut from 100 μm thick, O-temper, 99.99% Al capacitor grade foil from the Aluminum Company of America (Alcoa). This foil exhibited a typical [100] rolling texture, and only approximately 5% of the foil grains were oriented with the (100) plane parallel to the foil surface. In addition to the predominant (110) orientation, (111), (311), and occasionally higher index planes were present parallel to the foil surface. For purpose of comparison, a few experiments were carried out with 100 μm thick, 99.99% Al high cubicity aluminum foil from Showa Aluminum Corporation (Showa). For this foil, approximately 85% of the area was oriented with the (100) plane parallel to the surface. For both foils, the grains were typically 100-400 μm in diameter and extended through the foil thickness. All foil specimens were electropolished in perchloric acid and acetic anhydride at 25°C with a current density of 10 mA/cm². Selected specimens were heated in air at 600°C prior to anodization.

The aluminum specimens were anodized between two 100 cm² platinum counterelectrodes suspended from a Teflon head. The electrolyte contained 1 g/liter ammonium dihydrogen phosphate in water and was held at 85°C during most anodizations. For comparison, a few specimens were anodized in the same electrolyte at 30°C. A constant current was passed until the potential difference between the aluminum and the platinum reached the preset anodization voltage; after this, the current was permitted to decay to a desired value. The anodization current was recorded on a Houston 2000 X-t recorder during the anodization process, and the total charge was obtained by graphical integration. Capacitance values in a 50 Ω-cm aqueous ammonium borate solution were measured at 120 Hz in a Pyrex cell with platinized platinum counterelectrodes using a General Radio 1657 RLC Digibridge. Measurements for repetitive specimens indicate a reproducibility within ±1% for both the charge and the capacitance measurements. All listed values are averages of two or more individual determinations.

Relative concentrations of phosphorus and oxygen were measured with an Applied Research Laboratories SEMQ electron probe microanalyzer equipped with wavelength dispersive spectrometers. During each individual measurement, a 1 μm diam, 10 keV electron beam was rastered over a 25 × 25 μm area on the oxide surface. For all specimens, the electron beam penetrated through the anodic oxide film into the aluminum substrate; x-rays were produced within both the film and the substrate

down to a total depth of approximately 0.6 μm. Since P and O were present only in the film, the P Kα and O Kα intensities increased with the mass thickness (micrograms/square centimeter) of the anodic oxide.

The oxygen intensity can be used as a measurement of the relative mass thickness of the oxide film provided the oxygen concentration of the anodic oxide does not vary greatly with the anodization conditions. This was considered to be a valid assumption even though differences in the amount of phosphate present would cause small changes in the oxygen content. Both P Kα and O Kα measurements were standardized to the intensity measured on a specific foil that was not thermally treated and was anodized to 180V with a current density of 3 mA/cm². The measured values are given here as ratios to facilitate comparison between specimens. All listed P and O values are an average of eight or more measurements at different locations on the specimen and are reproducible within ±0.01.

Specimens for transmission electron microscopy and selected area electron diffraction were prepared by dissolution of the aluminum substrate in a warm solution of bromine in methanol. For the very fragile thermal oxide films, a modified dissolution technique was used which resulted in very small holes in the foil which were bridged on one side by the thermal oxide film. The surrounding aluminum foil acted as a support and allowed the thermal oxide to be examined at high resolution without a carbon support film. All micrographs and diffraction patterns were taken in a Hitachi HU-125 transmission microscope operated at 100 keV.

Results and Interpretation

Effect of current density—thermally treated foils.—Electropolished Alcoa foil specimens which had been heated for 2 min at 600°C were anodized in the aqueous ADP electrolyte. Several different values for the anodization current density were used to study the effect on capacitance and anodization charge. The experimental results are listed in Table I, and they clearly show an increase in capacitance as the current density is decreased. The total anodization charge and the weight of the oxide decrease with decreasing current density. The relative phosphorus values decrease faster than the relative oxygen values, but a considerable phosphorus concentration is present in all of the specimens.

The 180V anodic oxide which grew on (100) grains of the aluminum substrate is thicker than the oxide which grew on other orientations of the same substrate. The (100) substrate areas could be distinguished easily with light microscopy due to their slightly different interference color; they were measured separately during the microprobe measurements, as indicated in Table I. Much smaller differences between the anodic oxides grown on the other substrate orientations were noted, but these small differences were not investigated systematically.

The transmission electron micrographs in Fig. 1 correspond to the isolated oxide films of samples I-1 and I-3. The upper half of each micrograph shows the less crystalline dielectric grown on the (100) substrate orientation; the lower half of each micrograph shows a more crystalline dielectric grown on a different crystallographic orientation of the foil. The relatively large dark areas, prevalent especially in the upper half of Fig. 1A, represent regions of thicker, amorphous oxide. The bright areas contain large numbers of γ'-Al₂O₃ crystallites embedded in amorphous oxide. The crystal structure is more fully developed in the micrograph of Fig. 1B than in that of Fig. 1A. This is fairly obvious in the upper (100) substrate area of the micrographs, but is not as clearly visible in the lower non-(100) substrate areas.

A more quantitative measure of the depth development of the crystal structure in the non-(100) substrate areas may be obtained by a measurement of the remaining film thickness after most of the amorphous oxide has been stripped off in a solution of 5% H₃PO₄ and 2% CrO₃. This solution will remove amorphous oxide at a rapid rate with

essentially no attack of the crystalline oxide (18). For the 180V anodic oxides, most of the amorphous oxide has been removed after a 2 min stripping time in the boiling solution. The average thickness of the remaining film can be determined with the electron probe measurement of the oxygen intensity. Table II gives the weight fraction of the original anodic oxide thickness remaining as a function of stripping time for three of the specimens from Table I. The other specimens follow a similar trend, and it may be concluded that a decrease in the anodization current density produces an increase in the weight fraction of crystalline oxide in the resulting anodic oxide film.

Figure 2 shows an area of the isolated oxide from specimen I-6 grown on a (110) substrate orientation. Crystalline oxide growth decreases markedly with decreasing anodi-

zation voltage and this 60V dielectric shows a much lower degree of crystallinity than the 180V oxides. The structure consists of relatively large amorphous patches (dark gray) and brighter clusters of crystals and voids. The partly crystalline areas of the anodic oxide permit a greater field strength during anodization and are therefore thinner and appear brighter in the image. The small fuzzy black structures are the result of selective diffraction of the transmitted electron beam by specific crystallites. As the plane of the specimen is tilted slightly, different crystallites will show this diffraction contrast effect, which is also visible in Fig. 1.

An electron diffraction pattern of specimen I-6 is shown in Fig. 3. The oxide area selected for the diffraction pattern grew on a (111) grain of the aluminum foil; the six

strong arcs at the 220 positions are indicative of a pronounced (111) preferred orientation. Diffraction patterns for oxide grown on a (110) substrate show a (110) preferred orientation, while the diffraction patterns for oxide grown on a (100) substrate are weak and fairly random.

The crystal structure of the anodically grown crystalline oxide is a less ordered form of the thermally grown $\gamma-Al_2O_3$ and has been designated as $\gamma'-Al_2O_3$ in the literature (17, 19, 20). Both structures have a close-packed oxygen lattice; the differences lie in the greater or lesser degree of order in the positions of the aluminum atoms. All diffraction patterns examined corresponded to the $\gamma'-Al_2O_3$ structure; no evidence was seen of the additional diffraction lines present in the more highly ordered $\gamma-Al_2O_3$.

Microstructure of thermal oxide films.—During the short thermal treatment at 600°C, tiny crystallites of $\gamma-Al_2O_3$ are formed and grow into the aluminum metal. We believe that these thermal oxide crystallites are the nucleation sites for the anodic oxide crystal clusters seen in Fig. 1 and Fig. 2, and have therefore studied them in some detail. Micrographs of the isolated thermal oxide formed during oxidation times of 1 and 3 min at 600°C are shown in Fig. 4. The continuous film consists of the oxide originally present on the electropolished foil plus the amorphous oxide formed during heating. The overall

Fig. 3. Selected area transmission electron diffraction pattern of isolated 60V oxide grown on (111) substrate orientation.

“orange peel” structure is related to the topography of the electropolished foil, rather than to differences in oxide thickness (21). The specimens were tilted slightly to maximize topography and thickness contrast. In Fig. 4, a few of the well-developed thermal oxide crystallites are indicated by arrows; they are typically 10 nm wide after 1 min at 600°C and 40 nm wide after 3 min at 600°C. The small spots (circles) may be either crystallites at an early

stage of growth or flaws in the thermal oxide. Very few of these small structures were observed on foils without thermal treatment. Transmission electron diffraction patterns of specimens similar to that shown in Fig. 4B typically consisted of sharp spots which could be indexed to correspond to the (110), (111), and (311) planes of γ - Al_2O_3 .

These results are in general agreement with studies of crystalline thermal oxide growth reported in the literature. Previous work has been limited to very low oxygen partial pressures (22-24), or to relatively thick oxide films (21, 25-28). However, the morphologies observed for the early stages of the very rapid nonequilibrium growth in the present study were not markedly different from those observed for the very slow growth at low oxygen partial pressure within an electron microscope (22, 23).

Anodization of electropolished foil.—Specimens of electropolished Alcoa foil without thermal treatment were anodized at different values of the anodization current density. The experimental measurements on these anodic oxides are given in Table III. The capacitance of the dielectric films also increased with decreasing anodization current density, although the capacitance values were not as high as those of corresponding thermally treated specimens. Furthermore, the anodization charge, the phosphorus concentration, and the oxide thickness again decreased with decreasing current density. The transmission electron micrographs of these specimens show an increasing number of γ '- Al_2O_3 crystallites in the anodic oxide as the anodization current density is decreased. The principal differences between the micrographs of these specimens and the corresponding thermally treated specimens anodized at the same current density appear to be related to the number of nucleation sites for crystalline anodic oxide formation. For anodizations at relatively high current density, the anodic oxides grown on thermally treated foils tend to be more uniform with more fully developed crystal clusters, while the untreated specimens contain relatively large patches of amorphous oxide.

Electron diffraction patterns of the anodic oxide formed on electropolished foil without thermal treatment also show a preferred orientation related to the crystallographic orientation of the aluminum substrate. However,

the patterns are much weaker than for thermally treated foils and little crystallinity is observed for (100) substrate areas on the untreated Alcoa foils.

Effect of substrate orientation and anodization temperature.—For the Alcoa foils used in this investigation, the (100) grains comprised only approximately 5% of the total surface area. We observed that the difference in thickness and microstructure between the anodic oxide grown on (100) and non-(100) substrate areas was most pronounced near the grain boundaries of relatively small (100) grains which were totally surrounded by non-(100) grains. This led us to the investigation of anodic oxides grown on high cubicity Showa foil for which approximately 85% of the grains were of the (100) orientation and non-(100) grains were in the minority.

The first four entries in Table IV give data for anodic oxides grown under identical conditions on Alcoa and Showa foils with and without a thermal treatment. A comparison of specimens IV-1 and IV-2 is of particular interest because it indicates that the substrate orientation effect of a particular grain may be modified considerably by the orientation of the surrounding grains. The anodic oxide grown on (100) substrate areas is thicker than the anodic oxide grown on non-(100) substrate areas for both foils, but the corresponding measured oxygen intensity values are very different. For each foil, the thickness of the anodic oxide grown on the majority of the grains approaches an average value, while the substrate effect for oxide grown on the differently oriented grains is enhanced. Thus, the "thick" (100) substrate anodic oxide is thicker and less crystalline on the Alcoa foil, where it constitutes only 5% of the area, while the "thin" non-(100) substrate anodic oxide is thinner and more crystalline for the Showa foil, where it constitutes only 15% of the area. As a result of these compensating effects, the capacitance measured for the Showa foil is only slightly lower than that for the Alcoa foil.

Specimens IV-3 and IV-4 are Alcoa and Showa foils without heat-treatment anodized under identical conditions. In this case, the relative oxygen intensities measured for the (100) substrate areas are the same for both foils because very little crystallization occurs during anodization on this substrate orientation unless the foil

has been thermally treated. The anodic oxide grown on non-(100) substrate areas is thinner and more crystalline on the Showa foil, where it constitutes only 15% of the surface area.

The typical microstructure of the isolated 180V anodic oxide grown on thermally treated Showa foil is shown in Fig. 5. The area in the micrograph corresponds to the grain boundary region between two (100) grains of the substrate; it is at the same magnification as Fig. 1B, which shows the oxide grown near a (100)/non-(100) grain boundary on the corresponding Alcoa foil. The anodic oxide that grew over the grain boundary in Fig. 5 is highly crystalline. The rest of the microstructure is characteristic of the (100) substrate orientation and consists of crystal clusters separated by amorphous patches. The (100) crystal clusters are more fully developed in this specimen than in the corresponding Alcoa foil.

Crystalline anodic oxide grown during anodization in the ADP electrolyte near room temperature has a different microstructure. The crystals appear to grow primarily by enlargement of the original thermal oxide nuclei rather than by the clusterlike growth observed for 85°C anodizations. A comparison of the microstructures of the isolated anodic oxides from non-(100) substrate areas of thermally treated Alcoa foils anodized at 85°C and 30°C is given in Fig. 6. Without the thermal treatment, only a few isolated small crystals could be seen in the anodic oxide grown at 30°C.

Current efficiency.—The current efficiency is relatively independent of the anodization current density for 85°C formations in the ADP electrolyte. In Fig. 7, the total anodization charge has been plotted against the measured relative oxygen intensity for the data in the three tables. A weighted average between the (100) and non-(100) substrate measurements has been used for the oxygen intensity to take into account the very different substrate orientations of the Alcoa and Showa foils. With the exception of the two labeled data points, the measurements fall in a pattern close to a straight line. The anodization charge values for thermally treated specimens tend to fall slightly below the measurements for untreated specimens. This is as expected, since some amorphous and

tions is only 80% of the average for the other specimens. This value is in good agreement with the relative current efficiencies reported by Randall and Bernard (29) for anodization at 25° and 90°C in 0.01M NaH_2PO_4 with a current density of 1 mA/cm². Data point B corresponds to the 85°C anodization on thermally treated Showa foil (specimen IV-2). The apparent current efficiency for this predominantly (100)-oriented foil is 92% of the average for the other specimens.

Effect of surface films on the growth of crystalline anodic oxide.—Electropolished foil dried at room temperature is covered by an amorphous oxide on the order of 2 nm thick. The specimen preparation techniques used in a number of the investigations reported in the literature result in a somewhat different amorphous surface film of aluminum oxide that may modify or inhibit crystal growth within the anodic oxide. For example, Alwitt and Takei (15) chemically polished their specimens in $\text{HNO}_3 + \text{H}_3\text{PO}_4$ followed by cleaning in NaOH and water. They reported that anodization of these specimens in a citrate electrolyte produced an amorphous anodic oxide film unless the specimens were thermally treated prior to anodization. We have observed that this “bright dip” specimen preparation resulted in the growth of amorphous anodic oxide in citrate and phosphate electrolytes, while electropolished specimens anodized under the same conditions were highly crystalline.

The effect of surface films is of interest because the etched capacitor foil surface is typically covered by an amorphous oxide film (30, 31). For this reason, crystalline anodic oxide may not grow on etched foil during anodization at 85°C unless the surface film has been modified or removed by special cleaning steps and/or thermal treatment (32). The surface films may also effect the growth rate of the crystalline thermal oxide.

To simulate the surface condition of etched foil, we have generated a thin surface film on electropolished foil by an electrochemical method. The electrolyte consisted of 0.15M $\text{HNO}_3 + 0.011\text{M H}_3\text{PO}_4 + 400 \text{ ppm H}_2\text{SO}_4$ and was derived from an AC etch solution (33) by omitting the HCl and AlCl_3 , so that pits would not be etched into the electropolished foil. To create the simulated “AC etch film” in this electrolyte, the potential of the aluminum foil was switched at 20 Hz between -0.45 and $-2.25\text{V vs. a saturated calomel electrode}$.

A micrograph of an amorphous, nearly featureless 180V anodic oxide grown on electropolished Alcoa foil with the simulated “etch film” is shown in Fig. 8A. When the substrate containing the etch film was heated at 600°C for 5 min prior to anodization, the microstructure of the anodic oxide changed to that shown in Fig. 8B. The surface film inhibited the growth of crystalline thermal oxide, and a somewhat longer heating time was required to generate the crystalline thermal oxide under the amorphous film. This is indicated in Fig. 9, which shows the isolated thermal oxide formed in 5 min at 600°C on electropolished foil with and without the simulated etch film. The micrograph of Fig. 9A is focused on the fine structure of the residual etch film; the darker irregular shapes are the thermal oxide crystals which are growing into the aluminum metal. The $\gamma\text{-Al}_2\text{O}_3$ crystals in Fig. 9B have grown laterally to cover most of the aluminum surface.

Discussion

The relative phosphorus intensities listed in the tables are proportional to the phosphorus present in the total thickness of the aluminum oxide. Our measurements indicate a trend that the more crystalline films contain less phosphorus, but it is unlikely that the phosphorus concentration is uniform throughout the film. For anodic oxide films that were largely amorphous, Randall and Bernard (29) have determined with radiotracer techniques that the inner third of the oxide film is free of phosphorus. A similar result has been obtained by Thompson *et al.* (34) by direct STEM/EDS analysis of an oxide section prepared by ultramicrotomy. Phosphorus distributions in partly crystalline films may be more complex than in

Fig. 8. TEM of isolated 180V anodic oxides grown on non-(100) substrate areas of electropolished Alcoa foil covered by simulated “etch film.” A: 85°C anodization at 1 mA/cm². B: 5 min at 600°C + 85°C anodization at 1 mA/cm². Marker length is 200 nm.

amorphous films, since the $\gamma'\text{-Al}_2\text{O}_3$ crystallites are non-uniformly distributed within the anodic oxide film both laterally and in depth.

The crystalline anodic oxide films have a lower weight per unit area than amorphous oxide films anodized at the same voltage in the ADP electrolyte. The presence of crystalline anodic oxide permits a greater field strength (6); therefore, less oxide is required to sustain the anodization voltage at a specific current. The decrease in oxide thickness with increasing crystallinity qualitatively explains the increase in capacitance measured for the more crystalline oxide films anodized at low current density. For the more nonuniform films, the thickness of the dielectric also varies considerably from one point to another on a submicron scale.

To maximize the crystallinity of the anodic oxide grown in the ADP electrolyte, both the crystal nucleation and the crystal growth conditions need to be optimized. Thermal oxide crystallites formed during heating for a short time at 600°C provide effective growth sites for the crystalline anodic oxide. The substrate-related preferred orientation of the growing $\gamma'\text{-Al}_2\text{O}_3$ anodic oxide crystallites is established by the thermally formed $\gamma\text{-Al}_2\text{O}_3$ platelets that have grown epitaxially on the aluminum substrate during thermal treatment.

Initiation of crystalline oxide growth will also occur on electropolished foil in the ADP electrolyte. The number of crystalline sites increases markedly with electrolyte temperature and is influenced by the crystallographic orientation of the aluminum substrate. On any specimen, the (100) grains have a considerably lower number of crystalline sites than all other substrate orientations. Amorphous films deposited on the electropolished aluminum appear to interfere with the initiation of crystalline growth sites.

Growth of the individual sites is optimized by high electrolyte temperature, low current density, and high anodization voltage. A low current density primarily de-

Fig. 9. TEM of isolated thermal oxide grown on non-(100) substrate areas of Alcoa foil during heating for 5 min at 600°C. A: Electropolished foil with simulated "etch film." Arrow indicates a thermal oxide crystallite. B: Electropolished foil. Marker length is 100 nm.

creates the rate of oxide growth and increases the time required for the total anodization; this, apparently, favors crystalline oxide growth. The exact growth process is not known; the crystalline oxide may grow by conversion of amorphous oxide, by direct crystal growth, or by a combination of the two.

The crystal clusters described in the preceding text differ from the flaws containing γ' -Al₂O₃ reported by Shimizu and others (18, 35, 36). The flaws are typically seen in largely amorphous anodic oxide films formed in 25°C aqueous borate electrolytes with current densities greater than 1 mA/cm² and formation voltages greater than 200V. They occur in greater number on as-received and chemically cleaned foil than on electropolished foil. The crystal clusters are smaller and can be seen at much lower anodization voltages than can the flaws reported by Shimizu *et al.* The crystal clusters are much more numerous on electropolished foil than on chemically cleaned foil and are most prevalent in anodic oxide films formed at high anodization temperatures and low current densities in the ADP electrolyte.

Frequency Response of Plug-Flow Electrochemical Reactors

Thomas Z. Fahidy*

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

A theoretical analysis of PFER reactor response to sinusoidal perturbations in inlet electrolyte concentration, electrolyte temperature, and electric current is presented, on the basis of transfer functions. The existence of resonance, typical of systems under distributed forcing, is also shown.

The study of the dynamics of a PFER (plug-flow electrochemical reactor) has so far received very little attention in the electrochemical literature, [e.g., Ref. (1, 2)] although its steady-state design and performance have been thoroughly discussed (3, 4). The knowledge of dynamic behavior is important not only for a proper understanding of reactor transients (*i.e.*, transition from one steady state to another), but also for the design of control against deleterious effects of process perturbations (*e.g.*, in current or potential drop, inlet electrolyte flow rate, temperature, and concentration). An important aspect of PFER dynamics and, indeed, of any electrochemical reactor is its response to sinusoidal perturbations in process variables, called the frequency response. In systems such as the CSTER, where process variables, *e.g.*, electrolyte concentration and temperature, are not space dependent, the classical transfer-function approach is a convenient means of studying frequency response in terms of relatively uncomplicated algebraic functions. In distributed-parameter systems such as the PFER, where process variables are time and space dependent, the transfer-function approach is less straightforward, but it remains an inviting method to analyze the resonance phenomenon, characteristic of such systems (5). Resonance occurs when a perturbation is suddenly imposed along the characteristic space coordinate, acting essentially as a spatial amplifier for system response; as a result, the response variables will oscillate with distinctly larger or lower amplitudes at certain frequencies (resonance frequencies) than at neighboring frequencies. The existence of resonance has been amply documented in process equipment, *e.g.*, in heat exchangers (5, 6).

The subject of this paper is the extension of the theory of frequency response and resonance phenomena to a PFER by means of the transfer-function approach applied to both isothermal and nonisothermal operations, but in the absence of any dispersion effect. It illustrates a further application of well-established principles of chemical process dynamics to electrochemical engineering, with results connected directly to the rational design of electrochemical process control.

The general problem of transfer-function representation of the isothermal plug-flow reactor.—The geometry, electrode arrangement, and limitations pertaining to the PFER model have been previously discussed [e.g., Ref. (1-3)] in detail. The substance balance

$$\frac{\partial c}{\partial t} = -v \frac{\partial c}{\partial z} - k_1 i \quad [1]$$

with auxiliary conditions $t = 0$, $c = c^*(z)$, $i = i^*(z)$ and $z = 0$, $c = c^*(0)$, and $i = i^*(0)$ defines the concentration distribution of the electrolyte in time and distance in the reactor. In terms of perturbation variables

$$c(t, z) - c^*(z) \equiv y_1(t, z)$$

and

$$i(t, z) - i^*(z) \equiv x(t, z)$$

Eq. [1] may be replaced by its isomorphic equivalent

$$\frac{\partial y_1}{\partial t} = -v \frac{\partial y_1}{\partial z} - k_1 x \quad [2]$$

*Electrochemical Society Active Member.

with auxiliary conditions $t = 0$, $y = 0$, $x = 0$ and $z = 0$, $y_1 = y_1^0(t)$, $x = 0$. Using the Laplace transforms of y_1 and x with kernel $\exp(-st)$, Eq. [2] is transformed into the ordinary differential equation

$$\frac{dY_1(s, z)}{dz} + \frac{s}{v} Y_1(s, z) = -\frac{k_1}{v} X(s, z) \quad [3]$$

Let $X(s, z)$ represent the product of two mutually independent functions of each independent variable; *i.e.*, $X(s, z) = f(s)g(z)$. Let $F(s, z)$ be a bounded function defined as $F(s, z) \equiv \int g(z) \exp(z/v s) dz$. Then, using appropriate theorems of Laplace transform theory [e.g., Ref. (7)], the expression

$$Y_1(s, z) = Y_0(s) \exp\left(-\frac{z}{v} s\right) - \frac{k_1 f(s)}{v} [F(s, z) - F(s, 0)] \exp\left(-\frac{z}{v} s\right) \quad [4]$$

is obtained; $Y_0(s)$ is the Laplace transform of $y_1^0(t)$. Hence, a transfer-function formulation is formally possible

$$G_c(s, z) \equiv \frac{Y(s, z)}{X(s, z)} = \frac{Y_0(s)}{X(s, z)} \exp\left(-\frac{z}{v} s\right) - \frac{k_1 f(s)[F(s, z) - F(s, 0)]}{v X(s, z)} \exp\left(-\frac{z}{v} s\right) \quad [5]$$

although it is not unique in the sense that to any arbitrary space element z_1 along the coordinate z a transfer function $G(s, z_1)$ can be assigned; for practical purposes only, the exit position $z = L$ is of importance, where

$$G_c(s, L) = \frac{Y(s, L)}{X(s, z)} = \frac{Y_0(s)}{X(s, z)} \exp(-T_d s) - \frac{k_1 f(s)[F(s, L) - F(s, 0)]}{v X(s, z)} \exp(-T_d s) \quad [6]$$

and T_d is the transportation lag (or transportation time delay), *i.e.*, the time required for a flow element to traverse the entire reactor of length L with constant plug-flow velocity v . The following special cases lead to simplified forms of Eq. [6].

1. No change in the inlet concentration occurs: $y_1^0(t) = 0$. Since $Y_0(s) = 0$, the first term in Eq. [6] vanishes and

$$G_c(s, L) = \frac{k_1 f(s)[F(s, 0) - F(s, L)]}{v X(s, z)} \exp(-T_d s) \quad [7]$$

2. No change in the inlet concentration occurs. In addition, $x(t, z) = z^n f(t)$, n being an integer. Since $X(x, z) = z^n f(s)$

$$G_c(s, L) = \frac{k_1 F(s, 0) - F(s, L)}{v z^n} \exp(-T_d s) \quad [8]$$

where

$$F(s, z) = \sum_{r=0}^{n-1} (-1)^r \frac{n! z^{n-r}}{(n-r)! \left(\frac{s}{v}\right)^{r+1}} \exp\left(\frac{z}{v} s\right) + (-1)^n \frac{n!}{\left(\frac{s}{v}\right)^{n+1}} \exp\left(\frac{z}{v} s\right)$$

3. No change in the inlet concentration occurs. In addition, $x(t,z) = f(t)$ (not a function of z). This is a practically important case, representing, e.g., pulse, step, and periodic perturbations of the current in time. The transfer function assumes the relatively simple form

$$G_c(s,L) = k_1 \frac{\exp(-T_d s) - 1}{s} \quad [9]$$

Equation [9] is the starting point for the analysis of frequency response.

The frequency response of an isothermal PFER: resonance effect.—In the case of purely oscillatory perturbations expressible in terms of a sine or cosine function of the angle (ωt), and in view of the classical Euler-deMoivre relationship $\exp(\pm j u) = \cos u \pm j \sin u$, Eq. [9] may be represented by an amplitude function

$$M_c(j\omega, T_d) = \sqrt{2} k_1 \frac{\sqrt{1 - \cos T_d \omega}}{\omega} \quad [10a]$$

and by a phase-angle (or phase-shift) function

$$\phi_c(j\omega, T_d) = -\arctan \frac{1 - \cos T_d \omega}{\sin T_d \omega} \quad [10b]$$

$M(j\omega, T_d)$ is also known as the gain amplitude of the system. If the periodic current perturbation is expressed as $x(t,z) = x^0 \sin \omega t$, the response of the exit electrolyte concentration is given at sufficiently large times by

$$y(t,z) = M_c(j\omega, T_d) x^0 \sin[\omega t + \phi_c(j\omega, T_d)] \quad [11]$$

indicating a frequency-dependent perturbation amplitude and phase shift in the oscillatory concentration, with reference to current perturbation. Introducing $\beta \equiv T_d \omega$, Eq. [10a] and [10b] can be rewritten as

$$\psi_c(\beta) \equiv \frac{M_c(j\omega, T_d)}{\sqrt{2} k_1 T_d} = \frac{\sqrt{1 - \cos \beta}}{\beta} \quad [12a]$$

and

$$\phi_c(\beta) = -\arctan \frac{1 - \cos \beta}{\sin \beta} \quad [12b]$$

Equations [12a] and [12b] indicate the oscillatory nature of the transfer function past a monotonic domain of β : if perturbation in current occurs at frequencies increasing within this domain, the exit electrolyte concentration will oscillate with monotonically decreasing amplitudes until a threshold frequency called the first resonance frequency ω_1 is reached. If current oscillations occur at $\omega > \omega_1$ (i.e., $\beta > \beta_1$), the amplitude of the exit electrolyte concentration will oscillate itself, reaching local maxima and minima at gradually decreasing intervals of frequency. The phase shift will also oscillate in this fashion—this is the resonance phenomenon.

The characteristic resonance frequencies are found by satisfying conditions of local extrema for $\psi_c(\beta)$, defined by $d\psi_c(\beta)/d\beta = 0$, and by finding points of discontinuity for $\phi_c(\beta)$. Differentiation of Eq. [12a] yields the first condition

$$\frac{\sin \beta}{1 - \cos \beta} = \frac{2}{\beta} \quad [13]$$

whereas the second condition is satisfied at $\beta = 2\pi, 4\pi, 6\pi, \dots$, where $\phi_c(\beta)$ suddenly jumps from -180° to 0° upon increasing β at an infinitesimally small distance to the left. By inspection, Eq. [12a] has the value of zero at $\beta = \pi, 3\pi, 5\pi, \dots$, and since $\psi_c(\beta)$ cannot be negative, $\phi_c = 2\pi, 4\pi, 6\pi, \dots$, are the positions of local minima. The local maxima are found from Eq. [13] by an appropriate root finding procedure. The first five local maxima are given in Table I, and Fig. 1 and 2 depict the variation of the magnitude and phase-angle functions with the frequency angle.

Table I. The first five resonance maxima of the magnitude function of a PFER

Position of the maximum, β	Locally maximum value of $\psi_c(\omega)$	$\phi_c(\omega)$, degree
0	$1/\sqrt{2} = 0.7071^a$	0
2.86π	0.1536	-77.43
4.90π	0.09074	-81.18
6.94π	0.06458	-84.81
8.94π	0.05014	-85.00

^a Obtained by the series expansion of the function $\sqrt{(1 - \cos \beta)/\beta^2}$ and taking the limit as $\beta \rightarrow 0$.

Frequency response and resonance effect in the nonisothermal PFER.—The nonisothermal PFER is described by the substance balance Eq. [1] and by the thermal balance (1, 2)

$$\frac{\partial T}{\partial t} = -v \frac{\partial T}{\partial z} - k_2(T - T_a) + k_3 i^2 - k_4 i \quad [14]$$

with auxiliary conditions $t = 0, c = c^*(z), T = T^*(z), i = i^*(z)$ and $z = 0, c = c^*(0), T = T^*(0), i = i^*(0)$. The perturbation variables are defined as $y_1(t,z) \equiv c(t,z) - c^*(z), y_2(t,z) \equiv T(t,z) - T^*(z)$, and $x(t,z) \equiv i(t,z) - i^*(z)$. As in the previous section, it is assumed that there is no change in inlet conditions. If perturbations in current are sufficiently small, the linear approximation

$$i^2(t,z) - [i^*(t,z)]^2 \approx 2i^*(z)x(t,z)$$

may be employed to linearize Eq. [14], which can be rewritten as

$$\frac{\partial y_2}{\partial t} + k_2 y_2 + v \frac{\partial y_2}{\partial z} = f(z)x(t,z) - k_4 x(t,z) \quad [15]$$

where $f(z) \equiv 2k_3 i^*(z)$. In order to obtain transfer-function representations, the current perturbation must be once again space independent, i.e., $X(s,z) = X(s)$. The following cases can be distinguished.

1. $i^*(z) = \text{const}$. The transfer function is

$$G_T(s,L) = k_5 \tau_2 \frac{1 - \exp(-k_2 T_d) \exp(-T_d s)}{\tau_2 s + 1} \quad [16]$$

Fig. 1. The variation of the gain amplitude with frequency in an isothermal PFER (Eq. [12a]).

where $k_2\tau_2 = 1$. Equation [9] complements Eq. [16] for a full representation via transfer functions. The frequency response of electrolyte temperature to periodic perturbations in current is given by the gain amplitude

$$M_T(j\omega, T_d) = \frac{T_d}{\tau_2} \sqrt{\frac{1 - \exp(-T_d/\tau_2) - 2 \exp(-T_d/\tau_2) \cos \beta}{(T_d/\tau_2)^2 + \beta^2}} \quad [17a]$$

and phase angle

$$\phi_T(j\omega, T_d) = \arctan \frac{-\tau_2 + \tau_2 \omega \exp(-T_d/\tau_2) \cos \beta + \exp(-T_d/\tau_2) \sin \beta}{1 - \exp(-T_d/\tau_2) \cos \beta + \tau_2 \omega \exp(-T_d/\tau_2) \sin \beta} \quad [17b]$$

Hence, at sufficiently large times

$$y_2(t, z) = M_T(j\omega, T_d) x_2^0 \sin[\omega t + \phi_T(j\omega, T_d)] \quad [18a]$$

and (see Eq. [11])

$$y_1(t, z) = M_c(j\omega, T_d) x^0 \sin[\omega t + \phi_c(j\omega, T_d)] \quad [18b]$$

The resonance frequencies are obtained by setting $dM_T/d\beta = 0$ and solving the resulting equation

$$\frac{\sin \beta}{\cosh(T_d/\tau_2) - \cos \beta} = \frac{2\beta}{(T_d/\tau_2)^2 + \beta^2} \quad [19]$$

2. $f(z) = a_0 z^m$; a_0 and m are (experimental) regression parameters. If m is a noninteger, no closed-form analytical solution of Eq. [15] can be obtained, and hence transfer function representation becomes awkward. If m is an integer, the transfer function may be written, upon cumbersome manipulations, as

$$G_T(s, L) = \left[\frac{a_0 v}{(s + k_2)^2} + \frac{k_4}{s + k_2} \right] \exp(-k_2 T_d) \exp(-T_d s) + a_0 \left[\frac{L^m}{s + k_2} + \sum_{j=1}^m (-1)^j \frac{v^j m(m-1) \dots (m-j+1)}{(s + k_2)^{j+1}} L^{m-j} \right] \quad [20]$$

which degenerates to the simpler form of

$$G_T(s, L) = \frac{a_0 v}{(s + k_2)^2} [\exp(-k_2 T_d) \exp(-T_d s) - 1] + \frac{k_4}{s + k_2} \exp(-k_2 T_d) \exp(-T_d s) + \frac{a_0 L}{s + k_2} \quad [21]$$

in the specific case of $m = 1$. Equations [16], [20], and [21] all indicate the existence of resonance past a certain frequency; the mathematical form of $i^*(z)$ determines, however, the numerical value of the resonance frequencies and the shape of the given amplitude and phase angle curves.

Discussion

The frequency response of the isothermal PFER shows similarity to that of the steam-heated heat exchanger (8) with steam condensing in the outer pipe and a coolant flowing in the inner pipe [compare Fig. 1 and 2 to Fig. 9b and 10, respectively, and Eq. [12] to Eq. [62] in Ref. (8)], but the two responses are not identical. The transfer function analysis becomes much simpler if the perturbation in electrolyte concentration may be approximated as a linear function of the imposed current density

$$c - c^* \cong \alpha(i - i^*) \quad [22]$$

Here, variations in the inlet concentration of the electrolyte can be considered as a perturbation and Eq. [2] takes the rearranged form of

$$\frac{\partial y_1}{\partial t} + v \frac{\partial y_1}{\partial z} + \frac{k_1}{\alpha} y_1 = 0 \quad [23]$$

Fig. 2. The variation of the phase angle with frequency in an isothermal PFER (Eq. [12b]).

Then, the transfer function relating electrolyte concentration in the PFER and inlet electrolyte concentration is

$$G'_c(s, z) \equiv \frac{Y_1(s, z)}{Y_0(s)} = \exp\left(-\frac{k_1 z}{\alpha v}\right) \exp\left(-\frac{z}{v} s\right) \quad [24]$$

In the specific case of $z = L$, the transfer function

$$G'_c(s, L) = \exp\left(-\frac{k_1 T_d}{\alpha}\right) \exp(-T_d s) \quad [25]$$

represents a pure time-delay effect with gain magnitude

$$M'_c(\omega) = \exp\left(-\frac{k_1 T_d}{\alpha}\right) \quad [26a]$$

and phase angle

$$\phi'_c(\omega) = -T_d \omega \quad [26b]$$

for the exit electrolyte concentration. The absence of a resonance phenomenon is demonstrated by the independence of the response magnitude of perturbation frequency: the latter affects only the delay of the response.

The analytical construction of the frequency response of the nonisothermal CSTR is rather complicated (Eq. [20]), and can be simplified only by major assumptions [Eq. [16]]. The qualitative course of the gain magnitude and phase-angle curves for the $i^*(z) = \text{const.}$ case is shown in Fig. 3 for τ_2 values of modest size. Further simplifications may be carried out, however, for many practical electrolyzers where τ_2 is very large. Taking a typical electrolyzer tank of 0.1 m² cross-sectional area (assumed to be normal to the direction of flow) and an axial length of 2m, an average electrolyte density of 1200 kg/m³, and an average overall heat-transfer coefficient of 7.5 W/m² · K, the numerical value of $\tau_2 \cong 741$ min is computed. Thus, Eq. [16] degenerates to the form Eq. [9] (except for the coefficients), i.e., the frequency-dependent terms in gain amplitude and phase-angle expressions become identical, respectively, and the plots in Fig. 3 become identical to plots of the form shown in Fig. 1 and 2.

The preceding analysis suggests a semiquantitative means of detecting deviations from PFER behavior via experimentally obtained frequency response by perturbing the current in an electrochemical reactor sinusoidally over a carefully selected frequency band. A strong dissimilarity between experimental and PFER frequency response indicates the existence of considerable dispersion, although its true nature (the relative impor-

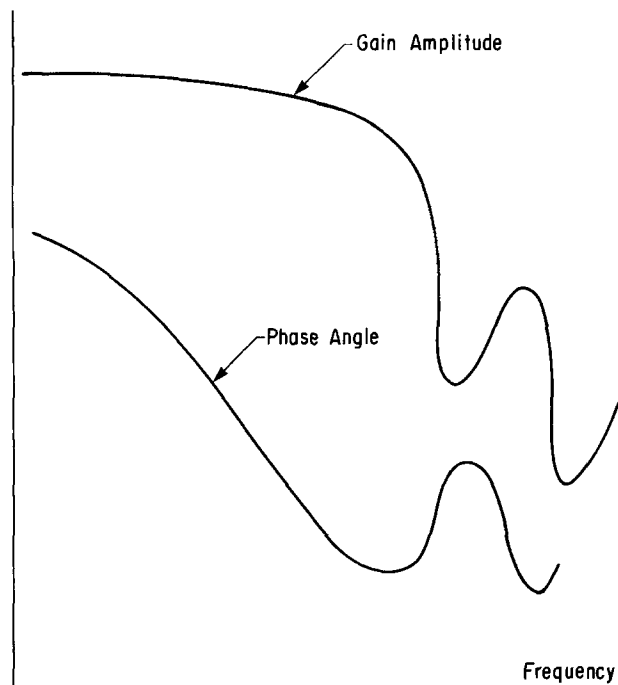

Fig. 3. Qualitative variation of the gain amplitude and phase angle with frequency according to Eq. [16] (only the first resonance peaks are shown).

tance of axial-to-radial dispersion) may not be easily determined; an experimental residence-time distribution study would be more quantitative. Nevertheless, the use of frequency response for this purpose, at least as a relatively fast preliminary investigation, could be attractive due to its experimental simplicity with respect to residence-time distribution. (The experimental investigation of PFER frequency response is beyond the scope of the current paper.)

Concluding Remarks

The major finding of practical importance of the transfer-function-based analysis of frequency response is the prediction of locally high oscillation amplitudes in electrolyte concentration and temperature at large-frequency perturbations in current due to its distributed-forcing effect: this phenomenon is in sharp contrast with continuous flow stirred tank electrochemical reactor (CSTER) response, where system inertia acts essentially as a low-pass filter and, consequently, concentration and temperature fluctuations are gradually smaller with increasing perturbation frequencies. The resonance effect in a PFER is an important factor to consider in the design and implementation of controllers on electrolyzers.

LIST OF SYMBOLS

c	electrolyte concentration
$G_c(s,z)$	transfer function for electrolyte concentration
$G_T(s,z)$	transfer function for electrolyte temperature
i	current density
j	$\sqrt{-1}$
k_1	coefficient in the mass balance of a PFER (reciprocal of the product of reactor height, valency, and Faraday's constant) related to electrolysis
k_2	coefficient in the thermal balance (ratio of the overall heat-transfer coefficient to the product of reactor height, density, and specific heat capacity) related to heat losses
k_3	coefficient in the thermal balance (reciprocal of the product of density, specific heat capacity, and electric conductivity) related to the Joule effect
k_4	coefficient in the thermal balance (ratio of the heat of the electrode reaction to the product of reactor height, density, specific heat capacity, valency, and Faraday's constant) related to the heat of reaction
k_5	coefficient in Eq. [16], equal to $2k_3i^*(z) - k_4$ if $i^*(z) = \text{const.}$
L	length of the electrode; characteristic length along the axis
s	Laplace transform variable
T	electrolyte temperature
T_d	transportation lag of the PFER, equal to L/v
t	time
v	electrolyte velocity
x	current perturbation variable
y_1	concentration perturbation variable
y_2	temperature perturbation variable
z	axial space coordinate
β	equal to $T_d\omega$
τ_2	the reciprocal of k_2 ; an apparent time constant
ω	perturbation frequency

Photoactive Synthetic Polycrystalline Pyrite (FeS₂)

A. Ennaoui, S. Fiechter, H. Goslowsky, and H. Tributsch

Hahn-Meitner-Institut für Kernforschung Berlin, Bereich Strahlenchemie, D-1000 Berlin 39, Germany

ABSTRACT

Polycrystalline layers of As-doped pyrite (FeS₂) have been produced in bromine atmosphere with the aim of developing this sulfide material for solar energy applications. Its photoelectrochemical behavior in contact with an aqueous I₃⁻/I₂ electrolyte was investigated. It operated as a photoelectrochemical solar cell and showed reasonably stable behavior under illumination. Optical measurements performed on FeS₂ show that visible light is absorbed in an extremely thin layer of 160Å in spite of the apparently indirect gap of this semiconductor ($E_g = 0.95$ eV). This would make this photosensitive material an interesting candidate for thin-layer solar cells. Scanning electron micrographs of the samples reveal well-developed crystallites of about 5-10 μm with distinct boundaries. Scanning laser spot analysis over macroscopic areas (5 mm) showed homogeneous as well as inhomogeneous regions. The photoelectric properties of these first polycrystalline pyrite samples studied are poor, but there is presently no reason to assume that they cannot be developed.

Single crystals of FeS₂ with pyrite structure have recently been considered in publications from our laboratory as a semiconducting material for photoelectrochemical and photovoltaic solar cells (1-3). FeS₂ crystals in contact with an iodide/iodine containing electrolyte have exhibited large quantum efficiency and very high stability against photocorrosion (3). We are still far from understanding the solid-state chemistry of single-crystalline pyrite in all details. Nevertheless, it seems to be appropriate to start the development of polycrystalline pyrite at an early stage, owing to its potential advantage as a cheap material with promising photoelectrochemical properties.

As a material in photoelectrochemical cells, FeS₂ has the advantage of being a d band semiconductor like MoS₂ or WS₂ with photoexcited holes reacting from quasi-nonbinding d states constituting the upper edge of the valence band (3).

Pyrite Preparation and Properties

Previous studies on pyrite synthesis.—Although large pyrite deposits have been found in the earth (4) and natural pyrite crystals of considerable size are well known, there has been no success in artificial growth of pyrite crystals in centimeter dimension. Synthesis of pyrite was first described by Wöhler (5) in the last century. Reacting sulfur and Fe₂O₃ in an open system, he succeeded in the preparation of small brass-yellow octahedra. Bouchard (6) reported on the growth of pyrite crystals with 3 mm edge length by chemical vapor transport with chlorine. Transport from hot to cold occurred in a temperature gradient from 715° to 655°C. Our own experiments (3) show that transport with bromine at a gradient from 650° to 550°C yields crystals up to 6 mm edge length, while in the presence of iodine as transporting agent a transport rate two orders in magnitude smaller has been established. Wilke and co-workers (7) did not obtain larger crystals in growing pyrite from the solution with PbCl₂ as solvent.

Up to now, no attempts to prepare polycrystalline layers of photosensitive FeS₂ have been reported. However, FeS₂ formation has been observed during corrosion of carbon steel in the presence of a H₂S gas/water mixture in nuclear power reactions, and the process, which is of electrochemical nature, has been studied (8).

Synthesis of FeS₂ powder.—Stoichiometric amounts of high purity, H₂-reduced iron powder and high purity sulfur lumps were heated up to 650°C in evacuated (10⁻⁵ mbar) and sealed quartz ampuls of 20 mm diam and 200 mm length. In the presence of a small amount of iodine (0.5 mg/cm³), the reaction was terminated within 100h.

Preparation of polycrystalline FeS₂ layers.—2g of yellowish-white shining FeS₂ powder and 5 mg As as dopant were filled in quartz ampuls ($\phi \approx 22$ mm, $l = 300$ mm) and evacuated to 10⁻⁵ mbar. After admittance of 0.5 mg/cm³ bromine, the tubes were sealed. FeS₂ powder was placed in one end of the ampul and, in order to clean the

growth chamber from persisting powder particles, the free end was heated up to 800°C for 6h. Afterward, the temperature was reversed. The FeS₂ powder was heated to 800°C, and the powder-free end was kept at 550°C (Fig. 1, stage I) for 10 days. On account of the high dissociation pressure of FeS₂ at 800°C [$p = 1$ atm (16)], a thermal decomposition of FeS₂ according to the simplified equation

was observed. Sulfur distilled into the cool end of the quartz ampul. The decomposition was accompanied with a strong coalescence (Ostwald ripening) of the produced FeS to large hexagonal pyrrhotite crystals (Fig. 1, stage II) up to 10 mm edge length and 2 mm thickness. By reversing the temperature gradient for 10 days, realized by the opposite position of the growth ampul in the furnace (Fig. 1, stage III), the pyrrhotite crystals were transformed into pyrite under preservation of their hexagonal shape (pseudomorphism). Investigations of the hexagonal surfaces with scanning electron microscopy revealed that the pseudomorphous crystals consisted of small pyrite crystals (5-10 μm edge length) that were grown together forming a reasonably homogeneous surface (Fig. 2). In some areas, larger pyrite crystals (0.5 mm edge length) appeared on the polycrystalline substrate.

Polycrystalline layers were also prepared by transport in a gradient from 650° to 600°C in evacuated and closed quartz ampuls ($l = 110$, $\phi = 22$ mm). The concentration of transporting agent NH₄Br amounted to 0.5 mg/cm³. 0.35 mg As was added to 1.15g FeS₂ feed material. The intergrown pyrite crystals of the layer had dimensions of 10-100 μm.

Solid-State Studies

Concerning the band structure of pyrite FeS₂ (9), two details are particularly interesting because they permit a

Fig. 1. Position of growth tubes in the temperature gradient of the furnace and growth region of polycrystalline layers.

Fig. 2. Scanning electron micrographs of polycrystalline FeS_2 . a(left): Front view of polycrystalline platelet. b(right): Edge side of platelet

better interpretation of the electric, magnetic, and optical properties.

First, the clear separation of a t_{2g} and a e_g energy band in relation with a low-spin t_{2g}^6 system which results in a 0.95 eV t_{2g}/e_g bandgap.

Second, a relatively broad e_g band has been predicted (9) and XPS data confirm a single strong 3d peak of 0.9 eV width arising from a d energy band at the top of the FeS_2 valence band (10). These XPS data have been confirmed and extended in our laboratory (3).

The reported high electron mobility of $230 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$ in synthetic crystals (11) confirms that the electronic structure of the material is sufficiently favorable for charge transport.

The electrical resistivity of our samples was measured using a four-probe technique. The measurements covered the temperature range from 76 to 500 K, and an exponential temperature dependence between 400 and 500 K according to the relation $l = l_0 \exp \Delta E/KT$ was found. The activation energy $\Delta E = 0.23 \text{ eV}$ of our samples is smaller than $\Delta E = 0.46 \text{ eV}$, previously reported for n-type single crystals of FeS_2 (9). At room temperature, the resistivity of our polycrystalline FeS_2 was $6 \Omega\text{-cm}$; Hall effect measurements gave a carrier concentration of $3 \times 10^{17} \text{ cm}^{-3}$. The Hall mobility in our samples was quite low: $3 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$. The pyrite layers studied showed n-type behavior in photoelectrochemical measurements.

Optical Experiments

Optical transmission measurements for FeS_2 have up to now only been performed in the infrared toward the bandedge region. Schlegel and Wachter determined the absorption constant of FeS_2 up to a photon energy of $h\nu = 1.1 \text{ eV}$, where it was found to be approximately $\alpha = 8 \times 10^6 \text{ cm}^{-1}$ (12). A crystal of natural pyrite (from Elba) with a cross section of $10 \times 5 \text{ mm}^2$ was polished down to a thickness of $\alpha = 8 \pm 0.5 \mu\text{m}$ while fixed to a glass support. This sample had holes on a surface area much smaller than 1%, so that a background was obtained in transmission. This gave rise to an apparent decrease of the absorption constant in the region of very high absorption coefficients. Since the small fraction of light passing through these holes does not depend on the wavelength, a calibration measurement is needed to adjust the absorption curve to the real values. This was done with the help of a null ellipsometer. In order to get the bulk properties, the surface of FeS_2 was etched using $\text{HF}/\text{CH}_3\text{COOH}/\text{HNO}_3$ (1:1:2), which, according to ESCA studies, yields a FeS_2 surface free of any covering layer (3). During the measurement, the FeS_2 was flushed with dry nitrogen. The complex refractive index determined at $n = 632.8 \text{ nm}$ was $n = 4.032 - 3.245i$.

The real reflective index was checked using the transmission interferences occurring in the range between 1800 and 2500 nm. The result was $\text{Re}(n) = 3.96 \pm 0.25$.

A cross check was made using published data on the reflection properties of pyrite in combination with a calculation based on the Kramers-Kronig relation (12, 9). The values obtained were $n = 3.6 - 3.03i$ [from Ref. (12)] and $n = 3.5 - 3.8i$ [from Ref. (9)]. They only differ by less than 30%, which might be due to surface layers, which were not controlled in these measurements. Such deviations are to be expected according to variations of interface properties (13). Therefore, our measurements have to be considered reliable. The absorption coefficient determined from our data can be calculated to be $\alpha = 6.4 \times 10^5 \text{ cm}^{-1}$ at 632.8 nm.

The relative absorption coefficient in the visible spectral region measurement with a Perkin-Elmer Model 330 would thus be calibrated as shown in Fig. 3. Beyond 1050 nm, a normal absolute measurement was possible.

It can therefore be concluded that FeS_2 is absorbing visible light within a narrow surface layer of approximately 160 \AA . Pyrite is thus absorbing at least one order of magnitude better than GaAs, which has a direct energy gap.

Photoelectrochemical Experiments

The FeS_2 samples were treated with an In-Ga alloy followed by Ag epoxy, making contact to a copper rod, which was then encapsulated with insulating resin (Scotchcast 3MXR 5241). A conventional three-electrode potentiostatic arrangement was applied. For photocurrent measurements, a 250W tungsten iodine lamp, a xenon lamp, or a helium neon laser were used.

Fig. 3. Adsorption coefficient of FeS_2 measured in transmission using a platelet $8 \mu\text{m}$ thick (exposed area: 50 mm^2). The value of $6.4 \times 10^5 \text{ cm}^{-1}$ at 632.8 nm was calibrated using ellipsometry. The insert shows the interference patterns of transmission.

Results

When an electrode, prepared of a polycrystalline FeS₂ layer, is placed in contact with an aqueous electrolyte containing 0.5M H₂SO₄ and polarized in an electrochemical cell with three electrodes, a much more complicated current voltage behavior is observed than is with single crystals (3). A photocurrent of the order of 10 mA·cm⁻² is measured in concentrated xenon light (~ 1 W·cm⁻²). It is superposed by a dark current, which is rapidly growing as the magnitude of the applied voltage is increased. The shape of the current voltage curve is complicated due to oxide formation, and corrosion to Fe³⁺ and SO₄²⁻ is clearly visible at elevated potentials. No oxygen evolution is observed. In the presence of redox systems such as I⁻/I₃ (E₀ = 0.53V), V²⁺/V³⁺ (E₀ = -0.7V), or S²⁻/S_n (E₀ = -0.51V), a FeS₂/redox electrolyte/carbon configuration operates as solar cell (Fig. 4). Instead of largely different redox potentials, the open-circuit photopotentials are comparable and equally small (0.024-0.08V). Both the poor limiting current behavior of the semiconducting FeS₂ layer and the constancy of the photovoltage indicate high concentrations of surface states and a situation of pinning of energy bands. Similar to single-crystalline FeS₂ (3), etching treatment improves the photoelectrochemical behavior. Since the electrochemistry of FeS₂ has been described using single crystals (3), we will limit ourselves to characterizing the photoeffect which has not yet been described with polycrystalline FeS₂. Figure 5 shows the spectral dependence of photocurrent efficiency (η) of polycrystalline FeS₂. Plots of $(\eta h\nu)^{n/2}$ with $n = 1$ and $n = 4$ are given in Fig. 6.

The plot $(\eta h\nu)^{1/2}$ vs. $h\nu$ gives a straight line, suggesting that the optical transition in FeS₂ is indirect and yields a bandgap of 0.95 eV consistent with theory (14). This is in good agreement with reflection measurements, which indicated an optical bandgap of 0.9 ± 0.1 eV (9), and with our optical results (Fig. 3). Laser spot measurements were made to test the homogeneity of the FeS₂ films produced. A sample of 0.7×0.5 cm was scanned over a distance of 0.5 cm in three distinct positions. Figure 7 shows that homogeneous and heterogeneous regions are present. It is possible that creeklike structures in the polycrystalline film which can be seen in the optical microscope are responsible for some of the variations.

Discussion

Pyrite (FeS₂), an abundant natural product which consists of cheap elements, has recently been proposed as a semiconductor material for solar cells (1-3). First experi-

Fig. 4. Power output characteristic of a synthetic polycrystalline FeS₂ liquid junction solar cell. Electrolyte: (a, left curve) 3M KI, 10⁻³M I₂ (pH 2). Layer preparation I (b, right curve) 1M CaI₂, 0.05M. Layer preparation II.

ments with synthetic single crystals yielded photovoltages of 200 mV and quantum efficiencies for photocurrent generation exceeding 90%, although neither doping nor interfacial properties has been optimized. The lack of knowledge of many solid-state properties makes it, at present, difficult to judge the development possibilities of this material with high reliability. However, information on certain parameters which are decisive for solar energy materials are becoming more transparent.

Our first experiments to produce polycrystalline layers of photosensitive FeS₂ were successful. These layers could even be operated in low efficient solar cells. The choice of As as doping agent was probably not favorable, especially since this additive reduces the mobility (11). The control of doping remains an important task which has to be accomplished for FeS₂, and we feel that the very low photopotential of our polycrystalline samples is due to a Fermi level, which is situated too distant from the conduction band. As shown by the improvement obtained between the sample of curve a and that of curve b in Fig. 4, some systematic progress has already been obtained. We hope to have shown that polycrystalline FeS₂ is an interesting solar material for long-term development, especially since ambient temperature and low temperature processes for FeS₂ synthesis in geological environments have also become known (17).

Our measurement of an indirect energy gap of 0.95 eV in polycrystalline FeS₂ layers (Fig. 6) is in agreement with optical (12) and electrical (9) measurements. Such an energy gap, which is only slightly smaller than those of CuInSe₂ (1 eV) and Si (1.1 eV), still permits a theoretical solar energy conversion efficiency between 14 and 18%

Fig. 7. Scanning laser spot analysis of polycrystalline FeS_2 in I^-/I_2 solution under short-circuit condition. (Three parallel scans on a 7 mm platelet in distinct regions. Scan velocity: $25 \mu\text{m}$ steps in X-direction. Beam width: $20 \mu\text{m}$.)

and a photovoltage output of approximately 0.5V. This, however, will necessitate a careful optimization of bulk and surface properties of FeS_2 . An important parameter is the nature of the electronic transition of FeS_2 . Scientists dealing with solar energy materials usually associate with indirect energy gaps a deep penetration of light which can only be compensated by high diffusion lengths of charge carriers (as in crystallized Si). Such materials cannot be used for light collection as very thin layers. Experience with transition metal sulfides of d band character such as WS_2 or MoS_2 , however, shows that indirect bandgaps can be associated with high absorption constants ($\sim 1 \times 10^5 \text{ cm}^{-1}$) (14). This is also the case for FeS_2 .

With an absorption coefficient of approximately $\alpha = 6.4 \times 10^5 \text{ cm}^{-1}$ in the visible, the photogeneration of electron-hole pairs occurs in a thin surface layer of approximately 160 \AA . The spectral dependence of photocurrents (Fig. 5)

shows a gradual decay from the near infrared toward shorter wavelengths in spite of a reasonably constant absorption coefficient. As many experiments showed, this decay depends on surface treatment (Fig. 4) and is smaller with a more ideal surface without any covering layer (as determined by ESCA measurements).

Further research will be needed to understand how the state of the surface interacts with holes, generated with different photon energy in a comparable distance from the semiconductor of electrolyte interface. Interestingly RuS_2 , which also has an extremely high absorption coefficient ($\alpha = 3 \times 10^5 \text{ cm}^{-1}$), a similar crystal structure, comparable energy gap ($E_g = 1.25 \text{ eV}$), and an analogous electronic structure, does not show a decay of photocurrents towards the UV region (15). This gives rise to the hope that it will be possible to develop solar cells which are only several hundred angstroms thick and extremely flexible and easy to handle.

The Effect of Thickness on the Performance of PTFE-Bonded Raney Nickel Hydrogen Electrodes in Relation to the Electrolyte Diffusivity of Catalyst Layers

T. Kenjo

Department of Applied Science for Energy, Muroran Institute of Technology, Mizumoto-cho, Muroran 050, Japan

ABSTRACT

The polarization resistance of Raney nickel hydrogen electrodes decreases with increasing thickness of catalyst layers, but there is a lower limit that can be attained by the thickness effect. The present study aims to prove that this limit depends on the electrolyte diffusivity of catalyst layers. The diffusivity was measured using multilayered electrodes where a ZrO_2 layer separates electronically the test layers from working layers. The theoretical polarization resistance was calculated on the basis of two different assumptions "ohmic potential drop" and "concentration polarization." The former predicts much higher electrolyte resistivity of catalyst layers than the observed value. However, the diffusivity values predicted by the latter agreed well to the experimental data. It has been thus proved that the concentration polarization assumption is valid and the electrolyte diffusivity is an essential factor to determine the lower limit of polarization resistance.

The structure and operating mechanism of Raney nickel hydrogen electrodes have been described by Mund and his co-workers on the basis of a thin film model (1-3). The distinguishing feature of this model is a thin electrolyte film which covers the inside face of macropore while leaving interparticle spaces for hydrogen diffusion. The hydrogen gas dissolves into the electrolyte film at the gas/film interface after diffusing through the macropore. The film is connected with each other by the electrolyte bridge. The electrochemical hydrogen oxidation takes place at the film/catalyst interface distributed in the catalyst layer like a three-dimensional network. The catalyst layer is therefore electrochemically reactive not only at the two-dimensional electrode/electrolyte-bulk interface, but also over a zonal area extending toward the gas-side edge of the electrode. This effective reaction area is a geometrical factor to determine the polarization loss. This viewpoint predicts that the polarization loss decreases with increasing thickness of catalyst layers. The predicted relationship has been found in the Raney nickel hydrogen electrodes (3, 4).

There is, however, a lower limit in the polarization loss attained by the "thickness effect." In load condition, the potential gradient arises in the thickness direction because of the ohmic resistance of the film. Taking the film resistivity ρ_t into account and assuming a linear function between the local polarization and faradaic current density, Mund derived the polarization resistance ω as a function of the thickness of catalyst layers d

$$\omega = \sqrt{\rho_t \rho_i} \coth \sqrt{\frac{\rho_t d^2}{\rho_i}} \quad [1]$$

where ρ_i is the interfacial resistance between the film and catalytic surface. When the catalyst layers are very thick ($\rho_t d^2 \gg \rho_i$), the polarization resistance tends to a limiting value $\sqrt{\rho_t \rho_i}$. This is the explanation for the limiting thickness effect in terms of the ohmic potential drop.

He estimated 10-20 Ω -cm as a ρ_t value at 80°C by parameter matching. The present author treated similarly the data of PTFE-bonded Raney nickel electrodes and obtained a value of the same order (4). However, it is still not certain if the film resistivity is really a limiting factor for the thickness effect, because the ρ_t value predicted has not been confirmed yet experimentally.

When hydrogen oxidation takes place in the electrode pores, the electrolyte film is diluted with the water formed. This concentration drop raises the equilibrium potential for the hydrogen oxidation and lowers the driving potential for the local current generation in the pores, resulting in the same effect as the ohmic potential drop assumed by Mund. The raise in the equilibrium potential can be expressed in terms of the concentration polariza-

tion, which is also a possible factor to limit the thickness effect.

In the present study, by using a multilayered electrode, direct measurements of electrolyte diffusivity and resistivity of the catalyst layers are attempted. The feature of the electrode is an electron insulating but electrolyte-permeable porous zirconia layer which is inserted between the test and working layers, thereby separating the former from latter layer electronically by holding an ionic contact between the two. The concentration polarization occurred in the test layer is measured as a potential difference between the electrodes with and without the test layer. The electrolyte diffusivity coefficient of test layer can be calculated from these polarization data.

Assuming these two types of potential gradient and using the diffusivity and resistivity coefficients thus obtained experimentally, we can calculate theoretical polarization values of electrodes based on the two different assumptions. Which of the two is valid can be tested by the fitting to the experimental polarization data. The goal of the present work is to determine whether the essential factor to limit the thickness effect is the concentration polarization or ohmic potential drop.

Experimental

Preparation of Raney nickel catalyst.—A melt of Ni-Al alloy containing 40% Ni and 60% Al by weight was prepared by using an induction furnace. It was quenched by pouring it into an iron cylinder. The ingot was crushed and powdered in a mill to a particle size smaller than 37 μ m. The Raney alloy powder was treated with 6M KOH solution at 80°C for 16h to leach aluminum. The Raney nickel precipitate thus obtained was washed with water and methyl alcohol alternately.

Preparation of the electrodes.—A weighed amount of a PTFE dispersion (D-1, Daikin Industrial Company) was added to the Raney catalyst. When the mixture was milled under blowing at room temperature, it became a paste, which was then calender-rolled by hand into sheets. The surfactant which had been contained in the dispersion was removed by washing with hot acetone. The PTFE content in the dry sheets was 10% in weight. These sheets were used as catalyst layers.

Gas-side layers were used to block the electrolyte leakage. Nickel black powder prepared from nickel formate was hydrophobized with PTFE and formed into sheets with the same procedure described above. Two sheets of them were attached to a stainless steel screen (used as a current collector) from both sides and pressed at 200 kg/cm². The raw layer obtained was heated in a nitrogen atmosphere at 380°C to sinter the PTFE hydrophobizer and to remove the surfactant contained. The catalyst

layer prepared previously was attached to the gas-side layer by pressing at 420 kg/cm². The double-layered electrode thus obtained was heated at 150°C in a hydrogen atmosphere for 1h to activate the catalyst layer.

Cell arrangement and polarization measurement.—The geometrical working area of the electrodes was a circle with a diameter of 3.5 cm. The electrolyte used was 6M KOH solution and it was circulated at a rate of 5 ml/min. The electrolyte temperature was maintained at 60° ± 1°C with an electric furnace. The ohmic drop was eliminated by the current interruption method (5).

Measurement of the concentration polarization in catalyst layers.—The zirconia layer was prepared similarly by binding a reagent-grade zirconia powder with the PTFE hydrophobizer. The catalyst, zirconia, and gas-side layers were arranged in a structure as illustrated in Fig. 1. The test layer is a Raney nickel layer, the concentration polarization in which is to be measured. The load current is sustained by the working layer which is catalyzed with 0.4% chromium-doped Raney nickel (6). Use of this catalyst not only lowers the polarization loss of the working layer, but also stabilizes its polarization characteristics, thereby providing more accurate and reproducible polarization data for the test layer.

Measurement of the gas diffusivity in the electrodes.—The cell arrangement for measuring the gas diffusivity is illustrated in Fig. 2. Hydrogen gas was supplied through the test electrode set at the gas side of the working electrode. The test electrode used was 0.32 mm thick. The gas diffusivity coefficient was calculated from the polarization difference between the working electrodes with and without the test electrode. Before measurement, the test electrode was wetted with the electrolyte by loading about 100 mA/cm² for 1h. This is a conditioning process to arrange the penetrating electrolyte in the pores to the amount in load condition.

Measurement of electrolyte resistivity in the catalyst layers.—The electrolyte resistivity of catalyst layers was measured by applying the current interruption method to the multilayered electrode illustrated in Fig. 1. The resistivity difference between the electrodes with and without the test layer is its electrolyte resistivity. The bulk electrolyte resistance in the geometry of electrolyte compartment used was calculated to be 13 mΩ, which is negligible in comparison to the total resistance measured.

Results and Discussion

Effect of the thickness on the polarization resistance.—Polarization curves of Raney nickel hydrogen electrodes are shown in Fig. 3 as a function of the thickness of catalyst layers. They are almost linear at low load currents, so that the polarization resistance ω can be calculated from the slopes. The experimental plots of reciprocal polarization resistance ω^{-1} vs. thickness d are given in Fig. 4. The solid line in the figure is the best fit curve calculated from Eq. [1] for $\rho_t = 7.5 \Omega\text{-cm}$ and $\rho_l = 4.0 \times 10^{-3} \Omega\text{-cm}^3$.

Fig. 1. Structure of multilayered electrodes used for measurement of electrolyte diffusivity.

Fig. 2. Cell arrangement for measurement of gas diffusivity

Fig. 3. Polarization curves of PTFE-bonded Raney nickel hydrogen electrodes. Thicknesses of the catalyst layers are as follows. Open circles: 0.045 mm. Closed circles: 0.086 mm. Open triangles: 0.12 mm. Closed triangles: 0.16 mm. Open squares: 0.22 mm. Closed squares: 0.42 mm. Ohmic drop eliminated.

Fig. 4. Reciprocal polarization resistance of Raney nickel electrodes as a function of thickness of catalyst layers. Solid line calculated from Eq. [1] for $\rho_l = 4.0 \times 10^{-3} \Omega\text{-cm}^3$ and $\rho_t = 7.5 \Omega\text{-cm}$.

The electrolyte resistivity in the catalyst layer expected from the ohmic drop assumption thus is 7.5 $\Omega\text{-cm}$.

Fig. 5. Ohmic polarizations of multilayered electrodes. Thicknesses of test layers are as follows. Open triangles: without test layers. Open circles: 0.14 mm. Open squares: 0.22 mm. Resistances per square centimeter of electrodes shown in the figure were calculated from the slopes.

Electrolyte resistivity of catalyst layers.—The ohmic polarizations of multilayered electrodes are given in Fig. 5 as they vary with the thickness of catalyst layers. The ohmic resistances per square centimeter of electrode area calculated from the slopes are shown also in the figure. If the test layers possess the expected electrolyte resistivity, resistances of 0.72 and 0.79 $\Omega\text{-cm}^2$ must be observed for thicknesses of 0.14 (circles in the figure) and 0.22 mm (squares), respectively. These expected deviations from the value for zero thickness 0.62 $\Omega\text{-cm}^2$ are detectable by the current interruption method used. Observed resistance values, however, scatter around the value for zero thickness, and no systematic increases are found, suggesting that the electrolyte resistivity is much smaller than that expected theoretically. The assumption of ohmic potential drop therefore is very questionable.

The electrolyte diffusivity in catalyst layers.—The polarization curves of multilayered electrodes with and without a test layer are shown in Fig. 6. The polarization difference between the two electrodes $\Delta\eta_c$ is due to the concentration polarization occurred in the test layer

$$\Delta\eta_c = \frac{RT}{F} \ln \frac{C_{\text{OH}^-}^t}{C_{\text{OH}^-}^c} \quad [2]$$

where superscript t denotes the diffusivity test, $C_{\text{OH}^-}^t$ is

Fig. 6. Polarization curves of multilayered electrodes. Thickness of test layers: closed circles are for without test layers, and open circles are for 0.11 mm. Ohmic drop eliminated.

Fig. 7. Electrolyte diffusivity coefficient of Raney nickel catalyst layer as a function of current density. Thickness of catalyst layer: 0.11 mm.

the concentration of OH^- ion at the test and working layer interface, $C_{\text{OH}^-}^c$ is the bulk concentration 6M, and the other symbols have the usual meanings. The electrode current density I^t is proportional to the concentration gradient in the test layer

$$\frac{I^t}{F} = D_{\text{KOH}^t} \frac{C_{\text{OH}^-}^c - C_{\text{OH}^-}^t}{d^t} \quad [3]$$

where D_{KOH^t} is the electrolyte diffusivity coefficient of test layer and d^t is its thickness 0.11 mm. By eliminating $C_{\text{OH}^-}^t$ from Eq. [2] and [3] and inserting the polarization data given in Fig. 6, we obtain D_{KOH^t} values as a function of current density. Figure 7 shows plots of D_{KOH^t} vs. current density. A gradual increase observed in a low current region is probably due to a proceeding in the electrolyte penetration with increasing load. A constant D_{KOH^t} value of $9.57 \times 10^{-6} \text{ cm}^2/\text{s}$ is attained at 100 mA/cm^2 . This value will be used for the calculation of polarization resistance of electrodes.

Gas diffusivity of the electrodes.—The gas diffusivity of electrodes was measured in fashion similar to the above case. In the cell construction shown in Fig. 2, the potential difference between the electrodes with and without the test electrode $\Delta\eta_p$ is due to the gas pressure drop that occurred in the test electrode

$$\Delta\eta_p = \frac{RT}{F} \ln \frac{P_{\text{H}_2}^t}{P_{\text{H}_2}^c} \quad [4]$$

where $P_{\text{H}_2}^t$ is the gas pressure at the compartment between the test and working electrodes, and $P_{\text{H}_2}^c$ is the operating pressure 1 atm. Figure 8 shows the polarization curves of electrodes with and without the test electrode. No significant polarization differences can be seen between the two curves. This indicates that the electrodes used in this study are so gas diffusive that the concentration polarization due to the gas pressure drop can be neglected.

Calculation of the polarization resistance with considering concentration polarization.—The geometric model used is a cylinder, the inside face of which is covered with a thin electrolyte film, as shown in Fig. 9. The analysis considers a differential element dx cut from the cylinder. The local current is generated at the film/cylinder-wall interface, and its gathering flows as the pore current in the axial direction.

The Volmer reaction is assumed as a rate-controlling step for the hydrogen oxidation in alkaline solution (7)

In this case the local current density i can be expressed as a function of local potential E (8)

Fig. 8. Gas diffusivity test of a wetted Raney nickel electrode by means of polarization difference. Open circles: without a test electrode. Closed circles: a test electrode of 0.32 mm thickness set at the gas-side of working electrode. Ohmic drop eliminated.

$$i = -F \left\{ k^+ C_{OH^-} \sqrt{P_{H_2}} \exp \left(\frac{\alpha F}{RT} E \right) - k^- C_{H_2O} \exp \left(- \frac{(1-\alpha)F}{RT} E \right) \right\} \quad [6]$$

where k^+ and k^- are the rate constants, C_{OH^-} and C_{H_2O} are the concentrations of OH^- ion and water in the film, respectively, and P_{H_2} the hydrogen pressure. The gas diffusion in the pore is very fast so that $P_{H_2} = \text{const.} = 1 \text{ atm}$ throughout the cylinder. At equilibrium potential $E = E_0$

$$k^+ F C_{OH^-} \exp \left(\frac{\alpha F}{RT} E_0 \right) = k^- F C_{H_2O} \exp \left(- \frac{(1-\alpha)F}{RT} E_0 \right) = i_0 \quad [7]$$

where i_0 is the exchange current density. Substituting Eq. [7] into Eq. [6] yields

$$i = -i_0 \left\{ \exp \left(\frac{\alpha F}{RT} \eta \right) - \exp \left(- \frac{(1-\alpha)F}{RT} \eta \right) \right\} \quad [8]$$

where η is the local polarization and $\eta = E - E_0$. When η is small, the exponential function can be approximated to the linear function

$$i = - \frac{i_0 F}{RT} \eta \quad [9]$$

The exchange current density i_0 can be derived from Eq. [7] in the form

$$i_0 = k^+ F C_{OH^-} \left(\frac{k^-}{k^+} \right)^\alpha \left(\frac{C_{H_2O}}{C_{OH^-}} \right)^\alpha \quad [10]$$

Assuming $\alpha = 1/2$, we obtain

$$i_0 = F \sqrt{k^+ k^-} \sqrt{C_{H_2O} C_{OH^-}} \quad [11]$$

Fig. 9. Thin film model used for the calculation of polarization resistance.

Equation [9] then becomes

$$i = -k \sqrt{C_{OH^-}} (E - E_0) \quad [12]$$

where $k = F \sqrt{k^+ k^-} \sqrt{C_{H_2O}}$. It is essentially constant because the change in C_{H_2O} is negligible in the concentrations around 6M.

The local potential E is assumed to be constant throughout the cylinder from the fact that the electrolyte resistivity in the catalyst layer is very low.

The equilibrium potential E_0 is a function of x owing to the concentration polarization. Applying the Nernst's equation to E_0 , we obtain

$$E_0 = E_0^o - \frac{RT}{F} \ln \frac{C_{OH^-}}{C_{OH^-}^o} \quad [13]$$

where $C_{OH^-}^o$ is the bulk concentration 6M and E_0^o is the equilibrium potential at $C_{OH^-} = C_{OH^-}^o = 6M$.

In load condition, the potential E_0 rises with x due to the lowering of the concentration, while the potential E remains constant throughout the pore. The driving potential $E - E_0$ for the local current generation therefore lowers with x . Hence, an additional improvement in the polarization loss by thickening the layer becomes less as the layer is thick. This is a qualitative explanation for the limit of thickness effect in terms of the concentration polarization.

The local current density is related to the pore current flowing in the axial direction J_p by making a current balance on the differential element

$$i = \frac{1}{2\pi r} \frac{dJ_p}{dx} \quad [14]$$

where r is the mean radius of pores.

The electrolyte used is KOH, and only the OH^- ion is electroactive. For this case, the gradient in the OH^- ion concentration is related to the ionic current J by

$$J = n_{OH^-} \left(1 + \frac{|n_{OH^-}|}{n_{K^+}} \right) D_{OH^-} F \frac{dC_{OH^-}}{dx} \quad [15]$$

where n_{OH^-} and n_{K^+} are ionic valences of OH^- and K^+ ions, respectively, and D_{OH^-} the diffusivity coefficient of OH^- ion (9). The pore current is proportional to the cross-sectional area of the film

$$J_p = 2\pi r \delta J = -2\pi r \delta D_{KOH} F \frac{dC_{OH^-}}{dx} \quad [16]$$

where $D_{KOH} = -n_{OH^-} (1 + |n_{OH^-}/n_{K^+}|) D_{OH^-}$ and δ is the mean thickness of the electrolyte films. Multiplying J_p by the number of pores per unit electrode area $1/\pi r^2$ to convert to the current density per unit electrode area I , we get

$$I = - \frac{2\delta}{r} D_{KOH} F \frac{dC_{OH^-}}{dx} \quad [17]$$

The factor $2\delta/r$ is the structural parameter of the electrode used and is involved in the experimental diffusion coefficient so that the term $2\delta/r D_{KOH}$ can be equalized to d_{KOH}^t , which appears in Eq. [3]

$$\frac{I}{F} = -d_{KOH}^t \frac{dC_{OH^-}}{dx} \quad [18]$$

Combining Eq. [12]-[14] and multiplying J_p by $1/\pi r^2$, we obtain

$$\frac{dI}{dx} = -K \sqrt{C_{OH^-}} \left\{ \eta_0 + \frac{RT}{F} \ln \left(\frac{C_{OH^-}}{C_{OH^-}^o} \right) \right\} \quad [19]$$

where $K = 2k/r$ and $\eta_0 = E - E_0$, which is the electrode polarization.

The electrode current density is obtained as an I value at $x = 0$ by integrating Eq. [18] and [19] simultaneously under the boundary conditions $C_{OH^-} = 6M$ at $x = 0$ and $I = 0$ at $x = d$. The integration was performed numerically using the modified Runge-Kutta method.

The K value is determined by the parameter matching from the slope of the polarization curve for the thin electrode; the linear part in the ω^{-1} vs. thickness plots in Fig. 4 indicates that the effect of concentration polarization is negligible in the thickness region. On fitting to the thin electrode data, $316 \Omega^{-1}\text{-cm}^{-1.5}\text{-mol}^{-1/2}\text{-atm}^{-1/4}$ was obtained as a K value. This value and the experimental D_{KOH}^{\dagger} value $9.57 \times 10^{-6} \text{ cm}^2/\text{s}$ being inserted into Eq. [19] and [18], respectively, the theoretical polarization resistances were calculated as a function of thickness. Figure 10 shows the relationship between ω^{-1} and thickness. The theoretical values (solid line) agree quite well with the experimental data (open circles). The thickness effect has been thus reproduced theoretically by assuming the concentration polarization. We can therefore say that the lower limit attained by the thickness effect in the polarization loss is determined by the electrolyte diffusivity, and not by the electrolyte resistivity in catalyst layers.

As seen in Fig. 6, when a current of, e.g., 200 mA/cm² flows across a test layer 0.1 mm thick, a concentration polarization of 14 mV arises. When Ohm's law is applied mechanically to this potential-current relationship, 7 $\Omega\text{-cm}$ is obtained as an apparent resistivity. This is very close to the ohmic resistivity expected from the parameter matching to Eq. [1], 7.5 $\Omega\text{-cm}$. Experimentally, the concentration polarization is almost a linear function of current density (Fig. 6) and the potential gradient due to the concentration polarization has a sign opposite of that due to the ohmic drop. The concentration polarization, therefore, is theoretically equivalent in effect on the driving potential to the ohmic potential drop brought about by the hypothetical resistivity of 7.5 $\Omega\text{-cm}$. This is why Eq. [1] leads to a theoretical curve fitting to the experimental data in spite of its starting from a different operating mechanism. These two, however, are physically different from each other. The fitness to Eq. [1] is just a coincidence resulting from the linear relationship between the concentration polarization and current density. A resistivity as high as 7.5 $\Omega\text{-cm}$ has not been found from the direct measurement so that the gradient in the driving potential in the pores should be attributed to the concentration polarization.

Chromium-doped Raney nickel catalyst.—The catalytic activity of Raney nickel is enhanced by doping a small amount of chromium (6). Figure 11 shows ω^{-1} vs. thickness plots for the hydrogen electrodes catalyzed with this Raney nickel. By assuming the same D_{KOH}^{\dagger} value, but using $K = 854 \Omega^{-1}\text{-cm}^{-1.5}\text{-mol}^{-1/2}\text{-atm}^{-1/4}$ obtained from the polarization data, the ω^{-1} values were calculated similarly. A solid line in Fig. 11 is theoretical, and open circles denote experimental data. The polarization loss is im-

Fig. 10. Reciprocal polarization resistance of Raney nickel electrodes as a function of thickness of catalyst layers. Solid line calculated from Eq. [18] and [19] for the experimental D_{KOH}^{\dagger} value: $9.57 \times 10^{-6} \text{ cm}^2/\text{s}$.

Fig. 11. Reciprocal polarization resistance of chromium-doped Raney nickel electrodes as a function of thickness of catalyst layers. Solid line calculated from Eq. [18] and [19] for the same D_{KOH}^{\dagger} values as in Fig. 10.

proved markedly by using this new catalyst. This indicates that the catalytic activity also is an important factor for the polarization loss and the K factor is its measure.

Depth profile of the local current density.—The local current density and concentration polarization can be calculated as a function of x from Eq. [18] and [19]. Figure 12 shows the depth profile for nondoped Raney nickel electrode polarized to 10 mV. The concentration polarizations η_c are given as differences from E° . The areas surrounded by the curves i and x coordinate correspond to the load current density sustained by the electrode, and the gaps between curves η_c and $\eta_c = -10$ mV to the driving potential. The lower limit in the polarization loss is reached at a limiting thickness not because the driving potential becomes zero at the gas-side edge of pore, but because increasing thickness makes the curve i steeper. As seen in Fig. 4, the polarization loss almost attains its

Fig. 12. Depth profiles of local current density (top) and concentration polarization (bottom) for various thicknesses. Thickness: (A) 0.3 mm, (B) 0.4 mm, (C) 0.5 mm.

lower limit at about 0.3 mm thick, where 60% of the full potential is still held as a driving potential at $x = 0.3$ mm (curve A in the bottom of Fig. 12). If more electrolyte-diffusive catalyst layers can be used, the profile becomes flatter and the thickness effect extends over a wider thickness range. From a practical point of view, this means that the performance improvement can be made by enhancing the electrolyte diffusivity as well as catalytic activity.

Conclusion

The polarization loss of Raney nickel hydrogen electrodes can be decreased by thickening the catalyst layers. However, there is a lower limit to the polarization loss that can be attained by the thickness effect. This limiting behavior has been described on the basis of concentration polarization assumption in contrast to the ohmic potential drop mechanism. The electrolyte diffusivity coefficient of catalyst layer required for the theoretical calculation was obtained by using a multilayered electrode installed with a zirconia layer to separate the test layer electronically from the working layer. The theoretical calculation by use of the experimental value reproduced well the experimental limiting behavior in the thickness effects, and the concentration polarization assumption has thus been proved to be valid. The importance of the electrolyte diffusivity in the catalyst layer has been pointed out as a performance controlling factor.

Electrochemical Behavior of Water in Immobilized Salt Electrolytes

II. Cyclic Voltammetry

Armand Bettelheim, Federico Broitman, and Uri Mor

Nuclear Research Center-Negev, Beer Sheva 84190, Israel

ABSTRACT

Cyclic voltammetry is used to determine the concentration of water and hydrolysis products in a pelletized LiCl-KCl-MgO mixture. This method, effective at temperatures above the melting point of the electrolyte, completes other electrochemical and thermal methods which have been previously used to investigate the various states of water at lower temperatures.

The determination of water and its reaction products in molten LiCl-KCl eutectic is of interest for the development of primary as well as secondary batteries for load leveling and electric vehicle applications. The presence of water as well as other contaminants formed near the electrodes during exposure to humid air could affect cell performance and accelerate self-discharge (1).

Cyclic voltammetry has been widely applied to liquid electrolytes to study redox reactions. Important param-

eters related to the reactions such as redox potential, rate constant, Tafel slope, and diffusivity of the redox species can be easily obtained (2, 3). This technique, recently used in solid electrolyte systems (4, 5), has not yet been applied to pelletized salt electrolytes. In these systems, a binder (such as MgO or SiO₂) is added in order to gel and immobilize the electrolyte, which would otherwise flow when subjected to the battery operation temperature, some 150°C above the electrolyte melting point. In a pre-

vious study (6), we reported the use of electrical conductivity and thermal measurements to detect water and hydrolysis products in a pelletized LiCl-KCl (64-36 mole percent [m/o])-MgO (50 weight percent [w/o]) mixture. In the present work, cyclic voltammetry is used for the *in situ* determination of water and hydroxyl ions and investigation of their electrochemical behavior.

Experimental

AR-grade LiCl, KCl, and MgO (Merck) are used. Pellets of electrolyte composed of LiCl-KCl (64-36 m/o) in presence of MgO (50 w/o) as binder are prepared as described in a previous publication (6).

A schematic diagram of the apparatus for cyclic voltammetric (CV) measurements of pellets is illustrated in Fig. 1. The platinum working and auxiliary electrodes are spot welded to a 0.5 mm diam platinum wire sheathed in glass. The reference electrode consists of a pure nickel wire inserted into a thin-walled, 2 mm od Pyrex tube containing a $10^{-2}M$ solution of NiCl₂ in LiCl-KCl eutectic. The Ni/Ni(II) ($10^{-2}M$) reference electrode, which has a potential 795 mV more negative than the Pt/Pt(II) ($10^{-2}M$) electrode (7), is allowed to be in contact with the pellet as shown in Fig. 1. The whole set is heated under vacuum at below the melting point and under dry argon after melting. The heating is achieved by means of a programmable device which permits a constant temperature within $\pm 1^\circ C$.

Melts of LiCl-KCl (in the absence of binder) are contained in alumina crucibles and are maintained at 430°C

in an atmosphere of dry argon. Additions of hydroxide and oxide ions are accomplished using KOH and CaO. Lithium chloride with a water content of 1.6% is used to increase H₂O concentration in the melt. The platinum working and auxiliary electrodes, as well as the Ni/Ni(II) ($10^{-2}M$) reference electrodes, are as described for the CV of pellets.

Cyclic voltammetry is performed using a PAR 174 potentiostat coupled with a PAR 175 sweep generator. The voltammograms are recorded on a Type 3078 Yokogawa X-Y recorder.

Results and Discussion

Figure 2 shows a typical cyclic voltammogram obtained at 430°C for a pelletized LiCl-KCl-MgO mixture originally containing 2.5 w/o water. The CV curve shows two cathodic peaks (I and II) at -1.48 and -2.26V. Plots of the peak current (i_p) vs. the square root of the scan rate ($\nu^{1/2}$) are linear, indicating diffusion-controlled processes (Fig. 3).

The addition of solutes to a pellet cannot be accurately accomplished but is relatively simple for a LiCl-KCl melt (in the absence of MgO) of the same eutectic composition and temperature. The CV at 430°C of a LiCl-KCl melt which has not been prepurified to remove water and hydrolysis products (Fig. 4, curve a) shows characteristics very similar to those of the pellet. Peaks I and II are attributed to the reduction of water and hydroxide ions, respectively, and the process occurring in region VII to oxidation of oxide ions. The identification of the various peaks is inferred on the basis of proportionality between known added concentrations of H₂O, OH⁻, and O⁻² ions in the melt and peak height. The relative potential position of various processes is in agreement with other studies conducted with several reference electrodes and various molten salt systems (8-12).

By varying the upper and lower limit of the potential sweep, some of the peaks corresponding to the different reduction peaks can be identified. For example, peak VI is the oxidation peak corresponding to the reduction peak I which increases when H₂O is added to the melt. The potential difference between the cathodic and anodic peaks ($E_{p,c} - E_{p,a}$) is 140 mV, which is similar to the theoretical

Peak	Pellet	E_p/V	Melt	Electrode reaction
I	-1.48	-0.84		$2H_2O + 2e \rightarrow H_2 + 2 OH^-$
II	-2.26	-1.94		$2 OH^- + 2e \rightarrow H_2 + 2 O^{2-}$
VII	+0.1 ^a	+0.5		$2 O^{2-} \rightarrow O_2 + 4e$

^a Due to the high oxide concentration, a distinct peak is not observed and the potential of the foot wave is reported.

to the melt (Fig. 4, curves b and d). The influence of basicity of the melt on $E_{1/2}$ suggests the involvement of hydroxyl ions in the reduction process. These results are in agreement with the overall reaction scheme (8)

Similarly, peak II is due to the reduction of hydroxyl ions. The presence of the corresponding peaks III, IV, and V indicates a sequence of oxidation reaction steps. No attempt was made to identify the reduction or oxidation products. However, the overall reaction [2] was deduced from the electrochemical measurements of Kan-zaki and Takahashi (8)

Wave VII is due to oxidation of oxide ions according to the reaction (12)

The currents of the OH⁻/H₂ and O²⁻/O₂ couples decrease to very small values when the melt is treated with HCl for a period of 1-2h (compare curves b and c to d and e in Fig. 4). This is probably a consequence of the reaction of OH⁻ and O²⁻ ions with HCl, as reported for LiCl-KCl-MgO pellets in a previous publication (6), and for the LiCl-KCl melt reported in other studies (11, 13)

Table I summarizes the CV data. The cathodic shift of peaks I and II for the pellet as compared to the melt is due to the high oxide concentration in the pellet and the expected dependence of redox potential on the p_{OH^-} and the $p_{O^{2-}}$ (8, 12). The large amount of oxide ions in the pellet also accounts for the high current obtained for wave VII. Moreover, the potential shift of this wave for the pellet is opposite in direction to peaks I and II, again in agreement for the proposed identification of the various electrochemical reactions in the melt and the pellet.

The comparison of the CV curves for the melt and the pellet allows not only the identification of the various electrode reactions, but also a quantitative estimation of H₂O and OH⁻ concentrations in the pellet. According to the Randles-Sevcik equation (14), the peak current (i_p) is directly related to the concentration (c) of the electroactive species and to the square root of the scan rate ($\nu^{1/2}$)

$$i_p = kAC(\nu/RT)^{1/2}(FnD)^{3/2} \quad [6]$$

where k is a constant for a given reaction, A is the electrode area, T is the absolute temperature, R is the gas constant, F is Faraday's constant, and ν is the potential sweep rate. In Fig. 5a, the peak current densities for various water concentration increases are plotted against the square root of scan rate. The slope of the straight line recorded before the first addition of water is related to the residual water concentration in the melt at the start of the measurements. If the slope measured for the initial unknown concentration is deduced from the values determined from the added concentrations, one obtains the corrected slopes corresponding to the added concentrations. The corrected values are plotted against the added concentrations of water in Fig. 5b. Assuming the same

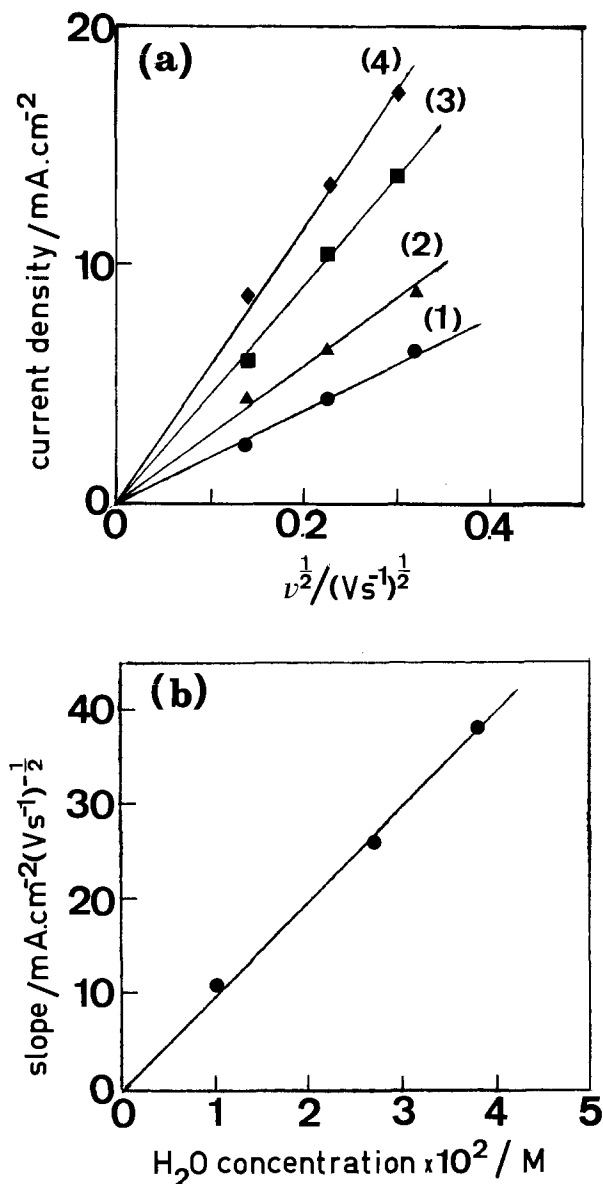

Fig. 5. a: Current density of peak I vs. the square root of scan rate for a LiCl-KCl melt at 430°C. Curve 1 is relative to the initial water concentration, while curves 2-4 are for the addition of 10^{-2} , 2.7×10^{-2} , and 3.8×10^{-2} M H₂O. b: Corrected slopes of curves in Fig. 5a vs. the water concentration in the melt.

diffusion coefficient for H₂O in the pellet and the melt maintained at the same temperature, the water concentra-

tion in the pellet can be estimated using the slope of i_p vs. $v^{1/2}$ for the pellet and the calibration curve shown in Fig. 5b. Using this procedure, an approximate value of 10^{-2} M is obtained for this specific example.

The same calibration technique can be used to determine the hydroxyl ion concentration in the pellet.

Conclusion

It has been shown that cyclic voltammetry can easily be applied to molten pelletized mixtures. The redox potentials for H₂O and different hydrolysis products agree with other published data (8, 12). CV also allows a quantitative determination of H₂O and OH⁻ ions at temperatures above the melting point of the electrolyte ($\geq 370^\circ\text{C}$). This technique completes other methods (ac electrical conductivity, DTA, and TGA) previously employed for the detection and characterization of the different states of water in pelletized specimen at lower temperatures (6).

Electrolytic Purification of Aqueous Solutions of Potassium Chloride Containing Manganese Ions

J. Fujioka and H. Riveros

Institute of Physics, National University of Mexico, Coyoacán, Mexico

ABSTRACT

The purification by electrolysis at a mercury electrode of aqueous solutions of potassium chloride containing manganese ions is investigated. The concentration of manganese decreased from 112 to 0.4 ppm after 20 min of electrolysis at -1.85V (vs. SCE).

The procedures reported over the last ten years to purify aqueous solutions of alkali metal chlorides involve the use of precipitating agents, ion-exchange resins, or both types of substances (1-18). Of these procedures, the great majority is focused on the elimination of calcium

and magnesium ions present in the solution (5-9, 11-15, 17, 18).

In this paper, the purification by electrolysis of aqueous solutions of potassium chloride contaminated with manganese is studied. This method of purification and

the impurity chosen are not very common in the field of purification of alkali halides.

The elimination of Mn^{2+} ions from aqueous solutions of KCl could be useful in the electrochemical production of Cl_2 and KOH, which generally involves the use of coated titanium anodes and mercury cathodes. The presence of Mn^{2+} in the aqueous KCl fed to the cells is very detrimental in that MnO_2 deposits on the coated titanium anodes. This causes the cell voltage and power consumption to increase. Furthermore, the removal of MnO_2 from the coated titanium anodes without damaging the coating on the anodes is difficult.

As a method of purification, electrolysis has been used on a small scale. In particular, in the purification of aqueous solutions of alkali halides, its use has been very rare. However, it has been proven that electrolysis is an effective method to remove certain unknown impurities found in high purity KCl, using a graphite electrode as the working electrode (19).

The use of electrolysis in the purification of aqueous solutions renders it possible to employ the same equipment used in the purification to check the decrease in the impurity concentration, and to observe some of the characteristics of the reaction by which the impurity is eliminated. This can be accomplished by applying a triangular potential $E(t)$ to the working electrode, and plotting the current $i(E)$ that flows through the cell (*i.e.*, using the technique known as linear potential sweep chronopotentiometry or linear sweep voltammetry). To interpret these i - E curves (voltammograms), the theory of stationary electrode polarography can be used (20-23). However, it must be remembered that the mercury electrode used in this study is much larger than the tiny drops used in polarography. The results of Reeves *et al.* (24) concerning the reduction of K^+ at a mercury cathode will also be helpful.

Experimental

A three-electrode cell (EG&G PAR Model 377A) was used both for the purification and the voltammetric study. The working electrode (Hg) had 12.8 cm^2 in contact with the solution, and the reference electrode was a saturated calomel electrode. The potential of the working electrode was controlled with the EG&G PAR Model 173 potentiostat, and the triangular signal was provided by the EG&G PAR Model 175 programmer. The voltammograms were recorded on the EG&G PAR Model RE 0074 X-Y recorder with the aid of the EG&G PAR Model 176 current-to-voltage converter. The analyses of the solutions were done with the Perkin Elmer Model 403 spectrophotometer. The mass spectrographic analysis of the salt was done by the Northern Analytical Laboratory.

The salt bridges communicating the reference and counterelectrodes with the cell were filled with solutions of pure KCl at the same concentration as that of the KCl contained in the cell.

Each of the voltammograms was obtained using 10 ml of solution. The scan rate utilized in all the voltammograms was 200 mV/s. All potentials are reported *vs.* the saturated calomel electrode.

Results

In order to fully appreciate the effect produced by the impurity, some voltammograms of pure KCl solutions were obtained. Curve A of Fig. 1 shows that the mercury oxidation is already noticeable at 0.02V and the reduction of K^+ is initiated approximately at -1.85V , approximately 0.5V above the value quoted by Bard and Faulkner (20). Curve B shows the response of the solution over a wider potential range. In this figure it can be seen that the anodic reaction

is reversible, while the cathodic reaction is almost irreversible. Reeves *et al.* (24) found that the irreversibility of this reaction is due not to the reduction of K^+

Fig. 1. Voltammograms of solutions containing: 2M KCl (A), 2M KCl (B), 2M KCl with 0.2 mM $MnCl_2$ (C).

which is a reversible reaction, but rather to the evolution of hydrogen

which is a very irreversible reaction. They also found that the reduction of K^+ is accompanied by a second, irreversible reduction process, attributed to the reduction of water

The effect of adding some Mn^{2+} ions to the solution was then studied. Curve C of Fig. 1 shows the voltammogram of a solution containing 2M KCl and 0.2 mM $MnCl_2$. It confirms that Mn^{2+} is reduced at a potential less negative than that of K^+ , as was already known (21), and shows that this reaction is irreversible.

To observe in greater detail the reduction of Mn^{2+} , 4M and 2M KCl solutions were prepared containing different concentrations of manganese. In Fig. 2 and 3, the voltammograms of these solutions are shown. It can be seen that two waves, situated around -1.63 and -1.74V , respectively, are produced. Curve A of Fig. 4 shows that the height i_p^+ of the first of these waves depends linearly on the concentration C_m of manganese and is independent of the concentration C_p of potassium. This behavior indicates that this wave is due to a reaction controlled by diffusion, the type usually found in stationary electrode polarography (20-22). On the other hand, the height i_p^- of the second wave, measured from the potential axis as a

Fig. 2. Voltammograms of 4M KCl solutions containing: 0.4 mM $MnCl_2$ (A), 1 mM $MnCl_2$ (B), 2 mM $MnCl_2$ (C), and 3 mM $MnCl_2$ (D).

Fig. 3. Voltammograms of 2M KCl solutions containing 0.2 mM MnCl₂ (A), 0.5 mM MnCl₂ (B), 1 mM MnCl₂ (C), and 2 mM MnCl₂ (D).

base line, exhibits a different behavior. The dotted lines of Fig. 4 show that i_p^- follows approximately straight lines as C_m increases, but the slopes of these lines depend on C_p .

The voltammograms of Fig. 2 and 3 also show that the current flowing through the cell in the reverse scan of the potential can be higher than the current produced during the forward scan. The comparison of these voltammograms reveals that this effect is accentuated if the ratio C_m/C_p is increased.

The presence of the second wave, the influence of C_p on the value of i_p^- , and the slow decay of the current during the reverse scan, must be the consequences of a second reaction involving manganese. The mechanism of this reaction will not be investigated in this communication.

Having observed some of the characteristics of the cathodic reaction, the purification of the solution was studied.

In the first place, a cyclic voltammetry of a solution containing 4M KCl and 4 mM MnCl₂ was performed. The potential of the mercury cathode was linearly varied from -1.4 to -1.8V and vice versa, at scan rate of 200 mV/s. The electrolysis was maintained for 90 cycles. In Fig. 5, the voltammograms of some of the cycles can be seen, showing that the amount of manganese gradually decreases.

Fig. 4. Variation of i_p^+ and i_p^- with the concentrations of Mn and KCl.

Fig. 5. Cyclic voltammetry of a solution containing 4M KCl and 4 mM MnCl₂. The numbers of the cycles are indicated in each case.

The analysis of the solution before and after the electrolysis indicated that the concentration of manganese decreased from 224 to 77 ppm.

Next, an electrolysis using agitation was performed. The solution contained 2M KCl and 2 mM MnCl₂, and was electrolyzed for 20 min with the potential of mercury fixed at -1.85V. The analysis of the solution indicated that the concentration of manganese decreased from 112.5 to 0.4 ppm. This result proves the feasibility of this method for purifying KCl contaminated with Mn. The net charge transferred during the electrolysis was nearly twice the charge of the manganese ions eliminated from the solution. This indicates that the current efficiency of this purification process is approximately 50%.

Finally, 20 ml of a solution containing 2M KCl and 2 mM MnCl₂ were electrolyzed for 1h. After the electrolysis, the solution was filtered through a 1.2 μ m millipore filter, and the water was evaporated to recover the salt contained in the solution. A mass spectrographic analysis of this salt indicated that the concentration of Mn atoms was 0.02 ppm.

Acknowledgments

The authors wish to thank M. C. Garza for the analysis of the solutions and E. Camarillo for his valuable comments and suggestions.

Electrochemical Activation of Prothrombin on Platinum Electrode

H. Durliat, C. Davet, and M. Comtat*

Laboratoire de chimie physique et électrochimie, UA no. 192, Université Paul Sabatier, Toulouse, France

ABSTRACT

When a solution of prothrombin in 0.15M NaCl is put in contact for 10 min with a platinum electrode held at a given potential (between 1.15 and 1.35V *vs.* NHE), it may react with a chromogenic substrate specific to thrombin. A characteristic band of this molecule appears on electrophoresis gel. Moreover, this electrochemically treated solution induces the clotting of a fibrinogen solution in which an immunoenzymatic assay allows the identification of fibrinopeptide A. The results are very dependent on the potential and the surface state of the electrode. For instance, the application of high potentials greater than 1.45V leads to a splitting of the prothrombin molecules into many fragments without any particular biological activity. However, an electrode modified by thrombin adsorption before the application of potential allows the specific splitting of prothrombin to thrombin. Further experiments have shown that it is possible to diminish the enzymatic activity of thrombin solutions under specific conditions of potential (0.35V) without splitting the molecules and that linear sweep voltammetry modifies only the intrinsic pathway of coagulation when carried out on human platelet-free plasma.

Some electrochemical experiments related to the interfaces between metals and plasma or coagulation protein solutions are described in the literature. These studies were carried out to explain facts observed during experiments about blood compatibility with various materials. For example, metals and alloys immersed in circulating blood or in plasma do not induce coagulation when their potential at zero current is negative with respect to a normal hydrogen electrode (NHE) (1, 2). Moreover, metals having a positive potential at zero current *vs.* NHE in blood, but maintained at a negative potential by means of a direct or alternating current, become nonthrombogenic (3, 4). Two examples widely cited are ac polarization of copper, which leads to the occurrence of copper oxides or complexes, and the polarization behavior of titanium alloy (Ti₆Al₄V). The positive spontaneous potentials of these alloys become negative, and thrombosis no longer occurs. Furthermore, the materials chosen to make cardiac valves, sometimes on the basis of the evolution with time of open-circuit potentials, are often cobalt and titanium alloys (5, 6). Physical and chemical justifications of these observations are very difficult because of the complexity of the biological phenomena and the lack of a satisfactory explanation of these experimental results (7, 8).

The electrochemical study of the behavior of coagulation factors in contact with metals may provide an explanation for these phenomena. But although the systems are simpler than the blood-metallic valve interface, the conclusions are not yet clear.

The changes observed in the voltammograms when prothrombin, thrombin, or fibrinogen are present in solution (9-11) are difficult to identify. Indeed, they can be attributed either to adsorption phenomena at lower concentrations or to charge transfer at higher concentrations.

With a fibrinogen solution, optical and electrochemical methods were used (10, 12, 13) to obtain information regarding the charge-transfer reaction of the proteins and to suggest a classification of semiconductor materials according to their thrombogenicity (14).

The electrochemical transformation of bovin prothrombin (9) on a platinum electrode is a hypothesis based only on the modification of the clotting time of a solution of fibrinogen in which electrolyzed prothrombin was added. Coagulation times diminished when the applied potential was greater than 0.45V, and the higher the potential the faster the clotting time. For example, a time of 27h when the potential was 0.95V become 9.5h when the potential was 1.45V.

It should be noted that these molecules did not act as electronic relays in the biological process. Heterogeneous electron transfer with a metal may eventually occur with oxidation of terminal amino acids or the reduction of disulfide bridges. All of the commonly used potential ranges, however (9, 11), appeared to be insufficient to cause this kind of electrochemical reaction which would probably lead to products with no noticeable biological activity.

We tried to work on this problem because the arguments in favor of the electrochemical transformation of prothrombin in thrombin were not satisfactory. New methods to improve the purity of the prothrombin solution, commercialization of chromogenic substrates specific to thrombin, and immunoassay of fibrinopeptide A were very helpful in carrying out all our experiments.

On the basis of the plasmatic coagulation scheme, particularly for the activation of prothrombin and for fibrinofornation (15-19), we were able to define an experimental strategy designed to identify thrombin in electrochemically treated prothrombin solution. Two tests related directly to the solutions in which an electrode, at a given potential, was kept: gel electrophoresis for the identification of the molecular mass of the various molecules present in the sample, and the use of chromogenic substrates specific to thrombin. Two additional tests were designed to measure the coagulation times of fibrinogen solutions mixed with electrochemically treated prothrombin solutions and to identify by an immunoenzymatic assay the fibrinopeptide A released during coagulation. At present, these four methods are all

* Electrochemical Society Active Member.

that exist for the identification of thrombin and the estimation of its biological activity.

Experimental Procedure

Reagents and tests of coagulation.—All the electrochemical experiments were carried out in 0.15M NaCl solution prepared from analytical-grade reagents and doubly distilled water at temperature of 25°C. Fibrinogen was from Kabi Diagnostica. Human prothrombin was from Sigma or was extracted and purified in the laboratory according to the method described in Ref. (20); its purity was checked by gel electrophoresis (21).

The method used to assay prothrombin was the measure of the clotting time at 37°C of a sample to which all the coagulation factors were added except prothrombin.

The results are given in percentage of prothrombin with respect to a test plasma. For each sample, a straight line was obtained, plotting the clotting time against the logarithm of the reciprocal of the dilutions of the samples. The prothrombin concentration of the test plasma, a pool of plasmas from different blood donors assumed to be in good health, was assumed to be equal to 100% (22).

The thrombin from Sigma was not of high purity (three bands on gel electrophoresis), but it was used without further purification; its enzymatic activity was measured either by the clotting time of a 0.2% fibrinogen solution or by the reaction on a chromogenic specific substrate (from Diagnostica Stago) Tos-Gly-Pro-Arg-pNA, where pNA is paranitraniline. The principle of this assay is based on the amidase activity of thrombin to release yellow paranitraniline, which absorbs light at 405 nm (23).

Electrophoresis was carried out in polyacrylamide gel with sodium dodecyl sulfate (21). A mixture of five proteins of molecular weight in the range of 12,000-78,000 allowed calibration of the gel under our experimental conditions.

Reagents necessary to perform all the coagulation tests were from Diagnostica Stago.

For some experiments, platelet-free plasma was used. The Kaolin Cephalin (KC) clotting time detects alteration of factors from the intrinsic system (22). In this test, coagulation was induced by recalcifying a sample in the presence of a platelet substitute and of a suspension of Kaolin, which activated the Hageman factor.

A deficiency in the extrinsic pathway was detected with the Quick time, comparing the coagulation time of the analyzed plasma in the presence of calcium thromboplastin to the coagulation time of a reference plasma (22).

Controlled potential experiments and cyclic voltammetry were performed using a Tacussel Model PRT 20-2X potentiostat and a Tacussel Model GSTP 2 function generator. The voltammograms were recorded using a Sefram X-Y recorder (Model Luxytrace).

A cell with two compartments was used: each compartment received 0.4 cm³ of solution. The working electrode was a platinum minigrad or a platinum disk of 2 mm diam. The reference electrode was a saturated calomel electrode, with a Luggin capillary filled with 0.15M NaCl solution. Both these electrodes were separated from the platinum auxiliary electrode by a low porosity glass frit. All the potentials were expressed *vs.* the normal hydrogen electrode.

All spectrophotometric measurements were carried out with a Beckman spectrophotometer (Model Acta IV).

Cyclic voltammetry experiments did not provide satisfactory results regarding the behavior of thrombin and prothrombin at the metal-solution interface. Voltammograms obtained at a sweep rate of 0.05 V/s between -0.55 and 1.25V with thrombin concentrations of about 4.16 units NIH¹ were identical to those obtained from the 0.15M NaCl solution. The results were the same with physiological concentrations of prothrombin. In this case,

¹Approximately 100 NIH units of thrombin correspond to the amount of thrombin obtained when physiological concentration prothrombin is completely transformed.

however, unlike the results observed with bovine prothrombin (9), changes in the curves were observed only after 5h of sweeping. These results are difficult to explain. They demonstrated particularly a decrease in intensity in the platinum oxide reduction zone, due probably to adsorption phenomena.

Several works have already treated this adsorption process by optical and electrochemical methods (24-25). The protein adsorption process on platinum is especially complex in the environment we used, as it competes with the adsorption of chloride and hydroxyl ions (26). It should be noted that with the potential limits chosen on the voltammograms no oxidation or reduction of the solvent that could modify the pH occurred.

Cyclic voltammetry, conducted on platelet-free plasma, led to a high oxidation current near 0.9V, noninterpreted. What is important is that the intrinsic pathway of the coagulation was altered without affecting the extrinsic pathway (the usual K.C. clotting time of 44s became 52s). Additionally, a very sticky, yellow film appeared on the electrode, confirming the significance of the adsorption phenomena in these systems. This film did not appear with platinum in contact with the plasma when there was no electric field. Controlled potential experiments were carried out from 5 to 20 min in 0.4 cm³ of solution. The potential was maintained at a value in the range of -0.40 to +1.75V, specified for each experiment. The results were always compared with those of a control experiment, which used nonpolarized platinum in contact with the same solution for the same length of time.

Results are presented in Fig. 1. With thrombin, the application of potentials lower than 0.05V for 10 min with 25 NIH units per cubic centimeter solutions produced a solution which, when mixed with chromogenic substrate, no longer led to a release of paranitraniline. Experiments conducted with potentials between 0.00 and 1.30V demonstrated a conservation of the enzymatic activity of thrombin. This activity disappeared completely with potentials greater than 1.35V.

For prothrombin, the use of potentials lower than 1.15V caused no change in detectable molecules using the four tests at our disposal. However, a potential of +1.25V applied for 10 min caused the occurrence of new molecular fragments in the solution. The molecular weights determined by electrophoresis were of about 10,000, 20,000, 40,000, 50,000, and 70,000, respectively (Fig. 2). One band corresponded to the remaining prothrombin; another corresponded to a thrombin-like molecule. From time to time, the solution had a thrombin activity similar to that observed physiologically. The clotting time and chromogenic tests indicated that, at best, 10% of prothrombin was transformed into thrombin.

Potentials higher than 1.35V induced a wild splitting of prothrombin molecules. This phenomenon can have a

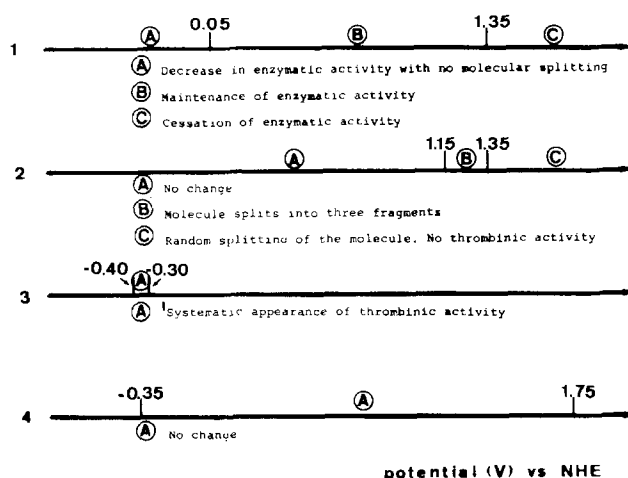

Fig. 1. Summary for various potentials applied for 15 min to different solutions. 1: Thrombin. 2: Prothrombin. 3: Prothrombin, platinum electrode covered with thrombin. 4: Platelet-free plasma.

number of causes (occurrence of chloride complexes of platinum, modification of the pH).

Other experiments were performed with electrodes modified by thrombin adsorption. First, in open circuit, the electrode was dipped for 5 min into a thrombin solution (250 unit/cm³). Then it was thoroughly rinsed in 0.15M NaCl solution until the cleaning solution had no enzymatic activity. A potential of -0.35V was then applied for 10 min to a prothrombin solution. In the previous experiments under the same electrical conditions, no modification of the molecule occurred. Here, however, three bands of molecular weights 52,000, 39,000, and 29,000 appeared on the electrophoresis gel. Moreover, the chromogenic substrate test demonstrated the occurrence of thrombin from the splitting of about 10% of the prothrombin molecules. No transformation occurred if the modified electrode was immersed into a prothrombin solution in an open-circuit experiment.

These experiments are reproducible, and it is possible to assay the fibrinopeptide A in a fibrinogen solution where electrochemically treated prothrombin was added. When the modified electrode was maintained at a potential of -0.35V in a 0.15M NaCl solution for various times before the electrolysis of prothrombin was carried out, it appeared that the higher the time the less the amount of thrombin formed in the electrical field.

With platelet-free plasma, the application of a variety of potentials in the range of -0.35 to +1.75V for 15 min resulted in no modification of the coagulation factors that can be assayed by clotting time tests. Nevertheless, application of potential equal to 1.25V for 3h lowered by 30% the fibrinogen concentration without any decrease in the prothrombin concentration.

Discussion

Depending on the potentials applied to the platinum electrode, it is possible to: (i) inhibit thrombin (a decrease in thrombinic activity was observed, with no break in the molecule, for potentials lower than 0.05V), (ii) split the prothrombin molecule into multiple fragments (potentials greater than 1.45V), and (iii) split the prothrombin molecule (with potentials between 1.5 and 1.35V); the resulting fragments will have molecular weights equal to those of the molecules obtained during enzymatic activation, by Stuart factor, particularly to thrombin. However, the thrombinic activity, deduced from measurements made on chromogenic substrates and immunoenzymatic assays of fibrinopeptide A, does not appear with regularity.

A similar splitting occurred with a potential of -0.35V when the platinum electrode was covered with adsorbed thrombin. In this case, the appearance of thrombinic activity was systematically reproducible.

In every case, the shape of the voltammogram and the range of potentials used (while the latter was too limited to cause the oxidation of amino acids or a reduction of disulfur bridges) demonstrate that the results were not caused by an electronic transfer. At the present stage of our research, we can only hazard some hypothesis to explain these facts.

With thrombin, positively charged at working pH, the molecule is attracted by an electrode with a sufficiently negative charge. It is then subjected to an intense electrical field, which causes structural modifications with a loss of enzymatic activity.

With prothrombin, at high potentials, the appearance on the surface of the electrode of platinum chloride complexes was noticed. These may play some role as catalyst in the hydrolysis of peptidic bonds. With lower potentials, we noticed biomimetic splitting of the molecule in the electric field. This may be due to a variety of causes. It may be the result of the molecules being adsorbed onto the electrode in such a way that some peptidic bonds are weakened and are therefore more sensitive to hydrolysis. This would be an electrocatalytic phenomenon in the hydrolysis of the peptide bond in the electrical field. Such a phenomenon has, to the best of our knowledge, never been described for biological molecules. It is comparable

Fig. 2. Electrophoresis in polyacrylamide gel. A: a prothrombin solution. B: a prothrombin solution put in contact with a platinum electrode held at 1.2V during 10 mn. The molecular weights corresponding to the various bands are as follows. 1: 70,000. 2: 50,000. 3: 40,000. 4: 20,000. 5: 10,000.

only to the hydrolysis of ethylacetate (27). It should not come as a surprise that the electrical fields weakened bonds which, in a biological process, are more sensitive to hydrolysis. If a 10% thrombin conversion can be reached, it is clear that this surface process creates nonadsorbed products on the electrodes which remain free for the adsorption of new prothrombin molecules.

The fact that the molecules thus formed are not consistently active leads us to assume a transformation of the structure of most of the prothrombin molecules in the electrical field. We could, of course, imagine that the electrical field activated another coagulation factor present in the prothrombin solution, itself capable of activating the prothrombin (*i.e.*, Stuart factor). In this case, there would be no reason to find a molecule similar to thrombin but having no enzymatic activity.

When the electrode, whose surface was first modified by the adsorption of thrombin, is brought to a potential of -0.35V, the negatively charged prothrombin molecule can reach the electrode because of the electrostatic interactions with thrombin. Under these conditions of potential, the molecule retains its structure, which explains the appearance of enzymatic activity. It is not thrombin which acts to split the molecule in an autocatalytic phenomenon, since without an electrical field there is no reaction.

The role of electrochemistry must also be emphasized in modifying the nature of platelet-free plasma (cyclic voltammetry induces an impairment of the intrinsic pathway, and the application of potentials near 1.25V for 3h caused the fibrinogen level to fall without producing a corresponding decrease in prothrombin).

Our experimental results have not all been satisfactorily explained. It is, however, necessary to emphasize their importance in the field of the fundamental biology of co-

agulation (they may suggest the existence of an electrochemical coagulation pathway). Ultimately, the use of an electrical field may make it possible to inhibit or to activate some factors of coagulation. We should not be too hasty in generalizing or in formulating rules for the choice of hemocompatible materials or for explaining their properties. In fact, it is enough to put physiological concentrations of albumin in contact with an electrode to protect prothrombin from the action of the electrical field.

Acknowledgments

This research was supported in part by the CNRS (ATP Matériaux hémocompatibles). We are deeply grateful to the late Professor F. Josso for the initiation of this work and his encouragement. The authors would like to thank Professor M. Jozefowicz (Paris Nord) and Dr. R. Eloy (Lyon) for helpful discussions, Dr. M. C. Boffa (Paris) for generous gift of prothrombin solutions, Professor B. Boneu and A. Baudras (Toulouse) for help in extraction of prothrombin, and Dr. J. L. Sérès (Lacq) for the fibrinopeptide A analysis.

Doped Polydithienothiophene: A New Cathode-Active Material

Maria Biserni, Annamaria Marinangeli, and Marina Mastragostino

Istituto chimico G. Ciamician, Università degli Studi di Bologna, 40126 Bologna, Italy

ABSTRACT

Films of doped polydithienothiophene, anodically synthesized on Pt or SnO₂-coated Pyrex electrodes in CH₂Cl₂ solution containing the monomer (dithienothiophene) and MX (M⁺ = N(Bu)₄⁺, X⁻ = ClO₄⁻, PF₆⁻) as the supporting salt, are electroactive. These films can be driven repeatedly, in CH₂Cl₂/MX solution, between the doped and the undoped state releasing and storing charges. The coulombs efficiency of the redox process is ca. 100%, and the charge involved is equal to 20% of that involved in the initial electrochemical preparation of the doped polymer. Doped p-DTT/Pt electrodes with high doping level (50%) have a value of V_{oc} of ca. 1V. In the discharge in CH₂Cl₂/MX solution of doped p-DTT/Pt electrodes at constant current density up to 0V, high values of charge are recovered with respect to the stored (40-60% at -2 mA·cm⁻²). All these features of doped p-DTT are attractive and relevant to its application in battery technology. However, doped p-DTT films preserved in CH₂Cl₂/MX solution show the disadvantage of a fast self-discharge (18-100h). This phenomenon is due not to polymer degradation, but to an undoping process, presumably owing to an uncontrolled redox reaction involving the used electrolytic medium.

Recently, much scientific work has been devoted to organic conducting polymers because of the large field of potential applications (as electrode materials of rechargeable batteries or as electro-optic display devices, etc.). The main interest concerns their ability to be switched, by chemical or electrochemical doping, from a neutral (nonconducting) state to an oxidized or reduced conducting state. The electrochemical preparation approach is more attractive than the chemical, because the polymer is produced directly in its conducting oxidized form, a wide selection of counterions being available from the electrolyte. The variety of aromatic compounds which have been found to undergo electrochemical polymeriza-

tion [pyrroles (1), thiophene (2), furan (2), carbazoles (3)] demonstrates the facility of this approach. Diaz *et al.* (4) indicate that the electrosynthesis of the polypyrrole proceeds via the oxidation of pyrrole with a mechanism involving a series of oxidation and deprotonation steps. The electrochemical stoichiometry is 2.2-2.4 electron/pyrrole ring, where 2 electron/pyrrole ring is involved in the polymer formation. The extra charge (0.2-0.4 electrons) accounts for the concurrent oxidation of the polymer which has a lower oxidation potential than the monomer.

In the present paper, we report a few electrochemical properties of doped polydithieno(3,2-b:2',3'-d)thiophene (shown in Fig. 1) relevant to their applications in battery

Fig. 1. Doped polydithieno(3,2-b:2',3'-d')thiophene (p-DDT), where $X^- = \text{ClO}_4^-, \text{PF}_6^-$.

technology. This material is a new electrogenerated conducting polymer (5).

Experimental

The monomer dithieno(3,2-b:2',3'-d')thiophene (DDT) was synthesized following the de Jong-Janssen method (6). Doped p-DDT was electrochemically prepared at controlled current and at controlled potential, on Pt and SnO_2 -coated Pyrex electrodes, in degassed and anhydrous ($[\text{H}_2\text{O}] < 0.1 \text{ mM}$) electrolytic medium formed by methylene chloride (CH_2Cl_2), the monomer 2 mM, and the supporting salt:tetrabutylammoniumperchlorate (TBAP) 0.1M. Tetrabutylammoniumhexafluorophosphate (TBAFP) 0.1M was also used as electrolyte. The cell had two separated compartments. Pt and saturated calomel electrode (SCE), with suitable liquid junction, were used as counter and reference electrodes. All the potential data are referred to SCE. The solvent CH_2Cl_2 (RPE, C. Erba) was purified by double distillation and followed by dehydration with activated molecular sieves (4A Pellets, 4 mm, C. Erba) under N_2 . TBAP "purum" Fluka was crystallized from methanol before use. TBAFP was prepared following the method of Lind *et al.* (7). All electrochemical experiments were performed with an Electrochemolab AMEL apparatus at 288 K. The spectroscopical measurements in visible, near IR were made utilizing a Perkin Elmer Model 323 Spectrophotometer.

Results and Discussion

Polydithienothiophene (p-DDT) was generated in its doped state with different anions ($X^- = \text{ClO}_4^-, \text{PF}_6^-$) typically at a constant current of $0.4 \text{ mA}\cdot\text{cm}^{-2}$ (the charge potential value was *ca.* 1.3V). The electrode surface becomes quickly covered by a black, adherent film of doped p-DDT. The thickness of the film was controlled by the electrolysis time and varied between $0.1 \mu\text{m}$ and 1 mm. Films of *ca.* $0.1 \mu\text{m}$ thick were grown by passing $13 \text{ mC}\cdot\text{cm}^{-2}$. The elemental analysis of these polymers indicates that the ratio of DDT units to X^- anions is 2:1; the conductivity measurements of these polymers gave σ values ranging from 3.10^{-3} to $1.10^{-2} \Omega^{-1}\cdot\text{cm}^{-1}$ (5).

Electrochemical reduction of the doped polymers to an undoped state was tested by cyclic voltammetry. Figures 2 and 3 report ten continuous cyclic voltammograms at Pt electrode in a solution of DDT in CH_2Cl_2 with ClO_4^- and PF_6^- , respectively, as anion of electrolyte. These figures show that the monomer oxidation starts at 1.2V with the growth on the electrode surface of the doped polymer. This polymer is reduced and, then, in the following cycle, oxidized at lower potentials than that of monomer oxidation. p-DDT films produced by sweeping continuously were transferred to an electrolytic medium not involving DDT and cycled between -0.5 and $+1.7\text{V}$ at different sweep rates ($20\text{--}200 \text{ mV}\cdot\text{s}^{-1}$). Linear relationships between the anodic and the cathodic peak currents and the sweep rate were found as expected for the reaction of surface localized material. The redox reaction is accompanied by color change, since the reduced film is red and the oxidized is black.

The electroreduction of the doped polymer produces the undoped film, and the electro-oxidation of this latter, in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution, regenerates the doped polymer, as demonstrated by the absorption spectra visible near IR recorded during the electrochemical cycle. Figure 4 shows the spectrum of the polymer film electro-synthesized, at $I = 0.3 \text{ mA}\cdot\text{cm}^{-2}$, on SnO_2 -coated Pyrex electrode

Fig. 2. Continuous cyclic voltammograms ($v = 0.2 \text{ V/s}$, from -0.5 to 1.7V and reverse) on Pt in an electrolytic medium (CH_2Cl_2 , TBAP 0.1M) involving DDT 2 mM.

Fig. 3. Continuous cyclic voltammograms ($v = 0.2 \text{ V/s}$, from -0.5 to 1.7V and reverse) on Pt in an electrolytic medium (CH_2Cl_2 , TBAFP 0.1M) involving DDT 2 mM.

with $Q = 47 \text{ mC}\cdot\text{cm}^{-2}$ and the spectrum of the film after its total electrochemical reduction ($Q_{\text{red}} = 9.4 \text{ mC}\cdot\text{cm}^{-2}$ at $I = -0.1 \text{ mA}\cdot\text{cm}^{-2}$). Figure 4 also shows a series of spectra taken during the gradual electrochemical reoxidation of the film in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution at $I = 0.1 \text{ mA}\cdot\text{cm}^{-2}$ and

Fig. 4. Series of absorption spectra. 1: Electro-synthesized doped p-DDT (with ClO_4^-). 2: Undoped p-DDT. 3-6: Gradually doped p-DDT (with ClO_4^-) during electrochemical reoxidation. 7: Electrochemically regenerated undoped p-DDT.

the spectrum of the fully rereduced film. The band at higher energy in the visible region is characteristic of the undoped polymer (π - π^* transition), and the two bands at lower energy in the near-IR region are characteristic of the doped polymer. The gradual evolution from the undoped to doped state is evidenced by the intensity variation of the characteristic bands with shift of the absorption peaks toward higher energy. A similar behavior has been observed in polythiophene (8), and the interpretation of the spectra bands is referred to Ref. (8). In our case, however, unlike highly doped polythiophene, the presence of a single broad band in the low energy region, which is characteristic of the free-carrier spectrum of the metallic state, was not observed. The redox process is a regenerative process which does not change the material; in fact, identical spectra were obtained after the first and second total reduction.

Figures 5 and 6 show the first and one-hundredth of the series of continuous cyclic voltammograms of

Fig. 5. Cyclic voltammograms of a p-DTT/Pt film in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M; the first and the one-hundredth cycles ($\nu = 0.2$ V/s, from -0.5 to 1.5 V and reverse). The p-DTT/Pt film has been produced by sweeping continuously (10 cycles, $\nu = 0.2$ V/s, from -0.5 to $+1.7$ V and reverse) in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M with DTT 2 mM.

Fig. 6. Cyclic voltammograms of a p-DTT/Pt film in $\text{CH}_2\text{Cl}_2/\text{TBAFB}$ 0.1M; the first and the one-hundredth cycles ($\nu = 0.2$ V/s, from -0.5 to 1.4 V and reverse). The p-DTT/Pt film has been produced by sweeping continuously (10 cycles, $\nu = 0.2$ V/s, from -0.5 to 1.7 V and reverse) in $\text{CH}_2\text{Cl}_2/\text{TBAFB}$ 0.1M with DTT 2 mM.

p-DTT/Pt film in CH_2Cl_2 solution (in absence of DTT). The films are quite stable and can be cycled without evidence of important decomposition over the time range of voltammetric experiments.

The separation and different shape of the oxidation and reduction waves of the polymer show that the redox process is not electrochemically reversible. However, the fact that the film can be repeatedly cycled indicates chemical reversibility of the doping-undoping process. The broadness of the waves suggests that the doping and undoping processes are complex. Presumably, reorganization processes of the polymeric chains are present; similar behavior has been observed with other polymers (9, 10).

Moreover, since the integrated charges under the oxidation and the reduction waves of p-DTT are approximately equal ($Q_{\text{ox}} \approx Q_{\text{red}}$), the coulombic efficiency ($Q_{\text{red}}/Q_{\text{ox}}$) over a cycle of charge-discharge is ca. 100%. These estimates have been made on cyclic voltammograms ($\nu = 20$ mV/s, from 1.4 to -0.5 V and reverse, in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution) of several p-DTT films, galvanostatically grown on Pt ($Q = 358$ mC/cm 2). The amount of charge was always ca. 20% of the total charge $Q_{\text{ox}} \approx Q_{\text{red}} \approx 0.2Q$ involved in the preparation of the film. This value is in accord with the charge concentration deducible from the results of elemental analysis of the electrosynthesized polymer, taking into account the fact that, as for polypyrrole (11), 2 electron/DTT unit should be involved in neutral polymer formation.

The same values of doping level of p-DTT (50%) were obtained when the polymer, grown galvanostatically, was exhaustively reduced to the neutral state at controlled potential of 0V in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution, as shown in Table I.

The fact that the redox process of the polymer film occurs at a far anodic potential value and that the charge which can be cycled (ca. 20% of that consumed in the initial preparation of the film) is not very diminished after 100 continuous cycles indicates the p-DTT doped as an attractive cathode-active material in battery application.

In order to test the performance of doped p-DTT as cathode-active material, we discharged at different constant currents, in $\text{CH}_2\text{Cl}_2/\text{TPAP}$ solutions, doped p-DTT/Pt films immediately after their electrogeneration.

Figures 7 and 8 show the variation of the electrode potential during electrochemical polymerization, at constant current density ($I = 0.4$ mA/cm 2) (regions A), and during the first discharge of the polymer films at selected constant current densities (regions B).

Table II reports, for two series of experiments with films of different thickness (some of which are shown in Fig. 7 and 8) the charge amounts recovered in the first discharges at different current densities together with the percentage of the charge recovered with respect to that stored in the doped polymer. The point where the discharging potential reached 0V was assumed as the indicator of the discharge completion.

Table III summarizes the coulombic efficiencies of six regenerative cycles of charge-discharge of a p-DTT/Pt electrode at $|I| = 0.4$ mA-cm $^{-2}$ in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution. This p-DTT/Pt electrode was obtained by reducing at $I = -0.4$ mA-cm $^{-2}$ with $Q_{\text{red}} = 72$ mC-cm $^{-2}$ a doped film electrosynthesized at $I = 0.4$ mA-cm $^{-2}$ with $Q = 358$ mC-cm $^{-2}$. During the recharge processes up to $Q_{\text{ox}} = 48$ mC-cm $^{-2}$,

the electrode potential (under current) increases up to $V_{\text{max}} = 1.15$ V in the same way in all successive cycles. The efficiency values were calculated by assuming the value of 0V of the discharging potential as the indicator of discharge completion (as in Table II). In the present case, however, so as not to accumulate charge in the regenerated active material, the discharge was stopped not at 0V potential, but only when all the stored charge was recovered. The data of Table III show that there are no significant differences of the coulombic efficiencies in the regenerative cycles.

Figure 9 shows the variation of the open-circuit potential *vs.* time of doped p-DTT/Pt electrodes in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution. The electrodes, as soon as coated with the polymer film, were removed in air from the electro-synthesis cell and immersed in degassed $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution. Then the films of the runs in Fig. 9 were discharged at constant current density, at different times after the end of their electro-synthesis. The percentage values of the recovered charge with respect to that stored in the polymers are reported in Table IV.

Fig. 7. $V(t)$ during processes at constant current densities. A: Electro-synthesis of doped p-DTT/Pt in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M solution with DTT 2 mM, $I = 0.4$ mA/cm², $Q = 358$ mC/cm². B: First discharges of films ($Q = 358$ mC/cm²) in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M at $I = -2.0$ (a), -0.8 (b), -0.4 mA/cm² (c).

Fig. 8. $V(t)$ during processes at constant current densities. A: Electro-synthesis of doped p-DTT/Pt in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M solution with DTT 2 mM, $I = 0.4$ mA/cm², $Q = 717$ mC/cm². B: First discharges of films ($Q = 717$ mC/cm²) in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M at $I = -2.0$ (a), -0.8 (b), -0.4 mA/cm² (c).

Fig. 9. $V_{\text{oc}}(t)$, in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ 0.1M solution of different films grown with 717 (a), 358 (b), 400 (c), 400 (d), 537 mC/cm² (e).

The comparison (at the same I) of the results in Table IV with those of Table II (concerning films discharged immediately after their preparation) indicates that about one-half of the cyclable charge is lost when the electrode potential is decreased by ca. 0.2V. The loss is not due to an irreversible degradation process of the polymer. In fact, if the films are charged again and immediately discharged, the percentages of the recovered charge are the same as those of Table II. No significant difference was observed (in the range time of 24h) if doped p-DTT/Pt electrodes were preserved in nondegassed solutions in the dark.

A decrease of the open-circuit potential and of the percentage of the charge recovered with respect to that stored (e.g., after 18h, $\Delta V_{\text{oc}} = 0.25$ V and the charge recovered with respect to that stored is 30%, at $I = 0.2$ mA·cm⁻²) was also observed with doped p-DTT grown on SnO_2 -coated Pyrex electrode ($Q = 60$ mC·cm⁻² at $I = 0.4$ mA·cm⁻²) and preserved in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution. This spontaneous decrease of V_{oc} with loss of charge over time, accompanied by a color change from black to red, was tested by spectroscopy.

Figure 10 shows the observed modification of the visible and near-IR absorption spectra. The same figure also reports the spectrum of the polymer after its exhaustive electrochemical discharge in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution and the spectrum of the polymer electrochemically recharged with $Q_{\text{ox}} = 10$ mC·cm⁻², after its discharge. Taking into

account the spectra of the doped and undoped polymers (Fig. 4), Fig. 10 suggests that in losing the charge, doped p-DTT does not undergo appreciable chemical degradation.

A point worth mentioning is that all the electrochemical results are reasonably reproducible, except the time in which the doped films, preserved in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution, lose their charge. Electrochemical and spectroscopic tests showed that the total self-discharge of identically doped p-DTT films occurred in an 18-100h time range. This suggests that film stability is related to some uncontrolled parameters such as, for instance, impurities of the solvent due to its partial decomposition. On the other hand, film of doped p-DTT preserved not in CH_2Cl_2 solution but in air are more stable. In fact, after 240h, the polymer preserved 65% of its charge. It was also observed that the lost charge occurred in the beginning (maximum, ca. 20h). In fact, spectra recorded after this time are practically unchanged.

As a battery application, a simple cell¹ was assembled utilizing oxidized and neutral polymer films, adherent to Pt, as the two terminals and immersed in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution. The oxidized form was galvanostatically electro-generated in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ -DTT solution with 717 mC·cm⁻² and the reduced form was obtained fully undoping a doped film of a thickness identical to that of the cathode. This battery yielded a maximum open-circuit voltage of ca. 0.6V and an initial short-circuit current density of 2.7 ± 0.3 mA·cm⁻². These preliminary results were taken from six batteries. The short-circuit current was calculated by utilizing the difference poten-

¹Since we observed that the neutral polymer requires a certain time (ca. 3h after its electrochemical preparation) before assuming a stable potential of ca. 0.3V, the battery was assembled when the neutral polymer was stable.

Fig. 10. Series of absorption spectra. 1: Doped p-DTT (with ClO_4^-) immediately after its electro-synthesis. 2: Doped p-DTT preserved for 18h after its electro-synthesis in $\text{CH}_2\text{Cl}_2/\text{TBAP}$. 3: Undoped p-DTT. 4: Electrochemically regenerated doped p-DTT (with ClO_4^-).

tial values measured under different conditions of the external load. The difference potential values were taken 0.5s after a discharge was commenced. During the initial 0.2s, the voltage fell very rapidly from the V_{oc} value and then decreased more slowly.

Conclusions

We observed that anodically synthesized doped p-DTT can release and store charge equal to 20% of the charge involved in its initial electrochemical preparation. Doped p-DTT presents some attractive features relevant to its application in battery technology, e.g., a high doping level which corresponds to a capacity of 54 mAh/g (with ClO_4^- as dopant), an initial value of V_{oc} of ca. 1V, high values of the charge recovered at constant currents up to 0V, with respect to that stored, from a maximum of 95% for $I = -0.04$ mA·cm⁻² to a minimum of 27% for $I = -4$ mA·cm⁻², cyclability with no evidence of appreciable degradation, and an apparent O_2 stability. On the other hand, film of doped p-DTT preserved in $\text{CH}_2\text{Cl}_2/\text{TBAP}$ solution had the disadvantage of a fast self-discharge. This phenomenon is not due to polymer degradation, but to an uncontrolled redox reaction involving the used electrolytic medium.

Work is in progress to investigate the behavior of this material in other nonaqueous solvents and in water.

Cycling Behavior of Thin Film LiAl Electrodes with Liquid and Solid Electrolytes

W. C. Maskell* and J. R. Owen*

Wolfson Unit for Solid State Ionics, Department of Metallurgy and Materials Science, Imperial College, London, England SW7 2BP

ABSTRACT

An Al foil was partially converted to β -LiAl by electrodeposition onto one side. The remaining unalloyed Al acted as a substrate for the film. Cycling was carried out with the film in contact with either the liquid propylene carbonate/1M LiClO₄ (PC) or the solid (PEO)₈LiCF₃SO₃. After initial substantial capacity losses, coulombic efficiencies were 97 and 99% with the PC and PEO electrolytes, respectively. There was an additional loss with PEO (2 μ A cm⁻²) due to a combination of oxygen and water vapor ingress and Li diffusion into the steel current collector. The loss in PC occurred during active operation, there being negligible loss on standing. Lithium incorporation into the film occurred readily due to the high diffusion coefficient of Li in β -LiAl. Stripping of the Li caused some cracking of the film as a result of the large molar volume change in forming α -Al(Li) from β -LiAl, but adhesion of the film to the Al substrate was strong. Literature values for the diffusion coefficient of Li in α -Al(Li) are low (10⁻¹⁶ and 10⁻²² cm²s⁻¹ at 140° and 25°C, respectively), indicating that the growth of a few monolayers of the α phase on the surface of the β -LiAl could prevent further discharge. A model is proposed whereby the β -LiAl at the interface with the electrolyte becomes "super depleted" on discharge, but not enough to nucleate α -Al(Li). Thus a diffusion gradient is set up in the β -LiAl film, causing the α -Al(Li) to grow from the α/β interface in a needle-like morphology towards the electrolyte. Such a model is compatible with the substantial capacity losses during initial cycles.

This study represents one aspect of a project to develop a rechargeable solid-state lithium battery for traction applications (1). An electrode of unalloyed lithium tends to display the problems of reaction with the electrolyte, dendrite formation, and shape change. Dey (2) showed that lithium alloys readily with aluminum, and a number of electrochemical studies of this binary combination in either molten salt or liquid organic electrolytes have subsequently been reported (3-13).

In the present study, results are presented for the LiAl electrode in contact with solid polyethylene oxide (PEO). Some work was also carried out using the liquid propylene carbonate/LiClO₄ (PC) as electrolyte for preparation of the LiAl alloy and for comparison with the investigations using PEO.

Experimental

The starting material was 99% pure aluminum foil of 50 μ m thickness. This was degreased with a jet of trichloroethylene, immersed in 7M NaOH for approximately 10s to etch the surface lightly, washed with water, and then dried in a stream of warm air.

Al samples for Li electrodeposition were mounted onto glass slides. All exposed immersed surfaces, apart from the deposition area, were masked with Parafilm (Gallenkemp U.K.), a thermoplastic tissue which adhered well with gentle heat from a hot-air gun. The electrochemical cell was assembled in a dry air box (water content < 5 ppm) with a massive Li strip as counterelectrode, Li wire as reference electrode, and propylene carbonate/1M LiClO₄ (PC) as electrolyte. The counterelectrode was of dimensions similar to those of the Al electrode and was placed parallel to it. Typically, 10 C-cm⁻² Li was deposited by passage of current at 1 mA cm⁻², forming a LiAl layer ~20 μ m thick; the supporting Al substrate was 30-40 μ m thick. For cycling tests in PC, the electroformed film was not removed from the electrolysis cell and the cell was assembled as follows

LiAl samples, for work involving PEO electrolyte, were washed with dry PC followed by acetonitrile and allowed to evaporate naturally prior to storage over Li metal in a dry argon box. Disks of 1 cm diam were cut to fit the cells (Fig. 1), which were semisymmetrical in the sense that after the first half-cycle both electrodes contained LiAl. Cells were assembled as follows

*Electrochemical Society Active Member.

the asterisk representing a steel current collector. The electrodes were of equal geometric area, each being a sample under study. Al foil was freshly etched as described above prior to assembly. The cells each contained four layers of electrolyte film (each layer was 35 \pm 5 μ m thick). The glass cell with steel pistons (Fig. 1) was assembled in a dry argon box, then removed and fitted into a spring holder (pressure 3 bar) for cycling in an oven at 140°C (in air). O-rings used were Viton,¹ which is stable at the operating temperature.

Galvanostatic charge/discharge was monitored and controlled using a Research Machines 380Z computer. Data were stored on a floppy disk.

Propylene carbonate (Koch Light, puriss.) was dried over 4Å molecular sieve before use. Analar LiClO₄ was predried under vacuum at 200°C for 70h. PEO film was prepared at A.E.R.E. Harwell Laboratory according to the method described by Sequeira *et al.* (14).

Scanning electron microscopy was carried out on a JEOL T200 machine. Specimens were prepared for sectional examination by simply tearing the foils to reveal the fracture surfaces.

Results and Discussion

Propylene carbonate electrolyte.—The first charge of an Al electrode at either 1.0 or 0.1 mA-cm⁻² and subsequent charges at 0.1 mA-cm⁻² showed similar characteristics (Fig. 2), in agreement with previous studies. The initial overpotential "spike" has been attributed to a nucleation

¹Vinylidene fluoride/hexafluoro-propylene copolymer.

Fig. 1. PEO cell arrangement

Fig. 2. Cathodic deposition of Li onto Al(Li) in propylene carbonate at 0.1 mA-cm^{-2} .

overvoltage for the initiation of the β -LiAl phase (6, 13). This was followed by a slow decrease in overpotential until the current was discontinued.

A typical discharge at 0.1 mA-cm^{-2} is shown in Fig. 3. There was an initial relatively rapid potential change, followed by an approximately linear increase with time and a rapid increase towards the discharge end point.

The 50 mV potential differential between charge and discharge reported by Epelboin *et al.* (10) and discussed by Baranski and Fawcett (13) was observed in the present study. The phenomenon appears to be associated with Li incorporation (335 mV vs. Li) as the stripping potential (385 mV) is close to the value calculable for the free energy of formation of β -LiAl.

Electrode capacity was determined to a cell voltage end point of 1.0V. Cycling data are shown in Fig. 4 and 5. The latter figure indicates a capacity loss of 6% per cycle. Comparison of the two figures clearly shows that capacity loss is minimal on wet stand, in agreement with the findings of Besenhard (8). Capacity loss only appears to occur during active operation, suggesting that a passivating film protects the surface on standing (8, 10). The amount of capacity loss was proportional to the charge time, *i.e.*, the charge passed, leading to a constant coulombic efficiency of 97% (3% loss per half-cycle) after the initial rapid decrease in the first few cycles (8).

Scanning electron micrographs of the two sides of the metal foil are shown in Fig. 6a and 6b. The Al surface,

Fig. 3. Anodic stripping of Li from LiAl in propylene carbonate at 0.1 mA-cm^{-2} .

Fig. 4. Cycling data for a symmetrical LiAl/propylene carbonate/ LiClO_4 cell at 0.1 mA-cm^{-2} and ambient temperature.

shown in Fig. 6a, is clearly flat apart from minor features, probably resulting from rolling. The β -LiAl surface is shown in Fig. 6b. The incorporation of Li has added surface features indicative of a nucleation and growth process. A solitary nucleus would be expected to grow three dimensionally and, because of the volume change upon Li incorporation, would protrude approximately spherically from the surface; each protrusion from the surface represents a single nucleation. These overlap and result in the morphology observed. Having merged, the α - β interface tends to become planar as it proceeds into the foil. The edge of the foil, charged to 10 C-cm^{-2} , observed from both the Al and LiAl sides, is shown in Fig. 6c and 6d, respectively. The plane at the interface of the active film and the substrate can clearly be identified indicating thicknesses of $20\text{-}25 \mu\text{m}$ and $35\text{-}40 \mu\text{m}$ for the β -LiAl and α -Al phases, respectively. The cracking of the LiAl layer in Fig. 6d was the result of mechanical damage during sectioning of the specimen and was not present away from the edge. It did demonstrate that the LiAl layer was less ductile than the Al substrate.

Micrographs of a 10 C-cm^{-2} film discharged to a cell voltage of 1.0V (discharge capacity 6.1 C-cm^{-2}) are shown

Fig. 5. Logarithm of discharge time vs. cycle number for a symmetrical LiAl/PC cell at 0.1 mA-cm^{-2} and ambient temperature. Data as in Fig. 4.

Fig. 6. Scanning electron micrographs. a: Al surface. b: Al surface after Li incorporation (10 C-cm^{-2}). c: Fracture edge of Al, LiAl (10 C-cm^{-2}) duplex foil viewed from Al side. d: As in c, viewed from LiAl side.

in Fig. 7. The surface cracking in Fig. 7a has been reported previously by Garreau *et al.* (11) and is a result of the volume reduction upon extraction of Li from the β -LiAl. Higher magnification micrographs of the cracks meeting the torn edge are shown in Fig. 7b and 7c.

The change in molar volume associated with Li stripping is 49%, which, in this experiment to 61% depth of discharge, should have resulted in a 30% overall volume change of the film. An isotropic contraction would then result in a 10% thickness change and a crack area corresponding to 20% of the film surface. Although the micrographs do not allow an accurate estimate of the thickness change, the fraction of crack area in Fig. 7a can be calculated reasonably well as follows. Average crack width equals $15 \pm 3 \mu\text{m}$. Total crack length in frame equals 0.52 cm. Total micrograph area equals $40 \times 10^{-4} \text{ cm}^2$. Therefore, the fraction of crack area in film surface equals $20 \pm 4\%$. The agreement with the theoretical value indicates that the film has a low porosity, which is important in considerations of the discharge mechanism below.

The final micrograph (Fig. 7d) shows the Al substrate surface after Li stripping observed from a shallow angle (18°). This may be compared with Fig. 6a and shows that, as the Li is stripped, the active film shrinks and the contraction imposes considerable strain on the substrate, causing mechanical deformation. It also shows that the LiAl is bonded strongly onto the substrate.

Polyethylene oxide electrolyte.—Cycling data for duplicate type-2 cells are shown in Fig. 8 and 9. Figure 10 shows a typical voltage-time curve for these cells. Capacities were calculated to a cell end point of 1.0V. On the first discharge, capacities were comparable to that in PC (5.9 and 4.9 C-cm^{-2} for PEO, 6.1 C-cm^{-2} for PC). Com-

parison of Fig. 8 and 9 shows that capacity loss was principally due to aging and not to cycling. It appears that coulombic efficiency of cycling after the initial rapid loss may have been $> 99\%$. This behavior contrasts with that in PC, where the loss occurred principally during cycling.

The linear loss of each cell with time shown in Fig. 8 was equivalent to a current of $1.2 \mu\text{A}$. This loss could be due to ingress of water vapor or oxygen into the cell converting the Li to an oxide or alternatively to diffusion of Li into the steel piston. The possibility of the latter was investigated by setting up a type-2 cell but omitting the Al electrode. The cell was shorted, with a resistor in the circuit (voltage drop across it $< 10 \text{ mV}$) to monitor the current due to Li alloy formation on the surface of the steel and subsequent Li diffusion (Fig. 11, 12).

A straight line passing through the origin is anticipated for semi-infinite diffusion (15) when current is plotted vs. $t^{-1/2}$. Both the long- ($> 1\text{h}$) and short-time ($< 100\text{s}$) data satisfy the semi-infinite theory but with different slopes. At short times, diffusion fronts are parallel to the surface and the surface area is greater than the geometric value by a factor equal to the roughness factor. At long times, diffusion fronts merge to form a planar front proceeding in the direction of the axis of the piston; in this case, the appropriate area is the geometric value. Hence, the ratio of the slopes in Fig. 11 and 12 reveals the reasonable value for the roughness factor of 2.

Clearly, Li loss into the current collector can be high and could rapidly exhaust a 10 C-cm^{-2} LiAl electrode when there is an electrolyte path between the active LiAl surface and the current collector together with electronic contact between the two. It was found that in type-2 cells stored at 140°C , electrolyte did squeeze between these two components.

Fig. 8. Initial capacity decrease and subsequent time-dependent loss on cycling of duplicate symmetrical LiAl/PEO cells. Current density: $0.1 \text{ mA}\cdot\text{cm}^{-2}$. Temperature: 140°C .

A further aspect of the data in Fig. 12 is the intercept at $t^{-1/2} = 0$ of $1 \mu\text{A}$, which could be due to ingress of water vapor and/or oxygen and is comparable to the losses noted in Fig. 8. Thus, the capacity losses revealed by cycling may result either from O_2 or H_2O ingress, Li diffusion into the current collector, or any combination of

Fig. 9. Capacity decrease of duplicate symmetrical LiAl/PEO cells vs. cycle number. Data as in Fig. 8.

Fig. 10. Voltage vs. time curve of a symmetrical LiAl|PEO cell at $0.1 \text{ mA}\cdot\text{cm}^{-2}$ and 140°C .

these. If residual currents were eliminated by effective sealing, a long-term cycling capacity of $2.5 \text{ C}\cdot\text{cm}^{-2}$ may be achievable for these cells. This is applicable to high depth of discharge under which condition secondary cells such as lead-acid often do not perform well.

Mechanism of charge/discharge.—There seems little doubt concerning the mechanism of Li incorporation as β -LiAl into the electrode. Where the surface is initially α -Al or α -Al(Li) then β -LiAl must nucleate on the surface. This nucleation requires a substantial overvoltage. The nuclei grow three dimensionally, overlap, and then grow into the α -phase approximately on a planar front. Incorporation takes place readily at $1 \text{ mA}\cdot\text{cm}^{-2}$; this can occur because Li has a high diffusion coefficient in β -LiAl (D_β), which is a consequence of the large Li vacancy concentration in this material (17-19). Wen *et al.* (9) carried out an extensive study of LiAl including measurements of D_β in the range $415^\circ\text{--}600^\circ\text{C}$. They found it to be concentration dependent, reaching a maximum value of $10^{-4} \text{ cm}^2\cdot\text{s}^{-1}$ at the lower phase limit. Thus the value of $10^{-8} \text{ cm}^2\cdot\text{s}^{-1}$ determined at 24°C by Jow and Liang (12) seems not unrea-

Fig. 11. Current vs. $t^{-1/2}$ for Li incorporation and diffusion into the steel piston showing data for short and long times.

Fig. 12. As Fig. 11 for data at long times only

sonably high. Using this latter value in an equation derivable from Fick's first law, the concentration difference (Δc) across the film may be calculated

$$\Delta c = id/D_\beta F$$

i is the current ($1 \text{ mA}\cdot\text{cm}^{-2}$), d the film thickness ($20 \mu\text{m}$), and F the Faraday constant. This revealed $\Delta c = 2 \times 10^{-3} \text{ mol}\cdot\text{cm}^{-3}$ (i.e., $2M$). The molar volume (V_m) of β -Li_xAl is $20 \text{ cm}^3\cdot\text{mol}^{-1}$ and to a first approximation may be assumed to be independent of x . The Li concentration, c , is given by

$$c = x/V_m$$

Hence

$$\Delta x = V_m \Delta c$$

Substituting in the above values for V_m and Δc leads to $\Delta x = 0.04$. This value of Δx represents a change from the equilibrium stoichiometry of the β phase at the α/β boundary of $\text{Li}_{0.96}\text{Al}$, which is approximately equivalent to 48 atom percent (a/o) Li (12) to LiAl. Therefore, in terms of mole fraction, the surface may reach 50 a/o Li. The low concentration difference required to sustain diffusion under the above charging conditions is important, since the fast diffusing β phase width extends only as far as 56 a/o (12).

A satisfactory mechanism of Li stripping, however, has not been proposed. The difficulty arises from the very low values measured for the diffusion coefficient of Li in α -Al(Li) (D_α). The data of Wen *et al.* (20) determined over the range $400^\circ\text{--}600^\circ\text{C}$ may be extrapolated to give D_α values of $10^{-16} \text{ cm}^2\cdot\text{s}^{-1}$ (140°C) and $10^{-22} \text{ cm}^2\cdot\text{s}^{-1}$ (25°C). This is in good agreement with the data of Williams and Edington (21) giving a D_α value of $10^{-16} \text{ cm}^2\cdot\text{s}^{-1}$ at 140°C . Clearly, at best, $D_\alpha/D_\beta \approx 10^{-8}$ and diffusion of Li will only occur at reasonable rates ($0.1 \text{ mA}\cdot\text{cm}^{-2}$) through very thin layers ($\sim 5\text{\AA}$) taking the molar volume of α -Al (Li) as $10 \text{ cm}^3\cdot\text{mol}^{-1}$ and phase width as 0.5 a/o ($D_\alpha = 10^{-16} \text{ cm}^2\cdot\text{s}^{-1}$). Thus it seems unreasonable to propose a model in which a coherent film of α -Al (Li) grows on the front face of the β -LiAl film. The next proposition to consider is the growth of an incoherent film of α -Al (Li). Such a proposal would suggest that the stripped film might be porous so that electrolyte could enter the pores generated as stripping proceeds. This would be possible for a liquid electrolyte (e.g., PC) but unlikely for PEO, which has a high viscosity and would be slow to enter small pores. In the case of PC, the cycling was carried out at room temperature, where D_α is several orders of magnitude lower than that assumed in the above calculation. Also, it was shown earlier that the stripped film was probably non-porous apart from macroscopic cracks. Thus, the proposi-

Fig. 13. Model for the charge/discharge processes of a LiAl electrode

tion of a mechanism via an incoherent film also appears untenable both for PC and PEO electrolytes.

A third possibility is that at the commencement of Li stripping α -Al(Li) is not nucleated at the front face. As a result, β -LiAl is driven into a Li-deficient region beyond its phase limit at the electrolyte interface. This is a metastable state which might be termed "superdepletion." Considering a calculation similar to the charging case, the magnitude of depletion can be small as a result of the very large diffusion coefficient, as reported by Wen *et al.* (9). (Very high D_β values can be explained by a thermodynamic enhancement factor or a large point-defect concentration.) Moreover, the critical superdepletion required for α -phase nucleation can be expected to be relatively large due to the severity of the structural rearrangement. Superdepletion sets up a concentration gradient in the β -LiAl film so that α -Al(Li) grows from the α/β phase boundary towards the electrolyte. The α phase might be expected to grow in a needle-like fashion towards the front face as the Li concentration gradient would tend to promote this type of morphology. Upon reaching the front face, lateral growth of α phase would take place until a coherent passivating film of α -Al(Li) covered the active surface, effectively preventing further discharge. This would tend to entrap β -LiAl between the α -Al(Li) needles from which Li could not be stripped. This would be manifested as a coulombic efficiency substantially below 100%. In fact, on the first charge/discharge in PC an efficiency of 61% was recorded. Some evidence in favor of this mechanism may be gleaned from examination of the photographs of the discharged film. The sides of the cracks, induced by volume reduction, and the fracture edges suggest the needle-like growth in the active film predicted above. Such a structure is not apparent in the undischarged film (particularly that shown in Fig. 6d). The model described above is depicted in Fig. 13.

Conclusions

The LiAl electrode shows a coulombic efficiency of 97% in PC and possibly in excess of 99% in combination

with a PEO electrolyte. There were additional losses in the latter case due to ingress of air or water vapor and/or diffusion of Li into the current collectors. Attention to cell design must be undertaken to minimize these additional losses. In all tests performed, there was no indication of shorting due to dendrite formation and no evidence of mass redistribution.

The initial capacity loss on cycling is unfortunate, but it may be acceptable considering the high theoretical energy density of LiAl. LiAl must be considered a promising electrode material for solid-state rechargeable Li cells.

Photoelectrochemical Characterization of CdSnP₂ Crystals

J. C. W. Folmer, J. R. Tuttle, J. A. Turner, and B. A. Parkinson*

Solar Energy Research Institute, Photoconversion Research Branch, Golden, Colorado 80401

ABSTRACT

Crystals of the II-IV-V₂ chalcopyrite semiconductor, CdSnP₂, were grown from a tin melt. Photoelectrochemical techniques were used to characterize the properties of this material. Doping level, carrier type, optical transitions, absorption coefficient, and minority carrier diffusion length were determined and compared with values obtained with other techniques. Polysulfide electrolytes were found to be most suitable for the formation of liquid junctions, but did not completely stabilize the material during extended illumination and resulted in the formation of a CdS overlayer.

The recent successes of the use of III-V semiconductors for photoelectrochemical energy conversion have been encouraging from a fundamental scientific viewpoint. A GaAs or GaAs_xP_{1-x} photoelectrochemical cell has been demonstrated to produce electricity at about 12% solar efficiency (1), while InP photocathodes, plated with small islands of noble metal catalysts, are capable of producing hydrogen gas from hydrogen ions at a solar efficiency in excess of 13% or act as the photocathode in a haloacid splitting cell (2). Practical large-scale systems for solar conversion from such materials are limited, mainly because of the relative scarcity and high cost of indium and gallium.

A class of materials exists isoelectronic with the III-V materials, but containing relatively more abundant metals from the groups adjacent to the Group III metals (Zn, Cd, Si, Ge, Sn). These II-IV-V₂ materials crystallize in the chalcopyrite structure (see Fig. 1). There has been considerable work on the optoelectronic properties of these materials (3), but very little on their application to photovoltaic or photoelectrochemical energy conversion. This is somewhat surprising considering that many members of this family have optical bandgaps in the energy range which is optimal for solar energy conversion (1.1-1.7 eV). The optical transitions in these materials are direct or pseudodirect, both of which result in a steeply rising absorption above the bandgap energy. Pseudodirect gaps are a consequence of band folding resulting from the doubled periodicity in the *c* direction of the chalcopyrite unit cell, placing the conduction band states with minimum energy at the gamma point in the Brillouin zone.

As a result, isoelectronic analogs of an indirect III-V material will have much steeper absorption edges (*i.e.*, ZnGeP₂ as compared to the indirect gap material, GaP, CdSnP₂, however, is isoelectronic with a direct gap material, InP). Steeply rising absorption edges are required for the construction of thin film devices.

We earlier reported a preliminary investigation of CdSnP₂ (4), and we now report on a more detailed study of the photoelectrochemical behavior of this compound. We have chosen to study CdSnP₂ (5) because it has a bandgap in the region of interest for solar conversion, it has been shown to have very favorable electronic properties (high absorption coefficients and carrier mobilities) (6), and it is isoelectronic with InP, a material which is used successfully in both photoelectrochemical photovoltaic and photoelectrolysis cells (2). When in contact with aqueous acid solutions, the high efficiency and stability of InP photocathodes has been attributed to the formation of a thin, hydrated, 6-10Å pore-free layer of indium oxide, through which carriers can tunnel freely (7). This oxide layer has been shown to provide stability against oxidative photocorrosion and also to passivate the radiationless recombination of photogenerated electrons and holes (8). Owing to the variety of possible surface oxides that can be formed from the components of a ternary material, the II-IV-V₂ compounds provide an opportunity for more detailed study of the role of surface oxides in the passivation of surface recombination and the protection against photocorrosion. A recent note dealt with the pho-

toelectrochemical characterization of CdGeP₂, another member of the II-IV-V₂ family (9).

Experimental

Crystal growth.—Barlike crystals of CdSnP₂ (maximum dimensions 7 × 3 × 2 mm) were grown from a tin melt as previously described (10). Quartz ampuls were loaded with cadmium (99.999%), red phosphorus (99.999%), and an excess of tin (99.999%) in an inert atmosphere glove box. The ampuls were then evacuated to a pressure of 2 μtorr (0.3 mPa) and sealed. The sealed ampuls were then placed in a furnace with the temperature-time profile dictated by a microprocessor-controlled programmer. The programmer controlled the overall cooling rate and superimposed temperature "spikes" at various intervals to control the nucleation of the crystallites. In some cases, nucleation was controlled by cooling a point on the ampul by contacting it with a copper wire which led out of the furnace (5). The crystals were recovered from the melt by heating in glycerol to melt away the main mass of tin and then dissolving the remaining tin in 1:5 nitric acid/water mixtures or an etchant consisting of 1 part HF, 3 parts nitric acid, and 4 parts water. A final bath of 4M KOH was used to remove white coatings of hydrated tin nitrate precipitate, which sometimes built up on the crystals during the tin dissolution process. The crystals usually occurred as radiating masses of dark gray bars similar to those shown in Ref. (3) and (5). X-ray powder diffraction was used to verify that the crystals had the chalcopyrite structure and lattice parameters identical to those reported in the literature for CdSnP₂ (11). The unintentionally doped materials were n-type.

¹¹⁹Sn Mössbauer spectroscopy showed an average isomer shift, relative to a calcium stannate standard, of 1.601 + 0.002 mm/s. In some samples, a small second Mössbauer peak could be seen at an isomer shift of 2.73 + 0.05 mm/s, consistent with the presence of less than 1% Sn₄P₃ (12). The Sn₄P₃ is assumed to be present as small occlusions in the CdSnP₂ crystals. Macroscopic (2 × 6 × 1 mm) platelike Sn₄P₃ crystals were also identified by x-ray diffraction and Mössbauer spectroscopy in the crystal

Fig. 1. The structure of cadmium tin phosphide showing the tetrahedral bonding throughout the structure. The *c/a* ratio is a measure of the distortion of the structure from the diamond structure, where this ratio would be 2.0. For cadmium tin phosphide, the *c/a* ratio is 1.95.

masses remaining after acid dissolution of the tin, but could be easily physically separated because of their different crystal habit and color.

Photoelectrochemical characterization.—Mott-Schottky (C^{-2} - V) plots were obtained using an automated computer-controlled capacitance measurement system which has been described elsewhere (13). Photocurrent spectra were also obtained with an automated system which controls the monochromator, collects photocurrent data, and corrects for the lamp response. A 250W tungsten lamp was the source, and the lamp spectral output was measured using a Model 2M thermopile with a quartz window (Dexter Research Center). Photocurrent-voltage response was also obtained with a computer-controlled system using a staircase voltage function and which collected photocurrent data using chopped light and a lock-in amplifier. Redox electrolytes were prepared from reagent-grade chemicals which were used as received with water purified through a Millipore ion exchange system with an organic absorption column and a final UV light treatment.

Electrodes were prepared by first making low resistance contacts to crystals with indium-gallium eutectic and securing them to a small copper plate. The copper plate was then connected to a wire and mounted at the end of a glass tube. Epoxi-Patch[®] epoxy was then used to insulate the copper and all but the desired crystal face(s). Indium-gallium eutectic was found to give consistently good low resistance contacts, but in some cases silver epoxy also proved adequate. Prior to the photoelectrochemical measurements, the crystals were etched in the HF-nitric acid etch described above. Extended stability runs used a 150W tungsten-halogen lamp positioned about 7.5 cm from the sample in a two-electrode cell with a platinum counterelectrode (the resulting light intensity is about 65 mW/cm²).

Results and Discussion

We attempted to determine the relative energy position of the conduction and valence bands and the doping level of the CdSnP₂ samples with capacity measurements. Mott-Schottky measurements (plotting $1/C^2$ vs. potential) were in general complicated by hysteresis between the forward and reverse scans, inversion effects, and potential regions where capacities were independent of potential. If the range of the potential scan was limited between -1.1 and about -0.65V vs SCE on a crystal with a smooth-crystal face, we obtained Mott-Schottky plots for n-type samples in sulfide/polysulfide solutions that showed close to linear behavior with a minimum of hysteresis (Fig. 2). The doping density obtained from the slope of the Mott-Schottky plot is 8.0×10^{17} , which agrees well with values obtained with the Hall technique ($3\text{--}5 \times 10^{17}$).

Fig. 2. Mott-Schottky plot of n-CdSnP₂ at 5000 Hz in a 1M Na₂S, 1M NaOH, 1M Na₂S₂ solution.

Fig. 3. Monochromatic photocurrent voltage behavior of n-CdSnP₂ in a 1M Na₂S, 1M NaOH, 1M Na₂S₂ solution at two different wavelengths but with identical photon flux.

The slightly higher photoelectrochemical value may be a result of the microscopic surface area of the crystal being larger than the macroscopic surface area which was used to calculate the slope. A rather negative value of the flatband potential is obtained from the analysis of the Mott-Schottky plot (-1.17V vs. SCE). The influence of a possible surface layer of cadmium sulfide on the flatband potential is not clear, since good Mott-Schottky behavior was not obtained in other redox electrolytes or buffers. The influence of the CdS layer on the photo-stability of the system is discussed later in this report.

Photocurrent-voltage curves for an n-type material in an aqueous sulfide/polysulfide solution illuminated at two different wavelengths, but with identical photon fluxes, are shown in Fig. 3. The figure shows that the quantum yield at shorter wavelengths is higher than at longer wavelengths. This can be explained by the fact that the shorter wavelength photons are absorbed in the space-charge region of the semiconductor/electrolyte interface and that the diffusion length of minority carriers (holes) is not long. The plateau region of the photocurrent curve can be analyzed with an equation derived from the Gärtner (14) model to obtain the minority carrier diffusion length for the crystal. A value of about 0.1 μm is obtained for 1050 nm excitation when a dielectric constant of 10.0 is assumed and when the doping density obtained from the Mott-Schottky data and an absorption coefficient of 5.6×10^4 cm⁻¹ are used.

Figure 4a shows the photocurrent spectra for an n-type CdSnP₂ sample in a polysulfide electrolyte. The photocurrent onset is usually at about 1.1 eV, but in some cases a subbandgap response is also observed. If the bandedge of a sample without the low energy response is analyzed for the transition type, by plotting the power dependence of the photocurrent-energy product against the photon energy, the best fit is found for direct transitions (the square of the energy photocurrent product) at 1.17, 1.23, and 1.37 eV (Fig. 4b). These values agree very well with the literature values, obtained with electroreflectance, of 1.16, 1.24, and 1.32 eV (15). The transitions can be identified as excitation from the three spin-orbit split valence band levels of the chalcopyrite structure (3). Such fortuitous results were not obtained on another crystal. Figure 5a shows the spectra of another sample (and perhaps another crystal face) obtained in a D₂O solution of polysulfide. In this case, the lowest lying transition is identified as an indirect transition at 1.11 eV, followed by direct transitions at 1.14 and 1.20 eV (Fig. 5b). D₂O is used to avoid a water absorption band at 1.27 eV or 975 nm (arrow in Fig. 4b), which could affect the interpretation of the highest direct transition in the first crystal. Substantial optical anisotropy in this material (16) and the partially polarized beam from the monochromator may also complicate the photocurrent spectra in CdSnP₂. A complete study of these effects is beyond the scope of this study.

Fig. 4. a: Photocurrent spectra of n-CdSnP₂ in polysulfide solution. b: Analysis of two of the direct transitions from the data in a. The arrow is at the energy of a water absorption band.

The stability of the n-type CdSnP₂ to photocorrosion was tested by continuous illumination of an electrode in polysulfide electrolyte for five days at short circuit. The time response of the current was characterized by an initial rapid decrease in the current followed by a slow rise to the maximum current density of 5 mA/cm², which then began to decay after three days, as seen in Fig. 6. Note that the log time scale greatly exaggerates the initial current variations with respect to the slow long-term degradation. The total charge per unit area passed through the interface was 2350 C/cm². The total charge passed through the electrode (47C) was almost sufficient to totally corrode the sample through the path most demanding of holes (55C) which is written in Eq. [1]. (Note that these products have not been identified as the final corrosion products, but are used only to estimate stability.)

After only several hours of the test, an orange-yellow layer was observed to form on several of the faces of the crystal. The layer was shown, by electron microprobe analysis, to contain both Cd and S but no Sn. Cathodoluminescence confirmed the layer to be CdS. The tin is assumed to dissolve as a sulfide complex or as a stannate.

Initially, the CdS layer did not reduce the current flow through the interface, presumably because the blue light, which would be absorbed by the layer, was already removed by the orange-yellow sulfide/polysulfide electrolyte. The layer was observed to grow thicker with time and eventually grew thick enough to absorb light beyond the short wavelength cutoff of the electrolyte, which resulted in the decay of the short-circuit current. This was

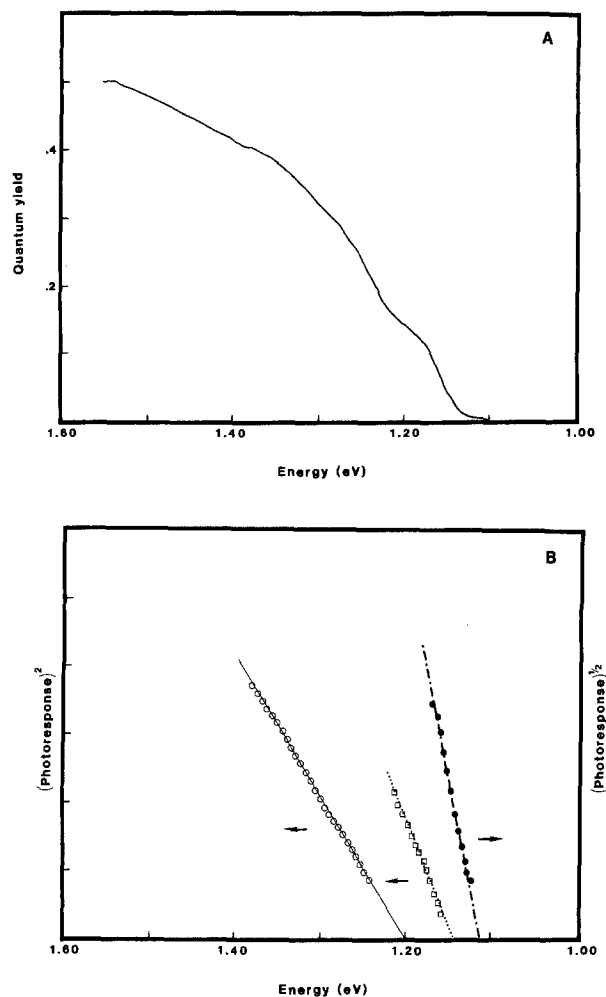

Fig. 5. A: Photocurrent spectra of another n-CdSnP₂ sample in a polysulfide solution in D₂O. B: Analysis of the spectrum in part A showing an indirect transition followed by two direct transitions.

verified by the decrease in the visible light response in the photocurrent spectra of a sample on which a substantial amount of CdS had accumulated. Presumably, the layer does not interfere with the transport of carriers to the electrolyte since the loss of photocurrent could be accounted for totally by absorption losses. If a blocking heterojunction was formed, the current would quickly decay to zero even with the formation of a very thin layer.

The layer forms with a coulombic efficiency of less than 1% because the thickness of the layer was less than 100 μm after the passage of enough charge to dissolve

most of the crystal. The exact percentage of photogenerated holes participating in the oxidation of the lattice to CdS is not known, but it is expected that it will be a strong function of the photocurrent density, as is the case with other semiconductor photoelectrodes (such as CdSe) (17).

Conclusion

Table I shows a summary of the materials parameters obtained from photoelectrochemical techniques for an n-type sample of CdSnP₂. It is clear from the table that reliable information about the materials properties of this material can be obtained with the photoelectrochemical techniques described in this communication. The high quantum yields at visible wavelengths (see Fig. 5a) obtained for this system confirm that the electronic properties of the material are favorable and high conversion efficiencies are achievable if the diffusion length of minority carriers can be increased to above 1 μm .

The marginal stability of the system, at least in the sulfide/polysulfide electrolyte, suggests that further work on the n-type material is needed in order to make this material attractive for use in a photoelectrochemical solar cell. The marginal stability of the n-type material in polysulfide solutions mimics the behavior of n-InP in similar solutions. However, p-type InP has been shown to be stable in several redox electrolytes, suggesting that the same may be true for p-CdSnP₂. Attempts to grow the latter material by doping with copper produced a low mobility compensated material with pronounced photoconductivity and subbandgap response (5, 18). A detailed study of this material is underway. Alternate methods for the preparation of p-type materials are also under investigation, as well as crystal growth and photoelectrochemical characterization of other members of the II-IV-V₂ family of semiconductors.

Electrode Kinetics in Nonaqueous Aprotic Solvents

Jacob Jorné*

Department of Chemical Engineering, University of Rochester, Rochester, New York 14627

Purnachandra G. Pai*

Energy Conversion Devices, Inc., Troy, Michigan 48084

ABSTRACT

The electrode kinetics of Na⁺ reduction are studied at dropping mercury electrode in four polar aprotic solvents, propylene carbonate (PC), dimethylformamide (DMF), dimethylsulfoxide (DMSO), and acetonitrile (AN), using the faradaic impedance method. The true rate constants measured for 1M NaClO₄ in PC, DMF, DMSO, and AN are 0.38, 0.21, 0.05, and 0.35 cm·s⁻¹, respectively. The corresponding cathodic transfer coefficients are measured to be 0.62, 0.81, 0.43, and 0.42, respectively. Na⁺ reduction is found to be a simple charge-transfer reaction, based on its conformance to the analysis using the classical Randles circuit. Using relative rate constants (k_{sh}^1)_{rel} for Na⁺ with water as reference solvent, a standard potential scale for Na⁺/Na vs. NHE is developed for all four solvents and compared with standard potential scales for K⁺/K vs. NHE. The surface potentials of all four solvents are calculated to be positive and discussed in terms of solvent dipole orientation. Comparison of rate constants and free energy of Na⁺ solvation is made to determine the effect of solvation on the kinetics of Na⁺ reduction in PC, DME, DMSO, and AN. The trend of standard rate constants follows the trend of sodium ion solvation in the nonaqueous solvents PC ≅ AN < DMF < DMSO.

The developments in electrochemical energy conversion and storage and the need for high energy density have created a growing interest in the electrochemistry of alkali metals in nonaqueous solvents (1, 2). The fact that the rate constant of an electrochemical reaction can vary significantly from one nonaqueous solvent to another raises a very fundamental question: What is the influence of the solvent on the rate of an electrochemical reaction?

The purpose of the present work is to study the electrode kinetics for sodium ion reduction in four popular aprotic solvents and to attempt to correlate the rate constants with the thermodynamics of ion solvation in the four solvents. A comparative study of the electrode kinetics of Na⁺ reduction was therefore conducted in four aprotic solvents: propylene carbonate (PC), dimethyl formamide (DMF), dimethyl sulfoxide (DMSO), and acetonitrile (AN), using dropping mercury electrode (DME) and the faradaic impedance method. These solvents are widely used in electrochemistry due to their high dielectric constants, the unavailability of a proton for reduction, their weak acidic and basic characters, and their relatively low viscosities.

The rate of a simple charge-transfer electrochemical reaction is affected by factors such as electrode kinetics, solvation, double-layer effects and thermodynamics. These aspects are discussed below.

Kinetics and energetics in nonaqueous solvents.—The electrode kinetics and the equilibrium of an electrochemical reaction are greatly affected by the nature of the solvent and the electrolyte employed. There are various reasons, usually difficult to explain in a simplified manner, for such differences in rate constants and equilibrium properties. Factors such as medium effects, solvation of ions, and the free energy, enthalpy, and entropy changes occurring during an electrode reaction, and double layer vary from one solvent to another. Thermodynamic measurements, namely, emf, calorimetric, and solubility measurements, are usually used for the study of free energy, enthalpy, and entropy changes for electrochemical reaction. The rate constants of an electrode reaction in different solvents also aid in the evaluation and comparison of the free energy changes associated with an electrode process.

Consider the electrode reaction at a mercury electrode

where $M_{(s)}^+$ is the solvated cation and M^\ddagger is the activated complex of the metal ion. For this reaction, the true heterogeneous rate constant may be expressed in general terms as

* Electrochemical Society Active Member.

$$k_{sh}^1 = \tau(kT/h) \exp [(-\Delta G_o^\ddagger - \beta nF\phi_{(m)}^0)/RT] \quad [2]$$

where τ is the transmission coefficient (taken approximately as unity), (kT/h) is the universal frequency factor, ΔG_o^\ddagger is the electrochemical standard free energy of activation, defined as the difference in free energy between the solvated ion and the activated complex, $\phi_{(m)}^0$ is the standard electrode potential of the metal, and β is the cathodic transfer coefficient. Equation [2] may also be written in the form

$$k_{sh}^1 = \tau(kT/h) \exp [(\Delta G_s^0(M^+) - \Delta G_s^0(M^\ddagger) - \beta nF\phi_{(m)}^0)/RT] \quad [3]$$

where $\Delta G_s^0(M^+)$ and $\Delta G_s^0(M^\ddagger)$ are the solvation energies of the ion and the activated complex, respectively.

In order to compare the standard electrode potential, $\phi_{(m)}^0$, in different solvents, one must have either a common reference electrode workable in all solvents under consideration or a means to determine the liquid junction potential between the solvents. Both of these conditions are not easily surmountable and hence pose problems in comparison of $\phi_{(m)}^0$. Furthermore, the energetics of the activated complex of M^\ddagger in various solvents is unknown, which makes the comparison of the rate constants in various solvents difficult. This has led to the concept of relative rate constant, $(k_{sh}^1)_r$, defined by

$$(k_{sh}^1)_r = (k_{sh}^1)_1 / (k_{sh}^1)_2 = \exp [(\Delta G_t^0(M^+) - \Delta G_t^0(M^\ddagger) + nF(\beta_2\phi_2^0 - \beta_1\phi_1^0))/RT] \quad (4)$$

where subscripts 1 and 2 refer to solvents 1 and 2, $\Delta G_t^0(M^+)$ and $\Delta G_t^0(M^\ddagger)$ are the standard electrochemical free energy of transfer of M^+ and M^\ddagger from solvent 2 to solvent 1, β is the cathodic transfer coefficient, and ϕ^0 is the standard electrode potential. Equation (4) is helpful in comparison and evaluation of standard electrochemical free energy of transfer of M^+ and M^\ddagger from one solvent to another when the rest of the parameters are known.

Double-layer effects.—The double layer plays a key role in the kinetics, since the electrode reaction occurs within the double layer. This complicates the simple charge-transfer process, and either a prior knowledge of the double-layer capacitance or the elimination of its effects on the reaction rates is essential in our study. At high concentrations of the solute, the effects of the diffuse double layer diminish substantially and one may neglect the variation of the diffuse double-layer potential with the total metal-solution potential difference. Thus, fairly concentrated (1M) solutions of NaClO₄ are used in this investigation.

The structure of the solvent and the solvation of the ion affect the structure of the double layer and the specific

adsorption of an ion on the electrode surface. It has been noted in several double-layer studies (5, 6) that ClO_4^- anion is less specifically adsorbed from various aprotic solvents than halide ions. The solvation in aprotic solvent depends on the polarizability of the anion which increases with the size of the anion (7). Hence it is considered that the choice of NaClO_4 as the solute minimizes the effect of specific adsorption on the kinetics of the electrode reaction.

Scope of the present work.—Since the effects of the medium on the electrode reaction and the role of a solvent in solvating an ion taking part in an electrode reaction are of particular interest to this study, the measurement of kinetic parameters and their comparison in various solvents make up the major part of this study. The investigation concentrates on the determination of the kinetic parameters for the reaction $\text{Na}^+ + e \rightleftharpoons \text{Na}(\text{Hg})$ in NaClO_4 -PC, DMF, DMSO, and AN solutions.

The free energies of transfer of cations from one solvent to another can also be related to the rate constants of those cations in the respective solvents. Using this principle and some extra thermodynamic assumptions, an attempt has been made to determine a relationship between free energies of transfer of Na^+ , from various solvents to water, and the rate constants for Na^+ reduction in various solvents.

Experimental

Faradaic impedance measurements.—Faradaic impedance measurements were conducted in 1M NaClO_4 in PC, DMF, DMSO, and AN to determine kinetic parameters for the reaction

at dropping mercury electrode (DME). Lower concentrations of 0.5 and 0.1M NaClO_4 in PC and 0.1M NaClO_4 in DMF were also employed. To reduce the ohmic resistance at low concentrations of NaClO_4 , tetrabutyl ammonium perchlorate (TBAP) was used as a supporting electrolyte. However, the results with TBAP were not used in the analysis because of a strong evidence of TBAP adsorption even at the potential for sodium reduction.

The DME (Heath Instruments, Benton Harbor, Michigan) was equipped with a Sargent Welch Scientific capillary which was rated for drop times of 2-5s and had an inside diameter of 0.03-0.05 mm. This capillary was further extruded to form an elongated tip to minimize the shading of the tip (8). The bulb at the base of the extruded portion was very small to minimize gas retention (9). The extruded capillary was cut at a right angle to form a smooth edge. The drop time was regulated by the mercury column. Within the potential range employed, the weight of the drops remained the same within 0.5%. A pool of mercury was employed as the counter and reference electrode.

All experiments were conducted in an argon atmosphere glove box. The solvents were purified by storage for 1 week over molecular sieves followed by vacuum distillation (10). The reflux ratio was 1:10. The water content in the purified solvents was measured gas chromatographically to be below 10 ppm in PC, and below 20 ppm in DMF, DMSO, and AN using Karl Fisher titration. Salts were dried at 100°C under vacuum with periodic flushes of argon.

The impedance bridge (Electroscientific Industries, Portland, Oregon, Model 290B) and the ac generator-detector (Model 861A) were used to measure the cell impedance. In all the measurements, the equivalent circuit for the unknown cell was considered to be a capacitance in series with a resistance. Sluyters-Rehbach and Sluyters (11) used a similar bridge circuit. A Model 280 Wenking potentiostat was used for the dc bias potential. The frequency range was 20 Hz-20 kHz. Two different methods were used for measuring the ohmic resistance at DME. The first was made using the impedance bridge in a resistance mode after compensating for the electrode capacitance at constant frequency. The second was conducted

in a capacitance mode, at constant frequency and a potential outside the faradaic region. Both methods gave concurrent results within 1%.

The behavior of 1M NaClO_4 solutions in all four solvents followed the classical Randles circuit. The Warburg's coefficient, σ , charge-transfer resistance, θ , anodic transfer coefficient, α , and the apparent rate constant, k_{sh}^{a} , were evaluated by analysis of the electrode admittance. The measured resistance and capacitance for each solution at constant potential and varying frequency were converted to electrode impedances and then to electrode admittances, after accounting for the ohmic resistance. The frequency dependence of the admittance components determines the Warburg's coefficient, σ , the charge transfer resistance, θ , and the kinetic parameters k_{sh}^{a} and α . In lower concentrations of 0.5 and 0.1M NaClO_4 in PC and DMF and in the presence of TBAP supporting electrolyte, specific adsorption was detected. The adsorption admittance was separated from the total admittance (11) to evaluate the kinetic parameters. The electrode admittance analysis is detailed elsewhere (10, 12, 39). The apparent rate constants were evaluated by approximation, $E_{1/2}^{\text{r}} \approx E_0$, and neglecting the difference in diffusion coefficients. However, the polarographic half-wave potentials obtained from the literature were corrected using the calculated activity coefficients following the Debye-Hückel equation (10). Furthermore, the true rate constant, k_{sh}^{t} , and anodic transfer coefficients, α , were obtained by correcting the apparent parameters for double-layer effect using the differential double-layer capacity curves.

Results and Discussion

Data analysis.—The data for the impedance measurements, after subtraction of the solution resistance, were converted to admittance

$$Y'_{\text{e1}} = \frac{\omega^{1/2}}{\sigma} \frac{p+1}{(p+1)^2 + 1} \quad [5]$$

$$Y''_{\text{e1}} = \frac{\omega^{1/2}}{\sigma} \frac{1}{(p+1)^2 + 1} + \omega C_d \quad [6]$$

where

$$p = \frac{\theta}{\sigma\omega^{-1/2}} = p'\omega^{1/2} \quad [7]$$

and plots of $(Y'_{\text{e1}})^{-1} \omega^{1/2}$ vs. $\omega^{1/2}$ were made, where Y'_{e1} is the real admittance and ω is the frequency. The trends of these plots indicate the presence of specific adsorption and deviation from the Randles circuit. An example is shown in Fig. 1 and 2 for 1M NaClO_4 in PC where no deviation from the classical Randles circuit is observed. Approximate Warburg's coefficients, σ , which can be estimated by extrapolation of $Y'_{\text{e1}})^{-1} \omega^{1/2}$ vs. $\omega^{1/2}$ plot at low frequencies to $\omega = 0$, were very close to the σ values obtained by numerical data fitting. An example of a plot of $\log \sigma$ vs. E for 1M NaClO_4 in PC is shown in Fig. 3. As expected from theory, this plot is a straight line with a slope of -15.74V^{-1} , which closely compares with the theoretical slope of -16.91V^{-1} . The values of $p' = \theta/\sigma$ were obtained by finding a frequency-independent C_d for each potential. The charge-transfer resistance, θ , was obtained at each potential by numerical fitting. A plot of $-\log p'$ vs. E is shown in Fig. 4. The anodic transfer coefficient, α , can be obtained from the slope; in this particular example, $\alpha = 0.38 \pm 0.15$. The apparent rate constant k_{sh}^{a} is obtained by extrapolating Fig. 4 to $E_{1/2}$. In this particular example, $k_{\text{sh}}^{\text{a}} = 0.81 \pm 0.17 \text{ cm s}^{-1}$.

The same analysis has been performed for all the experimental systems in the four various solvents. The details of the analyses are presented elsewhere (10).

Kinetic parameters.—A summary of apparent rate constants and anodic transfer coefficients for Na^+ reduction in the four solvents in presented in Table I.

The standard heterogeneous true rate constants were obtained by double-layer correction (12)

$$k_{\text{sh}}^{\text{a}} = k_{\text{sh}}^{\text{t}} \gamma_0^\alpha \gamma_{\text{R}}^\beta \exp(-anF\phi_s/RT) \quad [8]$$

Fig. 1. $(Y'_{ei} \omega^{-1/2})$ vs. $\omega^{1/2}$ plots in 1M NaClO₄-propylene carbonate. E vs. Hg pool: (Δ)-1.85V; (O)-1.875V; (∇)-1.900V (expanded scale).

Fig. 2. $(Y'_{ei} \omega^{-1/2})$ vs. $\omega^{1/2}$ plots in 1M NaClO₄-propylene carbonate. E vs. Hg pool: (Δ)-1.925V; (\square)-1.950V; (O)-1.975V.

Fig. 4. $-\log p'$ vs. E. plot for 1M NaClO₄ in propylene carbonate

where ϕ_2 is the potential of the outer Helmholtz layer and γ_0 and γ_R are the activity coefficients of the oxidized and reduced species, respectively. The coefficient α is related to the apparent α^a by

$$\alpha^a = \alpha + g$$

where $g = (RT/nF)d(\ln k_{sh}^a)/dE$ is the double-layer correction to the apparent anodic transfer coefficient (13).

The double-layer correction is frequently referred to as the "Frumkin correction." In order to determine ϕ_2 , it is necessary to know the potential dependence of the double-layer capacity. The capacity vs. potential curve can be integrated to give the electrode surface charge density q^M

$$q^M = \int_{E_z}^E C dE \quad [9]$$

where E_z is the potential of zero charge. The surface charge density is related to ϕ_2 according to the Gouy-Chapman theory.

Differential double-layer capacity curves in nonaqueous solvents.—The double-layer capacity studies in nonaqueous solvents are not as abundant as in aqueous systems. The double-layer capacitance curves for the propylene carbonate-NaClO₄ system are given by Biegler and Parsons (16). It may be noted that at far cathodic potentials, $E < -1.5V$ (vs. Ag/Ag⁺), the differential capacity is virtually independent of NaClO₄ concentration in PC. The differential capacitance curve for 0.5M NaClO₄ in dimethylformamide is reported by Doilido *et al.* (17). They studied the effect of deoxygenation of the solution on the ECM in this system. The potential of zero charge is taken as 0.80V vs. NCE. The differential capacity curves for 0.1M NaNO₃ and 0.1M LiClO₄ in DMSO are reported by

Table I. Apparent and true rate constants for Na⁺ reduction in nonaqueous systems

System	k_{sh}^a (cm/s)	k_{sh}^t (cm/s)	α , anodic transfer coefficient
PC-1M NaClO ₄	0.81 ± 0.17	0.38 ± 0.09	0.38 ± 0.15
DMF-1M NaClO ₄	0.35 ± 0.11	0.21 ± 0.07	0.19 ± 0.06
DMSO-1M NaClO ₄	0.90 ± 0.31	0.05 ± 0.03	0.57 ± 0.12
AN-1M NaClO ₄	1.93 ± 0.17	0.35 ± 0.04	0.58 ± 0.22

Payne (18). The 0.1M NaNO₃ curve is used for obtaining q_m . The potential of zero charge of the 0.1M NaNO₃-DMSO system is -0.303V vs. aqueous NCE (18). The differential capacity vs. potential curve for 0.8M NaClO₄ in acetonitrile shows that the ECM occurs at a potential -0.380V vs. SCE (19).

The potential ϕ_2 can be determined by the Gouy-Chapman theory for symmetrical electrolyte

$$q^M = 41.887 \times (DC^*)^{1/2} \sinh(19.46Z\phi_2) \quad [10]$$

where C^* , the bulk concentration, is in moles per cubic centimeter and D is the dielectric constant. The values of q^M are obtained by integration of the differential double-layer capacity curves according to Eq. [9]. The obtained values of q^M and the corresponding values of ϕ_2 , calculated according to Eq. [10], are shown in Table II.

Based on the calculated ϕ_2 , $d\phi_2/dE$ were calculated, assuming a linear relationship, and substituted in a differential form of Eq. [8] in order to obtain $d(\ln k_{sh}^a)/dE$, which was subsequently used to obtain g . In all the cases, the values of g so obtained were smaller than the error limits on α^a and, hence, no correction was applied to the value of α . However, based on values of ϕ_2 , the values of k_{sh}^a were corrected to obtain k_{sh}^t . The true rate constants, k_{sh}^t , along with the apparent rate constants, k_{sh}^a , and anodic transfer coefficient, α , are shown in Table I.

Rate constants in nonaqueous solvents.—The results in Table I show that standard rate constants for Na⁺ reduction in nonaqueous solvents are at least an order of magnitude smaller than the standard rate constant for Na⁺ observed in water (>3.4 cm s⁻¹) using low concentrations of NaI with 1M LiCl supporting electrolyte (13). Qualitatively, the trend of standard rate constants follows the trend of solvation of ions in the nonaqueous solvents.

The relative magnitude of the standard rate constants in the various solvents indicates that Na⁺ ion is solvated in the order PC \approx AN < DMF < DMSO. The relevant discussion of this trend with respect to solvation is given below.

Kinetic parameters in PC.—It is interesting to note that the rate constants for Na⁺ reduction in PC are comparable to those measured by Hills and Peter (20). Using voltammetric measurements at hanging mercury drop electrode (HMDE), they have obtained kinetic parameters for several cations in PC and DMSO. The peak potential separation for Na⁺ reduction remained unchanged at 60 mV at sweep rates of up to 10³ V s⁻¹, hence it was concluded that the k_{sh}^a for Na⁺ is greater than 1.0 cm s⁻¹ and Na⁺ reduction reaction is totally diffusion controlled in PC. Jorné and Tobias (21, 22) also have measured the standard rate constants for the reduction of alkali-metal cations in AlCl₃ (1M)-PC using micropolarization technique. They used stationary pools of alkali-metal amalgams for working and counterelectrodes. The measured apparent rate constant for Na⁺ in AlCl₃ (1M)-PC was 0.0492 cm s⁻¹, which is much lower than the rates measured by Hills and Peter and the current study. The difference may be attributed to the measurement techniques as well as the nature of the working electrode employed. Both the DME and HMDE have advantages over a stationary pool elec-

trode in that DME has a continuously renewed surface concentration which changes with the increasing drop size and HMDE can be extruded to perform the measurements instantaneously. This enables one to avoid the adsorption of reactants, products, and contaminants at the surface of the electrode. Hills and Peter (20) have claimed that adsorption of contaminants was avoided by preparing the Hg drop and conducting the measurements rapidly. Hence, the lower rate constant for Na⁺ in PC measured by Jorné and Tobias (21, 22) may be due to the adsorption of the impurities on the electrode surface. Hills and Peter (20) were unable to measure the cathodic transfer coefficient for Na⁺. However, the cathodic transfer coefficient of 0.61 measured by Jorné and Tobias (21, 22) closely agrees with our cathodic transfer coefficient of 0.62.

Kinetic parameters in DMF.—Baranski and Fawcett (23) have measured the standard rate constant for Na⁺ reduction in DMF and the effect of supporting electrolyte on the measured rate constant. The variation is only observed in apparent rate constants, since true rate constants, which are obtained through double-layer correction, are independent of concentrations of the active and supporting electrolytes. The method of measurement used by Baranski and Fawcett (23) is similar to this method, and their measured apparent rate constant of 0.16 cm s⁻¹ agrees reasonably with our rate constant of 0.21 cm s⁻¹. However, their cathodic transfer coefficient of ~ 0.5 differs from the present value of 0.81 for 1M NaClO₄ in DMF.

Analysis of the electrode admittance showed the presence of specific adsorption for 0.1M NaClO₄ + 0.5M TBAP in DMF for our study. Baranski and Fawcett (23) have noted that, when a supporting electrolyte of a larger ion is used in place of a smaller ion, e.g., TBAP in place of TEAP, there is a marked increase in the apparent transfer coefficient. However, for 0.1M NaClO₄ + 0.5M TBAP in DMF, in our case, there was no significant change in the transfer coefficient compared to 1M NaClO₄ in DMF. Similar specific adsorption was noticed for 0.5M NaClO₄ + 0.375 TBAP in PC and 0.5M NaClO₄ + 0.375 TBAP in PC during the analysis of our admittance data.

Kinetic parameters in DMSO.—In DMSO, the Na⁺ ion is strongly solvated (20), and, consequently, one should expect a lower standard rate constant for Na⁺ reduction. The measured standard rate constant of 0.05 cm s⁻¹ for Na⁺ reduction in DMSO is the lowest of all the four solvents. Hills and Peter (20) measured the apparent rate constant of 0.014 cm s⁻¹ for Na⁺ in DMSO, which is reasonably close to our measurement. However, they did not measure the cathodic transfer coefficient for Na⁺ because of the limitations of their methods. The Na⁺ reduction reaction is considered to be quasi-reversible (0.1 > k_{sh}^a > 0.01) because of the magnitude of the apparent rate constant. It may be noted that this is strictly a qualitative observation.

Kinetic parameters in AN.—AN is supposed to be a weak solvator of Na⁺ (23), and Na⁺ reduction in AN is reversible. A standard rate constant of 0.57 cm s⁻¹, using ac admittance technique, has been measured for Na⁺ in 0.1M TEAP supporting electrolyte in AN (23). The cathodic transfer coefficient measured was 0.55. This compares reasonably with the standard rate constant of 0.35 cm s⁻¹ and cathodic transfer coefficient of 0.42 measured in this study.

Energetics in nonaqueous solvents.—Free energy of transfer and standard potential.—Since the kinetic parameters and free energy of transfer are affected by the nature of the solvent, Eq. [11] may be used to compare $\Delta G_i^o(\text{Na}^+)$, $\Delta G_i^o(\text{Na}^{\#})$, and $\phi^o(\text{Na}^+)$ from water to various solvents

$$(K_{sh}^t)_r = (k_{sh}^t)_r / (k_{sh}^t)_w = \exp \{ [\Delta G_i^o(\text{Na}^+) - \Delta G_i^o(\text{Na}^{\#}) + nF(\beta_2\phi_2^o - \beta_1\phi_1^o)] / RT \} \quad [11]$$

Experimentally determined free energies of transfer for Na⁺ from water to various solvent are listed in Table III.

Table II. Surface charge densities and outer Helmholtz potentials in nonaqueous solvents

AN	+3.3	-2.3 ^c

^a Ref. (24), TATB assumption.

^b Ref. (26, 27).

^c Estimated from Ref. (28, 29).

It is noted that $\Delta G_t^\circ(\text{Na}^+)$ values in column I of Table III are listed by Popovych and Tomkins (24). These values are determined through the TATB extrathermodynamic assumption, which states that the free energy of solvation for tetraphenylarsonium ion (Ph_4As^+) is equal to the free energy of solvation of tetraphenylborate ion (Ph_4B^-) in all the solvents. Krishnan and Friedman (25) have given a brief explanation of this assumption. TATB assumption is one of many in a class of extrathermodynamic assumptions, which are generated through similar arguments. However, when a generalized scale for single free energies ΔG° are prepared through TATB assumption, errors may exist which may be uniform throughout. The values of $\Delta G_t^\circ(\text{Na}^+)$ in column II for PC and AN are derived from independent studies. The references are listed in Table IV. The values of $\Delta G_t^\circ(\text{Na}^+)$ from H₂O to PC and AN are given as +3.6 and +3.3 kcal/g-mol, respectively, in column I, which would indicate that Na⁺ is more solvated in H₂O than in PC and AN, which is not believed to be true. Solomon (26-27) has determined -0.5 kcal/g-mol for Na⁺ transfer through EMF measurements. Jorné and Tobias (30, 31) also have measured $\Delta G_t^\circ(\text{Na}^+)$ for Na⁺ transfer from water to $\text{AlCl}_3(1m)$ -PC to be negative (-4.2 kcal/g-mol). These measurements indicate Na⁺ to be more solvated in PC and $\text{AlCl}_3(1m)$ -PC systems than in water. Hence, the values of $\Delta G_t^\circ(\text{Na}^+)$ in column II of Table III are believed to be more reliable and are used in the determination of $\phi^\circ(\text{Na}^+)$, the standard potential of Na⁺ in various solvents.

In order to determine $\phi^\circ(\text{Na}^+)$ from Eq. [11], one must know $\Delta G_t^\circ(\text{Na}^\ddagger)$, the free energy of transfer of the activated complex. There is no information available regarding $\Delta G_t^\circ(\text{Na}^\ddagger)$. Generally, the activated complex is considered to have the same free energy in all the solvents. Consequently, $\Delta G_t^\circ(\text{Na}^\ddagger)$ may be considered to be zero. Parker (32), in an elaborate review of bimolecular reactions in nonaqueous solvents, has found this to be true. Solomon (27) also has demonstrated, in his study of ion solvation in methanol, that the free energy of transfer of the activated complex from water to an organic solvent to be, effectively, zero. Hence, based on this assumption and using $\Delta G_t^\circ(\text{Na}^+)$ in Table III and Eq. [11], the values of $\phi^\circ(\text{Na}^+)$ were calculated and are shown in Table IV.

Parker and co-workers (33) have determined the transfer properties of several ions in nonaqueous solvents,

using heats of solution and heat of precipitation measurements. With the aid of TATB assumption, they have developed a standard potential scale for K⁺/K vs. NHE, which is presented in Table IV. Comparison of $\phi^\circ(\text{Na}^+/\text{Na})$ and $\phi^\circ(\text{K}^+/\text{K})$ scales shows that Na⁺ is more electropositive than K⁺ in all the solvents under consideration. This observation is consistent with the findings of Jorné and Tobias (21) for $\text{AlCl}_3(1m)$ -PC system and of Solomon (27) for PC. Pleskov (34) has measured the standard potential of Na⁺ in AN to be -2.87V, which is comparable to -2.778 vs. NHE obtained in this study. It must be noted that $\phi^\circ(\text{Na}^+/\text{Na})$ is derived by assuming $\Delta G_t^\circ(\text{Na}^\ddagger)$ to be zero, and hence, any discrepancies in the values of $\phi^\circ(\text{Na}^+/\text{Na})$ obtained may be attributed to this assumption.

Surface potentials in nonaqueous solvents.—With the knowledge of $\phi^\circ(\text{Na}^+/\text{Na})$ in various solvents, the surface potential χ of a solvent may be calculated using the following

$$\Delta\phi^\circ(\text{Na}^+) = \phi^\circ(\text{Na}^+)_1 - \phi^\circ(\text{Na}^+)_2 \\ = \Delta G_t^\circ(\text{Na}^+)/nF + (\chi_1 - \chi_2) \quad [12]$$

where χ_1 and χ_2 are the surface potentials of the solvents under consideration. The calculated surface potentials for all the solvents studied are listed in Table IV. It is noted that all four solvents and water have positive surface potentials.

The surface potential of a solvent indicates the orientation of the solvent dipole at the interface of the solvent and the electrode. As a general rule, it is assumed that for dipolar aprotic solvents the sign of the surface potential indicates the charged end of the dipole pointing toward the electrode surface. Thus, if the surface potential of the solvent is positive, the positive end of the dipole is pointing toward the electrode and vice versa. However, this is an oversimplified view for the analysis of the surface potential of a solvent. There are other interactions occurring at the electrode surface besides the ion-dipole interaction and the specific adsorption of the solvent molecule. There exists considerable experimental evidence that points to the fact that preferred orientation of water dipole in aqueous solution is that with the negative end of the dipole toward the metal. However, it is known that water has positive surface potential (18, 36).

Payne (37), through the capacitance measurements at the mercury electrode, has concluded that the positive end (methyl group) of the PC dipole orients toward the electrode surface. This is in qualitative agreement with the surface potential of +0.179V obtained in this study. The conformational analysis of PC molecules adsorbed at a mercury electrode is presented by Brasseur and Hurwitz (40) and compared to experimental capacitance measurements. Yeager *et al.* (41) studied spectroscopically the ionic solvation in PC. Considerable electron density was found on all PC oxygen atoms, while the positive end was found to be diffuse.

An explanation for the orientation of simple aliphatic molecules at the mercury electrode is given by Payne (18). The two methyl groups, which form the positive end of

^e For 1M NaClO₄ systems.

the DMSO dipole, tend to orient themselves facing the electrode surface. Also, since DMSO has a large dipole moment (4.3D), owing to its sulfoxide group, a positive surface potential is observed at the electrode surface. The crystallographic data for molecular models at low temperature point to the suggestion that the DMSO dipole might be directed away from the normal to the electrode surface by as much as 60°. The obtained value of +0.185V for the surface potential of DMSO concurs with the considerations of Payne (18) and Solomon (27), since the value is positive and any discrepancy in the value itself may be attributed to experimental errors and extrathermodynamic assumption (TATB).

According to Payne (18), DMF molecules also follow the same trend at the electrode surfaces as DMSO. The DMF molecule with its large dipole moment (3.8D), due to the C-O end of the molecule, tends to orient the two methyl groups (the positive end) toward the electrode surface. This orientation of DMF is stronger than DMSO, and hence, reorientation does not occur as in the case of DMSO. A positive surface potential of +0.147V for DMF is consistent with the observations made by Payne (18, 5) through the double-layer capacity studies.

The AN molecule, in comparison, is not as large a molecule as DMSO, but has a comparable dipole moment (3.84D). The nitrogen (N⁻) forms the negative end of the dipole. Solomon (27, 28) has estimated the value for the surface potential of AN in the vicinity of -1.0V. The negative sign indicates that the N⁻ end of the AN dipole is oriented towards the electrode surface. This observation, however, is not consistent with our calculated value of the surface potential of +0.1V for AN. Using similar data for K⁺, $\Delta G_T^\circ(\text{K}^+) = 1.6$ kcal/g-mol (24) and $\phi^\circ(\text{K}^+/\text{K})$ from Table V (33), we can calculate a value of +0.128V for the surface potential of AN. This value is consistent with our findings and, hence, we may qualitatively state that AN dipole has the methyl group oriented toward the electrode.

Free energy of transfer of activated complex Na[‡].—In the foregoing discussion, it was assumed that $\Delta G_T^\circ(\text{Na}^\ddagger)$ in Eq. [11] was equal to zero. It may be noted that there are empirical methods of calculating $\Delta G_T^\circ(\text{M}^\ddagger)$ for an activated complex. However, the information so obtained is of very little use. Solomon (27) has stated that $\Delta G_T^\circ(\text{M}^\ddagger)$, which may be calculated empirically, explains everything but is of no value in predicting anything. Secondly, the extrathermodynamic assumptions made in the determination of single-ion free energies in any solvent result in certain error which may be small as compared to the magnitude of free energy of solvation of the ion [$\Delta \bar{G}^\circ(\text{M}^+)_{\text{solv}}$]. But, when compared to the free energy of transfer [$\Delta G_T^\circ(\text{M}^+)$], this error can be enormous. For example, single-ion solvation free energies in water for various ions are listed from ten different sources (28). For Na⁺, $-\Delta \bar{G}^\circ_{\text{solv}}(\text{Na}^+)$ varies between 72.4 and 107 kcal/g-mol. When $\Delta G_T^\circ(\text{Na}^+)$ is calculated for the transfer of Na⁺ from water to any other solvent, variations in $\Delta G_T^\circ(\text{Na}^+)$ could be as large as ~35 kcal/g-mol. In view of this fact, if one assumes $\Delta G_T^\circ(\text{Na}^\ddagger) = 0$, the error caused by such assumption will be much smaller than those caused through experimental errors and extrathermodynamic assumptions.

Solomon (27) has discussed the effect of the $\Delta G_T^\circ(\text{M}^\ddagger) = 0$ assumption on the proton discharge at Hg cathodes in MeOH and water. He has calculated $\Delta G_T^\circ(\text{H}^\ddagger)$ to be 35 cal/g-mol, which is very small compared to -2.9 kcal/g-mol used for $\Delta G_T^\circ(\text{H}^+)$. Solomon calculated $\Delta G_T^\circ(\text{H}^\ddagger)$ using his own measurements for $\Delta \bar{G}^\circ(\text{H}^+)_{\text{solv}}$ in H₂O of -235 kcal/g-mol and $\Delta \bar{G}^\circ(\text{H}^+)_{\text{solv}}$ in MeOH of -237.9 kcal/g-mol. However, when these values are compared to Izmailov's (38) measurements for $\Delta \bar{G}^\circ(\text{H}^+)_{\text{solv}}$, a $\Delta G_T^\circ(\text{H}^\ddagger)$ of -5 kcal/g-mol is obtained, which is roughly 70% larger than Solomon's value. This example is chosen to show the large inherent discrepancies and errors existing in $\Delta G_T^\circ(\text{M}^\ddagger)$ derived through extrathermodynamic assumptions, and it may be concluded that assuming $\Delta G_T^\circ(\text{M}^\ddagger) = 0$ will not add to the error to a great extent. Moreover, assuming the standard free energy of transfer of activated complex from water to any other solvent to be zero greatly simplifies the evaluation of the parameters such as $\phi^\circ(\text{M}^+)$ and χ . Through this assumption, the $\phi^\circ(\text{Na}^+/\text{Na})$ obtained can establish the trend of $\phi^\circ(\text{Na}^+/\text{Na})$ in various solvents and give a magnitude of $\phi^\circ(\text{Na}^+/\text{Na})$ and χ , which may be compared with $\phi^\circ(\text{Na}^+/\text{Na})$ and χ obtained through other similar assumptions.

Solvation in nonaqueous solvents.—In order to determine the effects of solvation and electrostatic ion-ion interactions in a solvent, the modified Born equation along with the donor numbers (DN) may be used. Tanaka (4) has listed DN for several solvents. Using these, the value of δ , the Latimer, Pitzer, and Slansky parameter, may be derived, which in turn will help derive the electrostatic free energy of transfer, $\Delta G_T^\circ(\text{Na}^+)_{\text{el}}$. Table V shows the calculated free energies of transfer for Na⁺ from water to various solvents. It is seen from Table V that $\Delta G_T^\circ(\text{Na}^+)_{\text{el}}$ is negative for DMF and DMSO and positive for PC and AN. This indicates that transfer of Na⁺ from water to PC or AN is "endergonic" and that from water to DMF or DMS "exergonic" (33).

Among the ion-ion- and ion-solvent-type interactions, the "Born-type" interactions contribute about 80% to the free energy of transfer of ion from vacuum to a dielectric medium. Consequently, the $\Delta G_T^\circ(\text{Na}^+)_{\text{solv}}$ reflects only 20% of the interactions between the ions and the solvent.

The values of $\Delta G_T^\circ(\text{Na}^+)_{\text{solv}}$, the solvation free energy of Na⁺ for transfer from water to all the solvents, are negative, and hence, the "ion-solvent interaction" or solvation free energy is higher in all four solvents than in water. The donor-acceptor interactions, H bonding interactions, and structure making and structure breaking interactions contribute to $\Delta G_T^\circ(\text{Na}^+)_{\text{solv}}$ (32). The dipole moments of the solvents also contribute significantly to $\Delta G_T^\circ(\text{Na}^+)_{\text{solv}}$. Generally, a solvent with a higher dipole moment is a better solvent. The dipole moments of H₂O, PC, DMF, DMSO, and AN are 1.84, 4.94, 3.82, 4.3, and 3.84D, respectively. It is noticed that there is no direct relationship between the dipole moments and $\Delta G_T^\circ(\text{Na}^+)_{\text{solv}}$.

In order to relate the rate constants in nonaqueous solvents to their solvation properties, one may consider the general observation regarding transfer of small cations from water to an organic solvent. $\Delta G_T^\circ(\text{M}^+)$ for such transfer is usually negative and, hence, the rate constants in organic solvents are usually lower than those in water.

Table V. Free energies of transfer for Na⁺ from H₂O to various solvents

Fig. 5. Plot of true rate constant vs. medium dependent activation energy of (Na^+) in various solvents. (○) current study; (Δ) Reeves *et al.* (13); (□) Hills and Peter (20); (▽) Baranski and Fawcett (23).

Reexamining Eq. [3] and [4], it may be deduced that the rate constant in a medium is exponentially proportional to $\Delta G_s^0(\text{M}^+) - nF\beta\phi^0$, which is the medium-dependent part of the activation energy. In order to illustrate this, $\log k_{sh}^0$ is plotted vs. $\Delta G_s^0(\text{Na}^+) - nF\beta\phi^0$ in Fig. 5. The relevant data for Na^+ reduction obtained from previous studies are also shown in Fig. 5 for comparison. The agreement is reasonable, considering the fact that those rate constants were obtained by different experimental methods and in somewhat different electrolytes. The values of $\Delta G_s^0(\text{Na}^+)$ in any solvent are obtained by adding $\Delta G_s^0(\text{Na}^+)_{\text{H}_2\text{O}} = -97$ kcal/g-mol (28) to $\Delta G_t^0(\text{Na}^+)$ in various solvents. The relationship between $\log k_{sh}^0$ and $\Delta G_s^0(\text{Na}^+) - nF\beta\phi^0$ is linear because the values of ϕ^0 were calculated accordingly. However, this plot can serve in determining the qualitative trend of the rate constants in various solvents. Once the solvation energy and the standard potential in a particular solvent are known, the true rate constant can be estimated from Fig. 5.

It is interesting to note that the trend of rate constants increases in the order $\text{DMSO} < \text{DMF} < \text{AN} \approx \text{PC}$. The same order is observed for free energy of transfer of Na^+ [$\Delta G_t^0(\text{Na}^+)$] from water to various solvents ($\text{DMSO} < \text{DMF} < \text{AN} < \text{PC}$).

In conclusion, $\text{Na}^+ + e \rightleftharpoons \text{Na}(\text{Hg})$ reaction is "fast" and reversible in PC, DMF, and AN and quasi-reversible in DMSO. The standard potential scale for Na^+ in PC, DMF, DMSO, and AN is comparable to the standard potential scale for K^+ in the same solvents. The difference in absolute potential between H_2O and four solvents is considered to be ± 70 mV. The surface potentials of PC, DMF, DMSO, and AN indicate their dipoles are oriented with the positive ends toward the surface. Na^+ ion is strongly solvated by DMSO and weakly by AN and PC; hence, the rate constant for Na^+ reduction in DMSO is the lowest and in PC the highest.

LIST OF SYMBOLS

A	Debye-Hückel constant (kg/mol) ^{1/2}
α	D/δ k_{sh}
α	activity coefficient

α	mean ion diameter (cm)
B	Debye-Hückel constant (kg/mol) ^{1/2}
C	concentration at the electrode surface (mol/cm ³)
C_d	double-layer capacitance ($\mu\text{F}/\text{cm}^2$)
D	diffusion coefficient (cm ² /s)
D	medium dielectric constant
E	dc potential (V)
E_0	standard potential (V)
F	Faraday constant (C/eq)
ΔG^0	standard free energy of transfer (kcal/g-mol)
ΔG_t^0	free energy of transfer (kcal/g-mol)
h	Planck's constant
i	current density (A/cm ²)
k	Boltzmann constant
k_{sh}	heterogeneous rate constant (cm/s)
k_{sh}^a	apparent rate constant (cm/s)
k_{sh}^t	true rate constant (cm/s)
k_0^a	standard rate constant (cm/s)
M^\ddagger	activated complex or transition state
M	metal
M	Molarity (mol/liter of solvent)
N_A	Avogadro's number
n	number of electrons transferred
p	$\delta/\sigma\omega^{-1/2}$ (s ^{-1/2})
p'	irreversibility quotient (θ/σ)
q	charge density (C/cm ²)
R	universal gas constant (J/g-mol-K)
R	resistance ($\Omega\text{-cm}^2$)
r	crystallographic radius (Å)
T	temperature (K)
t	time
V	potential (V)
x	distance (cm)
Y	admittance (mho/cm ²)
Y'	real admittance (mho/cm ²)
Y''	imaginary admittance (mho/cm ²)
Z	impedance ($\Omega\text{-cm}^2$)
Z'	real impedance ($\Omega\text{-cm}^2$)
Z''	imaginary impedance ($\Omega\text{-cm}^2$)

Greek letters

α	anodic transfer coefficient
β	cathodic transfer coefficient
γ	activity coefficient
δ	Latimer, Pitzer, and Slansky solvent parameter (Å)
δ	diffusion layer thickness (cm)
ϵ	permittivity of the dielectric medium
η	overpotential (V)
θ	charge transfer resistance ($\Omega\text{-cm}^2$)
σ	Warburg's coefficient ($\Omega\text{-cm}^2 \text{ s}^{1/2}$)
Γ	surface excess (mol/cm ²)
ψ	$nF(E - E_0)/RT$
ϕ_z	phase angle of the faradaic impedance
ϕ_M^0	standard equilibrium potential (V)
ϕ_2	potential of the outer Helmholtz layer (V)
ω	angular frequency (s ⁻¹)
χ	surface potential (V)

Suffixes

a	apparent
ct	charge transfer
el	electrode
el	electrostatic
f	faradaic
f	formal
mt	mass transfer
min	minimum

Metal Deposition-Dissolution in Molten Halides: On the Question of Measurability of Very Fast Electrode Reaction Rates

J. L. Settle and Z. Nagy*

Argonne National Laboratory, Chemical Technology Division, Argonne, Illinois 60439

ABSTRACT

Metal deposition-dissolution reactions in molten salts are very fast and difficult to investigate, as evidenced by large discrepancies in the reported exchange current densities. An error analysis of the dc relaxation techniques was carried out, and it was determined that the measurement of the exchange current density can have a systematic error if the surface reaction rate is much faster than the diffusion rate. This systematic error will result in measured exchange current densities approximately equal to the largest exchange current density measurable under the given conditions. This systematic error can also result in fortuitously linear $\log i_0$ vs. $\log C$ and $\log i_0$ vs. $1/T$ plots, even when the results are grossly in error. A computer curve fitting data evaluation coupled with a statistical sensitivity analysis is suggested to avoid these problems. The exchange current densities of iron, nickel, and molybdenum were measured in LiCl-KCl eutectic melt at 450°C using an improved double-pulse galvanostatic technique. Only that of iron could be measured reliably (1.7 ± 0.4 A-cm⁻² at 1.3×10^{-6} mol-cm⁻³ Fe²⁺ ion concentration). The nickel reaction is too fast to be measured (at least 5 A-cm⁻² at 1×10^{-6} mol-cm⁻³ Ni²⁺ ion concentration), and the molybdenum results are unreliable because of melt decomposition. The large discrepancies between these results and some results reported by earlier workers can be explained on the basis of the above-described error analysis. It is concluded that past experiments resulting in large exchange current densities should be reexamined with improved measuring and data-evaluation techniques because it is possible that the reported values represent only the applicability limit of the measuring technique rather than the true exchange current density.

Metal deposition-dissolution reactions are a special class of electrode reactions; their atomistic mechanism includes the electrochemical building or breaking of the metallic crystal lattice in addition to the usual series of elementary processes, such as chemical reactions at or near the surface, charge-transfer step(s), adsorption at the surface, material and charge-transport processes, etc. Under some conditions, the crystal building or breaking processes can be rate determining. Therefore, the elementary steps of these processes and the variables affecting these steps have to be elucidated for a full understanding of the overall reaction. These include the type and density of surface dislocations, diffusion of adatoms to and from these sites, incorporation (or exclusion) of adatom into the lattice, charge transfer at dislocation sites or at the smooth surface, two- or three-dimensional nucleation, etc. A good overall understanding of these processes exists

*Electrochemical Society Active Member.

for metal deposition in room temperature aqueous systems (1-7). On the other hand, our understanding of these processes in high temperature molten salts is much less satisfactory, as shown by a brief discussion in a recent review on the electrochemistry in molten salts (8). This is, at least partly, due to the fact that the high temperature electrode kinetics data base, from which the mechanistic conclusions could be drawn, is rather limited, and, as will be shown below, often contradictory. In addition to the obvious scientific importance, these reactions are part of many practical processes, such as metal winning and refining, batteries, and corrosion processes.

The aim of the present work was to investigate the kinetics of deposition-dissolution of transition metals in molten LiCl-KCl eutectic. This solvent has been a popular one among previous investigators, and much thermodynamic data and some electrode kinetic data are available (9). Three metals were investigated in this work: iron,

nickel, and molybdenum. A summary of previously reported exchange current densities of these metals (10-18) is presented in Table I. These data reveal the very large discrepancies among the results reported by different investigators and among the results reported by the same investigators when using different measuring techniques. The reported exchange current densities vary as much as three orders of magnitude. Results on other solid metals in LiCl-KCl eutectic, such as cobalt, chromium, copper, silver, and platinum, also exhibit large discrepancies (10, 12, 14-17, 19-25). These reactions are generally fast, and, therefore, relaxation techniques were used for the determination of their exchange current density. The most-often used techniques were dc relaxation techniques, particularly single- and double-pulse galvanostatic techniques and also voltage and potential step techniques. A comparison of the exchange current densities in Table I to the reported limitations of the measuring techniques (26, 27) revealed that many of the very large values are of the same order of magnitude as the upper limit of the techniques. It was also noteworthy that the potential-step technique gave consistently smaller exchange current densities than the double-pulse galvanostatic technique, indicating that the results may be method dependent. To ensure that our measurements are being performed with a method which can be reliably used for fast reactions, we have performed a detailed, comparative error analysis of all dc relaxation techniques and suggested several modifications to the existing techniques that improve their ability to measure large exchange current densities. Most of this work has been pub-

lished already (28-34) and will only be briefly summarized below.

Error Analysis

The limits of applicability of dc relaxation techniques have been determined in terms of time constants of the electrode system (28-31), and a comparison of all techniques has been published (32). In these studies, a field of applicability was defined for each technique, indicating the combinations of time constants for which the exchange current density is measurable with an error of less than 20%. The two main conclusions of these earlier studies, relating to the present work, were that the galvanostatic double-pulse technique is best suited for the measurement of large exchange current densities, and that the applicability field of every technique can be enlarged to reactions approximately two orders of magnitude faster by two modifications. These modifications are (i) the reduction of the errors of measurements by about an order of magnitude through the use of digital instrumentation (transient recorder) in place of an analog oscilloscope, and (ii) the use of the computer curve-fitting data-evaluation method instead of a graphical method. No attempt was made in these earlier studies to examine whether the large errors occurring outside the field of applicability display any systematic behavior. The error behavior outside the field of applicability is examined in this present investigation.

The method of error calculations was the same as reported earlier (28-32) and will be described here only briefly. Synthetic data were generated by using the basic

Table I. Reported exchange current densities in LiCl-KCl eutectic melt

equations of the particular relaxation technique at a fixed set of electrode reaction parameters and by including random errors in the data. The exchange current density was then calculated from these synthetic data using the data-evaluation method under investigation, and this "measured" exchange current density was compared to the exchange current density used in the synthetic data generation. Calculations were carried out for the following dc relaxation techniques: galvanostatic single- and double-pulse techniques, potential (and voltage) step technique, and coulometric technique. Both graphical and computer curve-fitting data-evaluation methods were examined. Some typical examples of the results are shown in Fig. 1-3.

Figure 1 shows an example of exchange current densities obtained by the potential-step technique. As the true exchange current density increases, the measured exchange current density increases only to around the largest value of the exchange current density measurable under the given conditions and then remains approximately constant while the error of the measurement increases. Similar results were obtained for all relaxation techniques, using both graphical and computer curve-fitting data analysis. Figure 2 shows an example of the $\log i_0$ vs. $\log C$ relationship obtained by the galvanostatic double-pulse technique. The experimental results are quite different from the exchange current densities used to generate the relaxation curves, but the expected linear relationship is still obeyed. This can be explained by two factors: (i) the largest measurable exchange current density is increasing as the concentration increases, and (ii) the type of error behavior indicated on Fig. 1 is followed. Figure 3 indicates that a fortuitously linear $\log i_0$ vs. $1/T$ plot can also be obtained in this example of the galvanostatic single-pulse technique even though the results are grossly in error. The explanation for this behavior is similar to that given for the data shown in Fig. 2. Again, similar behavior can be demonstrated for all techniques.

The error behavior does not always follow the potentially misleading character shown in Fig. 1-3; under certain conditions, the error is random and the measured exchange current density is widely scattered. Because of the potentially large number of calculations needed, no attempt was made to define the conditions under which the error becomes systematic. However, this is really immaterial; what is important, from a practical standpoint, is that such behavior can occur. Furthermore, there is no obvious indication in the experimental data when the system is outside the field of applicability of the experimental technique, but there are several techniques which can be used to extract information about the reliability of the data. Four such techniques are described below.

1. A plot of the experimental data can often reveal possible problems. At short times, a plot of potential vs.

Fig. 1. Comparison of known and measured exchange current densities. Potential-step technique, graphical data evaluation.

Fig. 2. Concentration dependence of known (circles) and measured (squares) exchange current densities. Double-pulse galvanostatic technique, graphical data evaluation.

square root of time should be concave toward the time axis for the galvanostatic single-pulse technique; a completely linear or convex plot indicates overwhelming diffusion control. Similarly, at short times, a plot of current density vs. square root of time should be convex to the time axis for the potential-step technique. For the coulometric technique, a plot of logarithm of the potential vs. time should be linear for a considerable time after the start of the experiment; the diffusional effects are serious when the plot curves soon after time zero. For the double-pulse galvanostatic technique, a plot of potential at the potential minimum vs. the square root of the prepulse length can be linear even when the results are grossly in

Fig. 3. Temperature dependence of known (circles) and measured (squares) exchange current densities. Single-pulse galvanostatic technique, graphical data evaluation.

error; a very large exchange current density and, consequently, the possibility of large error are indicated when negative intercepts are obtained on the potential axis. Unfortunately, none of these indicators is quantitative and borderline cases are difficult to decide.

2. The measured system parameters can be used to calculate the time constants of the system, and the system can be located on the applicability diagram of the measuring technique. However, as demonstrated above, this method is not reliable when the measured parameters place the system near the border of the applicability field.

3. The generation and evaluation of synthetic data were described in the above error analysis. When used properly, this is a powerful method for indicating the reliability of the parameters calculated from the experimental data. The measurement conditions have to be taken fully into consideration in the data generation (e.g., risetime of pulses, error of all measurements including the IR correction), and several data sets should be generated by varying the assumed exchange current density around the calculated value. The question is not only whether the parameters in question can be used to generate a data set similar to the experimental one, but also whether similar data sets can also be generated using different parameter (e.g., exchange current density) values, thereby indicating the insensitivity of the curve-fitting to that particular parameter. The generation of synthetic data sets requires negligible programming effort and computing time compared to the curve-fitting calculations, and it is worthwhile to make such calculations a routine part of all data evaluations.

4. Finally, a statistical sensitivity analysis can be carried out (33) by determining the covariance matrix of the parameters. This will indicate the information content of the experimental data with respect to the parameters. Results are reliable only if their standard deviation is small compared to the numerical value of the parameter (not more than a few percent). The last two methods, or a combination of them, are useful for very fast reactions, while for slower reactions the first two methods will suffice.

In summary, it was found that if the electrode system falls outside the field of applicability, because the surface reaction is fast compared to the diffusion to and from the surface (i.e., the diffusional time constant is small), the exchange current density measurement can display a systematic error, resulting in a measured exchange current density approximately equal to the largest exchange current density measurable with the measuring technique under the given conditions. This can result in exchange current densities whose values seem to fall within the field of applicability; furthermore, the dependency of the exchange current density on concentration and temperature can have the expected linear form, even though the measurements are grossly in error. There is not always an obvious indication in the experimental data that the exchange current density will be in error. The reliability of the measurement can be best established by a statistical sensitivity analysis of the results of the computer curve-fitting data evaluation. These conclusions are valid for all dc relaxation techniques (potentiostatic, galvanostatic, and coulometric) using both graphical and computer curve-fitting data-evaluation methods.

Experimental

Measuring techniques.—The galvanostatic double-pulse relaxation technique was used for most experiments. Some measurements were also carried out with galvanostatic single-pulse and coulometric (with constant-current pulse charging) relaxation techniques. Both graphical (26, 27) and computer curve-fitting (28, 29, 32) data-evaluation methods were used. A modified double-pulse galvanostatic technique was applied (34). This modification consisted of overcharging the double layer during the prepulse to produce a minimum in the overpotential relaxation during the second pulse; the minimum could be

adjusted to occur after the unavoidable ringing of the signal and, therefore, could be clearly observed. This modification was shown to have smaller error and a larger field of applicability than the unmodified technique (28, 34). Two graphical data-evaluation methods were used for the double-pulse technique based on the following equation (34)

$$\eta_m = \frac{\nu RT i_2}{n F i_0} + \frac{4RT i_2}{3 \sqrt{\pi} n^2 F^2 D^{1/2} C} [q^{3/2} - (q-1)^{3/2}] t_1^{1/2}$$

where η_m is the overpotential minimum after the prepulse, ν is the stoichiometric number of the reaction mechanism, i_2 is the measuring current density (second pulse), D is the diffusion coefficient, C is the concentration of the metal ion, q is the ratio of the time of the potential minimum to the prepulse length (t_m/t_1), and t_1 is the prepulse length; the other symbols have their usual meaning. The two methods are as follows. A series of measurements were made at varying prepulse lengths, with the prepulse current adjusted to keep the ratio q constant; the exchange current density¹ can be calculated from the intercept of a plot of potential at the minimum vs. square root of prepulse length. With this method, a considerable number of trial pulses are needed to achieve a constant q . In an experimentally easier method, the prepulse length was kept constant and the prepulse current was varied, resulting in a series of relaxations where the time of the potential minimum and, consequently, the q values varied from pulse to pulse. The exchange current density can be calculated from the intercept of a plot of potential at the minimum against $[q^{3/2} - (q-1)^{3/2}]$.

The curve-fitting data evaluations were carried out using a multidimensional nonlinear least squares technique based on the Levenberg-Marquardt algorithm (35, 36). More detailed descriptions and tests of the programs have been published before (28, 29, 32). The risetime of the pulses was taken into consideration in the data evaluations using a linear rise approximation; general relaxation equations for nonzero risetime were published previously (37). Two curve-fitting methods were used. A three-parameter curve-fitting was carried out to determine the exchange current density, the double-layer capacitance, and the diffusion coefficient. The experimental data were corrected for the IR drop in the electrolyte which was determined from the initial rise of the potential. The measurement of the IR correction involves a certain error, and this, in the extreme case, could result in a considerable error in the determination of a large exchange current density (31). Therefore, the following modification was used to improve the IR correction. Using the second method, a four-parameter curve-fitting was carried out to calculate, in addition to the above-stated variables, the solution resistance between the two working electrodes. The same IR-corrected input data as for the three-parameter fitting were used; therefore, the resistance calculated by the curve-fitting program was, in effect, the error of the original IR correction. An iterative procedure was then followed: the experimental data were now corrected using the adjusted solution resistance, a new four-parameter curve fit was calculated, and so on. This was continued until none of the calculated parameters changed more than 1%, which usually occurred within a few iterations.

Instrumentation.—A block diagram of the experimental setup is shown in Fig. 4. Two Hewlett-Packard pulse generators (Model 214B) were used to generate fast rising constant-voltage pulses which were converted into constant-current pulses by two large load resistors (R1 and R2). The first H-P pulse generator and the digital recorder were triggered simultaneously from an Instrument Research Company (Santa Barbara, California) Model 910A pulse generator, and the second H-P pulse generator

¹The value determined was actually that of i_0/ν because of the linearization of the current density-overpotential equation. The term "exchange current density" refers to this ratio throughout this communication.

Fig. 4. Block diagram of the experimental setup

was triggered, with adjustable delay, from the first one. To obtain a single-ended current measurement, the sum of the potential drops over R_3 and the cell was measured; the cell introduced only a small error, since its resistance was always at least three orders of magnitude smaller than R_3 . The cell voltage was measured through a Tektronix AM501 voltage follower and an EG&G PAR Model 115 amplifier and was recorded simultaneously with the current using a dual-channel transient waveform recorder having 10 bit amplitude resolution and 10 MHz sampling rate (Physical Data, Incorporated, Beaverton, Oregon, Model 523-A). Calibration of the instrumentation was carried out with an Electronic Development Corporation (Boston, Massachusetts) sine wave amplitude and frequency standard Model 4100. The recorded data could be viewed locally or sent to a VAX 11/780 computer for data evaluation and storage. Some preliminary data were recorded on a Tektronix 7623A storage scope and photographed. It was estimated that the error of measurements was less than 0.5% for the digital measurements and about 5% for the analog measurements.

Cell design.—Certain special requirements had to be fulfilled because of the large expected values of the exchange current densities to be measured. These requirements were, among others, (i) a uniform current distribution on the working electrode, (ii) electrode mounting allowing repeated polishing of the working surface, (iii) small solution IR drop included in the measured potential, and (iv) a small overall inductance to minimize the initial ringing of the signal. A general discussion of cell design requirements for measurement of kinetics of fast electrode reactions has been published previously (38). The cell was a two-electrode, thin-layer design, consisting of two identical working electrodes and no reference electrode. The use of two identical working electrodes, one polarized anodically and the other cathodically, has been shown to extend the range of the linear approximation of the current density-overpotential relation (39, 40), an approximation which is always used in the calculation of the exchange current density from the experimental data. This is especially important for a metal deposition-dissolution reaction; in this case, the linearization error is larger than for a redox reaction because the activity of one species remains unity throughout the reaction (40, 41). The measured potential relaxation included the sum of anodic and cathodic overpotentials and IR drop in the electrolyte; the latter was kept small by the thin-layer design. The large ratio of electrode diameter to interelectrode gap also ensured small edge effects and, consequently, a uniform current distribution. The cell is shown in Fig. 5. The cell body and the electrode holders were made of high purity boron nitride (Union Carbide, Grade HBC, containing less than 1% oxygen) and treated (after fabrication) at 1750°C in nitrogen atmosphere for 18h to remove surface oxide. The two metal rod working electrodes were press fit into the holders and polished. The electrolyte gap was controlled by a 1.25×10^{-2} cm thick

Fig. 5. Cell design. A: to coaxial electrical leads. B: steel support rod. C: metal electrode contacts. D: boron nitride housing. E: metal electrodes. F: boron nitride electrode holders. metal spacer between the electrode holders. The spacer and the alignment pins were fabricated from the same metal as the working electrodes to avoid contaminating the melt.

The overall cell arrangement was like a long micrometer; the top electrode holder was vertically movable to facilitate the introduction of electrolyte into the interelectrode gap. The movement was controlled by a micrometer head through a universal joint in order to avoid misalignments. The cell was immersed into the electrolyte contained in a beaker at the bottom of a furnace well, which was attached to the floor of a glove box. The cell was immersed to a level somewhat above the interelectrode gap; therefore, only boron nitride and the electrode metal were in contact with the melt. Fused quartz or boron nitride beakers were used to contain the melt. The furnace well was open to the helium-filled glove box; the oxygen and moisture contents of the atmosphere were kept below 5 ppm by continuous purification.

Short copper wires were used to connect the electrodes to two high-temperature coaxial cables (one for current and one for the potential measurement) which were made of solid copper wire conductor, glass capillary tube insulator, and copper tubing outer conductor. Such a coaxial arrangement has been shown to reduce the inductive EMF generation during fast galvanostatic transients (42, 43). The instrumentation was connected with regular coaxial cables using coaxial feedthroughs in the wall of the glove box, which was isolated from the circuit.

Electrode preparation.—The electrode materials were electron-beam zone-refined metal rods with a purity bet-

ter than 99.99% from Materials Research Corporation (Orangeburg, New York). They were machined slightly larger than the hole in the holder and were inserted under liquid nitrogen to obtain a tight fit in the boron nitride holder. Oil-based diamond compounds were used in the polishing, finishing with 0.25 μm size. A pair of electrodes, which were to be used together in an experiment, were polished together in a frame. Joint polishing developed a common plane through the boron nitride electrode holders such that, even if the electrodes were not perfectly perpendicular to this plane, the electrodes were parallel to each other in the cell; therefore a uniform interelectrode gap was ensured. The polishing frame rested on four metal feet made of the same material as the electrodes to avoid undercutting the soft boron nitride during polishing. After polishing and ultrasonic cleaning, the electrodes were vacuum dried at 260°C and were reduced in 5% hydrogen/95% helium at 450°C for 2h. The reduction was carried out in a furnace attached to the glove box, immediately before the final assembly of the cell in the box.

Electrolyte.—Most experiments were carried out in LiCl-KCl eutectic (44.2 and 55.8%) at 450°C. Some experiments were carried out at lower temperatures in triple halide melts: LiCl-RbCl-CaCl₂ eutectic (28.7, 67.7, and 3.6%) which melts at 270°C (44) and LiBr-KBr-CsBr eutectic (39.1, 18.2, and 42.7%), melting at 236°C (45). The eutectic salts were polarographic grade material prepared by Anderson Physics Laboratories, Incorporated (Urbana, Illinois). The salts were further purified by pre-electrolysis immediately before the experiment. The pre-electrolysis was carried out with a platinum screen working electrode in a stirred solution. The reference electrode was a metal/metal ion electrode made from the metal to be investigated, and it contained 1×10^{-5} mol-cm⁻³ metal ions. The potential of the working electrode was controlled at -0.8V to the nickel, -0.5V to the iron, and -1.0V to the molybdenum reference electrode. Consequently, the potential was always approximately -1.7V to a molar platinum reference electrode in LiCl-KCl eutectic. The reference electrode and a graphite counterelectrode were contained in fused quartz tubes and were separated from the main body of the melt by fritted disks. The pre-electrolysis was carried out for at least 18h, or until the residual current decreased below 5 $\mu\text{A-cm}^{-2}$. The required amount of metal ion was then introduced by constant current anodic dissolution of a metal wire electrode. Molybdenum could not be introduced into the melt by anodic dissolution because of fast disproportionation; therefore, anhydrous K₃MoCl₆ (Pfaltz & Bauer Incorporated, Stamford, Connecticut) was added to the melt. The wires used for reference electrodes and for metal dissolution were of the same source and quality as the metal electrodes to be investigated.

Results and Discussion

Preliminary experiments.—Early results with iron and nickel in LiCl-KCl eutectic indicated that the exchange current density of the reactions is very high (46). The double-pulse galvanostatic technique was used with analog instrumentation and graphical data evaluation; the results were very scattered, some being in the many tens of amperes per square centimeter, and the intercepts of the plots were often negative. This prompted an effort to make measurements in lower melting salts, with consequently lower exchange current densities, to prove the validity of the experimental approach. A few measurements were made with nickel in LiCl-RbCl-CaCl₂ eutectic melt at 340°C containing 1×10^{-6} mol-cm⁻³ nickel ions. An exchange current density of 0.45 ± 0.1 A-cm⁻² was obtained, but some plots still resulted in negative intercepts. The system was at the very edge of the applicability field (28). Further measurements were carried out with an even lower melting salt and improved experimental and data-evaluation techniques selected on the basis of the above-described error analysis.

Nickel in LiBr-KBr-CsBr.—Measurements were carried out with analog instrumentation and computer curve-fitting data evaluation. Galvanostatic single- and double-pulse and coulometric pulse relaxation techniques were used to compare their performance to the predictions of the error analysis. The temperature was varied from 275° to 331°C while the Ni²⁺ ion concentration was kept at 4×10^{-7} mol-cm⁻³. The temperature dependence of the exchange current density is shown in Fig. 6 for data taken with double-pulse galvanostatic and coulometric techniques; the points show the average of four to fourteen measurements with a spread of approximately ± 0.2 A-cm⁻² for each point. The results for single-pulse galvanostatic technique were widely scattered, and plots of potential vs. square root of time indicated complete diffusion control. The apparent heats of activation, calculated from the slopes of the lines on Fig. 6, are 39.4 and 41.8 kJ-mol⁻¹ for the double-pulse and coulometric techniques, respectively. The double-layer capacitance values were 33 ± 11 $\mu\text{F-cm}^{-2}$ with all three techniques. The diffusion coefficients were rather large, 2.7, 11, and 114×10^{-5} cm²-s⁻¹ at 275°, 303°, and 331°C for the double-pulse technique, 3.0, 4.9, and 29.7×10^{-5} cm²-s⁻¹ for the single-pulse technique, and 1.9, 6.4, and 46×10^{-5} cm²-s⁻¹, respectively, for the coulometric technique. This system has not been investigated by other workers; therefore, no other values are available for comparison. However, indicators discussed in the error analysis section prove that the exchange current densities measured with the double-pulse galvanostatic technique are reliable: the system is within the field of applicability and the standard deviations are low. For the single-pulse galvanostatic and coulometric techniques, the electrode system is on the border of the applicability field for the determination of the exchange current density and, indeed, the single-pulse data were unreliable and the coulometric results were somewhat lower and more scattered than the double pulse results. These findings are in agreement with the applicabilities of the relaxation techniques predicted by our earlier error analysis (32).

Iron in LiCl-KCl.—Experiments were carried out with digital instrumentation coupled with curve-fitting data evaluation. The temperature was controlled at 450°C, and the Fe²⁺ ion concentration was 1.3×10^{-6} mol-cm⁻³. Eight experiments were carried out using the double-pulse

Fig. 6. Exchange current density of nickel in LiBr-KBr-CsBr. Triangles: double-pulse galvanostatic technique. Circles: coulometric technique.

Fig. 7. An example of the galvanostatic double-pulse relaxation curve together with the smooth curve generated by the computer curve-fitting data evaluation.

galvanostatic technique. An example of relaxation curves is given in Fig. 7, showing both the digital data (connected with a continuous line) and the smooth curve generated by the curve-fitting data-evaluation program. The results were an exchange current density of 1.7 ± 0.4 A-cm⁻², a double-layer capacitance of 120 ± 10 μF-cm⁻², and a diffusion coefficient of $10 \pm 1.5 \times 10^{-5}$ cm²-s⁻¹. The exchange current density is higher than any values previously reported for this system (12, 17); this will be discussed in more detail below. The double-layer capacitance is comparable to those reported for iron [191 μF-cm⁻² at 3×10^{-6} mol-cm⁻³ Fe²⁺ concentration, from Ref. (17)] and for other metal electrodes in halide melts containing the corresponding metal halides (10, 16, 17, 20, 47, 48). These large capacitance values are generally explained as a pseudocapacitance caused by the presence of adatoms (adions) on the surface (8, 47, 48), a phenomenon well demonstrated for metal deposition-dissolution in aqueous solutions (2, 3, 7). For solid electrodes, the surface roughness also contributes to the large capacitance. The diffusion coefficient was measured by several workers using chronopotentiometric and chronoamperometric techniques: Poinet and Barbier reported 1×10^{-5} at 450°C (49), Piron *et al.* reported 5.6×10^{-5} at 466°C (50), and Inman *et al.* reported 2.1×10^{-5} at 500°C (51). The discrepancy between our results and those previously reported can be explained as follows. The double-pulse galvanostatic measurements were carried out in a few microseconds time range; therefore, during a considerable portion of the measuring time, the dimension of the surface roughness of the electrode and that of the diffusion layer were comparable, resulting in a nonlinear contribution to the diffusion flux. A direct comparison of diffusion coefficients measured in molten LiCl-KCl eutectic with the double-pulse galvanostatic technique and linear potential sweep technique has indeed shown that the former technique tends to result in diffusion coefficients several times larger than those for the latter (16). A few experiments were also tried with single-pulse galvanostatic and coulometric techniques. The results, not surprisingly, were unreliable: the values calculated for the exchange current density were widely scattered, exhibiting large standard deviation, and appropriate plots of the data indicated complete diffusion control.

Nickel in LiCl-KCl.—Seventy-five runs were made, mostly with the double-pulse galvanostatic technique, using digital instrumentation and curve-fitting data evaluation. The nickel ion concentration ranged from 9×10^{-7} to 1×10^{-5} mol-cm⁻³, and the temperature was 450°C. The exchange current densities were very scattered, ranging from tens to thousands of amperes per square centimeter;

the high standard deviations and the graphical plots of the data indicated that the values were unreliable. A minimum value for the exchange current density was determined by generating synthetic data for the conditions of the experiment at a series of exchange current density values. It was determined that an exchange current density up to 5 A-cm⁻² at 1×10^{-6} mol-cm⁻³ could have been determined; therefore, the true exchange current density of the nickel reaction must be larger than 5 A-cm⁻². The double-layer capacitance ranged between 10 and 40 μF-cm⁻², and the diffusion coefficient was between 0.3 and 3.0×10^{-5} cm²-s⁻¹. Previously reported diffusion coefficients range from 0.73 to 4.14×10^{-5} cm²-s⁻¹ (49, 52-58).

Molybdenum in LiCl-KCl.—A few measurements were attempted at 450°C using digital instrumentation with galvanostatic double-pulse technique and curve-fitting data evaluation. Difficulties were encountered because of the instability of Mo³⁺ ion in the melt; the concentration was continuously decreasing, and a black precipitate appeared in the melt. Similar behavior was observed by Senderoff and Mellors, who attributed it to disproportionation to Mo⁵⁺ and molybdenum metal (59). Because of the close similarity of their observations to ours, further work was not carried out on this phenomenon, even though it would deserve further studies since other workers have found Mo³⁺ to be a stable species in the same melt (18, 60). Exchange current densities on the order of a few amperes per square centimeter were observed at a Mo³⁺ ion concentration of approximately 1×10^{-4} mol-cm⁻³; this exchange current density is much larger than the values of Selis (18), who did not report any melt instability. It is possible that our large exchange current densities are due to a large surface area caused by the precipitated metal powder; this is corroborated by a very large (around 800 μF-cm⁻²) double-layer capacitance.

A comparison of these exchange current densities, measured in the LiCl-KCl melt, to literature values and an evaluation of all reported exchange current densities with respect to the applicability diagrams of the measuring techniques revealed two facts: our exchange current densities were always larger than any previously reported value, and the reported values of the exchange current densities have placed all the electrode systems considered in this work at the edge of the applicability fields of the respective measuring techniques.

For the case of nickel, our minimum exchange current density² of 5 A-cm⁻² at 450°C and at a nickel ion concentration of 1×10^{-6} mol-cm⁻³ can be compared to the results of Bouteillon *et al.* (11-13), who, for similar conditions, report an exchange current density of about 0.1 A-cm⁻² using the potential-step technique. (The different investigators used different temperatures and metal ion concentrations, therefore comparisons are somewhat approximate; see Table I). Laitinen *et al.* (10) obtained approximately 0.5 A-cm⁻² using the double-pulse galvanostatic technique with graphical data evaluation, and Haruyama *et al.* (16, 17) reported values in the low amperes per square centimeter range for the same technique. Bouteillon *et al.* also used the double-pulse galvanostatic technique (14) and reported values near 100 A-cm⁻²; however, these results are so far outside the field of applicability of the technique that they cannot be considered reliable. The error may have been caused by a nonlinear extrapolation technique to correct for the solution IR drop. A similar trend with measuring technique can be demonstrated for iron. Bouteillon (12) found an exchange current density near 0.01 A-cm⁻² with the potential-step technique, while Haruyama *et al.* reported about 1 A-cm⁻² using the double-pulse galvanostatic technique with graphical data evaluation (17). Both of these values are lower than our 1.7 A-cm⁻².³

²Equivalent to a standard apparent rate constant of 0.026 cm-s⁻¹, assuming a transfer coefficient of 0.5 and taking the metal concentration as unity.

³Equivalent to a standard apparent rate constant of 0.008 cm-s⁻¹, assuming a transfer coefficient of 0.5 and taking the metal concentration as unity.

A certain amount of approximation is involved in the comparison of the reported exchange current density values to the applicability diagrams of the experimental techniques. Much information is needed on the details of the experiments which are not reported by the investigators, and estimated values must be used. One needs values for the double-layer capacitance, diffusion coefficient, risetime of pulse generators, accuracy of the measurements, and the size of the uncorrected IR drop. Even with these uncertainties, the trend is clear both for iron and nickel dissolution-deposition reactions: the electrode system always falls near the edge of the applicability field of the respective measuring techniques.

It can be concluded that reported exchange current densities are a strong function of the experimental techniques used for their measurement. The potential-step technique with graphical data evaluation resulted in the lowest exchange current densities for both iron and nickel. The galvanostatic double-pulse technique with graphical data evaluation gave considerably larger exchange current densities; this is in agreement with the fact that the latter technique can be used for much faster reactions than the potentiostatic measurement. Finally, our measurements, which were carried out with an improved double-pulse galvanostatic technique, resulted in even larger exchange current densities. This conclusion is corroborated by the result of the error analysis described above in which it was found that a measured exchange current density may indicate only the limitation of the technique rather than the true exchange current density of the reaction when the latter is outside the field of applicability of the measuring technique. These results suggest that large exchange current densities reported in the literature should be reexamined using improved experimental and data-evaluation techniques to prove their validity.

Acknowledgments

This work was performed under the auspices of the Division of Materials Science, Office of Basic Energy Sciences, U.S. Department of Energy. We are grateful to Dr. V. A. Maroni for his critical reading of the manuscript.

ABSTRACT

A traveling, dual-beam laser interferometer has been used to investigate mass-transfer boundary layers on planar electrodes in turbulent channel flow. The effect of secondary flows induced near the electrode/electrolyte interface by small flow obstacles in laminar bulk flow is compared to the effect of turbulent bulk flow produced by high electrolyte flow rates in an obstacle-free flow channel. It is shown that mass-transfer enhancement can be attained more efficiently by the use of small flow obstacles than by the use of high flow velocities.

Turbulent fluid flow can often be successfully employed to increase interfacial transport rates in a variety of industrial unit operations. Many electrochemical processes, such as electrowinning, electrochemical synthesis, and electro dialysis, tend to be rate limited by slow mass transfer. The application of turbulent in place of laminar electrolyte flow in these processes permits higher operating current densities and thereby improves the space-time yield of the electrochemical system. The most direct method to induce turbulent flow in an electrochemical cell is to raise the electrolyte velocity (1), but this technique may result in an unacceptable increase in electrolyte pumping power (2). Other viable methods include insertion of flow obstacles into the electrolyte flow stream (3), moving nets across the electrode surface (4), applying magnetic fields (5) or ultrasonic waves (6), and use of suspended particles (7).

The limiting current technique (8) is a powerful tool that has been used by many investigators (9) to characterize the local distribution of mass-transfer rates at electrode surfaces under conditions of turbulent flow. Of particular relevance to the present study are applications of the limiting current technique (3, 10-18) to evaluate the enhancement of mass-transfer rates by placing flow obstacles in the electrolyte flow stream. These investigations have provided valuable data to guide the optimal section of fluid flow rates, cell geometry, and obstacle shape, size, and spacing.

The purpose of the present work is to employ interferometry (19, 20) to characterize mass-transfer enhancement by turbulent flow, thereby providing data complementary to those obtained by the limiting current technique. In this method, local variations in the phase of transmitted light are measured, and the corresponding variations in refractive index (linearly related to concentration under the conditions of this study) are subsequently derived. The technique provides direct, continuous visualization of the local concentration boundary layer at any level of current density on continuous (unsectioned) electrodes. The interferometric method has been previously applied to study electrochemical mass

transfer under conditions of pure diffusion (21-24), natural convection (25-29), forced convection (30-32), combined forced and natural convection (33), and turbulent flow (32, 34).

Experimental

Flow channel.—Mass-transfer experiments were carried out in a 3m long rectangular-duct flow channel (35-37), the heart of which is depicted in Fig. 1. Gravity feed from a storage tank provides a steady flow of electrolyte. The duct is $w = 1.00$ cm wide and $h = 2.54$ cm high. The $L = 100$ cm long electrodes fully occupy the space between the two parallel, optically-flat glass sidewalls downstream of a 200 cm long (140 hydraulic diameters) entry region. All experiments were performed with the cathode facing down and the anode facing up. This configuration will produce less-dense electrolyte regions above more-dense regions, eliminating the possibility of electrolyte flow induced by natural convection. The primary current density distribution in this cell was calculated (31) to be

Fig. 1. Semiscale drawing of the flow channel. Channel width $w = 10.0$ mm. Channel height $h = 25.4$ mm. Electrode length $L = 100.0$ cm.

* Electrochemical Society Active Member.

nearly uniform; local current densities deviate from the average current density by no more than 1% for 97% of the electrode surface. The deviations from uniform primary current density occur only within a few centimeters of the coplanar junctions between conductor and insulator, *i.e.*, at the leading and trailing edges of the electrode. When current is passing, the electric field effect (and the associated small nonuniformity of the primary current density distribution) is moderated by the presence of charge-transfer and mass-transfer overpotentials. The resulting tertiary current distribution is even more uniform than the primary distribution. Near the limiting current density, the current distribution reflects local variations in mass-transfer boundary-layer thickness.

Flow obstacles.—Experiments were performed with five different obstacles placed in the flow channel, and the sizes, shapes, and spacings of these obstacles are shown in Fig. 2. The sizes and shapes were chosen to approximate those employed by Leitz and Marincic (3), and the spacings were chosen to be sufficiently large to allow flow disturbances to decay between obstacles. Figure 2 also illustrates the sizes of the obstacles relative to the local mass-transfer boundary layer thickness. The largest obstacle is a 12.7 mm diam, 10.0 mm long glass circular cylinder sandwiched between the two glass sidewalls, midway between the two electrodes. This object occupies 50% of the channel cross section, and it can create turbulence by increasing the local electrolyte flow velocity. The other four obstacles shown in Fig. 2 are a rectangular parallelepiped, a triangular parallelepiped, and two semicircular cylinders. All four of these obstacles, extending across the entire 10.0 mm channel width, were machined from acrylic and were glued to the cathode surface. The three larger obstacles extend 0.76 mm from the cathode surface and occupy 3% of the channel cross section. The smallest obstacle extends 0.28 mm from the cathode surface and occupies only 1% of the channel cross section. The dashed curves in Fig. 2 indicate the edge of the 99% mass-transfer boundary layer¹ predicted (38, 2, 9) for laminar flow conditions ($Re = 500$ and $Re = 1500$). Figure 2 shows that the dimensions of the smaller obstacles are comparable to those of the mass-transfer boundary layers expected under laminar flow conditions.

Electrolyte and electrode preparation.—The 99.999% pure copper electrodes were designed with two goals in

¹ The distance from the electrode surface where the local concentration reaches the sum of the surface concentration plus 99% of the total concentration difference (bulk less surface).

Fig. 2. Placement and sizes of obstacles in the flow channel. Ordinate: distance from cathode surface (mm). Abscissa: distance from cathode leading edge (cm). The 0.28 mm semicircular cylinder is attached to the cathode surface at $z = 22$ cm, the 0.76 mm semicircular cylinder at 32 cm, the 0.76 mm triangular parallelepiped at 47 cm, the 0.76 mm rectangular parallelepiped at 62 cm, and the 12.7 mm diam large circular cylinder is wedged between the two glass sidewalls at $z = 82$ cm. Dotted line: Mass-transfer boundary edge (Eq. [2]), calculated as twice the Nernst boundary-layer thickness (33).

mind: (i) the horizontal electrode surfaces should be flat and smooth, and (ii) the test beam should traverse the cell parallel to the surface. These requirements were met by first polishing a vertical side of each electrode flat and optically smooth. Then, a right-angle polishing jig was used to prepare the electrode working surfaces perpendicular to the reflecting sides. The cell was then aligned so that the test beam was parallel (to within 0.1°) to the electrode working surface by reflecting the beam from the side under exactly normal incidence (the reflected beam retraced its path back to its source). The working surface profile was flat to within $1 \mu\text{m}$ over 80% of its width. However, the edges were very slightly rounded (to about $10 \mu\text{m}$) below the level of the center of the surface.²

The aqueous CuSO_4 electrolyte was prepared by dissolving reagent-grade $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ crystals into twice-distilled water in a 25 gal polyethylene container. The dependence of electrolyte refractive index on CuSO_4 concentration was determined with an Abbé critical-angle refractometer, and sample concentrations were determined by gravimetric analysis. Least squares analysis provided a linear correlation for the refractive index at $\lambda = 632.8 \text{ nm}$ (He-Ne laser), $0 \leq C \leq 0.1\text{M CuSO}_4$, 20°C . All electrolysis experiments employed 0.1M CuSO_4 electrolyte and were conducted at 20°C .

Interferometer.—A cross section of the duct and dual-emission laser interferometer is shown in Fig. 3. A He-Ne laser was modified to emit light from each end of the laser cavity, and the interferometer was mounted on the carriage of a lathe bed to permit travel of the instrument along the length of the electrodes (35-37). The plane of focus (optically conjugate to the film plane of the camera) was located at the inside of the glass sidewall farthest from the camera, $x = 0$ (Fig. 1). This is the recommended plane of focus for the observation of cathodic boundary layers in which the refractive index decreases toward the electrode surface (40).

Electrochemical experiments.—Steady-state, constant-current electrodeposition of Cu onto a downward facing cathode was studied at $Re = 500, 1500, 5000$, and $10,000$ ($v_{\text{avg}} = 3.5, 10.5, 35$, and 70 cm/s , respectively). Average current densities ranged from 2.0 to 25.0 mA/cm^2 . Local

² This small deviation from planarity has been shown (39) to result in reflection of the test beam from the rounded electrode edge, which can cause anomalous curvature of the interference fringes in the immediate vicinity of the electrode surface.

Table I. Experimental matrix

v_{avg} (cm/s)	Re	i_{avg} (mA/cm ²)	Flow obstacles present
3.5	500	2.0	Yes
3.5	500	5.0	No
10.5	1,500	2.5	Yes
10.5	1,500	5.0	No
35	5,000	15.0	No
35	5,000	25.0	No
70	10,000	25.0	No

limiting current densities under laminar flow conditions at the trailing edge of the cathode surface range from 3.8 mA/cm² at Re = 500 to 5.5 mA/cm² at Re = 1500. Average limiting current densities under turbulent flow conditions ranged from 34 mA/cm² at Re = 5000 to 56 mA/cm² at Re = 10,000. Average applied current densities are listed in Table I. Note that limiting current densities are not approached, except near the trailing edge of the cathode for the single experiment at Re = 500 and $i_{avg} = 5.0$ mA/cm², which was performed for qualitative comparison purposes only.

The five obstacles were placed in the flow channel for some of the laminar flow experiments (Re = 500 and 1500); no flow obstacles were employed for the turbulent-flow experiments (Re = 5000 and 10,000). The four attached flow obstacles together occlude less than 0.3% of the cathode surface area. The current density, calculated by dividing the cell current by the projected cathode area, is therefore a good approximation to the true average current density.

Results and Discussion

The effect of electrolyte flow velocity on the steady-state mass-transfer boundary layer, formed by constant-current electrodeposition of Cu from 0.1M CuSO₄ without obstacles in the flow channel, is illustrated in Fig. 4. The curvature of the interference fringes seen near the electrode surface indicates reduced CuSO₄ concentration in the mass-transfer boundary layer. In this region, the electrolyte refractive index is lower than that in the bulk electrolyte, where the interference fringes are straight and perpendicular to the plane of the electrode surface. To a first approximation, the shape of an interference fringe represents the CuSO₄ concentration profile, with a displacement of one fringe spacing corresponding to a concentration change of 0.0022M CuSO₄. Inspection of Fig. 4 leads to the following observations.

1. Increasing the electrolyte flow velocity from Re = 500 to Re = 10,000 reduces the mass-transfer boundary layer thickness from (approximately) 1 to 0.1 mm.

2. The interfacial concentration gradient appears to be similar in all four experiments, even though the current density varies by a factor of five.

3. The apparent location of the electrode/electrolyte interface shows considerable deviation from its actual location, marked by the "0" ordinate designation, observed in the absence of refractive-index gradients. In the absence of mass-transfer boundary layers, the interference fringes are arranged to be straight and perpendicular to the plane of the electrode surface. There is, however, a very slight curvature of the fringes within 0.2 mm of the electrode surface caused by reflection from the very slightly rounded edge of the electrode surface (39).

4. The decrease of electrolyte concentration at the interface (relative to the bulk solution) appears to be much larger for the laminar-flow experiments than that for the turbulent-flow experiments.

Of the four observations listed above, only the first correctly describes the CuSO₄ concentration profiles. Observations 2-4 are artifacts of light-ray deflection (refraction) in the mass-transfer boundary layer. Simple methods of interpretation of interferograms which neglect light-curvature effects can lead to large errors (40, 41) in derived current densities, concentration changes, and boundary-layer thicknesses. Quantitative reduction of experimental interferograms to concentration profiles requires extensive computations to account for light-ray curvature effects. Correction procedures of varying degrees of complexity have been developed (26-30, 40-49). In general, larger interfacial refractive-index gradients result in greater light-ray deflection, which in turn requires more complex computational procedures. The present study employed a complex iterative procedure (42), which was shown to be accurate for the steep refractive-index (concentration) gradients expected.

Previous studies of the mass-transfer boundary layer formed by constant-current electrodeposition under laminar channel flow conditions have been reported elsewhere (31). Local steady-state concentration profiles were found to be consistent with well-established heat- and mass-transfer correlations (38, 2, 9) and the appropriate solution to the convective-diffusion equation (31), provided that the experimental interferograms were interpreted by the above-mentioned procedure (42) to properly account for light-ray deflection.

Quantitative interpretation of interferograms measured under turbulent flow conditions proved to be very difficult. The interference fringes and the associated de-

Fig. 4. Experimental interferograms showing the effect of electrolyte flow velocity on steady-state mass-transfer boundary layer thickness. Ordinate: distance from the cathode surface (mm).

rived current densities showed rapid and random fluctuations. Current densities (interfacial concentration gradients) varied between 10 and 100% of the expected values over time intervals of ca. 0.03s, as revealed by analysis of high speed (up to 64 frame/s) motion pictures of the interferograms. Concentration differences (between bulk and interface) showed similar fluctuations, while boundary-layer thicknesses showed somewhat smaller fluctuations. This observation is an indication that the smoothly varying, one-dimensional concentration profiles employed in the computational procedure (42) to interpret the interferograms cannot account for the (expected) random perturbations of local concentrations within the mass-transfer boundary layer, caused by turbulent eddy motion. This result could be expected, because the interferometric measurements produce a two-dimensional representation of a three-dimensional concentration field. Local refractive-index information is averaged along the optical path of the test beam, but the stirring action of the turbulent fluid motion can lead to substantial and random variations along the same optical path, an effect not easily accounted for in the computational procedure to interpret interferograms.

In Fig. 5, the measured Nernst boundary-layer thicknesses³ in the obstacle-free channel are compared with those predicted by the Chilton-Colburn analogy (50)

$$\text{Sh}_{\text{avg}} = \frac{d_e}{\delta_N} = \frac{f}{2} \text{Re Sc}^{1/3} \quad [1]$$

where f is the Fanning friction factor (51), and the other terms are defined in the List of Symbols. The error bars reflect the uncertainty due to the above-mentioned fluctuations in the experimental interferograms. The measured Nernst boundary-layer thicknesses show fair agreement with those predicted by the Chilton-Colburn analogy, with the greatest deviations occurring near the leading edge of the cathode ($z < 5$ cm), as expected, because the mass-transfer boundary layer is not fully developed in that region. Note that the Nernst boundary-layer

³ The Nernst boundary layer thickness is defined by the ordinate location where the extrapolated interfacial concentration gradient intersects with the extrapolated bulk concentration.

Fig. 5. Turbulent boundary-layer thicknesses. Ordinate: Nernst boundary-layer thickness δ_N (mm). Abscissa: Distance z from cathode leading edge (cm). Solid line: Thickness computed from Eq. [1]. Broken line: Represents uncertainty of computed values due to a 10% uncertainty in diffusion coefficient data. Circles: Derived from experimental interferograms, $\text{Re} = 5000$, $i_{\text{avg}} = 15.0 \text{ mA/cm}^2$. Triangles: $\text{Re} = 5000$, $i_{\text{avg}} = 25.0 \text{ mA/cm}^2$. Squares: $\text{Re} = 10,000$, $i_{\text{avg}} = 25.0 \text{ mA/cm}^2$.

thickness at $\text{Re} = 10,000$ is only about 0.03 mm, whereas the precise location of the electrode/electrolyte interface can only be determined (on the interferogram) with an accuracy of ± 0.005 mm. It is therefore beyond the practical resolution limit of double-beam interferometry to measure boundary-layer thicknesses for Reynolds numbers much larger than 10,000.

Figures 6-9 display interferograms of the concentration field in the immediate vicinity of the four flow obstacles attached to the cathode surface. Note that the presence of a flow obstacle can produce a major effect on the mass-transfer boundary layer downstream of the obstacle. This effect is caused by disruption of the hydrodynamic flow near the obstacle, and it is unrelated to the nonuniform current density distribution expected in the vicinity of the obstacle. The following conclusions can be made by inspecting Fig. 6-9.

1. Significant secondary flows are induced by the three larger obstacles at $\text{Re} = 1500$, and all four obstacles have a relatively small effect on the mass-transfer boundary layer at $\text{Re} = 500$.

2. The smaller semicircular cylinder has little effect at either $\text{Re} = 500$ or $\text{Re} = 1500$.

Consideration of the above observations in light of the sizes of the flow obstacles relative to those of the local mass-transfer boundary-layer thicknesses (see Fig. 2) leads one to the following generalization: the secondary flow induced by small flow obstacles significantly thins the local mass-transfer boundary layer only when the characteristic dimension (*i.e.*, the distance that the obstacle protrudes from the electrode surface into the electrolyte) of the obstacle is comparable to, or exceeds the local mass-transfer boundary-layer thickness.

Figures 10 and 11 illustrate interferograms of the mass-transfer boundary layers just upstream of, and up to 12.5 cm downstream from, the triangular-parallelepiped obstacle attached to the cathode surface. It is seen that the secondary flow induced by the triangular parallelepiped effectively thins the local mass-transfer boundary layer for more than 2.5 cm (33 times the obstacle height) downstream of the obstacle for $\text{Re} = 1500$, and for about 1 cm downstream from the obstacle at $\text{Re} = 500$.

Conversion of the experimental interferograms of the mass-transfer boundary layers in the presence of flow obstacles at $\text{Re} = 500$ and $\text{Re} = 1500$ was performed exactly as described above for $\text{Re} = 5,000$ and $\text{Re} = 10,000$. Difficulties similar to those encountered for interpretation of interferograms under turbulent flow conditions were experienced when interferograms of the wake regions just downstream of the flow obstacles were analyzed. In Fig. 12 and 13, the Nernst boundary-layer thicknesses measured at $\text{Re} = 500$ and $\text{Re} = 1500$ are compared with those predicted by the well-known Norris-Steird correlation (38, 2, 9)

$$\text{Sh}(z) = 1.23 \left(\text{Re Sc} \frac{d_e}{z} \right)^{1/3} \quad [2]$$

for heat and mass transfer under laminar flow conditions. The measured Nernst boundary-layer thicknesses show the expected agreement (31) with the Norris-Steird correlation at locations remote from the vicinity of the flow obstacles. Significant thinning of the local mass-transfer boundary layer is observed only at $\text{Re} = 1500$ for the flow obstacles attached to the cathode surface, which is consistent with the previous qualitative observations of the interferograms. The large cylinder sandwiched midway between the cathode and anode shows the expected reduction of local mass-transfer boundary-layer thickness caused by restriction of the flow channel cross-sectional area.

It is instructive to compare the effective reduction in local mass-transfer boundary-layer thickness caused by placing a flow obstacle on the electrode surface with that obtained by increasing the electrolyte flow rate. For example, Fig. 8, 11, and 13 show that the otherwise laminar mass-transfer boundary layer at $\text{Re} = 1500$ is substantially

Fig. 6. Experimental interferograms of the 0.28 mm semicircular cylinder. The electrolyte flow is from left to right. Left: $i_{\text{avg}} = 0$. Center: $Re = 500$, $i_{\text{avg}} = 2.0 \text{ mA/cm}^2$. Right: $Re = 1500$, $i_{\text{avg}} = 2.5 \text{ mA/cm}^2$.

Fig. 7. Experimental interferograms of the 0.76 mm semicircular cylinder. Designations as in Fig. 6

Fig. 8. Experimental interferograms of the 0.76 mm triangular parallelepiped. Designations as in Fig. 6

thinned for at least 2.5 cm downstream from the triangular parallelepiped flow obstacle. The Nernst boundary-layer thickness is reduced from about 0.25 mm just upstream from the obstacle to about 0.08 mm 1.5 cm downstream from the obstacle. The electrolyte flow velocity required to produce a Nernst thickness of 0.08 mm can be computed from Eq. [1] to correspond to $Re = 2790$. The pressure drop (directly related to pumping power and cost) required to maintain a given average flow velocity is given by

$$\frac{dP}{dz} = 2\rho v_{\text{avg}}^2 \frac{f}{d_e} \quad [3]$$

Since the friction factor f varies only slightly (51) from $1500 \leq Re \leq 2790$, and the flow velocity v is proportional to the Reynolds number Re , the ratio of the pressure drop for the two flow velocities considered is approximately

$$\frac{(dP/dz)_{Re=2790}}{(dP/dz)_{Re=1500}} = \left| \frac{2790}{1500} \right|^2 = 3.5$$

Therefore, reduction of the Nernst thickness from 0.25 to 0.08 mm by increasing the electrolyte flow rate from $Re = 1500$ to $Re = 2790$ requires a 3.5-fold increase in pressure drop.

The corresponding increase in pressure drop caused by attachment of triangular-parallelepiped flow obstacles to

Fig. 9. Experimental interferograms of the 0.76 mm rectangular parallelepiped. Designations as in Fig. 6

the electrode surface can be computed from the correlation presented by Leitz and Marincic (3)

$$f = \frac{\alpha}{Re} + 0.175n_p d_e \frac{1 - \beta^2}{\beta^2} \quad [4]$$

where α is a specific channel dimension parameter, n_p is the number of promoters per centimeter along the length of the channel, and β is the ratio of the open area perpendicular to the flow at the obstacle to the cross-sectional area of the channel without the obstacle. For the triangular obstacle and the given flow-channel dimensions (Fig. 1), the parameters are $\alpha = 16.6$ and $\beta = 0.97$. If triangular-parallelepiped flow obstacles were spaced 2 cm apart along the length of the cathode ($n_p = 0.5 \text{ cm}^{-1}$), the friction factor f computed from Eq. [4] for $Re = 1500$ would increase by a factor of 1.7 over that for a smooth electrode. Therefore, insertion of triangular-parallelepiped

flow obstacles results in a 70% increase in pressure drop at $Re = 1500$.

The electrolyte pumping costs associated with various means to enhance mass-transport rates at the electrode surface are directly related to the power dissipation, which is the pressure gradient multiplied by the average electrolyte velocity. The power dissipation, therefore, varies in direct proportion to the friction factor and as the cube of the average electrolyte velocity. Reduction of the Nernst thickness from 0.25 to 0.08 mm by increasing the electrolyte flow rate therefore requires a 6.4-fold increase in power dissipation, which may be compared to a 1.7-fold increase in power dissipation caused by insertion of triangular-parallelepiped flow obstacles.

Conclusions

Double-beam interferometry has been shown to provide qualitative and quantitative information about mass-

transfer processes under turbulent flow conditions. Derived mass-transfer boundary-layer thicknesses under turbulent flow conditions show the expected agreement with well-established heat- and mass-transfer correlations.

It is shown that the insertion of certain flow obstacles in an otherwise laminar flow stream can result in increased mass-transfer rates. The increased pressure drop and associated pumping power caused by the presence of the flow obstacle are shown to be substantially less than those required to produce the same increase in mass-transfer rates by an increase in flow velocity.

Reaction Pathways of the Anodic Oxidation of Formic Acid on Pt Evidenced by ^{18}O Labeling—A DEMS Study

O. Wolter,^{*,1} J. Willsau, and J. Heitbaum

Institute of Physical Chemistry, 5300 Bonn, Germany

ABSTRACT

Using either normal formic acid in H_2^{18}O or ^{18}O -labeled formic acid in H_2^{16}O , the following results were obtained: the oxygen atoms of formic acid are homogeneously exchanged with water; the strongly bound intermediate, however, does not exchange oxygen with water; the ^{18}O -labeled intermediate is oxidized in H_2^{16}O to $\text{C}^{18}\text{O}^{16}\text{O}$ by a three-electron process; direct oxidation of $\text{HC}^{16}\text{O}^{16}\text{OH}$ in H_2^{18}O delivers $\text{C}^{16}\text{O}^{16}\text{O}$.

The anodic oxidation of formic acid has attracted much attention in the last several decades because it was considered to be a possible fuel for direct energy conversion in fuel cells (1-3). In addition, the electrode process was regarded as a simple one which could be taken as a model for organic electrocatalysis (4).

It turned out, however, that the anodic oxidation of formic acid on Pt is by no means a simple process, as the excellent reviews of Capon and Parsons (4-6) show. These authors concluded from the charge obtained in the double-layer region that formic acid is oxidized in a dual path mechanism which is principally written as (5)

Direct oxidation of formic acid is assumed to occur via a so-called "reactive intermediate," described as COOH (5). In parallel, the formation of a strongly bound intermediate takes place which inhibits the direct oxidation and is stable up to at least 0.6V (5, 6). The intermediate is formed especially fast in the hydrogen region on Pt and was assumed to be $\overset{+++}{\text{C}}\text{OH}$ based on the charge consumed to oxidize it as well as on comparison with methanol (6).

While the $\overset{+++}{\text{C}}\text{OH}$ species seemed to be widely accepted in the early seventies, this being supported by radiometric measurements (7), recently vibrational spectroscopy has given strong evidence (8) that the adsorbed species is $\overset{+}{\text{C}}\equiv\text{O}$. This view was corroborated by investigations on single-crystal electrodes (9) and by measuring the number of electrons per site (eps) transferred when the adsorbate is desorbed as CO_2 (10).

In contradiction to these findings, the authors of the present paper were able to measure the number of electrons consumed by the formation of one CO_2 molecule out of the adsorbate. In the case of methanol, it turned out that three electrons are released upon oxidation of the intermediate to CO_2 , and, therefore, CO was excluded to be the inhibiting intermediate (11, 12). Analogous experiments for HCOOH are reported below. In addition, ^{18}O labeling was used to obtain direct evidence for the dual path mechanism mentioned above. This type of measurement is made possible, now, by differential electrochemical mass spectroscopy (DEMS) (13) developed by the authors. This method offers the unique advantages of on-line monitoring the volatile products of an electrochemical process and discriminating between different reaction pathways by isotope labeling.

Experimental

The mass spectroscopic technique (DEMS) applied in the following experiments is described elsewhere (13). In short, it uses a porous Teflon membrane as the inlet system, being directly connected with the ion source of a mass spectrometer. A porous catalyst layer is attached to the membrane on the electrolyte side. It is prepared from

a conducting lacquer (Doduco, Dürrwächter AG) and activated by cycling the electrode between H_2 and O_2 evolution in H_2SO_4 . The surface layer diagram has its usual shape (13), and the catalyst behaves like smooth polycrystalline Pt. This is corroborated by electron microscopy, showing that the catalyst consists of smooth Pt particles of 5 μm mean size. Figure 1 reproduces the respective microphotograph. Therefore, the porous catalyst layer resembles more smooth Pt than a high surface area electrode prepared by platinization.

A minicell containing about 1 ml electrolyte was used, constructed in a way that the solution could be exchanged under potentiostatic control. For example, ^{18}O -labeled formic acid in H_2^{18}O could be adsorbed at a constant potential, and then it was possible to substitute the solution quantitatively by H_2^{16}O . This procedure took about 2-4 min. It should be emphasized that all solutions were carefully deaerated by Ar and that oxygen had no access at any stage of the experiment. Special attention was paid to this point because the experiments with methanol (12) have shown that oxygen or its reduction intermediates react with the adsorbed species. The ion current of the product in the mass spec was recorded in parallel to the current potential curve in the usual way (13). H_2^{18}O was 90% enriched and used as obtained from Ventron GmbH. ^{18}O -labeled formic acid could be prepared from the normal chemical (p.A. grade, Merck) by oxygen exchange with H_2^{18}O as will be shown below. In all cases, the base electrolyte was 0.5M H_2SO_4 (Merck Suprapure) in H_2^{16}O or H_2^{18}O , respectively. Millipore water was used as H_2^{16}O . Solutions were deaerated by

¹ Present address: IBM, GMTC, 7037 Sindelfingen, Germany.

99.999 Ar. All potentials were measured against a hydrogen electrode (RHE) and are reported with respect to this reference.

Results

Homogeneous oxygen exchange between H_2O and $HCOOH$.—Direct experimental evidence for the dual path mechanism (5) of the formic acid oxidation is gained if the origin of the oxygen atoms in the product molecule CO_2 is known. This information can readily be obtained by DEMS using ^{18}O isotope labeling. At first, it has to be found out, however, whether oxygen is exchanged between H_2O and $HCOOH$. It is one advantage of DEMS that a homogeneous isotope exchange reaction can be monitored as well (15).

The experiment was done using the membrane inlet system without the catalyst layer in order to make sure that no heterogeneous exchange reaction takes place. Under these conditions, the acid evaporates through the membrane and the incoming flux into the mass spectrometer is directly proportional to the concentration of the respective species in the solution. The flux is directly related to the measured ion current I_1 which is given in the diagrams below. In previous papers, I_1 was called mass intensity (MI) (11-14).

The cell was filled with $0.5m H_2SO_4$ in H_2O at a ratio of $^{18}O:^{16}O = 9$. At $t = 0$, normal formic acid was added, thereby obtaining a $0.02m$ solution, and the different ^{18}O -labeled formic acid molecules were recorded as a function of time. The fragment spectrum of unlabeled formic acid has the measured intensity distribution for CO_2 (44): HCO_2 (45): H_2CO_2 (46) of 100:12:15,² CO_2 being the base peak. Consequently, the mass numbers 44, 46, and 48 can be identified as $HC^{16}O^{16}OH$, $HC^{16}O^{18}OH$, and $HC^{18}O^{18}OH$, respectively.

Figure 2 shows the result indicating that oxygen is completely exchanged between formic acid and H_2O , since the ion current of the originally added $HC^{16}O^{16}OH$ decreases, whereas that of $HC^{18}O^{18}OH$ increases with time. $HC^{16}O^{18}OH$ appears as an intermediate, having its maximum concentration after 6 min. The reaction obeys pseudo first-order kinetics and probably proceeds via a formate anion as intermediate, which means that both oxygen atoms are equivalent. The fact that formate is present only to a small extent in acidic solutions explains the rather slow oxygen exchange rate.

It should be noted that exactly the same result was obtained with the catalyst layer attached to the membrane when the potential was kept constant at $0.1V$. Therefore, a heterogeneous catalysis of the oxygen exchange reaction between formic acid and water seems not to occur within the limits of error.

Anodic oxidation of $HC^{16}O^{16}OH$ in $H_2^{18}O$.—Since oxygen is homogeneously exchanged between formic acid and water, the anodic oxidation of $HC^{16}O^{16}OH$ in $H_2^{18}O$ was studied in a single potential scan experiment immediately after addition of the acid to the electrolyte at $E = 0.1V$. Figure 3 shows the respective I-E curves together with the production rate of the differently labeled CO_2 species. Note that the ion currents differ by about two orders of magnitude from those in Fig. 2.

The intensity ratios of the different CO_2 species (44, 46, 48) correspond exactly to the homogeneous oxygen exchange reaction throughout the whole potential range, as can be easily deduced by comparing the intensity ratios at different times with those obtained from Fig. 2. This shows that both O atoms originate from formic acid which is directly oxidized to CO_2 . One exception is to be observed, however, namely, in the peak around $0.7V$, where an exceptional high intensity of $C^{16}O^{18}O$ is measured, which considerably exceeds the expected value. Evidently, within the peak around $0.7V$ a different type of mechanism takes place, and, as a whole, the result of Fig. 3 gives evidence of the dual-path mechanism (5) of the formic acid oxidation.

² This distribution differs from that reported in the literature (16) because of the high partial pressure of H_2O in our ionization chamber.

Fig. 2. Ion currents of masses 44-50 as function of time. The signal is due to evaporation of formic acid into the mass spec after adding $HC^{16}O^{16}OH$ to $0.5m H_2SO_4$ in $90\% H_2^{18}O$ at $t = 0$. The obtained solution contained $0.02m HCOOH$.

On the nature of the strongly bound intermediate.—Number of O atoms present in the adsorbate.—Accepting the usual view (5, 6, 8-10) that the extra reaction in the

Fig. 3. Electro-oxidation of $0.01m HCOOH$ on a porous Pt electrode. Base electrolyte is $0.5m H_2SO_4$ in $H_2^{18}O$ (90% enriched). First cycle after adding $HC^{16}O^{16}OH$ at an electrode potential of $100 mV_{RHE}$ is shown. Sweep rate is $6.25 mV \cdot s^{-1}$. a: The solid line shows the cyclic voltammogram; the broken line shows the surface layer diagram in base electrolyte. b, c: Corresponding I_1/E curves for the masses 44-48 during the anodic (b) and cathodic (c) scan.

peak at 0.7V originates from a strongly bound intermediate formed within the hydrogen region on Pt, experiments were done to find out how many oxygen atoms this adsorbate contains. Therefore, formic acid was equilibrated with base electrolyte of the isotope ratio $^{16}\text{O}:^{18}\text{O} = 0.84$. It is assumed that HCOOH adjusts itself to the same ratio, due to the homogeneous oxygen exchange reaction. This solution was brought into contact with the electrode at $E = 0.1\text{V}$ for 3 min, thus allowing the adsorbate to form. Then, the solution was quantitatively replaced by $\text{H}_2^{16}\text{O} + 0.5\text{m H}_2\text{SO}_4$, and an anodic scan was recorded, as is shown in Fig. 4. Evidently, the strongly bound intermediate was formed, and it is desorbed in a peak around 0.7V, the product being CO_2 , represented by the mass numbers 44, 46, 48. The intensity ratios between these species in the desorption peak amount to $\text{C}^{16}\text{O}^{16}\text{O}:\text{C}^{16}\text{O}^{18}\text{O}:\text{C}^{18}\text{O}^{18}\text{O} = 84:100:0$. This corresponds exactly to the isotope ratio of the initial solution and shows unambiguously that the adsorbate contains one oxygen atom only. Otherwise, the ratios would have been $\text{C}^{16}\text{O}^{16}\text{O}:\text{C}^{16}\text{O}^{18}\text{O}:\text{C}^{18}\text{O}^{18}\text{O} = 71:168:100$, as can be calculated statistically ($8.4^2:2 \cdot 8, 4 \cdot 10:10^2$).

Reactions between the strongly bound intermediate and the solution.—The results of the preceding section seems to indicate that the strongly bound intermediate does not react with water, *e.g.*, exchanging oxygen. To ensure this, $\text{HC}^{18}\text{O}^{18}\text{OH}$ in ^{18}O -base electrolyte (both containing 90% ^{18}O) was adsorbed at 0.1V for 3 min and afterwards the solution was replaced by ^{16}O -base electrolyte. After 2.5 min waiting at this potential, $\text{HC}^{16}\text{O}^{16}\text{OH}$ was added to yield a 0.005m solution. The potential was kept constant for another 2 min to allow the adsorbate to react with the solution. Finally, an anodic scan was performed and the ion currents of the mass numbers 44, 46, and 48 were recorded. Figure 5 shows the result.

Evidently, only $\text{C}^{16}\text{O}^{16}\text{O}$ is formed by the direct oxidation of bulk $\text{HC}^{16}\text{O}^{16}\text{OH}$. Within the desorption peak, however, $\text{C}^{16}\text{O}^{18}\text{O}$ is predominant. The intensity of $\text{C}^{17}\text{O}^{16}\text{O}$ (45) corresponds to the isotope ratio of ^{17}O in the preadsorbed formic acid,³ whereas the intensity of $\text{C}^{16}\text{O}^{16}\text{O}$ slightly exceeds the ^{16}O ratio. This is explained by the continuous adsorption of $\text{HC}^{16}\text{O}^{16}\text{OH}$.

This experiment shows clearly that the strongly bound intermediate does not exchange oxygen with H_2O . Moreover, it does not react with bulk HCOOH either, at least outside the potential range of desorption.

Number of electrons consumed to oxidize the adsorbate to CO_2 .—Analogous to the experiments with methanol (12), the number of electrons necessary to form the CO_2 molecule out of the adsorbate was measured. This was done using the equation (12, 14)

³ The ^{18}O -labeled water used in our experiments contained 3.5 atom percent ^{17}O .

Fig. 4. Electrodesorption of preadsorbed formic acid on a porous Pt electrode in the absence of bulk HCOOH 0.01m HCOOH (equilibrated with base electrolyte of the isotope ratio $^{16}\text{O}:^{18}\text{O} = 8.4:10$) was adsorbed at $E = 100\text{ mV}_{\text{RHE}}$ for 3 min. Then the electrolyte was substituted by base electrolyte in H_2^{16}O (3.5 min). Figure shows first anodic scan after exchange at a sweep rate of $3.125\text{ mV}\cdot\text{s}^{-1}$. a: Cyclic voltammogram. b: Corresponding I_i/E curves for the masses 44-48.

Figure shows first cycle after this procedure at a sweep rate of $6.25\text{ mV}\cdot\text{s}^{-1}$. a: Cyclic voltammogram. b, c: Corresponding I_i/E curves for the masses 44-48 during the anodic (b) and cathodic (c) scan.

$$I_i = K^+ \frac{1}{n} AI \quad [1]$$

with I_i being the ion current (A) of species i ; K^+ the proportionality constant, including all factors not specific for a given electrochemical process; n the number of electrons necessary to form one product molecule; A the current efficiency; and I the faradaic current (A).

In order to compare the total charge used within the desorption peak with the corresponding mass signal, one has to integrate Eq. [1]

$$Q_{ii} = K^+ \cdot \frac{1}{n} \cdot A \cdot Q_f \quad [2]$$

with Q_{ii} being the amount of product detected in the mass spec and Q_f the faradaic charge of the desorption process.

The constant K^+ is measured by an adsorption/desorption experiment for which n is known. Thus, CO is adsorbed at constant potential, removed from the solution by Ar flushing and desorbed as CO_2 by an anodic sweep. If the integration is done over a complete potential cycle, starting and ending with the same surface condition, $n = 2$ exactly (12). A is proven to be 1 by recording the second cycle which coincides with the surface layer diagram as well as by showing that no product other than CO_2 is formed.

With HCOOH , the analogous procedure was performed. The strongly bound intermediate was formed at 0.15V, then the solution was substituted by the base electrolyte and the adsorbate desorbed in an anodic scan. Figure 6 shows the $I-E$ curve together with the ion current of CO_2 .

Fig. 6. HCOOH-adsorption-desorption experiment in $0.5m$ H_2SO_4 on a porous Pt electrode. HCOOH was adsorbed at $0.15V$ for 3 min from a $0.01m$ solution. Then, excess fuel was removed by replacing the solution by base electrolyte. a: The solid line shows the surface layer diagram in $0.5m$ H_2SO_4 ; the dashed line shows the first anodic scan at a sweep rate of 6.25 $mV \cdot s^{-1}$ after exchange of the electrolyte. b: Corresponding I_1/E curve for CO_2 (44) during the electrodesorption of the preadsorbed HCOOH.

Integration of both curves together with $K^+ = 1.5 \times 10^{-7}$, obtained by the CO-adsorption-desorption experiment, gives $n = 3.0 \pm 0.15$. Therefore, $(CO)_{ad}$ can be ruled out as the strongly bound intermediate, but $(HCO)_{ad}$ is more likely.

Conclusions

Formic acid exchanges oxygen atoms with water. Taking this into account, it could be shown clearly that formic acid is oxidized on Pt in a dual path mechanism. The direct oxidation occurs without loss of oxygen (5)

The second reaction proceeds via a strongly bound intermediate, preferentially formed within the hydrogen region (6) by splitting off an oxygen atom from the acid. The most probable way by which this can occur is the formation of a water molecule as proposed by Parsons (6)

In principle, the analogous process could take place with an intermediate like $(COOH)_{ad}$ (5) to give CO_{ad} . But at $0.15V$, the rate of the direct oxidation of formic acid is

very slow, whereas the formation of the strongly bound intermediate is rather fast (6). Therefore, reaction [4] seems to be more likely. Moreover, the adsorbate $(CHO)_{ad}$ has the correct stoichiometry to be oxidized to CO_2 in a three-electron process, and we were able to prove that the adsorbate contains hydrogen (17). In conclusion, the present paper provides direct evidence for the dual-path mechanism described by scheme [I], where the "reactive intermediate" probably is $COOH_{ad}$ and the "inhibiting intermediate" is HCO_{ad} . Indirect evidence for the dual-path mechanism was recently given by Adzic (18) as well as by Pletcher (19).

Unfortunately, however, the intermediate proposed in Eq. [4] contains a carbon oxygen double bond and therefore does not match with the vibrational spectroscopy data (8). Several reasons could be envisaged for this discrepancy: strong shift of the adsorption band, perhaps due to bridge bonding; high absorption cross section of CO, being formed in a side reaction; oxidation of the initially formed intermediate to CO_{ad} by oxygen impurities in the solution (11, 12).

Electrochemical and Spectroscopic Studies of Sulfur in Aluminum Chloride-N-(n-Butyl)Pyridinium Chloride

R. Marassi,¹ T. M. Laher, D. S. Trimble, and G. Mamantov*

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37996-1600

ABSTRACT

The behavior of sulfur in aluminum chloride-N-(n-butyl)pyridinium chloride (AlCl_3 -BPC) was studied using Raman spectroscopy and electrochemical techniques. In basic (BPC-rich) melts, sulfur can be reduced to sulfide, probably in the form of an AlSCl_2 -like species. No oxidation to positive oxidation states of sulfur is observed in basic melts. In acidic (AlCl_3 -rich) melts, sulfur can be oxidized to S(I) and eventually to S(IV), which is only stable in the melt for short periods of time. No reduction to sulfide-like species or formation of low oxidation states is observed in acidic melts.

Mixtures of aluminum chloride and N-(n-butyl)pyridinium chloride (BPC) form melts which are liquid at or near room temperature (1, 2). Raman spectroscopic (3) and potentiometric (4) studies indicate that the acid-base properties of this system can be described by the expression

where $K = 1.2 \times 10^{-13}$ at 40°C (5). Substantial changes in the Lewis acidity of these melts may be made by varying the AlCl_3 /BPC molar ratio. Electrochemical studies of several organic and inorganic species in this system and other related systems indicate that the solute chemistry and electrochemistry of these species are dependent on the melt acidity (6).

Several studies have been published on the electrochemistry of sulfur in alkali metal chloroaluminate melts, partly because of potential use of positive oxidation states of sulfur as cathode-active materials in secondary molten salt batteries (7-10). In basic (NaCl -rich) AlCl_3 - NaCl melts, sulfur can be reduced to sulfide in the form of an AlSCl_2 -like species and oxidized to S(I) (11-13). In acidic (AlCl_3 -rich) AlCl_3 - NaCl melts, sulfur, in addition to being reduced, undergoes successive oxidations through several intermediates leading eventually to S(IV) in the form of SCl_3^+ (14, 15). In contrast to the work on sulfur in the AlCl_3 - NaCl system, only a brief voltammetric study of sulfur in AlCl_3 containing room temperature melts has been reported (16).

Experimental

AlCl_3 -BPC melts were prepared by slowly mixing preweighed amounts of AlCl_3 and BPC while stirring inside a Vacuum Atmospheres dry box with a moisture level less than 3 ppm. The preparation of AlCl_3 (17) and BPC (2) is described elsewhere. Sulfur was obtained from Alfa Products (99.99%); $\text{SCl}_3\text{AlCl}_4$ was prepared according to the method outlined by Mamantov *et al.* (18). Standard procedures were employed to clean aluminum and tungsten (both Alfa Products, 99.999%) wire electrodes. An H-type cell, which was constructed with a center compartment, equipped with a stirring bar, and two outer compartments for the counter and reference electrodes, was employed for electrochemical studies. Fine porosity frits (4.5-5.0 μm) were used to separate the different compartments. Threaded glass joints and Teflon bushings were used to insert the electrodes into the cell, which was held at 60°C by means of a simple glass furnace. Working electrodes were either glassy carbon (GC) (Tokai) or tungsten (W) sealed in glass with the exposed surfaces polished with 0.1 μm alumina. Working electrodes for coulometric studies were fabricated from reticulated vitreous carbon (RVC). Counter and reference electrodes were tungsten and aluminum coils, respectively, dipped in AlCl_3 -BPC (66.7 mole percent [m/o] AlCl_3). All electrochemical experiments were performed inside the dry box.

¹ Present address: University of Camerino, Camerino, Italy.

Cyclic and normal pulse voltammetric measurements were conducted using a PARC Model 174A polarographic analyzer and a PARC Model 175 universal programmer. Coulometric studies were performed utilizing a PARC Model 173 potentiostat equipped with a PARC Model 179 digital coulometer. All current-potential and current-time transients were recorded with a Houston 2000 X-Y recorder.

Samples for Raman spectroscopic studies were loaded into 5 mm pathlength Pyrex cells inside the dry box and then sealed under reduced pressure. Raman spectra of the samples were obtained using a JY-2000M instrument equipped with a LEP (900015) controller and an argon ion laser.

Results and Discussion

Solubility and Raman spectroscopic studies of sulfur and $\text{SCl}_3\text{AlCl}_4$ in AlCl_3 -BPC melts.—Initial experiments were conducted in order to determine the solubility and stability of various sulfur species in basic (BPC-rich) and acidic (AlCl_3 -rich) AlCl_3 -BPC melts. Sodium sulfide (Na_2S) was found to be insoluble in these melts. On the other hand, elemental sulfur is slightly soluble in both acidic and basic AlCl_3 -BPC melts. No quantitative solubility data are, however, available at present. Several attempts were made to determine the nature of the dissolved sulfur by means of Raman spectroscopy. No evidence for Raman bands due to species such as S_8 was found for basic melts, probably because of the rather low solubility of elemental sulfur in these melts. Although the solubility of elemental sulfur was observed visually to be greater in acidic AlCl_3 -BPC melts, no Raman bands were observed. These results contrast with the results reported for AlCl_3 - NaCl melts (19), where bands assigned to S_8 were detected.

Sulfur (IV) in the form of $\text{SCl}_3\text{AlCl}_4$ was found to dissolve in both acidic and basic AlCl_3 -BPC melts. In the latter case, a rapid reaction occurred resulting in a red solution. In acidic melts, the reaction between $\text{SCl}_3\text{AlCl}_4$ and the melt is much slower, as shown by Raman spectra taken at different times. A typical Raman spectrum of a fresh solution of $\text{SCl}_3\text{AlCl}_4$ in AlCl_3 -BPC [60 (m/o) AlCl_3] is shown in Fig. 1A. The bands at 208, 276, 501, and 523 cm^{-1} can be assigned to SCl_3^+ (18). The other bands may be attributed to AlCl_4^- , Al_2Cl_7^- , and the BPC cation (6). The spectrum changes with time, as may be seen in Fig. 1B, obtained using the same sample after six days at 60°C . The bands for SCl_3^+ have almost completely disappeared. In addition, the ratios of the intensities of the $\text{Al}_2\text{Cl}_7^-/\text{AlCl}_4^-$ bands at 310 and 351 cm^{-1} have changed, reflecting an increase in the Al_2Cl_7^- concentration, and hence in melt acidity, at the expense of AlCl_4^- . No other bands attributable to sulfur species may be detected from the spectra. The decomposition produces gases, shown by an increase in pressure inside the sealed sample cell; however, several attempts to collect and identify the gaseous products failed. The results clearly indicate a reaction between tetravalent sulfur and the melt leading to an increase in melt acidity.

Fig. 1. Raman spectra of $\text{SCl}_3\text{AlCl}_4$ (0.115M) in $\text{AlCl}_3\text{-BPC}$ (60 m/o AlCl_3) at 60°C (photon counting mode, $\tau = 250$ ms): fresh solution (A) and same solution 6 days later (B).

Electrochemistry of sulfur in basic $\text{AlCl}_3\text{-BPC}$ melts.—On the basis of the spectroscopic studies outlined in the previous section, only elemental sulfur has been studied in basic (44.9 m/o AlCl_3) $\text{AlCl}_3\text{-BPC}$ melts. A voltammetric scan over the entire electrochemical window of the basic melt containing elemental sulfur reveals only a single reduction wave at ca. -0.60V vs. Al (2.0:1.0 $\text{AlCl}_3\text{-BPC}$) at both GC and W electrodes (Fig. 2). The reduction process in both cases appears to be totally irreversible. Similar behavior has also been observed in basic $\text{AlCl}_3\text{-MEIC}$ melts (16).

Coulometry was conducted at an RVC electrode held at a potential of -0.75V . The value of n , computed from the amount of charge passed or from $\log i$ vs. t plots, was 2.1 ± 0.1 . This clearly indicates that the reduction process occurring in basic $\text{AlCl}_3\text{-BPC}$ is the reduction of sulfur to a sulfide species.

Plots of $\log(i_a - i)/i$ vs. E , constructed from pulse voltammetric experiments at W electrodes at 60°C , were linear, with slopes in the range 155–180 mV depending on the pulse width. Assuming a two-electron process, this corresponds to a value of ~ 0.2 for the transfer coefficient. Scan rate cyclic voltammetric studies at GC and W electrodes (Tables IA and IB, respectively) show that, while the half-peak width remains rather constant, the peak potentials shift to more negative values with increasing scan rate. Based on the shift of the peak potentials with the

scan rate, the transfer coefficients at 60°C are 0.21 and 0.18 at W and GC electrodes, respectively. These calculations should be taken with caution, since the reduction process probably involves prekinetic (bond cleavage if sulfur is present as S_8) and postkinetic (reaction with the melt to form an AlSCl -like species) complications.

Electrochemistry of sulfur in acidic $\text{AlCl}_3\text{-BPC}$ melts.—Electrochemical studies of the behavior of sulfur in acidic $\text{AlCl}_3\text{-BPC}$ over the composition range 66.7–52.2 m/o AlCl_3 indicate that the electrochemistry of sulfur is essentially the same over the entire acidic composition region of the melt. The cyclic voltammograms, shown in Fig. 3a and 3b (W and GC electrodes, respectively) for sulfur solutions in $\text{AlCl}_3\text{-BPC}$ (60 m/o AlCl_3), may be considered representa-

tive of the electrochemical behavior of sulfur in acidic melts. Two oxidation processes (waves A and B) and two reduction processes (waves C and D) are observed; no electrochemical activity is observed below 1V, indicating that no reduction of elemental sulfur occurs in acidic melts. The dotted lines in Fig. 3 show the electrochemical behavior observed when the potential scan is reversed after wave A but before wave B. On this basis, two redox pairs may be tentatively assigned to peaks A-D and B-C.

Exhaustive coulometry, conducted on a sulfur solution in AlCl₃-BPC (60 m/o AlCl₃) at an RVC electrode at a potential such that only the oxidation process attributed to wave A occurs, yields an *n* value of 1.19, indicating that the redox pair A-D can be attributed to the couple S(SI). Log *i* vs. *t* plots were concave, suggesting chemical complications. The S(SI) redox couple was also studied using cyclic and normal pulse voltammetric techniques. Tables IIA and IIB show relevant parameters for couple A-D obtained during a scan rate study in a sulfur solution and the same solution, respectively, after exhaustive coulometry at 2.1V [S(I) solution]. This scan rate study and subsequent studies were conducted over a scan rate range of 5-200 mV/s. A brief scan rate study of the ferricinium/ferrocene couple, which is known to be a simple reversible redox couple in AlCl₃-BPC (20), exhibited purely diffusion-controlled behavior in AlCl₃-BPC (60 m/o AlCl₃) at 60°C over the entire scan rate range studied. The data in Table II pertain to cyclic voltammograms where the potential sweep was reversed before wave B. For both waves, the parameters are scan rate dependent. It may be seen from Table II that the data for wave A are quite similar regardless of the scan direction [direct oxidation of sulfur or reduction of S(I)]. The peak potentials move in the positive direction and the current functions decrease with increasing scan rate in both of the cases. At low scan rate, the half-peak width approaches the value expected for an electrochemical process involving dimerization (33 mV at 60°C), while it becomes close to the value expected for a first-order process at the higher scan rates (66 mV at 60°C). The most revealing parameter is, however, the current ratio *i*_p^D/*i*_p^A, which is quite different in sulfur and in S(I) solutions. In the former case, the current ratio is small (increasing moderately with the scan rate), while the same parameter is close to 1 in S(I) solution. If the final product of the oxidation of sulfur is S₂Cl₂, which escapes from the diffusion layer, it is expected that at higher scan rates, less of it can escape (12). In the case of S(I) solutions utilizing a closed cell, some S₂Cl₂ will be in the gas phase and some will be in solution. The electrochemistry of soluble S₂Cl₂ is dependent only on the diffusion of that species in solution, and hence the current ratio is close to 1 and not affected by the scan rate. Thus, a set of equations such as

or

where reaction [2] prevails at low scan rates and reaction [3] at high scan rates, may, at least partially, account for the observed behavior. In reactions [2] and [3], sulfur has been written as a monomer. However, a set of rapid chemical reactions leading to the fragmentation of sulfur rings or chains initiated electrochemically or chemically such as those proposed in basic AlCl₃-NaCl melts (12) does not change the overall picture.

The conclusions for wave A deduced from the cyclic voltammograms are supported by the pulse voltammetric experiments at both W and GC electrodes (Table III). The product *i*_p^C/*i*_p^B is not constant with increasing pulse width, thus indicating a process which is not purely diffusion controlled. The slopes of the logarithmic plots constructed from the pulse polarograms are close to the theoretical value for a simple one-electron process at short pulse widths and approach the value expected for a second-order process at longer times, in agreement with the trend observed in the half-peak width of the cyclic voltammograms.

Results from exhaustive coulometric experiments of sulfur solutions in AlCl₃-BPC (60 m/o AlCl₃) melts, conducted at an RVC electrode held at a potential such that the oxidation process attributed to wave B can occur, indicate that wave B results from the oxidation of S(I) to S(IV). This evidence is supported by the fact that S(IV), as shown by the Raman results, is stable (at least initially) in acidic AlCl₃-BPC melts. However, the log *i* vs. *t* behavior observed for coulometric experiments is rather complex, indicating that the charge-transfer process leading to S(IV) involves chemical complications.

A cyclic voltammetric scan rate study of the overall electrochemical process was conducted at GC and W electrodes on a sulfur solution in AlCl₃-BPC (60 m/o AlCl₃) melt at 60°C (Tables IVA and IVB, respectively). In addition to the scan rate dependence of the various current functions, useful information can be obtained by examining the current ratios. These parameters as a function of the scan rate are shown in Fig. 4 for the GC electrode. The ratios *i*_p^C/*i*_p^B, *i*_p^C/*i*_p^D, and *i*_p^D/*i*_p^A increase until a steady value is reached at the scan rate of about 20 mV/s. At the same time, *i*_p^B/*i*_p^A decreases to a steady value at the same scan

rate. The shapes of the cyclic voltammograms, as well as the relative values of i_p^C/i_p^D , i_p^C/i_p^B , and i_p^D/i_p^A at GC electrodes, suggest that the couple B/C is irreversible and/or that, as evidenced by the Raman results, S(IV) decomposes readily to give a product which is reducible at the potentials of wave D. At W electrodes, the values of i_p^C/i_p^B and i_p^D/i_p^A , both close to one, and the large value of i_p^C/i_p^D suggest a quasi-reversible behavior of both redox couples and/or that the decomposition of S(IV) is less favored having less time to occur because of the increased reversibility of the B/C couple. This is consistent with the fact that wave B occurs at much more positive potentials at GC than at W electrodes resulting in a greater possibility of interaction of S(IV) with the solvent.

In the absence of chemical complications, the ratio i_p^B/i_p^A should be 5.19 (21) if, as indicated by the coulometric results, wave B corresponds to the oxidation of S(I) to S(IV). The results indicate that this value is approached only at low scan rates. The same kind of behavior has been observed for the ratio i_d^B/i_d^A in normal pulse voltammometric experiments performed at different pulse widths. Table III lists the results of a typical run at a W electrode. It may be seen that the ratio i_d^B/i_d^A increases

from about 0.9 to 1.7 over the pulse width range 57-484 ms, compared to a theoretical value of 3. At GC electrodes, wave B is reasonably well defined only at long pulse times (484 ms).

An additional feature was noted in the $i-t$ curves at GC electrodes. When the potential is stepped to the rising part of wave B and, hence, when the oxidation of S(I) to S(IV) occurs at an appreciable rate, after an initial decay the current rises to a maximum before decaying again with a behavior similar to the one observed for a nucleation-type mechanism. The same happens at W electrodes for both waves A and B at much shorter times as reflected by the values of $i_d t^{1/2}$. As may be seen from Table III, this parameter reaches a maximum value at 102 ms.

A reaction sequence that may explain the experimental evidence may be written as follows

where S(I) is regenerated at the electrode by a reaction of S(IV) with the solvent. When a volatile product such as S_2Cl_2 that may escape from the diffusion layer is formed, a rigorous fit of the experimental data with the theory of catalytic processes (22, 23) is not expected. However, at both GC and W electrodes, the current function $i_p^B/v^{1/2}$ decreases with increasing scan rate as expected for a catalytic process. The ratio i_p^C/i_p^B is almost 1 at W, where the couple B/C is quasireversible, and close to 0 at GC, where the same couple appears irreversible. The above considerations and the proposed mechanism hold only if the rate of the chemical reaction regenerating S(I) is lower than the rate at which S(I) is complexed and escapes from the diffusion layer as S_2Cl_2 .

The chemical reaction between S(IV) or SCl_3^+ and the melt leading to regeneration of S(I) or S_2Cl_2 may be written as

which takes into account that, as evidenced by the Raman results, decomposition of SCl_3^+ leads to melts of increased acidity and to the buildup of vapor pressure (Cl_2 and S_2Cl_2) in the sample cell.

Conclusion

It may be seen that the electrochemical behavior of sulfur in $\text{AlCl}_3\text{-BPC}$ melts is quite different from that observed for $\text{AlCl}_3\text{-NaCl}$ melts. In basic $\text{AlCl}_3\text{-BPC}$ melts, sulfur can only be reduced; in $\text{AlCl}_3\text{-NaCl}_{\text{sat}}$ melts, it is possible to reduce sulfur to sulfide and oxidize it to S(I). In acidic $\text{AlCl}_3\text{-BPC}$ melts, no evidence has been found for low oxidation state sulfur species that are important in determining the electrochemistry of sulfur in $\text{AlCl}_3\text{-NaCl}$ melts. In addition, SCl_3^+ is not stable in acidic $\text{AlCl}_3\text{-$

Fig. 4. Current ratio vs. scan rate curves for the oxidation of sulfur in $\text{AlCl}_3\text{-BPC}$ (60 m/o AlCl_3) at 60°C at a GC electrode: i_p^B/i_p^A , (triangles), i_p^D/i_p^A , (dots), i_p^C/i_p^D , (circles), and i_p^C/i_p^B , (squares). Electrode area = 0.0707 cm^2 ; $C_s = 1.65 \times 10^{-2} \text{ M}$.

BPC melts, and it is not possible to reduce sulfur to sulfide. In comparison, in acidic AlCl_3 -NaCl melts, tetravalent sulfur is stable and can be used as active cathode material in long lasting secondary batteries (7-10).

Electroreflection Measurements on Semiconductor/Electrolyte Interfaces to Determine the Voltage Distribution

G. A. Scholz*¹ and H. Gerischer*

Fritz-Haber-Institut der Max-Planck-Gesellschaft, D-1000 Berlin 33, Germany

ABSTRACT

The electroreflectance signal from a semiconductor electrode surface is sensitive to the magnitude of the space charge. It is used to determine the voltage distribution between the space-charge layer and the Helmholtz double layer at an electrode/electrolyte interface. In this paper, the first of two, we describe the experimental arrangements and measurements of the electroreflectance spectra for n-MoSe₂ and n-WSe₂ under anodic and cathodic bias. Important features in the spectra are found to be in agreement with existing theories. Flatband values inferred from the electroreflectance spectra are in agreement with those from Mott-Schottky plots. The effects of Fermi level pinning on the electroreflectance spectra are demonstrated with n-GaAs.

The Group VI transition metal dichalcogenides have been shown to be promising electrodes in electrochemical photocells (1, 2). The primary reason for their appeal is that the upper valence or lower conduction band of the n- or p-type materials, respectively, consists predominantly of metal d_{z^2} atomic orbitals, which are nonbonding with respect to the chalcogen atoms (3) and are shielded by the chalcogen layers against interaction with the electrolyte. Therefore, holes, which may possibly be created in the valence band of an n-type specimen and swept to the crystal surface by a Schottky barrier, will not necessarily cause the photoanodic destruction of the electrode with the exception of the reactions occurring at defects and steps (4).

One very important parameter in accessing the performance of an electrochemical solar cell can be defined by the photovoltage yield

$$\frac{e_0 V_{OC}}{|U_{FB} - U_{redox}|} < 1 \quad [1]$$

which, for a good cell, should be as close to unity as possible.

*Electrochemical Society Active Member.

¹Present address: Energy Research Institute, Simon Fraser University, Burnaby, British Columbia, Canada V5A 1S6.

In Eq. [1] the open-circuit photovoltage is V_{OC} , U_{FB} is the flatband potential at which a space charge is absent, and U_{redox} corresponds to the potential of the redox couple in solution. Changes in U_{redox} should produce corresponding changes in V_{OC} since the degree of band bending (in the dark) is determined by U_{redox} , providing no change in the Helmholtz double-layer voltage drop (V_H) is produced. If a change in V_H does appear, V_{OC} may be unexpectedly small or, in extreme cases, may even become independent of U_{redox} . Some common situations that will result in large variations of V_H are the pinning of the Fermi level by a sufficiently large density of surface states (5), or the creation of an inversion layer by, for example, the injection of holes into the valence band of an n-type semiconductor (6). In every case, a Helmholtz voltage will appear at the expense of the space-charge voltage (V_{SC}).

Bard *et al.* (7) have pointed out that the concept of Fermi level pinning at semiconductor/electrolyte interfaces is a major cause for the observed discrepancies between V_{OC} and $U_{FB} - U_{redox}$, analogous to the discrepancies between barrier heights and metal work functions in semiconductor/metal interfaces. As examples, they cite their results for n- and p-GaAs (8) and those of Tributsch *et al.* (2) for some of the Group VI dichalcogenides. In this

work, we have investigated n-MoSe₂ and n-WSe₂, via modulation spectroscopy, and determined ΔV_H and ΔV_{SC} across the electrode/electrolyte interface as a function of the applied voltage because this will provide further insight as to whether it is Fermi level pinning or hole injection that is the dominant mechanism responsible for the apparent inconsistencies observed. The optical properties of the above transition metal dichalcogenides have been extensively reviewed (9), and are very suitable for electroreflectance measurements primarily because of their excellent resistance to corrosion. In addition, their highly anisotropic character is also of value because it allows the preparation of high quality surfaces by simply peeling off (using sticky tape) some of the top layers, so that, for example, it is possible to quickly and easily repair electrodes with corroded surfaces. In this paper, we discuss the experimental arrangement and present some general results of electroreflectance measurements on n-MoSe₂, n-WSe₂, and n-GaAs in contact with an electrolyte. These results will serve as a basis for the second paper in this series where detailed results of the changes in V_{SC} and V_H as a function of the applied voltage will be presented for n-MoSe₂ and n-WSe₂ in the presence of various electrolytes.

The electroreflectance technique has already been applied by Tomkiewicz *et al.* to monocrystalline (10) and polycrystalline (11, 12) CdSe electrodes in order to monitor the voltage distribution between the space-charge and Helmholtz layers. They found that the reflectance signal disappears at the flatband potential of the monocrystalline material, as should be expected, and that the amplitude of the signal increased linearly with the modulation voltage, indicating a negligible change of the voltage drop in the Helmholtz layer. A decrease in the amplitude of the electroreflectance signal obtained with the polycrystalline layers as they are biased from flatband to depletion has been interpreted as Fermi level pinning by surface states. Lemasson *et al.* (13) have determined the flatband potential of ZnSe by electroreflectance, and Tomkiewicz *et al.* (14) have applied this technique to CdIn₂Se₄ crystals in order to analyze the influence of photoetching on the position of the flatband potential and the variation of the potential drop in the Helmholtz double layer.

Methods

Modulation spectroscopy has in the past been used as a powerful tool in studying the electronic band structure of semiconductors (15, 16) because one measures a derivative-like signal which considerably enhances features in the ordinary optical structure. The technique essentially consists of inducing changes in the transmission or reflection of a sample by applying a periodic perturbation. Common techniques that have been used include, among others, electromodulation (17), piezomodulation (18), and thermomodulation (19). These induced changes will be large at the fundamental edge and at any critical point for which $\nabla k(E_f - E_i) = 0$, so that one obtains detailed information predominantly on the critical points in the band structure. The theoretical ground work was laid by Franz and Keldysh (20), who calculated the effect of an electric field on the optical absorption associated with interband transitions. A very general theoretical description of the electroreflectance phenomena which can be observed in the low field region has been given by Aspnes (21). The Franz-Keldysh theory does not explicitly include excitonic effects, which can dominate in the region near the fundamental absorption edge, so that subsequent calculations by Blossey, which include excitonic effects (22), are expected to apply to the transition metal dichalcogenides.

Because of the possibility of modulating the very large electric fields associated with space-charge layers (23), electroreflectance (ER) can be an ideal technique in the study of the semiconductor/electrolyte interface. The principles and techniques of electroreflectance have been reviewed by Cardona (15) and Seraphin (16, 24), and,

more recently, the application to semiconductor electrodes has been discussed by Pollak (25).

The electroreflectance signal is defined by

$$\frac{\Delta R}{R_0} = \frac{R(E) - R_0}{R_0} \quad [2]$$

where $R(E)$ is the optical reflectance when an internal electric field E is present, and R_0 is the reflectance in the absence of such a field. The reflectance change depends on both, the real part ϵ , and the imaginary part ϵ_i of the dielectric constant ϵ and their changes $\Delta\epsilon$, $\Delta\epsilon_i$ (27)

$$\Delta R/R_0 = \alpha(\epsilon_r, \epsilon_i)\Delta\epsilon_r + \beta(\epsilon_r, \epsilon_i)\Delta\epsilon_i \quad [3]$$

It turns out that at low photon energies (typically ≤ 3 eV), the factor α can be much larger than β so that the reflectance change is mainly controlled by the change of the real part of ϵ (24, 36).

If an external voltage is applied to a semiconductor/electrolyte interface, it will essentially appear either as V_{SC} across the space-charge layer, or as a combination of V_{SC} and V_H if for some reason a large number of carriers is present on the crystal surface, as will be the case, for example, in the three situations mentioned above. The height of a Schottky barrier is related to the concentration N_0 of ionized donors or acceptors in n- or p-type semiconductors by (28)

$$V_{SC} = e_0 \frac{N_0 x_0^2}{2\epsilon\epsilon_0} \quad [4a]$$

or

$$x_0 = \left(\frac{2\epsilon\epsilon_0}{e_0 N_0} V_{SC} \right)^{1/2} \quad [4b]$$

respectively, where e_0 is the elementary electric charge, ϵ the static dielectric constant, ϵ_0 the permittivity of free space, and x_0 the depletion-layer thickness (Fig. 1). Aspnes has treated electric field modulation in a Schottky barrier (29, 30) by using the relation

$$\Delta R/R_0 = E^2 L(h\nu) \quad [5]$$

where $L(h\nu)$ is the spectral line shape function which is entirely determined by the band structure and contains the influence of the electric field. By combining this with the correlation between the field strength in a depletion layer and the voltage drop V_{SC} , he obtained the reflectance signal when modulating V_{SC} . For a depletion layer, the field strength at the surface E_s can be approximated by (28)

$$E_s^2 = \frac{e_0 N_0}{2\epsilon\epsilon_0} V_{SC} \quad [6]$$

Fig. 1. Simple one-dimensional band schematic of a depletion layer with an effective thickness x_0 . The other symbols have their usual meaning.

while the field strength in the depletion layer, which depends on the distance x from the surface and becomes zero at $x = x_0$, can be approximated by

$$E^2(x) = \frac{e_0 N_0}{2\epsilon\epsilon_0} \left(1 - \frac{x}{x_0}\right)^2 V_{sc} \quad [7]$$

Since x_0 depends on V_{sc} (Eq. [4b]), a modulation of V_{sc} will complicate Eq. [7]. However, within a range of the depletion layer thickness $x \leq 0.2x_0$, one can neglect the variability of x_0 caused by the modulation of V_{sc} and assume that the reflectance change should be proportional to V_{sc}

$$\Delta R/R_0 \propto V_{sc} L(h\nu) \quad [8]$$

The conclusion is that when the space-charge layer extension $x_0 > 1/a$, where a is the absorption coefficient for light of the respective wavelength, the effective field strength modulation is proportional to $V_{sc}^{1/2}$, so that Eq. [8] can be applied. In particular, this means that the doping level must be low enough to fulfill this condition. Note that the applicability of the "low field strength" case of the theory (21, 30) is simultaneously guaranteed.

If a change in the Helmholtz layer voltage drop is produced at a semiconductor/electrolyte interface, ΔV_H will appear at the expense of ΔV_{sc} for a given applied voltage, so that the magnitude of the ER signal will decrease, since it is, of course, not sensitive to ΔV_H . Therefore, if some care is taken that no stray voltages develop, such as, for example, those caused by IR drops in the semiconductor or electrolyte or, even worse, voltage losses due to a surface layer produced by electrochemical reactions, one can write to a good approximation

$$\Delta V_{app} = \Delta V_{sc} + \Delta V_H \quad [9]$$

By comparing the ER signals produced under different situations (such as the presence of a variety of redox systems, different methods for preparing electrode surfaces, etc.) it is possible to infer the magnitude of ΔV_H by monitoring, via ER measurements, the relative changes in ΔV_{sc} .

Experimental

The experimental arrangement for measuring the ER spectra is sketched in Fig. 2. In essence, the Fermi level of the semiconductor electrode is modulated via the standard three-electrode potentiostatic configuration using a saturated calomel electrode (SCE) as reference, and 0.1N H_2SO_4 as support electrolyte. All voltages are reported with respect to the SCE. Modulation was accomplished with a low frequency (16 Hz) variable amplitude square wave voltage from a PAR 175 Universal Programmer externally triggered with a Philips pm 5132 function generator. The modulating voltage could thus be conveniently varied in amplitude, polarity, and frequency. In an at-

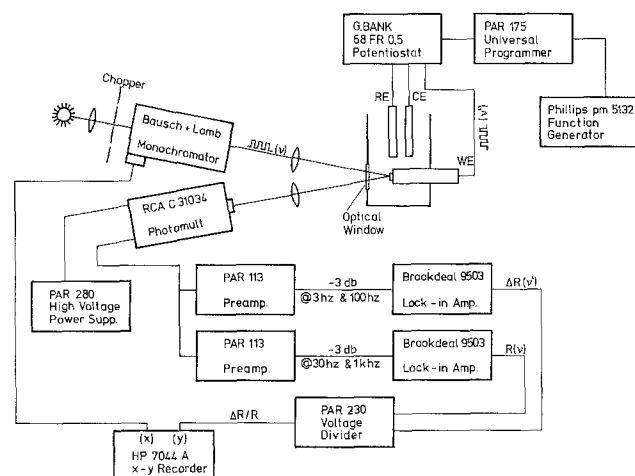

Fig. 2. Experimental arrangement for measuring the electroreflectance spectra of semiconductor electrodes in an electrochemical cell.

tempt to keep corrosion at a minimum, the polarization voltages for the n- and p-type semiconductors were usually set anodic or cathodic, respectively, of their flatband potential, so that high impedance depletion layers, with their negligible current flows, were produced.

Chopped (~ 300 Hz) unpolarized light from a Bausch and Lomb double monochromator was then focused at near normal incidence to the electrode surface, and ΔR (16 Hz), along with R (~ 300 Hz), was measured with an RCA C31034 photomultiplier tube via two EG&G Brookdeal 9503 lock-in amplifiers. The monochromatic light was of very low intensity, and so possible photovoltages were of no concern. Low frequency intermodulation products from the 16 and 300 Hz signals could be minimized by varying the frequency of either the ΔR or R signal slightly, and was necessary for a sufficient reduction of the noise level.

To insure a good quality ER signal and to minimize corrosion problems, great care was taken with the transition metal dichalcogenides so that no steps, or similar corrosion centers, were exposed to the electrolyte. It was possible, due to the anisotropic nature of these dichalcogenides, to prepare surfaces of several square millimeters in area parallel to the basal planes which, even under the microscope (at 50 times magnification), appeared free of steps and other crystal imperfections.

Results and Discussion

To illustrate the basic soundness of using changes in the ER signals magnitude as a measure of changes in V_{sc} , we show in Fig. 3 the room temperature ER spectra of the E_1 and $E_1 + \Delta_1$ transitions (31) of n-GaAs following different surface preparation methods. The ER spectra was first taken after polishing the crystal with 1 μm diamond paste (Fig. 3a) and then, with identical apparatus settings, after subsequent etching in a 2% solution of bromine in methanol (Fig. 3b). Modulation was from 0 mV (found to be $\sim V_{FB}$ from a Mott-Schottky plot) to 600 mV anodic.

Fig. 3. Electroreflectance spectra under anodic bias of a n-GaAs electrode in 0.1N H_2SO_4 . a: After polishing with 1 μm diamond paste. b: After subsequent etching in a solution of 2% Br_2 in methanol.

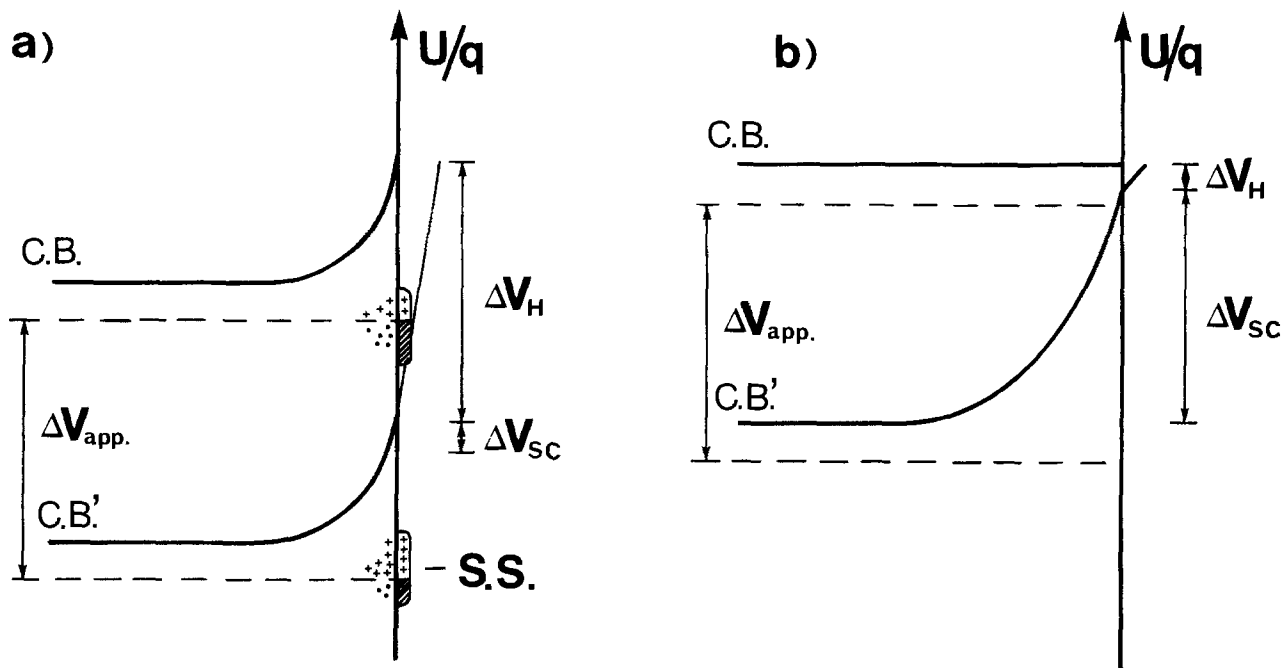

Fig. 4. The voltage distribution across the GaAs/0.1N H₂SO₄ interface, showing only the conduction band. a: After mechanical polishing created surface states or surface near states in the bulk (SS) which will pin the Fermi level so that V_{sc} remains constant and $\Delta V_{app} = \Delta V_H$. b: After subsequent etching removes the surface states so that V_H remains constant and $\Delta V_{app} = \Delta V_{sc}$.

The probable reason for the absence of an ER signal in the former case (Fig. 3a) is the creation of a large number of crystal defects in a layer close to the surface which form traps for electrons, but it is also possible that surface states act as donor/acceptor sites which will screen the electric field from the bulk crystal. In any case, the Fermi level is pinned relative to the surface, so that ΔV_{app} will appear across the double layer as ΔV_H (Fig. 4a), and, as expected, no ER signal is observed (Fig. 3a). Tomkiewicz *et al.* (14) have already described similar effects on the ER signal and interpreted this as pinning of the Fermi level due to an abundance of surface states. It should be mentioned that a decrease of the line shape factor $L(h\nu)$ could also have a similar effect (26), although it appears unlikely that this effect would be so drastic.

After etching the crystal surface and removing this damaged layer, the Fermi level is no longer pinned (Fig. 4b), and V_{sc} can vary with the applied voltage so that an ER signal can be observed (Fig. 3b). Various etches (combinations of acids, H₂O₂, etc.) resulted in ER curves which had the same structure but differed in their magnitudes. The ER curve shown in Fig. 3b, after etching with the bromine in methanol solution, yielded the largest signal and therefore identifies this etching solution as superior for preparing a GaAs surface low in defects.

Typical room temperature ER spectra of n-MoSe₂ and n-WSe₂ near the fundamental gap are shown in Fig. 5 and Fig. 6, respectively. The voltage modulation was performed from close to the flatband potential to anodic or cathodic voltages. Whereas in the anodic case currents were restricted to well below 1 μ A, in the cathodic case larger currents ($\approx 50 \mu$ A) were generated.

Even though MoSe₂ and WSe₂ lose much of their excitonic structure at room temperature, one structure labeled A₁ at 1.53 eV (MoSe₂) and 1.63 eV (WSe₂) (3) remains very well defined. According to the literature (32), A₁ corresponds to the $n = 1$ state of a Wannier-type exciton resulting from a nondegenerate direct transition at the Γ point in the Brillouin zone. By simultaneously monitoring the reflectivity in addition to the ER spectra, we found experimentally² that A₁ is located at 1.55 ± 0.01 and 1.63 ± 0.01 eV for our MoSe₂ and WSe₂ samples, respectively, in good agreement with other work (3, 33). Therefore, by using exciton binding energies of 67 and 50 meV (34), re-

²The largest gradient of the steep negative slope, following the peak in R , is taken as the position of the A₁ excitons.

spectively, we can place the absorption edge at room temperature near 1.62 and 1.68 eV for our MoSe₂ and WSe₂ samples, respectively. By referring to Fig. 5 and 6, we can see that for both dichalcogenides the ER structure appears well to the low energy side of the direct gap, and clearly shows that the ER structure is excitonic in nature.

Fig. 5. Room temperature electroreflection spectra from n-MoSe₂ for a 500 mV square wave modulation from V_{FB} when (a) polarizing anodically (depletion layer), and (b) polarizing cathodically (accumulation layer). The edge is indicated by E_g , and the excitons position by A₁.

Fig. 6. Room temperature electroreflection spectra from n-WSe₂ for a 500 mV square wave modulation from V_{FB} when (a) polarizing anodically (depletion layer), and (b) polarizing cathodically (accumulation layer). The edge is indicated by E_g , and the excitons position by A_1 .

For clarity, we will discuss the ER spectra from accumulation layers (dotted lines) later, and first discuss those produced from depletion layers (solid lines). Keeping in mind that ER spectra are largely dependent on the real part of the dielectric constant (ϵ_r), we can compare them with the $\Delta\epsilon_r$ curves computed numerically by Blossey (22) for Wannier excitons. Theory predicts that in excitonic $\Delta\epsilon_r$ spectra, the first zero below the edge, corresponding to A_1 , is pinned for fields small compared to the excitonic ionization field (E_i). For somewhat larger fields, about $E \sim E_i/2$, the zero is expected to shift to lower energies because of the second-order Stark effect, and, finally, for $E \geq E_i$, the zero will move rapidly to higher energies. A very rough estimate of E_i for the A_1 state yields $\sim 3 \times 10^5$ V-cm⁻¹ for both dichalcogenides, and is arrived at by dividing the excitons binding energy by its effective Bohr radius. Experimentally, we observe that for low fields ($V_{sc} \leq 1/2V$), the first zero below the edge is consistently at 1.558 ± 0.002 and 1.627 ± 0.002 eV for MoSe₂ and WSe₂, respectively (Fig. 5 and 6). When V_{app} was increased further, the zero crossing shifted toward lower energies (Fig. 7), but an eventual reversal of the zero shift toward higher energies was never observed. The A_1 position is therefore in excellent agreement with Blossey's excitonic ER theory and the zero shifts suggest that the electric fields induced were always below $E_i/2$, that is, below about 10^5 V-cm⁻¹, so that judging from Eq. [4] the doping levels (N_0) should be near or below about 5×10^{17} cm⁻³. The Mott-Schottky plots for these crystals (Fig. 9) confirm this by indicating doping levels of 3×10^{16} and 1×10^{16} cm⁻³ for the n-MoSe₂ and n-WSe₂ samples, respectively.

Knowing the solid-state properties of the semiconductor and using models such as Blossey's, we could, in principle, determine the magnitude of the electric fields from the zero shifts (Fig. 7) in the ER spectra themselves. However, even ignoring the simple facts that the electric

Fig. 7. Shift in the zero crossing (A_1) for increasingly anodic polarization. The data points are collected from several samples of each type.

field in a space-charge layer is not constant and that the dichalcogenides have extremely anisotropic electrical and optical properties, the zero shift is such a small effect that nothing else than the general trend of the shift can be established with any certainty because of the relatively large scatter in the measurements.

If a cathodic bias, relative to the flatband potential, is applied to an n-type semiconductor, an accumulation layer is formed. The ER signals from cathodically biased n-MoSe₂ and n-WSe₂ is shown in Fig. 5b and 6b, respectively, and one can observe marked changes in comparison with the ER spectra produced by depletion layers (Fig. 5a and 6a). In particular, we note that at the A_1 position a peak has developed in place of the zero crossing, and the ER signals now have a striking similarity to the $-\Delta\epsilon_r$ rather than to the $\Delta\epsilon_r$ curves computed by Blossey. This interchange of line shapes is expected and is explained in terms of field inhomogeneities (35). Whereas for an anodic bias (depletion layers) the penetration depth of the electric field is greater than 200 nm and therefore in the order of, or greater than, the penetration depth of light (≤ 200 nm), for cathodic bias (accumulation layers)

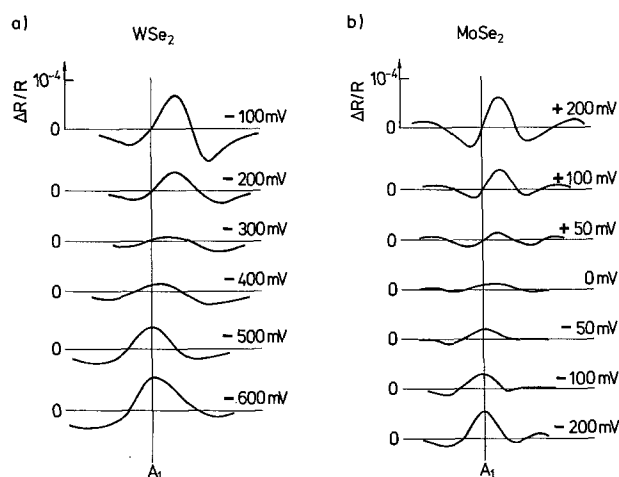

Fig. 8. Room temperature ER spectra taken by modulating at a constant amplitude of 200 mV, but varying the dc bias in 100 mV steps. V_{FB} is located between the bias where the spectra change line shape; e.g., at 0 ± 20 mV and -350 ± 50 mV for n-MoSe₂ and n-WSe₂, respectively.

Fig. 9. Mott-Schottky plot of the dichalcogenides in contact with 0.1N H₂SO₄. Frequency: 500 Hz.

the penetration depth is in the order of 10-20 nm and therefore much less than that of the light. Under these conditions, $\Delta\epsilon_r$ and $\Delta\epsilon_i$ are mixed (35) and since $n_o > k_o$ (36), as is often the case in this energy range, an interchange of the line shapes will occur. The additional change in sign, when compared to the calculated $\Delta\epsilon_i$ curves, is not caused by the reversal of the electric field, but comes about because for anodic polarization relative to V_{FB}

$$\Delta R (\text{anodic}) = R(E) - R_o$$

and for cathodic polarization relative to V_{FB}

$$\Delta R (\text{cathodic}) = R_o - R(E) = -\{R(E) - R_o\}$$

The change in the ER spectra when going from an anodic to cathodic bias is therefore a very useful means by which the flatband potential of the dichalcogenides can be determined. In Fig. 8, we show a series of ER spectra produced by keeping the amplitude of the modulating voltage constant but varying its dc bias. The change in amplitude and position of the ER spectra signals the position of V_{FB} so that, judging from Fig. 8, the flatband potentials for our n-MoSe₂ and n-WSe₂ crystals occur at 0 ± 20 and -350 ± 50 mV, respectively. The respective flatband potentials deduced from the Mott-Schottky plots (Fig. 9) are 0 ± 50 and -280 ± 50 mV and are therefore in excellent agreement.

In conclusion, the various ER spectra observed can be understood within the framework of existing theories. In the second paper of this series, the voltage distribution within the n-MoSe₂ and n-WSe₂ electrolyte interface is investigated as a function of the applied voltage, and in the presence of a variety of redox couples.

Acknowledgments

Valuable discussions with Dr. K. Doblhofer and the technical assistance of S. Wasle are gratefully acknowledged. One of us (G.A.S.) would also like to thank the Max-Planck-Gesellschaft for the very generous support received during the stay at the Fritz-Haber-Institut.

Photocorrosion of n-CdSe in Sulfide Electrolytes

K. W. Frese, Jr.,* and D. Canfield

SRI International, Menlo Park, California 94025

ABSTRACT

The stabilization efficiency for n-CdSe in polysulfide electrolytes has been determined. Under experimental conditions, the corrosion current was 1 to 500 ppm of the photocurrent. A hole tunneling model was used to provide the link between stabilization efficiency and the photocurrent decay parameter. The surface coverage of sulfide was shown to depend on current density and electrolyte concentration. The stability of the electrode was a function of electrode potential and electrolyte composition. More cathodic potentials and increasing sulfur content of the electrolyte enhanced the stability. The stability of the electrode appears to be controlled by a chemical step involving adsorbed sulfur.

A limiting problem in the application of photoelectrochemical solar cells is stability of the photoelectrode. The n-CdSe-polysulfide system has been of considerable interest in this connection. Detailed studies of the redox properties of the electrolyte are now being conducted, and models for the photocurrent decay are now being investigated. A number of issues need consideration to fully understand this system. These are, first, properties and models for the photocurrent decay; second, models for the stability, including the effect of photocurrent density, concentration (adsorption), electrolyte composition, and electrode potential, and third, use of the results of the first and second items to obtain predictions of the long-term stability from accelerated decay results. The study described here is an attempt to deal with some of these issues.

The model for the stabilization efficiency, S , used here is an extension of our earlier work (1-4). Adsorption of the reducing agent and dissolution of the corrosion product are now considered in the mechanism. The decaying photocurrent is assumed to be controlled by hole tunneling through a corrosion layer. It will be shown that this assumption allows determination of S from the photocurrent decay characteristics. The existing literature (5-8) concerning the polysulfide electrolyte was used to provide a description of the electrolyte composition.

There is a large body of work concerning CdSe and CdS electrodes in sulfide electrolytes that has preceded our efforts. The recent review by Hodes (9) can be consulted for details.

Experimental

All measurements were made on n-CdSe (11 $\bar{2}$ 0) single-crystal electrodes (Cleveland Crystals) with donor densities of $1 \times 10^{17} \text{ cm}^{-3}$. The surfaces were chemomechanically polished with 1% $\text{Br}_2/\text{CH}_3\text{OH}$ mixed 50/50 (v/v) with 1M HCl. The electrodes were etched before each measurement using a cotton-tip applicator saturated with the etch solution. A Pine analytical rotator and RDE-3 potentiostat were used to control the rotation speed and electrode potential. The electrode was illuminated with a tungsten-halogen lamp. All chemicals were reagent grade. Stock solutions of polysulfide electrolyte were prepared and added to the cell to form the desired composition. High purity N_2 was continuously bubbled through the electrolyte. Voltages are reported vs. the saturated calomel electrode.

Theory

Kinetics of stabilization with an adsorbing two-equivalent reducing agent.—Consider the following mechanism that is proposed to describe the case when oxidation of adsorbed sulfide species competes with the anodic corrosion of the CdSe electrode.

Equations [1] and [2] were included in the earlier model (1, 2) for weakly interacting one-equivalent reducing agents. They represent bond breaking steps corresponding to removal of an electron pair bond between lattice atoms, A and B. Here we assume both holes are captured by the more electropositive element, e.g., Cd. B represents elemental Se

The reducing agent participates in the following events: adsorption, desorption, electron transfer, and surface dissolution. These steps are

R^- is a two-equivalent reducing agent, e.g., S_n^{2-} ; M_v is a vacant adsorption site, k_3 and k'_3 are rate constants for surface hole capture, and k_{diss} is a rate constant for removal of the oxidized form. The meaning of Eq. [6] is that an electrolyte species, e.g., SH^- , removes the adsorbed oxidized species, e.g., S_{ad} .

Considering steps 1, 2 and 4, 5 (those that contribute to the observed photocurrent density, j) and the steady-state analysis given previously (2, 10), Eq. [7] is obtained

$$j = \frac{2k_1k_2}{k_{-1}} (h^+)^2 + j_3 \quad [7]$$

where j_3 and S , the stabilization efficiency, are defined by

1555

$$j_3 = 2k_3(R^-)_{ad}(h^+) = Sj \quad [8]$$

Equation [8] may be used to eliminate the steady-state hole concentration. Performing this operation on Eq. [7] and rearranging the result yields

$$S = \frac{2}{1 + \left[1 + \frac{2\alpha j}{(\Theta M_T)^2} \right]^{1/2}} \quad [9]$$

where Θ is the steady-state coverage of R^-_{ad} , M_T is the total number of sites, and the composite rate constant $\alpha = k_1 k_2 / k_{-1} k_3^2$. Equation [9] states that S will decrease as j increases or as Θ decreases. These predictions have already been shown (2, 11) to agree with the experiment for the one-equivalent nonadsorbed reducing agent case. In that case, an equation very similar to Eq. [9] was applied, but with ΘM_T replaced by C_{R^-} , the concentration of reducing agent in solution.

Stabilization efficiency and tunnel model.—One of our objectives in the present work is to quantify the instabilities of the CdSe (1120) single-crystal electrode. The photocurrent decay method can be used to measure corrosion rates. By modelistic interpretation of the characteristic photocurrent decay parameter

$$\alpha \equiv \frac{-d \ln(j/j_0)}{d \Sigma q} \quad [10]$$

we can obtain values for the stabilization efficiency, correlate results, and ultimately extrapolate the behavior of electrodes to different conditions of photocurrent density and redox species concentrations. In Eq. [10], j is photocurrent, j_0 is initial photocurrent, and Q is the integrated photocharge.

A model for the decay of photocurrent in the CdSe-alkaline polysulfide system has been suggested (12, 13). The essential assumptions of the model are diagrammed in Fig. 1. The photocorrosion of CdSe in the presence of sulfide species leads to a layer of CdS on the CdSe surface. This occurs because in the corrosion process Cd^{2+} ions are produced along with elemental Se. The selenium is assumed to be rapidly dissolved by the sulfide electrolyte, and the Cd^{2+} ions form CdS by a precipitation mechanism. A key element in this picture is the relative energy level for hole transport, ΔE_{VB} , in the CdS and CdSe.

By consideration of the bandedges CdS and CdSe, it is found that the CdS valence band is about 0.64V below the CdSe valence band. Transport of holes from CdSe to the electrolyte species can occur by tunneling through this potential step at the interface between the two solid phases. This tunnel process was also used to discuss the behavior of the Si/SiO₂ electrode in aqueous electrolytes (14, 15).

With simple arguments we can begin to build a quantitative model. We will adapt the tunneling probability, P_T , for the rectangular barrier as the controlling factor in the decay of the photocurrent. Then we have

$$P_T = \exp - \left[\frac{2}{\hbar} (2m \Delta E_{VB})^{1/2} x \right] \quad [11]$$

where m is the hole effective mass in CdS, $0.8 m_0$, x is the thickness of the CdS layer, and \hbar is Planck's constant divided by 2π .

Next we formulate an expression for the thickness, x , in terms of the stabilization efficiency, S , the photocurrent, and Faraday's law. The stabilization efficiency (see Eq. [9]) is the fraction of photocurrent that flows to the redox species; so that $(1 - S)j$ is the corrosion current density. Therefore, x may be written

$$x(\text{cm}) = \frac{\bar{V}_m}{nF} \int_0^t (1 - S)j dt \quad [12]$$

The integral represents the corrosion photocharge passed

$$j(t) = j_0 e^{-bx(t)}$$

$$b = \frac{2}{\hbar} (2m \Delta E_{VB})^{1/2}$$

$$x(t) = \frac{V}{nF} (1 - S) Q$$

Fig. 1. Tunnel model for photocurrent decay of CdSe in sulfide electrolyte.

up to time t , \bar{V}_m is the molar volume of CdS (29.97 cm³/mol), F is the Faraday constant, and $n = 2$. The goal of this analysis is to obtain S , which has been modeled in terms of j , concentration, corrosion, and electron-transfer rate constants. If we assume that S is constant during the time domain where the photocurrent is controlled by tunneling, Eq. [12] may be rewritten $x = 1.55 \times 10^{-4} (1 - S)Q$, where Q is the integral photocharge passed. Substitution for x and the physical constants in Eq. [11] leads to Eq. [13]

$$j = j_0 \exp - [\alpha Q] \quad [13]$$

where $\alpha = 1.14 \times 10^4 (1 - S)$. Equation [13] will be used below as the basis for determination of the stabilization efficiency, S . Once S is known, the surface coverage parameter $(M_T/\sqrt{\alpha})\Theta$ can be obtained by means of Eq. [9]. Since total concentration of sites and the rate constants in α are unknown, we cannot obtain absolute values for the coverage. However, the coverage parameter should be simply related to an adsorption isotherm (see below).

Polysulfide electrolyte composition.—The composition of polysulfide electrolytes has been investigated (6, 7) by combining spectroscopic and thermodynamic methods. According to the work of Giggenbach (5, 6), the dominant species are SH^- , S_2^- , S_3^- , S_4^- , and S_5^- . The concentration of the various species is determined by $[OH^-]$ and, more importantly, by the ratio, X_s , of sulfur to sulfide (Na_2S), used in preparing the electrolyte. Solutions rich in sulfur contain increased amounts of higher polymers. As the pH is increased, smaller polymers are favored. The majority of measurements reported here were performed using the $X_s = 1$ electrolyte in 1M NaOH. The effect of X_s on elec-

trode stability was also investigated at constant current density.

It is of interest, therefore, to have some indication of the composition of these electrolytes. The results of our calculations using Fig. 5 of Ref. (6) and Eq. [2] of Ref. (7) are given in Table I. All concentrations are expressed in moles per liter. A common electrolyte mix is described on the first line of Table I. This 1:1 polysulfide mix is actually dominated by the hydrosulfide ion. Since the pK_a of this ion (5) is 17.1, there are virtually no $S^{=}$ ions present. Addition of one sulfur causes large increases in the acidity in moderately basic solution. As expected, larger sulfur/sulfide ratios lead to progressively longer chains. A saturated solution ($X_s = 3.5$) exclusively contains $S_4^{=}$ and $S_5^{=}$ species. These calculations provide a guide concerning the composition of the electrolyte. However, it is not clear (16) that they are exact under our conditions, i.e., ionic strength $>1M$.

Results

Typical photocurrent decay curves are shown in Fig. 2. The CdSe electrode was rotated at 1600 rpm and the electrode potential was 0.0 V (SCE). The insets show plots of $\ln(j/j_0)$ vs. the integrated charge density. These plots were linear after a period of nearly constant photocurrent. The absolute value of the slope of these logarithmic plots is to be identified with the parameter, α , (Eq. [10] and [13]) defined above. A large number of decay curves at various initial current densities and concentration were obtained. In each case, the coverage parameter, $(M_T/\sqrt{\alpha})\theta$, a measure of the steady-state surface coverage, was obtained as described earlier. The dependence of these values on initial photocurrent is shown in Fig. 3. It can be seen that the steady-state coverage dropped as the photocurrent increased. However, the slope of the log plot was practically constant for each concentration. A value of $350 (A/cm^2)^{-1}$ was typical. The plots of Fig. 3 were extrapolated to $j = 0$, yielding values for $(M_T/\sqrt{\alpha})\theta_0$. It was found that a universal curve could be obtained by normalizing the coverage using the zero current value of the coverage parameter at each concentration. These results are shown in Fig. 4.

It was expected that $(M_T/\sqrt{\alpha})\theta_0$ values should vary with concentration in a manner consistent with an adsorption isotherm for the polysulfide species. Figure 5 (solid symbols) shows a plot of the zero current coverage parameter as a function of $\log[S^{=}]$. The data appear to conform to a logarithmic isotherm such as the approximate form of Frumkin's isotherm (17).

The steady-state sulfide coverage at $j = 10 \text{ mA/cm}^2$ is also plotted in Fig. 5. These data behave qualitatively similar to the zero current data. However, no thermodynamic meaning can be attached to these steady-state results. The general isotherm-behavior of the derived coverage parameter is both reasonable and expected.

The stability of the electrode as measured by the photocurrent half-life was investigated as a function of X_s . The results are shown in Fig. 6. A large increase in stability was found for electrolytes rich in sulfur. The half-life of the photocurrent was also determined as a function of electrode potential. These results for $X_s = 1$ are summarized in Fig. 7 for several sulfide concentrations. At a critical potential, V_c , an exponential increase in half-life was observed. The quantity V_0^* is the onset potential for the

Fig. 2. Photocurrent vs. time and relative photocurrent vs. integral charge for RDE n-CdSe (1120). Electrolyte: 0.3M each $Na_2S/S^{=}$ in 1M NaOH. 1600 rpm, $V_{DISK} = 0.0 \text{ V(SCE)}$.

anodic photocurrent. The rate of increase of $t_{1/2}$ with voltage was greater for more concentrated electrolytes. It has already been shown (18) that electrode potential affects the stability of CdS in $10^{-3}M Na_2S$ solution. In that case stability decreased sharply for potentials positive of $\sim -0.8V$ (SCE).

Discussion

The decay curves in Fig. 2 show there is a region of nearly constant photocurrent before the decay sets in. Part of the charge passing in this region is due to oxidation of adsorbed sulfide and part is due to oxidation of CdSe (CdS formation). According to our model, the fraction of charge for the latter process is $(1 - S) = a/1.14 \times 10^4$. Table II shows decay characteristics for various conditions. Of particular interest is the $(1 - S)$ value calculated from the decay curve proper using Eq. [10] and [13], and the total charge density, $(1 - S)Q$, that measures the amount of corrosion product that is formed before the decay begins. A typical value of this charge is $\sim 10^{-4} \text{ C/cm}^2$. Note especially the last entry in Table II where the conditions strongly differ from the remaining data. The average for the data in Table II is $2.4 \times 10^{-4} \text{ C/cm}^2$. Formation of a

monolayer of CdS requires about $1.6 \times 10^{-4} \text{ C/cm}^2$ so that 1.5 layers ($\sim 4\text{\AA}$) of corrosion product are necessary to initiate the decay process. This result is very reasonable and provides an indication of the layer thickness required for the tunnel model to be applicable.

The values of stabilization efficiency reported in Table II are high. The corrosion current ranges from 5 parts per thousand to 1 ppm for the 1M electrolyte at (30 mA/cm^2) . The electronic barrier for holes that results from the formation of CdS makes this system moderately susceptible to photocurrent decay. A similar but more severe problem exists for the Si/SiO₂ system, where the ideal electronic barrier for holes is 4-5 eV.

According to the plots in Fig. 3 and 4, the coverage as a function of initial photocurrent density may be represented by

$$\Theta = \Theta_0 e^{-Bj} \quad [14]$$

where Θ depends on concentration in a manner consistent with the Frumkin isotherm (Fig. 5). The empirical factor B , appears to be independent of concentration.

Fig. 5. Coverage parameter vs. log concentration of sulfide for zero photocurrent (lower curve) and 10 mA/cm^2 (upper curve) (conditions as in Fig. 3).

Fig. 6. Photocurrent half-life for n-CdSe (1120) RDE in 0.1M Na₂S, 1M NaOH electrolyte with various amounts of sulfur added. $V_{\text{DISK}} = 0.0 \text{ V (SCE)}$, 1600 rpm. Initial photocurrent, 10 mA/cm^2 .

Since the adsorption step (Eq. [3]) and the dissolution of sulfur oxidation product (Eq. [6]) proceed at a finite rate, it is expected that the coverage should drop as the current density increases. According to the simple sequence of steps, Eq. [3]-[6], the coverage should decrease with j according to

$$\frac{\Theta}{\Theta_0} = 1 - \frac{j}{(k_{\text{ad}} + k_{\text{diss}})} \quad [15]$$

where concentration terms would appear in the k 's.

This relation is not in agreement with the observations (Eq. [14]), and further mechanistic analysis is needed. A difficulty is that the change of coverage with current is independent of Na₂S concentration contrary to the proposed Eq. [6].

Two interesting observations following from our analysis are that the intercepts of the $\log [(M_T/\sqrt{\alpha})\Theta_0]$ plots depend on concentration and that the slopes are independent of concentration. We have already discussed the behavior of the zero current values of $(M_T/\sqrt{\alpha})\Theta_0$ parameter in terms of adsorption properties.

Now we will postulate a different mechanism that gives an improved interpretation of the values of $(M_T/\sqrt{\alpha})\Theta_0$ and

also rationalizes the concentration independent slopes in Fig. 3 and 4.

In a recent paper (19), we have shown that both OH⁻ and S²⁻ are important coadsorbing species in the basic Na₂S solutions. In 1M OH⁻ the CdSe is saturated with OH_{ad}⁻. As Na₂S is added to the electrolyte, S_{ad}²⁻ replaces OH⁻ until saturation is again obtained. These equilibria are included in the mechanism below. In addition, the dissolution of adsorbed sulfur is written in two steps. The following steps are considered in place of Eq. [3]-[6]. Here M_v stands for a vacant site and the asterisk indicates an activated form of adsorbed sulfur

For convenience, both hole transfer steps are combined in Eq. [18]. In summary, the new mechanism accounts for the competitive adsorption of OH⁻ and S²⁻ and maintains the key feature that S_{ad} has to undergo some type of rearrangement or activation with rate constant, k_a , in order to be desorbed. This rearrangement is postulated to be the rate-limiting step. At this time, we do not know the identity of the activated state of sulfur. The process might be, for example, conversion from a strongly bound to a weakly bound state involving different bonding properties. Another possibility is that the rate-determining step is a chemical combination of adjacent S atoms to form S_{nad} which then could be removed by S²⁻ to form S_{n+1}²⁻. Note that S₂²⁻ is not stable under our conditions according to the data of Gigenbach (5, 6) (Table I). It is plausible that some S_{ad} is desorbed as S₃²⁻ as in the X_s = 1 electrolyte.

The goal of the present analysis is to obtain a relationship for Θ/Θ_0 analogous to Eq. [15]. Conservation of sites requires that

$$1 = \Theta_{\text{OH}^-} + \Theta_{\text{S}^{2-}} + \Theta_{\text{S}} + \Theta_{\text{V}} \quad [21]$$

where we have used Θ_{V} to indicate the fraction of sites that are vacant. In the analysis, Θ_{OH^-} and $\Theta_{\text{S}^{2-}}$ are eliminated by the thermodynamic definitions of K_1 and K_2 , respectively. The high stability of the system (Table II) justifies the approximation that the rate of hole transfer, Eq. [8], equals the photocurrent, j_p . In terms of the rate limiting step, Eq. [19], we have

$$j_p = \frac{k_a}{n} \Theta_{\text{S}}^n \quad [22]$$

where n is the number of S atoms and k_a is the rate constant. The results of combining Eq. [16]-[19], and Eq. [21] and [22] is

$$\frac{\Theta}{\Theta_0} = 1 - \left(\frac{n j_p}{k_a} \right)^{1/n} \quad [23]$$

where Θ_0 is the coverage at zero photocurrent. Its value is given by

$$\Theta_0 = \frac{K_2(\text{SH}^-)(\text{OH}^-)}{1 + K_2(\text{SH}^-)(\text{OH}^-) + K_1(\text{OH}^-)} \quad [24]$$

By suitable algebraic manipulation, Eq. [23] can be written, for low coverage

$$\ln \Theta \cong \ln \Theta_0 - \left(\frac{n}{k_a} j_p \right)^{1/n} \quad [25]$$

Plots of the experimental data according Eq. [25] with $n = 1$ were shown in Fig. 3.

The most important observation is that the constant slopes in Fig. 3 and 4 are rationalized by means of Eq. [25], thereby supporting the rate-determining step in Eq. [19]. In the revised mechanism, a role of OH⁻ concentration is suggested in Eq. [16], [17], and [20]. Equation [24] predicts that Θ_0 will be maximal at a certain [OH⁻] and that electrode stability will depend on pH. The deleterious effect of too-high (OH⁻) would probably be most noticeable when large S_n²⁻ polymers dominate in the electrolyte. Preliminary flatband potential data (20) show that there is less negative charge on the CdSe surface in electrolytes richer in sulfur but with constant OH⁻ composition. This could mean that OH⁻ competes better with larger S_n²⁻ species. It follows that less adsorbed sulfide means lower stability because OH_{ad}⁻ is not efficiently oxidized by illuminated CdSe.

Having presented our data and analysis, it is important to compare our results with those of previous studies. Most notable is the work performed by the groups at the Weizman Institute in Israel. In many ways, our data supports and extends these investigations. Hodes (9) has recently reviewed photoelectrochemistry in polysulfide electrolytes.

The Weizman groups have considered a number of properties, including photocurrent decay under stationary conditions, effects of electrolyte composition, and kinetic modeling (21). Our experiments generally differ in two ways. We used a lower range of sulfide concentration and a rotating electrode. In addition, we tried to obtain more detailed quantitative data relating to corrosion rates and surface coverage.

Our kinetic model follows from the derivations given earlier (1, 4) concerning one-equivalent nonadsorbing reducing agents. We assume that the corrosion current is second order in hole concentration. This was proven by means of the concentration dependence of the stabilization efficiency for the CdSe electrode using the iron cyanide electrolyte. We also assume that the oxidation of adsorbed sulfur is two equivalent. In both of these respects, we differ from Tenne *et al.* (21). The first-order corrosion reaction proposed in Ref. (21) is known to lead to photo-

current-independent stability as long as diffusion control is avoided. In our results and those of Tenne *et al.*, the photocurrent level exerts a strong influence on the stability.

Siberstein and Tomkiewicz (23) found then that both CdS and CdS_xSe_{1-x} are formed as corrosion products on stationary electrodes. These corroded surfaces were formed in 30-day experiments with initial photocurrents of ~ 50 mA/cm². These conditions are quite different from ours. We used much lower photocurrents, short times (< 1h), and rotating electrodes. In addition, according to Ref. (23), electrodes aged in the dark did not show Se/S exchange. While we cannot rule out the CdS_xSe_{1-x} surface composition, the finding of the above authors does not necessarily mean such mixed compounds were formed in our experiments. We can add that the energy level for hole conduction in CdS_xSe_{1-x} will be more closely matched to that of CdS. The stabilization efficiencies reported here would be lowered to the extent that CdSe_xS_{1-x} replaced CdS.

It has been reported that an optimum stability obtains for a sulfur/sulfide ratio of about 1.3 or 2 (9). Our data do not show such a trend. As Fig. 6 indicates, the stability, as measured by the photocurrent half-life, increases and accelerates as X_s approaches 4. Since the value of 1.3 matched the optimum in the known rate of sulfur dissolution, it was concluded previously (9) that removal of elemental sulfur controls the photocurrent decay. This may be true for certain stationary conditions, but this conclusion cannot be made from our results. It is reasonable that the dissolution of adsorbed sulfur occurs at a faster rate at the RDE because of the effective stirring rate. The enhancement of stability by increasing the sulfur content of the electrolyte (Fig. 6) may be related to the dissolution rate of sulfur. The argument is based on the fact that, if the rate of removal of adsorbed sulfur is increased, a greater steady-state coverage of sulfide should result. The effect of X_s on the dissolution rate of sulfur has been reported (24). It was found that sulfur dissolved more rapidly as X_s increased to ~ 4.0 [see Fig. 7, Ref. (24)]. This known behavior explains the results in Fig. 6. Our calculations in Table I, therefore, indicate that larger polymer species such as S₄²⁻ and S₅²⁻ may be most effective in removing dissolved sulfur. Considering the nonpolar character of sulfur, it is not too surprising that increasing the sulfur content of the ions in solution promotes faster dissolution. On the other hand, there may be special stability associated with a certain size polymer which is formed by addition of sulfur from the electrode surface to an existing favorable polysulfide species in the electrolyte.

Since the free energies of formation of the polysulfide species differ by ~ 1 kcal-mol (8), we expect the changes in thermodynamic redox properties for different compositions to be small.

The effect of electrode potential on stability is an interesting one. We have already observed the effect on the n-CdSe/iron cyanide system (26) using the rotating ring-disk corrosion competition method. An effect of voltage on stability of CdSe in sulfide electrolytes was described earlier (22). At negative potentials and constant light intensity, lower photocurrent and, thus, higher stability are obtained. Our effect of voltage is different because we adjusted the light intensity to keep the photocurrent level constant. Therefore, another voltage effect was observed in our results.

Two possible explanations for the present case are the following. It is reasonable to expect that adsorbed sulfur is present on the surface as a reaction product. If the steady-state coverage with sulfur could be lowered, then the stability of the electrode should increase because more sulfide can be adsorbed. If part of the adsorbed sulfur is electrochemically reduced to sulfide and desorbed, by the preceding argument the stability should increase. The extent of the reduction of sulfur should depend on the cathodic voltage in agreement with the observations.

Alternatively, we can explain the data in Fig. 7 by in-

volving a recombination mechanism. It has been suggested (25,26) that if corrosion intermediates such as (A · B)⁺ can function as recombination centers, then their steady-state concentration will depend upon the concentration of electrons, n_s, at the surface. Higher cathodic bias means higher n_s and less (A · B)⁺ and lower corrosion rate. Without additional detailed analysis, we cannot decide which model is correct. But if the recombination mechanism is correct, it appears from the quantity V₀* - V_c that the energy level of the recombination center depends on concentration of sulfide. It is clear that the recombination effect on stability is not unique to systems with adsorbed redox species.

Summary

It has been shown that, by recognizing the electronic properties of substrate and corrosion layer, the photocurrent decay can be used to obtain information about the corrosion properties of semiconductor electrolyte systems. Because of the complexity of the system, detailed models had to be applied. A tunnel model for hole photocurrent was combined with the relation for stabilization efficiency to determine a quantity proportional to sulfide surface coverage. It was shown that such coverage data behaved, with respect to concentration, as expected on the basis of a general adsorption isotherm. The dependence of the coverage on current density was also investigated. The results indicated that the coverage was quite low for the current densities and concentrations used. This is not unexpected, since we designed the experimental conditions so that relatively fast decays would be observed. Our data suggest that one to two monolayers of corrosion product are sufficient to allow application of the tunnel model for hole current. Electrode potential and electrolyte composition have major influences on the electrode stability. Higher sulfur ratios and more cathodic voltages enhance the stability. While detailed modeling has led to the stability data, exact interpretation in terms of a kinetic mechanism has not been done. However, we were able to conclude that the stability of a rotating CdSe electrode is determined by a chemical process probably involving surface adsorbed sulfur.

ABSTRACT

The cathodic decomposition of InP is studied by cyclic voltammetry and *in situ* ellipsometry. During the hydrogen evolution, an indium-rich film grows on the surface of the semiconductor. Afterward, this film undergoes transformations between oxidized and reduced forms following the electrode polarization. A theoretical model based upon a three: "InP/oxide or indium/electrolyte" or a four: "InP/oxide/indium/electrolyte" medium enables one to correctly interpret the ellipsometric data.

An electrochemical modification of the surface of a semiconductor, say, n-type, can occur just as well during an anodic reaction as a cathodic one. The former reaction, which will lead to the dissolution of the semiconductor or to the formation of an oxide on its surface, has been the most studied. These surface transformations, which can be usable, for instance, in electronics—etching (1) or the preparation of a MOS structure (2)—are, on the other hand, disastrous in a photoelectrochemical cell (3).

The cathodic reaction has mainly been used as a means to activate the semiconductor: for example, hydrogen coming from the reduction of the electrolyte can diffuse into the electrode and modify its properties. Concerning oxides, it is possible to enhance their conductivity (4) or to change their color (5). There have not been many studies published on the cathodic decomposition of semiconductors. In this last case, it seems that the nature of the products of this decomposition depends on the particular bonding of the semiconductor. Thus, for covalent compounds such as Ge and Si, the surface will be covered with hydrides (7), while it will become metallic with II-VI compounds having a strong ionic character (6). A recent study (8) shows that the decomposition of III-V compounds also yields a deposit of the metallic element. It is noteworthy that for InP in an acidic medium the metal (indium) after anodic dissolution forms a passivating film which protects the semiconductor against corrosion. This last point indicates the possibility offered by this kind of reaction to modify in a useful manner the surface of semiconductors. This is particularly interesting for InP, as its use in optoelectronics (9) and in photoelectrochemistry (10) mainly comes from its surface properties. *In situ*

methods are necessary to understand the mechanisms of such reactions. For instance, the ring-disk method can be useful in addition to cyclic voltammetry (8). However, it is necessary that the products of the decomposition go into the solution so as to be detected at the ring. On the other hand, optical methods will be directly sensitive to any surface modification at any potential. Thus, in this way, Kolb *et al.* (11) have studied the decomposition of ZnO and CdS by electroreflectance.

Here we present some results relating to cathodic modifications of InP using ellipsometry coupled with voltammetry. By this optical method we will see in particular that the indium cathodic film transforms into an oxide whose behavior is different from that of the initial oxide. This could be interesting, as we know the nature of the oxide film greatly influences the performance of InP devices.

Experimental Details

The InP single crystals are (100) oriented and have an electron concentration of $2 \times 10^{18} \text{ cm}^{-3}$. The face in contact with the electrolyte has been chemomechanically etched with a 1% bromine-methanol solution, warm methanol rinsed, and argon dried. An ohmic contact on the rear side of the electrode was made by an indium solder at 350°C in a hydrogen stream.

Cyclic voltammetry was done by means of a classical electrochemical setup already described (12). The electrolytes were prepared with "millipore" purified water and chemicals were Merck Suprapur grade. They were purged by argon bubbling. A saturated calomel electrode (SCE) served as a reference for the potential applied to the working electrode.

The optical cell was a Plexiglas cylindrical vessel with quartz windows fixed to give an angle of incidence of 70° at the mounted working electrode. The optical measurements were conducted with an automatic ellipsometer equipped with a He-Ne laser (632.8 nm). Data acquisition was made for 15 rev of the rotating analyzer, which rotates at 15 rev/s, hence averaged over 1s. The time interval between two measurements was 12s.

Just after etching and prior to any polarization, we determined by ellipsometry the thickness (d) and the optical index (n) of an equivalent layer lying on the surface of the samples ($1.6 < n < 2.0$ and $1.5 < d < 4$ nm). These values were calculated with the aid of a one-layer model, by considering this layer as transparent ($k = 0$) and by taking $n = 3.535 - i 0.308$ (13) for the index substrate. With respect to ellipsometry, the equivalent layer takes into account the residual oxide (14), the carbon contamination (15), and all the surface imperfections (16).

Results

For a better understanding of the phenomena concerning the basic electrolyte, electrochemical and ellipsometric results are presented separately.

Electrochemistry.—Figure 1 illustrates the electrochemical behavior of InP at pH 10. Three points are typical of this behavior.

1. There is one domain of potential (Fig. 1a) in which the current is stable and does not present any oxidation or reduction peaks. On the anodic side, this domain is limited by the beginning of oxidation; the corresponding potential is $V_A = -0.1V$. The cathodic limit, $V_C = -1.35V$, located in the domain of the onset of hydrogen evolution,

is such that no peak exists during the following anodic scan.

2. As soon as the electrode polarization reaches potentials more cathodic than V_C , a well-defined oxidation peak appears on the next anodic scan (Fig. 1b). After this peak, the current intensity remains almost constant until V_A . The next forward scan (anodic to cathodic) also becomes marked by a reduction peak (dashed line) located just before strong hydrogen evolution sets in (Fig. 1b).

From this point, I-V voltammograms always keep the same shape on condition that the cathodic limit remains more negative than V_C . An increase in either cathodic or anodic current only takes place after a larger number of scans (Fig. 1c) or if the working electrode is held at a potential less than V_C (Fig. 1d). It should be observed that this rise is more marked when the cathodic potential is more negative. However, the evolution of hydrogen which perturbs the optical measurements restricts the cathodic potential to around $V_{H_2} = -1.50V$.

3. This last point concerns the existence of a quasi-stable cycle (Fig. 1e). As for the one described in point 1 above, it is limited by V_A and V_C , but the current now presents two peaks, one of oxidation and one of reduction.

The stability of this cycle necessitates several potential scans during which the current diminishes. On the other hand, the form and the position of the two peaks remain unchanged.

Ellipsometry.—The surface modifications lead to a variation of the two ellipsometric parameters Ψ and Δ (15). Their evolution, which occurs during the various electrochemical polarizations (Fig. 1), has been drawn in the (Ψ , Δ) plane (Fig. 2).

Along with the electrochemical measurements discussed above, three other types of behavior can be distinguished.

1. During this first cycle, the (Ψ , Δ) variations are small and the corresponding A_0 point stays near the one obtained initially with InP covered with its residual layer.

2. When the potential becomes more negative than V_C , one observes an appreciable change of Δ , A_0 moving towards the B_1 point (solid curve). This rise is especially strong, as the thickness of the equivalent layer is large. The return to the anodic potential V_A brings back the (Ψ , Δ) point to the vicinity of A_0 , slightly above it (A_1). In a more and more distinct manner, this phenomenon happens again during the running scans, the point A_j always being located above the point A_{j-1} . It is noteworthy that now after the first cathodic scan, the major part of the variation of $\Delta(A_{j-1} - B_j)$ occurs with the reduction peak.

Finally, holding at potentials more cathodic than V_C leads not only to a rise of Δ , but also to one of Ψ . In the reverse (anodic) scan, the corresponding point A_{j+1} is located much further on A_j than the one obtained in a non-stop cycle.

3. The quasi-stable electrochemical cycle ($V_A - V_C$) described in Fig. 1e gives ellipsometric results (upper

Fig. 1. I-V voltammograms of InP in aqueous medium, pH 10 (buffered solution: H_3BO_3 , KCl, NaOH); voltage sweep: 10 mV s^{-1} . a: Continuous polarization between $V_A = -0.1V$ and $V_C = -1.35V$. b: First potential excursion at $V_{H_2} = -1.50V$ followed by the immediate anodic (solid line) and cathodic (broken line) scans. c: Two " $V_A - V_{H_2}$ " cycles obtained in a time interval of 30 mn; initial (solid line), final (dot-dash) line. d: The electrode potential is kept 2 mn at V_{H_2} ; initial cycle (solid line), final cycle (dotted line). e: Quasi-reversible " $V_A - V_C$ " cycle obtained after c and d and after stabilization (see text).

dashed curve, Fig. 2), which also requires a minimum delay of scanning to be stable. Note that the (Ψ , Δ) values of the extremities of the cycle are different from those attained when polarizing beyond V_C .

Discussion

The results as a whole give evidence of a surface transformation of the semiconductor which occurs during the reduction of the solvent. Keeping in mind what was recalled in the introduction, we will suppose that the cathodic decomposition of InP leads to a surface rich in indium. The position of the potential of decomposition, located just below the conduction band, thermodynamically allows (3) the following reaction

with the P^{3-} going into solution as PH_3 (17a). Note that a similar decomposition mechanism was proposed for GaAs (17b).

A primary interpretation of the ellipsometric data can be made through a simple model based upon three media: substrate/layer/electrolyte. Two cases emerge when the layer consists of oxide or of indium. Curves labeled Ox₁ and Ox₂ correspond to a transparent oxide layer for which the refractive indexes are, respectively, equal to 1.6 and 2.0. The curve labeled (In) corresponds to an indium layer on InP having an index value of $n = 1.44 - i 2.8$ (18).

The change from the Ox curve to the In curve necessitates a more complex model, one either the same as above with the intermediate layer composed of a mixture of oxides and indium, or a four-media model: InP/oxide/indium/electrolyte, where the respective part of oxide and indium can be exchanged. These various models, considering the small thickness involved, give similar results. In the following, our analysis uses the last model, which seems the more accurate to describe the surface transformations of InP. The variations of Ψ and Δ calculated from this model are reported in Fig. 3. Curves lying between "Ox" and "In" represent a growth of indium upon oxide films of different thicknesses. Note that the choice of our theoretical model is, *a posteriori*, justified as all the experimental variations of Ψ and Δ remain in an area limited by the "Ox" and "In" curves.

In order to get a better correlation between the ellipsometric and the electrochemical behavior, it is interesting to express the variations of Ψ and Δ in terms of the applied potential V (Fig. 4a and 4b).

In the course of the first scan at potential smaller than V_C , the large ellipsometric variation, which essentially concerns Δ (through a rise), indicates that a surface modification happens at the same time as hydrogen evolves. Our explanation is that the surface grows richer in indium. When returning to positive potentials, the decrease of Δ when the current becomes anodic (peak) shows an oxidation of the "cathodically activated" surface. During the following negative scans, the strong increase of Δ begins with a potential more anodic than the

Fig. 3. Ellipsometric models. Solid curves are relative to the three-layer model: oxide or indium of constant index on InP. Dashed curves represent the four-layer model in which indium grows on InP covered with oxide of constant thickness.

Fig. 4. Variations of Ψ and Δ with the applied potential. Top: During a complete potential sweep (solid line) and after a hold on at V_{H_2} (dashed line). Bottom: During the " $V_A - V_C$ " cycle of Fig. 1.

previous "activation" potential (Fig. 4a). This, added to the existence of a cathodic current peak, shows that indium now is formed from the reduction of the oxide previously fabricated.

If the polarization becomes more negative, a new increase of Δ occurs which is similar to the one observed in the first scan. Here the formation of indium comes from the decomposition at one and the same time of the remaining oxide and of the substrate.

Later on, the amount of indium will increase at each cathodic sweep just as does the oxide at the next anodic scan. An amplification of this phenomenon appears when the electrode is maintained at more cathodic potentials (Fig. 4a).

The quasi-stable cycles (Fig. 4b) obtained after several scans between V_A and V_C , without then reactivating the electrode, are easily explained by an oxidation reduction of the indium film. The quasi equality of the electrical charges required for the reactions, anodic as well as cathodic, indicates that there is no indium dissolution in this basic electrolyte. On the contrary, such a dissolution occurs in an acidic medium (8). The disparity in magnitudes between these cycles and those going to the decomposition implies, on the one hand, a lesser important thickness of indium, in accordance with an unreactivated elec-

trode, and, on the other hand, an oxide layer remaining below the metallic layer. This last remark means the reduction of the oxide due to a potential scan as far as V_A is not fully achieved.

The last point of this discussion concerns the nature of the oxide grown from the cathodic metal film. To answer this question, electronic spectroscopy techniques, unfortunately *ex situ*, such as ESCA, XPS, etc., will be required. However, the following observations already give one some ideas about this oxide.

First, it is different from the oxide which initially exists on the surface of InP after etching and being in contact with electrolyte. This is simply proved by the absence (Fig. 1a) and the presence (Fig. 1b) of one reduction peak. From its electrochemical and ellipsometric behavior, it is also different from the anodic oxide grown in this electrolyte at potentials slightly higher than V_A . In general, these oxides are composed of indium and phosphorus-mixed oxides, especially when thicknesses are smaller than 30Å (19). Here, on the contrary, indium is the predominant element as the oxide is grown from an indium-rich surface.

The composition of this oxide would, therefore, be close to that of In_2O_3 and most likely under a more or less hydrated form as $\text{In}(\text{OH})_3$. This is supported by the dissolution of this oxide in an acidic medium.

Conclusion

For the entire body of results, good agreement is found between ellipsometric and electrochemical measurements. Ellipsometry confirms a cathodic decomposition of InP and follows *in situ*, the oxidation and the reduction of the film coming from this decomposition. Furthermore, this optical technique gives information on the nature of the various films which cover the electrode.

This work once again shows the utility of using electrochemical reactions to modify the surface of semiconductors. Thus, with InP we were able to transform the residual layer into an indium-rich one, this latter being oxidized or reduced according to the applied potential. An extension of this process to other media, especially acidic, would offer the possibility of getting surfaces of various compositions.

Effects of Corona-Discharge-Induced Oxygen Ion Beams and Electric Fields on Silicon Oxidation Kinetics

II. Electric Field Effects

Douglas N. Modlin*

Department of Electrical Engineering, Stanford University, Stanford, California 94305

William A. Tiller

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

Using an *in situ* corona discharge ion current source directed to the front side of oxidizing silicon wafers, the effect of the electric field induced in the oxide on the back side of the wafers was studied. Oxidation enhancement was found to occur when the surface of the oxide was positive relative to the silicon. No enhancement or a slight retardation occurred for the opposite sign of field. This is exactly opposite to the effect found by Jorgensen (1), which has been traced to his use of platinum electrodes, in that the presence of the platinum dramatically influences the growth rate of the SiO_2 via the formation of an intermediate phase of platinum silicide. The results and analysis presented here support the theory that neutral O_2 is the diffusing species in the thermal oxidation of silicon.

In the early 1960's, Jorgensen (1) described an experiment wherein porous platinum electrodes were applied to a silicon sample which was subsequently oxidized. He found that the oxidation rate could be enhanced or retarded depending upon the sign of dc current flow through the electrodes. When the Si was at a positive potential with respect to the electrode, the oxidation rate was enhanced, and when it was at a negative potential with respect to the electrode, the rate was retarded. Based on this result and the results of a permeation experiment (2) also utilizing Pt electrodes, Jorgensen (1-4) deduced that a negatively charged oxygen species was the oxidant and presumed that O_2 from the gas phase entered the SiO_2 and therein acquired a negative charge. Similar results were observed a few years later by Laverty *et al.* (5), although their conclusions differed from those of Jorgensen. These findings were at variance with the findings of Deal and Grove (6) and Doremus (7), whose work supported a neutral oxidant model. Raleigh (8, 9) also criticized the conclusions of Jorgensen and provided an alternate explanation for the experimental results which was based on the superposition of an electrolytic decomposition reaction at the Si/ SiO_2 interface and the normal oxidation reaction. He also showed that no sustained oxidation was possible without electron flow in an external circuit connecting the silicon and the Pt electrode, since any nonohmically-induced field would be canceled by charge redistribution within the SiO_2 .

An even more striking variance with other oxidation results was that Jorgensen (1) and Laverty *et al.* (5) found the oxidation rate to be parabolic no matter whether the current was positive, negative, or zero; *i.e.*, no linear oxidation region was observed. In recent years, this type of totally parabolic oxidation behavior has been associated with the oxidation of silicon via an intermediate metal silicide layer (10), and theoretical analysis of oxidation under such conditions indicates why this behavior occurs (11). Thus one might suspect that perhaps Jorgensen's Pt electrodes were deposited, in part, on Si without an intervening SiO_2 layer and that his data related to oxidation via an intermediate platinum silicide layer. Since this is such an important issue in the fundamental understanding of silicon oxidation, the old experimental data need to be reexamined and new experimental evidence generated. The purpose of the present paper is to provide such new experimental data so that this issue can be put to rest.

In a companion paper (12), oxidation enhancement via the use of low energy oxygen ion beams in a neutral oxy-

gen ambient was studied for the intermediate temperature range 600°-950°C. With this new technique (13), no Pt electrodes need be placed on the wafer, as a constant-current ion beam is generated via a corona discharge between a Pt needle and a Si wafer located ~0.5 cm from the needle tip. Oxidation on the front side (FSO) of the wafer involves enhancement effects from both oxygen ions and the associated electric field, and this has already been reported on (12). Oxidation on the back side of the wafer (BSO) involves enhancement effects only from the electric field associated with the current flow, and these results will be reported upon here. Since our observations were exactly opposite to those reported by Jorgensen (1-4), we went on to explore the effects of Pt contamination on Si oxidation, and those results are also presented in this paper.

Experimental

Techniques.—The experimental apparatus and protocol used in the present study are identical to those described previously (12, 13). As can be seen in the inset of Fig. 1, the Si wafer rests on a 2.5 in. diam quartz substrate (1.6 mm thick) the bottom of which is coated with a 2 in. diam, 1 μm thick, sputter-deposited layer of Pt. The entire assembly rests on a 0.002 in. Pt sheet which is spot welded to a 0.010 in. Pt lead-in wire. This ensemble provides electrical contact to the Si sample while allowing back-side oxidation to occur. The quartz plate acts as a diffusion barrier between the Pt and the Si, yet the electrical conductivity of the quartz is sufficiently high at 900°C to pass a 10 μA current with a voltage drop of less than 100V (15). This is deemed acceptable because it is small compared to the ~1-3 kV required to generate an oxygen ion beam current of 10 μA .

Electric field effects on BSO.—The oxide thickness on the back sides of the wafers was difficult to measure with high accuracy because the wafers were usually placed on the experimental apparatus with the unpolished sides of the wafers adjacent to the quartz substrate. This was necessary because, if the polished sides were placed against the substrate, it was very difficult to remove the wafers after the corona treatment without breaking them. Apparently, the wafers stuck to the quartz substrate (which was also polished flat) after the corona treatment because (i) the oxygen between the wafers and the substrate was expelled during the corona treatment and (ii) the wafers tended to form a weak bond to the substrate. Although it was less desirable to study the unpolished surfaces, numerous control experiments without the corona showed that the oxide thicknesses measured on the unpolished sides of the wafers agreed with measurements on the pol-

* Electrochemical Society Active Member.

Fig. 1. Illustration of the apparatus used for generating an ion beam. The inset shows a magnified view of the ion beam generator.

ished sides to within about 2-5%. Another problem with back-side oxide thickness measurements taken after the corona treatment was that the wafer surfaces were somewhat disrupted at the points of electrical contact to the quartz substrate; however, it was found that a reasonably good ($\pm 10\%$) measurement could be made by averaging the results of 6-12 ellipsometric measurements taken in between the disrupted areas at 3-6 separate locations on the wafers.

Data obtained for Si(111) at 900°C with $I = -5$ and $-10 \mu\text{A}$ are shown in Fig. 2. Despite the obvious nonlinear effect, these oxidation curves show a significant oxidation enhancement and are seen to be parallel to those for wafers oxidized under the standard conditions. For this sign of current, the oxide surface on the back side of the wafer is positive relative to the Si. In Fig. 3, data are plotted for $I = +5 \mu\text{A}$, where the Si wafer has a positive potential compared to the quartz plate. In this case, the results are found to lie slightly below the standard dry O_2 data for 900°C , although, because of the expected scatter band of the BSO data, a firm conclusion concerning a retardation effect or a null effect does not seem to be justified. We note that these results are opposite in sign to those found by Jorgensen (1).

Platinum effects.—In order to ascertain whether or not the samples oxidized in our apparatus were contaminated with Pt from the needle or from the back-side quartz electrical contact at a level sufficient to affect the oxidation rate in the experiments of Fig. 2 and 3, the front sides and back sides of such samples were analyzed with Auger electron spectroscopy (AES), Rutherford back scattering spectroscopy (RBS), and secondary ion mass spectroscopy (SIMS). Pt presence was not indicated using any of these techniques, and we conclude that possible Pt contamination was at too low a level to have influenced the oxidation rate. This conclusion is supported by the fact that the BSO and FSO proceeded at the normal rate for $I = 0$.

Fig. 2. Comparison of back-side oxidation for $\langle 111 \rangle$ -oriented wafers exposed to -5 and $-10 \mu\text{A}$ at 900°C to data obtained under standard conditions.

Fig. 3. Comparison of back-side oxidation data for $\langle 111 \rangle$ -oriented wafers exposed to $+5 \mu\text{A}$ at 900°C to data obtained under standard conditions.

To determine the effect on Si oxidation for deposition of Pt on an initial SiO_2 layer, an experiment was performed wherein $\sim 50\text{\AA}$ of Pt was sputter deposited on a Si(111) wafer after $\sim 300\text{\AA}$ of SiO_2 had been thermally grown at 900°C . After oxidation for 0.5h at 900°C , the Pt films were observed to "ball up," to give Pt islands ~ 500 - 1000\AA in diameter, and, after 5h of oxidation, most of the Pt islands disappeared leaving only small spots to register their prior locations. RBS spectra for the 0.5 and 5h states confirmed that a 30% decrease in Pt signal occurred at the surface after the 5h oxidation. Although most of the Pt was lost to the ambient gas as a volatile oxide after 5h, SIMS analysis¹ showed that sufficient Pt had diffused through the oxide to provide a Pt concentration of $\sim 5 \times 10^{17}$ atom/ cm^3 at the Si/SiO₂ interface.

After etching off the surface Pt, the oxide thickness was measured for various oxidation times at 900°C . To account for the original oxide layer thickness, 1h has been added to each of these subsequent oxidation times to arrive at the total oxidation time, and the data are plotted in Fig. 4. From Fig. 4, we see that the Pt does, in fact, dramatically enhance the oxidation rate over what would normally occur at 900°C . Instead of following along the 900°C standard oxidation curve, the Pt-coated samples oxidized at an accelerated rate. The back-side oxides, which were not coated with Pt, grew at the normal rate.

In an additional experiment, $\sim 50\text{\AA}$ of Pt was deposited on a Si(111) substrate containing only a native oxide layer that had been argon sputter etched for 1 min to remove only the surface monolayer. These samples were then oxidized at 850° and 900°C . Apparently, the native oxide layer was thick enough, and the Pt layer thin enough, that the

¹ The SIMS work was carried out by Charles Evans and Associates (San Mateo, California).

Fig. 4. Data obtained for $\langle 111 \rangle$ -oriented silicon with a 300\AA initial SiO_2 layer that was subsequently coated with $\sim 50\text{\AA}$ of Pt and oxidized at 900°C .

Pt balled up into unreacted Pt islands instead of reacting to form PtSi. It was observed that, for both $T = 850^\circ$ and 900°C , the FSO was enhanced, while the BSO proceeded at the normal rate, indicating that physical contact is needed for the catalytic action of Pt to influence the oxidation rate (see Fig. 5).

SEM studies showed that the Pt balled up on the surface in the same manner as noted for the 300\AA thick oxide. Figure 6 shows depth profiles for Pt and O^{16} obtained using SIMS on a sample oxidized for 10h at 850°C with $\sim 50\text{\AA}$ of Pt deposited on the native oxide. Here, one sees a classically shaped diffusion profile extending from the surface to the Si/SiO₂ interface with the Pt concentration increasing significantly at the Si/SiO₂ interface. Apparently, the Pt balled up into small islands which to some extent connected to PtSi in the early stages of the oxidation, thus producing the interface peak.

To test the hypothesis that the deposited Pt in the Jorgensen (1) and the Laverty *et al.* (5) experiments formed platinum silicide, the following experiment was performed at 850°C in dry O₂. After a standard chemical cleaning (13) and a 5 min sputter etch, $\sim 1200\text{\AA}$ of Pt was sputtered onto the front side of a Si(111) wafer which had previously been cut into eighths and reassembled in the sputtering chamber. The samples were placed side by side in a diffusion furnace, and the eighths were removed for testing after different oxidation times. Just prior to the oxidation step, a 20 min anneal at 850°C in ultrahigh purity argon took place to facilitate the PtSi formation.

In Fig. 7, the results of the sputter-cleaned samples (open triangles) are plotted along with the "zero field" results of Jorgensen (1) and of Laverty *et al.* (5) on a background of standard oxidation data. In addition, data for oxides grown on Si with an intermediate layer of TaSi₂ and NiSi₂ at 850°C have been included (24, 25). We note that our data, the TaSi₂ and NiSi₂ data, the Jorgensen (1) and the Laverty *et al.* (5) data, plus the standard 1200°C data, all exhibit a slope of 1/2. In addition, all the 850°C data fall fairly close to one another. Further, we note that our back-side data fall at the expected location for a standard oxidation.

Discussion

Electric field dependence of oxidation enhancement.—On the back side of the wafer, a negative electric field is developed in the oxide as a consequence of a positive ion beam incident on the front surface. In this case, we find that the oxidation enhancement is either zero or slightly negative. For the opposite situation of a negative ion beam incident on the front surface, the resulting oxide field is positive and the oxidation enhancement is strongly positive.

Since no significant Pt contamination of the Si samples from the experimental apparatus was detected using SIMS, AES, and RBS, and the BSO and FSO proceeded at the normal rate for the $I = 0$ case, we deduce that the observed electric field dependencies were not significantly influenced by Pt contamination.

Fig. 5. Data obtained for $\langle 111 \rangle$ -oriented silicon oxidized at 850° and 900°C after an $\sim 50\text{\AA}$ Pt deposition on the native oxide.

Fig. 6. Concentration profile at platinum in an SiO₂ layer grown at 850°C for 10h with a sputter-deposited layer of platinum $\sim 50\text{\AA}$ thick on the surface. The platinum was deposited onto the native SiO₂ layer.

Interpreting the Jorgensen experiments.—In his early work, Jorgensen stated that "platinum electrodes were sputtered on the silicon to a thickness of approximately 2000\AA and the SiO₂ layer was grown underneath the platinum film" (4). This is an important point, in that Jorgensen's interpretation of his results is based on the assumption that Pt films remain on top of the SiO₂ layer and do not, in any way, affect the oxidation process. However, Jorgensen's experimental protocol outlined in the above quote and much of the experimental data of this paper point to a mechanism involving oxidation via a platinum silicide layer which would have formed as soon as his samples were heated.

In the last decade or so, the reaction of Pt thin films with silicon substrates has been extensively studied due to the importance of PtSi and PtSi₂ as Schottky barriers and metallization interconnect materials in semiconductor technology (17, 18). This reaction is now known to become quite complicated, depending on experimental conditions such as purity of the starting materials, cleaning procedures, thermal history of the sample, etc. In any event, we expect that the Pt would have either reacted with the Si, remained on the surface, or both. The combination of Jorgensen's data with those presented in this paper suggests that the results of Jorgensen's experiment

Fig. 7. Comparison of data for oxidation of PtSi obtained in our investigation to the oxidation data presented by Jorgensen and Laverty *et al.* Data for silicon, TaSi₂, and NiSi₂ oxidation under standard conditions are included for reference.

cannot be interpreted so as to deduce the identity of the diffusing species in the thermal oxidation of silicon. Since we have shown that the oxidation rate of silicon is increased via intimate contact with Pt, it is quite clear that the Pt electrodes were not inert, as was assumed by Jorgensen. This point is made rather dramatically by considering the disparity between the currently accepted distinctly "nonparabolic" oxidation at 850°C and Jorgensen's "parabolic" no-field growth rate.

The dominant diffusing species in Si thermal oxidation.—It has been repeatedly shown by radioactive tracer experiments (20-23) that the diffusing species in the thermal oxidation of Si is oxygen and not silicon. One can rule out the possibility of either O^+ or O_2^+ as the dominant form, since the ionization energy of either species is too high (it exceeds the free energy of formation of SiO_2), even though they could explain our BSO results. Hall (26) has suggested that the energy levels for oxygen ions in SiO_2 can be estimated by considering their electron affinities in vacuum. Because the electron is attached by relatively short-range forces, Hall argues that the electron affinity will be only slightly reduced in the SiO_2 lattice. Since the vacuum electron affinities for O and O_2 are ~ 1.7 and ~ 0.4 eV (27), respectively, the energy of an electron bound to either species should lie below the SiO_2 conduction band by an amount roughly equal to the electron affinity.

If Hall's assertion is correct, then the energy levels for both O and O_2 ions would be located at a level considerably above the Fermi level in the Si. The SiO_2 conduction band lies about 4.2 eV (28) above the Si conduction band at room temperature, so the energy levels for O and O_2 would be above the Fermi level in the Si by 1.95 and 3.3 eV, respectively. Hence we can conclude that it is thermodynamically unfavorable to form interstitial O^- and O_2^- species by the transport of electrons or holes across the SiO_2 layer to the SiO_2 /gas interface. Such a process would require the charged carriers to flow against the gradients of their electrochemical potentials. Any effects of the oxidizing temperature on the bandedges or on the electron energies are not expected to meaningfully alter this conclusion.

From experiment, neutral O_2 diffusion through the bulk SiO_2 layer is consistent with the linear pressure dependence of the parabolic rate constant, B , reported in the literature (29, 30). The sublinear pressure dependence reported for the linear rate constant, B/A , is consistent with dissociation, and possibly ionization, of the O_2 very near the Si/ SiO_2 interface (31, 32). Combined, this yields neutral O_2 species diffusing through the bulk SiO_2 (thickness $\approx 1300\text{\AA}$) and subsequent transformation to O or O^- at the edge of the Si/ SiO_2 interface blocking layer (33).

Measured values of the total electrical conductivity, σ_T , of SiO_2 films grown on Si can also be used to support the proposal that neutral O_2 is the dominant diffusing species. Wagner oxidation theory predicts a value for the parabolic rate constant, B , as given by (34)

$$B = \frac{kT}{N_0 q^2} \int_{P_{O_2}^i}^{P_{O_2}^0} \sigma_T t_{ion} t_{el} d(\ln P_{O_2}) \quad [1]$$

where k is Boltzmann's constant, N_0 is the atomic density of oxygen in SiO_2 , q is the electronic charge, $P_{O_2}^i$ and $P_{O_2}^0$ are the O_2 pressures at the Si/ SiO_2 and SiO_2 / O_2 (gas) interfaces, respectively, while t_{ion} and t_{el} are the transference numbers for ions and electrons, respectively. Evaluating this integral under the assumptions that t_{ion} and t_{el} are independent of the oxygen pressure and that O_2^- is the electrically active species (being consistent with the linear pressure dependence for B), one obtains an expression for B of the form

$$B = \frac{kT \sigma_T t_{ion} t_{el}}{N_0 q^2} (P_{O_2}^0 - P_{O_2}^i) \quad [2]$$

Using Wagner's (14) measured values of $\sigma_T \approx 3 \times 10^{-10} \Omega^{-1}\text{-cm}^{-1}$, $t_{ion} \approx 0.9$, $t_{el} \approx 0.1$, and $P_{O_2}^i \ll P_{O_2}^0$ at 900°C, one finds $B(1 \text{ atm}) \approx 1.2 \times 10^{-4} \mu\text{m}^2/\text{h}$, as compared to the measured value of $B(1 \text{ atm}) \approx 3.7 \times 10^{-3} \mu\text{m}^2/\text{h}$ (6, 29, 30).

Since the calculated value of B is a factor of 30 smaller than the measured value, it seems unlikely that oxygen ions could sustain the oxidation reaction at the observed rate.

Srivastava *et al.* (14) have also shown that σ_T for SiO_2 grown on Si varies with the substrate doping for room temperature substrates in the 3.3-22 $\Omega\text{-cm}$ range, whereas the oxidation rate does not, so a portion of the above-used value for σ_T comes from the substrate dopant and our value of $B \approx 1.2 \times 10^{-4} \mu\text{m}^2/\text{h}$ is an overestimate. Thus, the disparity between the measured B and our ion-origin-calculated B may be $\approx 10^2$. This calculation further supports the view that neutral O_2 is the dominant oxidant during thermal oxidation.

Conclusions

1. Electric-field-enhanced oxidation occurs when the surface of the SiO_2 is made positive relative to the silicon. No enhancement or a slight retardation occurs for the opposite sign of field. This is exactly opposite to the effect found by Jorgenson (1-4).

2. The Jorgensen results cannot be used to deduce the identity of the diffusing species in the thermal oxidation of silicon, since the Pt electrodes were not inert as assumed but, rather, dramatically influenced the oxidation kinetics via PtSi formation, etc.

3. A thermodynamic argument shows that it is energetically unfavorable to form interstitial O^- and/or O_2^- species by the transport of electrons or holes across the SiO_2 layer to the SiO_2 /gas interface.

4. Based on 1-3 above, and the fact that the parabolic oxidation rate as calculated from the Wagner oxidation theory is much too low to sustain the observed oxidation rate, it is concluded that the dominant oxidant during the thermal oxidation of Si is neutral O_2 . This conclusion applies strictly to oxides thicker than about 3000 \AA , since the growth mechanisms for thin oxides are complex and, as yet, not fully understood.

The Influence of an Electrolyte on Impedance Characteristics in n-GaP Electrodes

G. Nogami, R. Shiratsuchi, H. Nakamura, and H. Taniguchi

Department of Electrical Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu 804, Japan

ABSTRACT

Impedance of n-GaP electrodes was measured by using a microcomputer-aided measuring system. Mott-Schottky plots were quite dispersive. Large frequency dispersion was ascribed to the interface state which was assumed to be formed as a result of corrosion. Charging and discharging of the interface states by ions in the electrolyte were determined by charge transfer at the electrode-electrolyte interface and diffusion in the electrolyte, which could be characterized by charge-transfer resistance R_t and diffusion impedance Z_w . R_t became predominant at low ionic concentration. It is pointed out that the influence of an electrolyte must be taken into consideration in interpreting the impedance data of some kinds of semiconductor electrodes.

In developing suitable semiconductor electrodes for solar energy conversion, GaP electrodes have also been extensively investigated by many workers (1-12). However, the long-term stability of the GaP electrode, especially of the n-GaP electrode to be used at an anodic mode, is rather questionable. In such a system, the kinetic stability has been studied: anodic decomposition of illuminated n-type semiconductor is prevented by means of competing hole reactions with reducing species added to the solution (10). In discussing the kinetic stability, a full characterization of the electrode may be required. Impedance measurements are a useful tool for characterizing the electrode. Impedance measurements on this material have been made by Madou *et al.* (6). They discussed the frequency dispersion of Mott-Schottky plots on the basis of an empirical law, but they did not refer to the role of an electrolyte. Nakato *et al.* (8) have reported that surface intermediates may be formed in an n-GaP electrode by photogenerated holes. If this phenomenon should be commonly observed in this material, impedance characteristics must reflect the detailed characteristics of the electrolyte used because intermediates are formed as a result of an electrode reaction. The flatband potential in an n-GaP electrode is typically about $-1.0V$ vs. SCE. A large band bending results in a weak inversion layer where some holes are present. Surface holes contribute to the formation of the intermediates as photogenerated holes do: even at dark, some kinds of decomposition may proceed, although the rate may be quite slow. Alternatively, the hole injection from redox couples to the GaP electrode plays the same role, as suggested by several workers (1-4). In other words, intermediates may be formed when the electrode is immersed in an aqueous electrolyte.

The objective of the present study is to propose a model which enables us to detect the formation of an interface layer or intermediates by impedance measurements. It is pointed out that if there exist intermediates which can ex-

change charges (electrons) with ions in the electrolyte, the impedance of that system is influenced by a Warburg (diffusion) impedance of the electrolyte and charge-transfer resistance at the electrode-electrolyte interface.

Experimental Results

The $\langle 100 \rangle$ n-GaP wafers were supplied by Sumitomo Electric Industries, Limited. The doping concentration was $5 \sim 7 \times 10^{17} \text{ cm}^{-3}$. The wafers were mirror polished and then etched for ~ 30 s using a mixture (by volume) of six parts nitric acid one part hydrochloric acid, and one part perchloric acid. Ohmic contact was made using a Sn/In alloy which was annealed at 550°C under N_2 for 5 min (12).

A microcomputer-aided measuring system was used to obtain the impedance data. The amplitude of the ac signal across the sample was ~ 3 mV (rms). Outputs of in- and out-of phase of a dual-phase lock-in amplifier (PAR 5204) were converted into digital signals by 12 bit A/D converters (Datel ADC HZ-12BGC). Resultant data were stored and analyzed by an NEC PC 8001 microcomputer. This system permitted a quick measurement and supplied many more data than a usual system did. Capacitance C and resistance R in a series equivalent circuit diagram and capacitance C_p and conductance G in a parallel equivalent circuit diagram, as well as the modulus and phase of impedance, were quickly printed out. About 30 samples were studied. Figure 1 shows the typical current-voltage curve under a chopped light illumination of $\sim 60 \text{ mW/cm}^2$. Light source used was a 150W Xe lamp. The electrolyte was 0.1M KOH solution. All samples studied showed approximately the same J-V characteristics as Fig. 1. Dark current was low, implying that thermal generation rate of holes at the electrode surface was very low. Anodic dark current was also caused by electron transfer from the electrolyte to the semiconductor bulk via intermediates or surface states. Low dark current implies that electron-

Fig. 1. Current-voltage characteristics for the N-GaP 6, under a chopped light illumination of $\sim 60 \text{ mW/cm}^2$. The electrolyte used was 0.1M KOH solution.

transfer rate is very low. This fact is suggestive in considering the equivalent circuit diagram.

Impedance characteristics differed from sample to sample, even though they were subjected to the same experimental conditions. All samples studied showed, more or less, a large frequency dispersion in Mott-Schottky plots. Figure 2 shows the Mott-Schottky plots for the same sample (N-GaP 6) as in Fig. 1. The slopes are much smaller than that expected from the doping concentration (a dotted line). Each slope gives nominal large doping concentration: the doping concentrations estimated from the slopes were larger than that specified by the supplier ($5 \sim 7 \times 10^{17} \text{ cm}^{-3}$) by a factor of $30 \sim 50$. Moreover, the intersections of the C^{-2} -V plots with the V axis do not converge to a common point on the V axis.

By replotting the data in Fig. 2, we obtain the Bode plots; Fig. 3 shows the modulus and phase of the impedance against frequency with an external bias as a parameter. Figure 4 shows the pH dependence of the Bode plot for a freshly prepared sample. It is clearly seen that impedance is largely influenced by ionic concentration in the electrolyte. There are two characteristic regions at pH 13 and 1. The slope of the $\log |Z|$ vs. f plot is ~ -1 at low

Fig. 2. Mott-Schottky plots for the same sample as in Fig. 1. Series equivalent capacitance C was plotted. The slope of the dotted line reflects the real doping concentration. The flatband potential is estimated from the turn-on potential in the J - V curve (Fig. 1).

Fig. 3. Bode plots for the N-GaP 6 with an external bias as a parameter.

frequencies where phase angle is ~ 90 , and lower than $-1/2$ at high frequencies where phase angle approaches zero.

Figure 5 depicts the temperature dependence at pH 10.0. After measurements at 70°C , the sample turned deep yellow, implying that the surface structure may change drastically. This fact implies that some sort of decomposition occurs even at dark: elevated temperature promoted the rate of reaction. Figure 5 shows that the Bode plot at 70°C differs from that at low temperatures. As is discussed below, resistance R_s , which characterizes the relaxation time of the interface state, may increase as a result of formation of the surface layer.

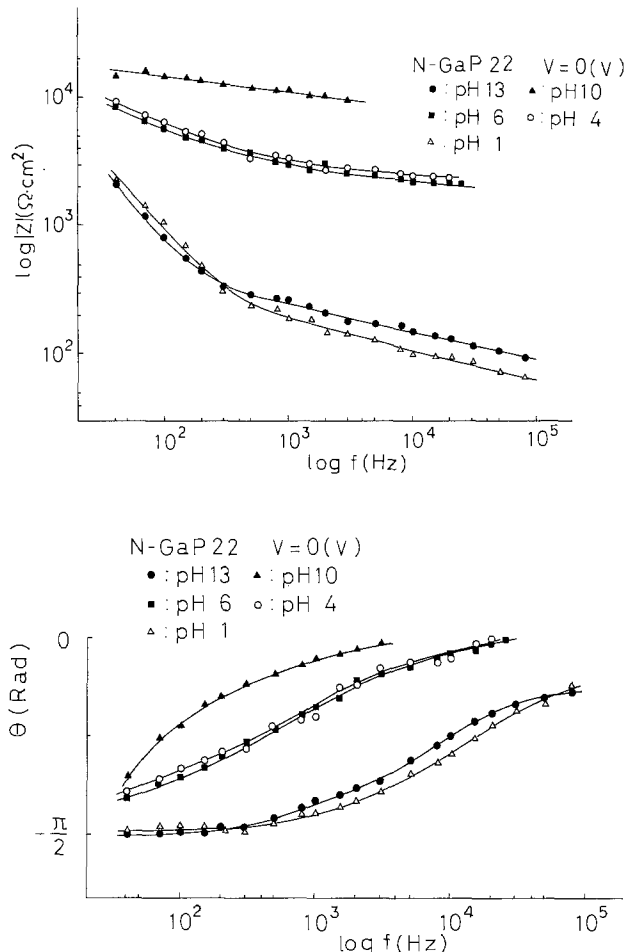

Fig. 4. pH dependence of Bode plots at 0 V vs. SCE for a freshly prepared sample (N-GaP 22).

Fig. 5. Temperature dependence at 0 V vs. SCE and pH 10.0 (N-GaP 22).

Discussion

Impedance measurements offer a useful tool for evaluating a semiconductor electrode. However, interpretation for a Mott-Schottky plot in a semiconductor-electrolyte contact is based on the theory applicable to a metal-semiconductor contact. Any type of capacity in the electrolyte is usually neglected in the equivalent circuit because it is so large. The present results suggest that impedance characteristics in a semiconductor-electrolyte contact cannot be explained, at least in an n-GaP electrode, unless the effects of the electrolyte are taken into consideration.

There have been proposed several possible mechanisms which cause large frequency dispersion in $C-V$ characteristics (14, 15): nonuniform current distribution (due to edge effects, surface roughness, etc.), residual faradaic process, surface states, and the frequency dispersion of the dielectric constant. However, these mechanisms cannot explain, in the authors' opinion, the observed large frequency dispersion which gives one or two orders of magnitude larger (nominal) doping concentration.

One of the authors (G.N.) has proposed a new idea which can explain the above-mentioned phenomenon (16, 17): charging and discharging of the interface states, distributing rather deep into the semiconductor bulk, by ions in the electrolyte cause large frequency dispersion in $C-V$ characteristics. The basic idea is that the interface states are in quasi equilibrium with the Fermi levels of the semiconductor and electrolyte. Figure 2 clearly shows that the conventional interpretation for a dispersive Mott-Schottky plot could not be applicable to our system. Hence, we try to apply the model proposed elsewhere (16, 17): the equivalent circuit as shown in Fig. 6 is considered here. In Fig. 6, the deep interface state, the penetration length of which is 300\AA or more, is assumed; the depletion layer width of our system [$N = 6 \times 10^{17} \text{ cm}^{-3}$, $\epsilon = 10.2 \epsilon_0$ (18)] is typically $200 \sim 300\text{\AA}$ with a band bending of $1 \sim 2 \text{ eV}$.

The assumption of the interface state which distributes in the forbidden gap is rather speculative, but it is possible that the surface structure may be drastically altered by corrosion. In fact, as mentioned above, the sample turned deep yellow after measurements at 70°C , implying that the atomic composition at the surface changed drastically. Elimination of atoms, for example, Ga atoms, from the electrode surface may result in a rearrangement of energy levels: the introduction of new levels into the forbidden gap is likely to occur. The energy level of the interface state is also unknown. The fact that $C^{-2}-V$ plots are dispersive at the very vicinity of the flatband potential implies that the energy level of the interface state may be rather shallow: the level seems to lie just below the bulk Fermi level (17, 19).

In Fig. 6, C_w and R_w are diffusion capacitance and resistance, respectively, while R_t is the charge-transfer

Fig. 6. The equivalent circuit used in the interpretation of the experimental results.

resistance. R_t gives a measure of a rate of charge exchange between the electrolyte and the interface states. Charging and discharging of the interface states by the ions (for example, OH^- or H^+) in the electrolyte can take place as the following reactions: for discharging, electrons must be transferred from the interface state to the electrode surface (R_s), then transferred to the ions (R_t), and finally the reaction products must diffuse away into the bulk of the electrolyte (R_w). The rate-determining step will determine the impedance characteristics.

The product of C_s and R_s shows the relaxation time of charging and discharging of the interface states by ions in the electrolyte. The product of C_{ss} and R_{ss} shows the additional relaxation time of charging and discharging of the interface states by electrons in the semiconductor bulk. This branch becomes effective if the energy level of the interface state is shallow. One may ask if a parallel branch of C_{ss} and R_{ss} might result in large dark current. It is noteworthy here that the interface state has different effects on $C-V$ and $J-V$ characteristics. If we consider the case where anodic dark current is caused by the electron transfer from the electrolyte to the semiconductor bulk via interface states, we must assume a constant and high electron-transfer rate in order to explain large dark current. On the contrary, the limited amount of charges can cause large interface state capacitance C_{ss} , because they only swing to and fro in accordance with the small amplitude ac signal. Relaxation times $R_s C_s$ and $R_{ss} C_{ss}$ are both constant and independent of an external dc bias in the present configuration (19). Observed large frequency dispersion (Fig. 2) implies that both mechanisms might be operative. An equivalent circuit diagram as shown in Fig. 6 predicts quite an interesting phenomenon that the total capacity of that system can exceed the Helmholtz capacity ($50 \mu\text{F}/\text{cm}^2$ or more) if C_w , C_s , and C_{ss} are large. In the present analysis, however, we assume for simplicity that $R_{ss} C_{ss}$ is large enough: electron transfer between the interface state and the semiconductor bulk is assumed to be negligible. This assumption will not alter the following conclusions.

Charge-transfer resistance R_t depends on concentration of electrolyte through the exchange current density i_0 (20)

$$R_t = \nu RT/nF i_0$$

where n and ν are the electrode reaction valence and stoichiometric factor, respectively. R_t is also dependent on temperature because i_0 is determined by a Boltzmann factor. R_t is independent of frequency, if the amplitude of the ac signal is small enough. The diffusion (Warburg) impedance Z_w is typically given by

$$Z_w = R_w (1 - j)$$

where

$$R_w = 1/\omega C_w = RT\nu^2/n^2 F^2 C (2\omega D)^{1/2}$$

with D being the diffusion coefficient. R_w depends on temperature, frequency, concentration, and diffusion coefficient. D is also determined by a Boltzmann factor: D increases and then R_w decreases with temperature. If we assume that $C_H \gg C_L$, then the impedance of our system is given by

$$Z = \frac{1}{j\omega C_L} + \frac{1 + j\omega\tau_{ws}}{j\omega C_{ws} (1 + j\omega\tau_{ws})}$$

where $C_{wsl} = C_1 + C_{ws}$, $C_{ws} = C_w C_s / (C_w + C_s)$, $\tau_{ws} = RC_{ws}$, $\tau_{wsl} = RC_{wsl} / C_{wsl} = \tau_{ws} C_1 / C_{wsl} < \tau_{ws}$, and $R = R_w + R_t + R_s$. Two inflecting points in the Bode plot, f_l and f_h , are given by $1/\tau_{ws}$ and $1/\tau_{wsl}$, respectively.

At low frequencies, $\omega\tau_{wsl} < \omega\tau_{ws} \ll 1$; then we obtain

$$|Z| = \frac{1}{\omega} \left(\frac{1}{C_L} + \frac{1}{C_{wsl}} \right), \quad \theta = -\frac{\pi}{2}$$

If $C_w \gg C_s$, the slope of the $\log |Z|$ vs. f plot will precisely equal -1 . At intermediate frequencies, where $\omega\tau_{wsl} < 1 < \omega\tau_{ws}$, we obtain the following relationships under the assumption of $1/\omega C_L \sim 0$

$$|Z| = \frac{C_{ws}}{C_{ws} + C_1} R; \quad \theta = 0$$

At high frequencies, $1 \ll \omega\tau_{wsl} < \omega\tau_{ws}$,

$$|Z| = \frac{1}{\omega C_1}; \quad \theta = -\frac{\pi}{2}$$

Characteristic features of our system can be found at intermediate frequencies, where $|Z|$ depends on $R = (R_t + R_s) + R_w$; R_t and R_s are independent of frequency, while R_w depends on $\omega^{-1/2}$, and R_t corresponds to a differential resistance. Hence, the assumption that R_t is independent of frequency may be incorrect if the amplitude of the ac signal is large. We assume here that the amplitude of 3 mV rms used is small. Then the slope of a Bode plot at intermediate frequencies may range from 0 to $-1/2$ as typically found in Fig. 4. The inflecting point in Fig. 4 may therefore correspond to f_l ; the higher inflecting point f_h could not be observed in the frequency range used. Considering these situations, we will obtain the schematic Bode plots as shown in Fig. 7. We can see some characteristics in Fig. 7. Charge transfer and diffusion impedance become predominant at low ionic concentrations, so that the resultant Bode plot may show gradual change. At high temperatures or high ionic concentrations, both R_w and R_t become low so that the impedance of the semiconductor electrode becomes comparable with them. The slopes of the Bode plot may range from -0.5 to -1 at low frequencies where R_w and the reactance component of the electrode are comparable (16), and from 0 to -0.5 at intermediate frequencies where R_w and $(R_t + R_s)$ are comparable.

R_s determines the relaxation time of charging and discharging of the interface states. R_s is easily expected to be sensitive to the past history of the electrode. Hence, R_s may differ from sample to sample. Some samples may have large R_s and others small R_s . This may be the reason why the N-GaP 6 (Fig. 3) and N-GaP 22 (Fig. 4) show different impedance characteristics. The inflecting points in

Fig. 7. Schematic Bode plots for the charge-transfer resistance R_t , diffusion resistance R_w , and R_s .

the $\log |Z|$ vs. f plot, f_l and f_h , are also dependent on R_s . Increase in R_s will result in lowering of f_l and f_h . If R_s increases as a result of the formation of the defective surface layer, f_l will disappear and f_h will appear, as typically found in the Bode plot at 70°C (Fig. 5). The surface layer may be formed due to accelerated reaction rate at 70°C.

There are some differences between the present results (for n-GaP) and the preceding ones [n-TiO₂ (16)]. In TiO₂ electrodes, appreciable influences of the charge-transfer resistance R_t on the impedance characteristics could not be found, although the electrolyte used was sufficiently high (1M KOH): the slopes of the Bode plots ranged from -0.5 to -1 , which was explained by considering the diffusion resistance R_w only. The present result suggests that a charge-transfer resistance must also be taken into consideration in interpreting the impedance data, especially at low ionic concentrations.

Conclusions

A computer-aided measuring system enabled us to collect quickly a great number of data. Rather corrosive n-GaP electrodes have shown a variety of interesting C-V characteristics. Temperature and pH dependences of C-V characteristics have clearly shown that the effects of the electrolyte must be taken into consideration in order to explain the impedance characteristics of the electrolyte/n-GaP interface. In the present study, too, we could not find the role of the Helmholtz capacitance. In general, impedance characteristics of the electrolyte-electrode interface are determined by the charge transfer and dielectric response. The latter contributes to the Helmholtz capacitance which is determined by the dielectric constant of the electrolyte. The present result may imply that the impedance characteristics of the electrolyte/n-GaP interface may be controlled by the charge transfer between the electrolyte and intermediates at the electrode surface.

It has been confirmed in some detail that intermediates are certainly formed in the n-GaP electrodes: intermediates are interpreted here as the interface states.

Effect of Trace Elements on Etching of Aluminum Electrolytic Capacitor Foil

K. Arai, T. Suzuki, and T. Atsumi

Showa Aluminum Corporation, Research and Development Laboratory, Sakai, Osaka, Japan

ABSTRACT

An investigation was made as to the effect of trace impurities, particularly bismuth and boron, on etching morphology and capacitance of aluminum electrolytic capacitor foil. It was found that as little as 2 wt-ppm bismuth in foil strongly accelerated surface etching, inhibited tunneling, and consequently lowered capacitance. 3 wt-ppm boron also enhanced surface etching, but lowered capacitance less than bismuth. The reason for these results was considered

Etching of aluminum electrolytic capacitor foil is generally performed in hydrochloric acid (1) or sodium chloride solution (2). The capacitance of aluminum electrolytic capacitors is mostly determined by etching. Since impurities contained in aluminum markedly influence etching, it is essential to control them in order to manufacture excellent aluminum electrolytic capacitor foil. A number of studies (3-12) on the effect of impurities or alloying elements contained in aluminum have been reported.

We have found that trace bismuth or boron in aluminum greatly influenced etching morphology. Herein we report the effect of these elements on etching morphology and capacitance.

Experimental

Sample preparation.—The samples used were three kinds of 99.99% aluminum foils, manufactured by conventional semicontinuous casting, 0.1 mm thick annealed at 823 K for 1h in a dry inert gas (Ar) atmosphere. Table I shows the chemical compositions of these samples. Sample A contains iron, silicon, copper, and 2 wt-ppm bismuth. Sample B contains iron, silicon, copper, and 3 wt-ppm boron, and sample C contains only iron, silicon, and copper. Sample C is the standard. Anodic stripping voltammetry, atomic absorption spectrophotometry, and absorption spectrophotometry were used as the methods to analyze these samples.

Fig. 1. SEM photographs of surface (top row) and cross section (bottom row) after 30s etching. First column: sample A. Second column: sample B. Third column: sample C.

Fig. 2. SEM photographs of surface (top row) and cross section (bottom row) after 630s etching (first and second etching). First column: sample A, capacitance = 1.60 F-V/m². Second column: sample B, capacitance = 1.97 F-V/m². Third column: sample C, capacitance = 2.50 F-V/m².

tion shows, the surface of sample A was dissolved the most, so the foil thickness of sample A was reduced.

At the final etching, these tendencies remained the same. The tunneling density decreased in order from C to B to A. On the other hand, the degree of surface dissolved was decreased in order from A to B to C. Accordingly, the capacitance of sample C was the highest, that of sample B, containing trace boron, was next, and that of sample A, containing trace bismuth, had the lowest capacitance of all samples. In 99.99% Al as electrolytic capacitor material, it was found that trace bismuth and boron in aluminum greatly influenced the etching morphology and capacitance.

Depth profiles by an IMA.—To resolve the existent state of trace bismuth and boron in aluminum, depth profiles were measured by an IMA. Figure 3 shows bismuth depth profiles of sample A containing bismuth and of sample C not containing bismuth addition after annealing at 823 K for 1h. The longitudinal axis in Fig. 2 indicates ion intensity, while the transverse axis indicates sputtering time by Ar ion and the corresponding distance from the oxide-metal interface. The sputtered depth was measured by means of a Talystep instrument (Rand Taylor Hobson Corporation) with maximum resolving power of 0.5 nm. The position of the oxide-metal interface was estimated from the total ion curve because the efficiency of ionization at the oxide layer is much higher than at the aluminum substrate (13). In sample A, the peak of concentrated bismuth is in the aluminum substrate near the oxide layer. However, the peak in sample C was very low. It appears that bismuth atoms are concentrated at the metal-oxide interface by annealing at 823 K for 1h.

Next, bismuth depth profiles at various temperatures were measured to study the behavior of bismuth during annealing. The results are shown in Fig. 4. Reports con-

cerning diffusion of bismuth atoms in aluminum have not appeared, but the study of surface segregation in aluminum-based dilute alloys has been reported (14, 15). It is suggested that solute atoms in a metal are concentrated at the surface by annealing.

Figure 5 shows iron depth profiles of samples A and C. In samples A and C, the iron content is almost the same; the height of the iron peak after annealing at 823 K for 1h is also the same. Iron was concentrated at the metal-oxide interface.

Figure 6 shows magnesium depth profiles of samples A and C. Magnesium was concentrated at the outer surface, unlike iron. This fact agrees with measurements made using Auger spectroscopy (15). In samples A and C, the magnesium content is less than 1 wt-ppm. However, magnesium easily concentrated at the surface by annealing, and there was no difference in the degree of concentration in samples A and C.

Reliable results for the other principal elements, silicon and copper, could not be obtained because of the low sensitivity of the IMA and the existence of interfering elements. The difference of etching morphology between A and C (Fig. 1 and 2) is not due to the concentration of iron and magnesium on the surface.

The grain size of each sample was of about 50-200 μm diam, and there were minimal differences between the samples. The texture of each sample, which affects its capacitance sensitivity, particularly cube texture, developed remarkably. However, the differences of cube texture were minimal.

Therefore, it is thought that the difference in bismuth between samples A and C caused the difference in the etching morphology and capacitance; that is, concentrated bismuth on the surface reacts nobly to aluminum. It was thought that if the surface layer in sample A, which contains much Bi, was removed, then capacitance similar to that of sample C should be obtained. However, we

Fig. 5. Iron depth profiles in (a) sample A and (b) sample C after annealing at 823 K for 1h

Fig. 6. Magnesium depth profiles in (a) sample A and (b) sample C after annealing at 823 K for 1h

Fig. 7. Boron depth profiles in sample B. a: Strong surface etching part. b: Normal homogeneous part after annealing at 823 K for 1h

could not make such a comparison because the etching morphology of the sample when the surface layer was removed, was not uniform and was unlike either of the original samples.

Figure 7 shows boron depth profiles of both the normal etching and the portion of strong surface etching in sample B containing 3 wt-ppm boron. The concentration peak of the portion with strong surface etching was higher than that of the portion with normal etching, and boron was concentrated at the outer surface in both portions, in a manner similar to the behavior of magnesium in aluminum (Fig. 6). It is thought that the difference in surface boron concentration caused the difference in etching morphology.

Effect of Powder Characteristics on Microstructure and Properties in Alkoxide-Prepared PZT Ceramics

R. C. Buchanan* and J. Boy

Department of Ceramic Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

The effects of coprecipitation parameters on agglomerate structure in PZT (53:47) powders prepared from butoxide precursors were studied. Results showed that differences in agglomerate structures developed during coprecipitation persisted throughout subsequent processing steps, and the resulting sintered densities and microstructures to be correlated with the agglomerate structures. Coprecipitation parameters which most significantly affected the powder characteristics included temperature, dilution, pH, and hydrolysis rate (controlled by H₂O concentration). Such processing parameters as powder rinsing, calcination temperature, and spray drying conditions also significantly influenced the developed microstructures. For equivalent processing conditions, the most dense and uniform microstructures were developed with the softer (and smaller) agglomerate structures, achieved from an acid (pH 3.7) medium of low (3-5 volume percent) solids content with rapid hydrolysis (~32 ml H₂O/min) and low temperature rise (10° to 15°C). Measured dielectric constants on the sintered PZT samples were found, generally, to increase with average grain size.

Commercial PZT (lead zirconate titanate) ceramic powders are typically formed from calcined mixtures of oxide or carbonate precursors. Difficulties with mixing often lead to incomplete reactions and localized inhomogeneities in the microstructure of the sintered ceramic. This condition in PZT contributes to a lack of reproducibility in the dielectric properties and aging characteristics and has the effect of limiting PZT use for many critical transducer applications. Consequently, alternate methods for powder preparation aimed at achieving intimate mixing by coprecipitation or by suspension of the oxide precursors in a finely dispersed and highly reactive state have been investigated.

In preparing PZT ceramics, chemical coprecipitation from alkoxide precursors of Zr and Ti has been a widely used technique. Brown and Mazdiyasi (1) used Zr and Ti alkoxide solutions blended with lead isoamyl oxide in distilled water to bring about decomposition and precipitation of the PZT phase. Excess lead oxide in the form of Pb(OR')₂ was added to compensate for Pb loss during sintering. Calcination of the powder at ~500°C for 30-60 min produced the PZT phase.

Haertling and Land (2) prepared high purity PLZT powders from materials consisting of lead oxide (PbO),

* Electrochemical Society Active Member.

lanthanum acetate (La(AC)₃), zirconium tetra-n-butoxide (ZNB), and titanium tetra-n-butoxide (TBT). The procedure consisted of weighing out the proper amounts of PbO and butoxides followed by blending in isopropyl alcohol. Lanthanum acetate solution was then added to the blending mixture which hydrolyzed the butoxides and produced a precipitate of mixed hydroxides, a process which was accelerated by the heat produced in the exothermic reactions.

Modifications to the basic alkoxide process aimed at producing coprecipitated PZT and PLZT with different powder characteristics have been described by many authors (3-6). The coprecipitation process has also been used for adding minor ingredients to PZT compositions, either as sintering aids or for property control. Wittmer and Buchanan (7) achieved significant reduction in the densification temperature of PZT (53:47) by incorporation of up to 1 weight percent (w/o) V₂O₅ during coprecipitation. The as-dried coprecipitated powders were found to be x-ray amorphous, but powders calcined as low as 350°C produced XRD patterns characteristic of tetragonal PZT, with only slight lattice distortion. More recently, Tuttle (8) coprecipitated powders of PSZT + Nb₂O₅ using a process similar to that employed by Wittmer and Buchanan (7). PbO, SnO₂, and Nb₂O₅ were added to the

blending mixture of TBT and ZNB. A 4:1 alcohol:water solution was used as the precipitating agent and superior dielectric properties were reported for the fired coprecipitated powders. Fired densities between 92.4% and 95.6% theoretical were obtained by firing at 1380°C using a standard double-crucible technique.

From the reported work, it is evident that much sensitivity attaches to the alkoxide precipitation process, when such parameters as pH, dilution, dispersion, temperature, and method of hydrolysis of the butoxide mixtures are considered. These parameters greatly affect agglomerate cohesion and size distribution in the precipitated powders (9). The effects of postprecipitation processing—washing, drying, calcination, dispersion, pressing—on powder characteristics and final densification have also been explored and were found to significantly influence the final densities and microstructures achieved (6-8).

The object of this study, therefore, was to investigate the relative influence of the coprecipitation and processing parameters on the powder characteristics, final densification, microstructure, and dielectric properties of sintered PZT ceramics.

Experimental

The PZT composition chosen for this study was $\text{Pb}(\text{Zr}_{0.53}\text{Ti}_{0.47})\text{O}_3$. This composition is near the morphotropic phase boundary for the PbZrO_3 - PbTiO_3 system and is known to give optimum permittivities and coupling coefficients (10, 11). The powders were prepared by coprecipitation from starting high purity materials of electronic-grade PbO (Hammond Lead Products, Incorporated, Hammond, Indiana), tetra-n-butyl titanate (E. I. du Pont de Nemours, Incorporated, Wilmington, Delaware), and zirconium tetra-n-butylate (Dynamite Nobel Company, Norwood, New Jersey).

Initially, a modified version of Wittmer's (7) coprecipitation procedure was used. This procedure had only one blending step during coprecipitation and was termed the "single-step" process. It was modified such that the precipitated slurry was filtered in a Buchner funnel to speed dewatering and washing of the precipitate. The coprecipitation procedure consisted of: (i) mixing the stoichiometric amounts of PbO, TBT, and ZNB (200g batch) in a blender at medium speed for about 15 min, (ii) adding a precipitating solution consisting of deionized water (30-100 volume percent [v/o]) in isopropanol (~250 ml of solution for a 200g batch; pH ~5.0), (iii) blending the thickened mixture for ~15 min until a smooth slurry was obtained, (iv) filtering the slurry using a Buchner funnel with solvent washing as appropriate, and (v) drying the washed powder in a vacuum oven at 150°C for 4h.

With this single-step blending, a significant rise in the temperature (85°-95°C) and viscosity of the mixture occurred, which made it difficult to maintain fluid mixing. To eliminate these problems, the process was further modified by diluting the batch with additional alcohol and using a two-step procedure which separated the coprecipitation and blending processes. This two-step coprecipitation procedure may be detailed as follows. First, to 200 ml of a 50/50 solution of isopropanol and n-butyl alcohol in a polyethylene beaker was added, while magnetically stirring, 85 ml of a mixture of Ti and Zr butoxides and PbO, calculated to give a 50g batch of (53:47) PZT composition. A wetting agent, Darvan C (~5 drops) was also added to aid dispersion. Second, 200 ml of the water/isopropanol solution (to which glacial acetic acid or ammonium hydroxide was added for pH control) was added at 40-60 ml/min to cause precipitation of the mixed oxides. Third, after stirring an additional 10 min, the precipitated mixture was transferred to a high speed blender and blended for 15 min to produce a smooth, relatively stable slurry. Fourth, the blended slurry was then directly spray dried using a laboratory spray drier (Buchi Model 190, Brinkman Instrument Company) or else was washed and vacuum dried as described.

Several parameters in the coprecipitation process for lead zirconate titanate prepared from the butoxide pre-

cursors were investigated. These included the percentage of water, the rate of addition, and the pH of the precipitation solution. Also investigated were the solids content of the PbO and butoxide mixtures, the blending process, the temperature rise during coprecipitation, and the washing of the precipitate with different solvents. In evaluating the above parameters, the following ranges were used: concentration of suspended solids ranged from 2.0 to 7.0 v/o; water content of the precipitating water/alcohol solution varied from 25 to 100 v/o (12.5-49 v/o total liquid content) and was added at the rate of 6 to 60 ml/min. The pH range studied varied from 3.0 to 12.0, while the temperature rise during coprecipitation ranged from 10° to 15°C (two-step blending) to 70°C for the single-step process. Where vacuum drying was used, washing of the filtrate was carried out using deionized water, isopropanol, or a 60 v/o isopropanol mixture of the two solvents.

Calcination of the spray- or vacuum-dried precipitated powders was carried out in open platinum crucibles at 600°-850°C, to develop the PZT phase and promote grain growth. The calcined powder was milled for 5h in polyethylene jars using ZrO_2 grinding media. A 60/40 v/o isopropanol/water solution with Darvan C dispersant was found to be the most effective milling medium. A binder solution consisting of 1.0 w/o polyvinyl alcohol in water was added for the final hour of milling. The milled slurry was spray dried, and pellets ~1.6 cm diam and 0.3 cm thick were uniaxially pressed at 207 MPa. The pressed pellets were sintered on Pt foil supported on ZrO_2 setters at 1280°C/4h using the standard double crucible technique of Okazaki *et al.* (4) or in air at 950°C/1h (for samples containing 0.5 w/o V_2O_5 as flux additive) (7).

The spray-dried, vacuum-dried, and calcined powders as well as crushed sintered samples were analyzed by x-ray diffraction, using a Phillips Norelco diffractometer with filtered Ni K_α radiation at 40 kV and 10 mA filament current, at a scanning rate of 1° 2 θ /min. The powders were also subjected to DTA and TGA analysis using a thermal analysis system (du Pont 1090). Particle size distribution measurements were made using an x-ray sedimentation analyzer (Micromeritics) and surface area measurements by a BET technique. SEM analysis on powders and sintered sections were made using an ISI-DS-130 scanning electron microscope equipped with an energy dispersive x-ray analyzer. Sample densities were measured by water and mercury immersion techniques. Dielectric constant and dissipation factor measurements were made at 1.0 kHz using a capacitance bridge. Poling of the samples proved to be difficult with the smaller average-grain-sized samples.

Results and Discussion

Figure 1 shows SEM photomicrographs for the dried, as-precipitated powders prepared by the one- and two-step blending processes. Both powders were precipitated from acid medium of pH = 5. With the single-step process (Fig. 1a), the morphology of the precipitated powders appeared to consist of hard, nearly dense agglomerates within the size range 2-5 μm . Reed *et al.* (12) differentiated between soft and hard agglomerates (aggregates), the latter being postulated to be held together by chemical or diffusion bonds, compared to soft agglomerates, which are believed to be bonded by van der Waal's bonds or by magnetic forces. In contrast to the single-step process, powders prepared by the two-step blending (Fig. 1b) gave soft agglomerates in the size range 1-4 μm . These powders also showed a distinct subagglomerate structure with cluster sizes of ~0.1 μm . These differences are illustrated in Fig. 2, which shows agglomerate size distributions for the PZT coprecipitated powders as a function of pH and blending process. Significantly larger size distributions were measured with the single-step blending process at equivalent pH (8.5), confirming the trend noted in Fig. 1. Agglomerate size distributions also increased with pH for the same blending process.

The striking difference in morphology between the two powders in Fig. 1 and 2 can be attributed to the more

Fig. 1. SEM micrographs of "as-precipitated" powders comparing precipitating procedures: a: One-step. B: Two-step blending processes.

highly dispersed state, greater fluidity, and lower temperature of the two-step blending process. As indicated for the single-step process, there was difficulty in maintaining homogeneous mixing during coprecipitation due to gelation of the mixture and the high temperatures ($\sim 90^\circ\text{C}$) experienced during the hydrolysis reaction. With the diluted mixture used in the two-step process, the maximum temperature experienced was approximately 40°C . This lower temperature would be expected to slow

Fig. 2. X-ray sedigraph plot of agglomerate size distribution for coprecipitated PZT powders as a function of pH and blending process.

the hydrolysis reaction (13), and, as pointed out by Yoldas (14), dilution of the reacting species with neutral solvents also slows the reaction rate and enhances the uniformity of the hydrolysis reaction throughout the system. In contrast to the present finding where hard agglomerates were obtained at the higher precipitating temperatures ($85^\circ\text{--}95^\circ\text{C}$), work by van der Graaf *et al.* (15) revealed that ZrO_2 powders precipitated at room temperature yielded harder agglomerates than powders precipitated at higher temperatures ($\sim 100^\circ\text{C}$), which yielded the softer agglomerates.

The effect of water content and rate of addition on the amorphous character of the precipitated powders, as determined by x-ray diffraction analysis, is illustrated in Fig. 3. Water contents of 33 and 67 v/o in the precipitating alcohol/water solutions were equivalent to 16 and 33 v/o of the total liquid content. Rates of water addition, as indicated, varied from 5.5 to 22 ml/min. The x-ray diffraction patterns for the dried precipitated powders were characterized by the presence of an amorphous hump, confirming the very small crystallite size of the powders and the absence of a clearly distinct PZT phase. Superimposed on the amorphous hump were crystalline diffraction peaks of unreacted PbO. The intensities of these peaks decreased with increasing hydrolysis (water content and addition rate), in line with the completely amorphous powders reported by Brown (1), Haertling (16), and Wittmer (7). Calcination of the powders at $800^\circ\text{C}/4\text{h}$ gave only the PZT phase.

Harder and somewhat larger agglomerates were evident in the precipitates formed from low water content solutions due to the higher temperatures experienced. Differences in the precipitated agglomerate structures were also retained throughout subsequent processing. This is illustrated in Fig. 4, where SEM fracture micrographs of calcined ($800^\circ\text{C}/4\text{h}$), pressed (207 MPa) but unfired samples are compared with fired ($950^\circ\text{C}/1\text{h}$), polished, and thermally etched sections for powders precipitated with 25 and 67 v/o H_2O in the precipitating solution. The bimodal cluster and grain size distribution obtained with the 25 v/o H_2O solutions were in sharp contrast to the smaller clusters and uniform grain sizes obtained with the 67 v/o H_2O precipitate. These microstructures would not be predicted from the respective pressed (5.0 vs. 4.4 g/cm^3) and fired (7.5 vs. 7.8 g/cm^3) densities for the two powders (25 vs. 67 v/o H_2O). Coprecipitated powders sintered at $1280^\circ\text{C}/4\text{h}$ (without V_2O_5 additions) showed essentially the same trends.

DTA heating and cooling curves for the water- and/or alcohol-rinsed coprecipitated powders are presented in Fig. 5. The DTA analyses showed exothermic reaction

Fig. 3. X-ray diffraction patterns showing decrease in unreacted PbO content of "as-precipitated" PZT powder with increasing H_2O content and faster addition rate of the precipitating solution.

Fig. 4. SEM photomicrographs of fracture surfaces of unfired PZT (single-step process) samples from precipitating solutions containing the following: A: 25 v/o H₂O. B: 67 w/o H₂O (pH 5). C: Fired (950°C/1h), polished, and thermally etched photomicrographs of A and B shown in C and D, respectively.

peaks occurring at approximately 200°, 300°, and 530°C. TGA analysis showed the first two peaks to be associated with weight losses, the maximum losses occurring near 300°C, and all weight loss occurring below ~400°C. The peaks were attributed respectively to loss of residual alcohol, elimination of the butoxide decomposition products, and formation of the PZT phase. Rinsing with H₂O suppressed the exothermic peaks at ~200° and 300°C, in contrast to rinsing with (isopropyl) alcohol, which enhanced the lower peak and shifted the second peak to a higher temperature. With no rinsing of the precipitate, the peak at 300°C was disproportionately larger, consistent with a higher content of organic residues.

In terms of densification, the H₂O-rinsed powders gave significantly lower fired densities (~91% ThD) compared the alcohol/water rinsed with (~96% of ThD), with isopropanol-washed samples intermediate at 95% ThD. The

Fig. 5. Differential thermal analysis curves comparing washing media: isopropanol, water, and isopropanol/water solution.

base density for PZT (53:47) was taken as 8.0 g/cm³. These observations are consistent with fired densities obtained by Haberko (17) on water- and alcohol-washed stabilized ZrO₂ powders. The differences were attributed to the weaker bonded agglomerates formed with alcohol-washed powders as a result of reduced surface ionic absorption.

Figure 6 shows the effect of pH on the agglomerate structure of the "as-precipitated" powders following initial spray drying. The acid powder (pH 3.7) had an average agglomerate size of ~5 μm with a well-defined sub-agglomerate structure. In contrast, the basic powder (pH 11) had an average agglomerate size of ~10 μm, appeared harder, and had a less distinct substructure. The increase in the agglomerate size for the basic powders was confirmed by the sedigraph analysis shown in Fig. 7. The powders precipitated by the pH 3 solution had an average agglomerate size of ~0.5 μm, which increased to ~0.9 μm for the pH 10 solution with a narrower size distribution. The difference in average size distribution between the SEM and sedigraph data was due to the partial breakup of the spray-dried agglomerates by addition of a defloculant and by mechanical dispersion during the sedigraph tests.

Figure 8 shows SEM fracture micrographs for sintered (1280°C/4h) samples of the two powders discussed in Fig. 6. The pH 3.7 powders, which had a uniform pressed microstructure, yielded a very dense microstructure and smaller average grain size (~10 μm) than the pH 11 sample (~20 μm avg GS). Both samples were calcined at 800°C/4h, which throughout this study generally resulted

Fig. 6. SEM photomicrographs of precipitated powders following drying for precipitation conditions of pH 3.7 (A) and pH 11 (B).

Fig. 7. Agglomerate size distribution of precipitated PZT powders showing effect of pH on equivalent spherical diameters.

in larger grain sizes for the basic powders. The grain-size disparity was in line with the size disparity and hardness of the agglomerated structures formed during coprecipitation of the powders. Transgranular and intergranular cracks were observed, particularly for the larger grain-sized sample due in part to microcracks introduced by quenching to prevent accumulation of liquid phase on the sample surface.

BET surface areas determined for the two powders were $132 \text{ m}^2/\text{g}$ (pH = 3.7) and $128 \text{ m}^2/\text{g}$ (pH = 11) compared to the $26 \text{ m}^2/\text{g}$ reported by Biggers *et al.* (6) for PZT pow-

Fig. 8. SEM photomicrographs of fracture surfaces of fired ($1280^\circ\text{C}/4\text{h}$) PZT for precipitation conditions as follows. A: pH 3.7. B: pH 11. Both calcined at $800^\circ\text{C}/4\text{h}$.

ders precipitated from aqueous medium. This difference reflects the more highly dispersed conditions prevailing during the coprecipitation process. The large surface area also reflected the very small crystallite sizes ($\sim 150\text{-}200\text{\AA}$) of the precipitated powders. The pH, therefore, did not greatly affect crystallite size formation; rather, it affected agglomeration tendency and bonding within the structures formed.

This difference in agglomeration tendency caused marked differences in powder morphology on calcination. Figure 9 shows SEM fracture micrographs of calcined powders following spray drying, a second milling, and pressing at 207 MPa. For the powders calcined at $800^\circ\text{C}/4\text{h}$, (Fig. 9a, 9b), the aggregates for the pH 3.7 powders were readily broken up after milling but were solidified or essentially sintered for pH 11 powders, indicating the formation of much harder agglomerates in the basic powder during coprecipitation. In general, powders calcined at $750^\circ\text{C}/4\text{h}$ (Fig. 9c, 9d) gave smaller and more uniform aggregate sizes, but always larger for the basic powders.

Figure 10 shows SEM fracture micrographs of the sintered ($950^\circ\text{C}/4\text{h}$) samples for the pH and calcination conditions detailed in Fig. 9. The effect of pH and calcination conditions on the pressed and fired densities are shown in Fig. 11. Densities obtained for the pH 3.7 and 11 powders were similar for equivalent calcination and sintering conditions, but were lower for other pH values. Powders calcined at $750^\circ\text{C}/4\text{h}$ gave highest densities for both pH conditions.

The existence of density maxima at pH 3.7 and 11.0 in the densification curves coincides with the observed stability maxima, as a function of pH, for colloidal suspensions of oxide materials such as SiO_2 . At the lower pH values (2.5-3.5), the particles have very little ionic charge, and stability is maintained by a hydration layer surrounding each particle rather than by electrostatic repulsion. Dried solutions of such acid pH powders, therefore, tend to be bonded by van der Waals forces and, in consequence, are softer and less agglomerated. In contrast, in the pH range 9-11, electrolyte presence causes develop-

B: pH 11, calcined $800^\circ\text{C}/4\text{h}$. C: pH 3.7, calcined $750^\circ\text{C}/4\text{h}$. D: pH 11, calcined $750^\circ\text{C}/4\text{h}$.

Fig. 10. SEM photomicrographs of fracture surfaces of fired ($950^{\circ}\text{C}/1\text{h}$) PZT + 0.25 w/o V_2O_5 obtained for precipitation and calcination conditions in Fig. 9. A: pH 3.7, calcined $800^{\circ}\text{C}/4\text{h}$. B: pH 11, calcined $800^{\circ}\text{C}/4\text{h}$. C: pH 3.7, calcined $750^{\circ}\text{C}/4\text{h}$. D: pH 11, calcined $750^{\circ}\text{C}/4\text{h}$.

ment of net charges on the particle surfaces and stability is maintained by electrostatic repulsion (19, 20). Dried solutions of high pH, therefore, tend to be more strongly bonded, resulting in larger and harder agglomerate structures. These observations are in keeping with the observed agglomerated states as a function of pH for the precipitated PZT powders, and suggest a state of maximum dispersion for the pH 3.7 and 11 suspensions. This, in turn, would lead to higher packing and sintered densities, and to the marked differences in the grain size and microstructures noted.

The average grain size for the powders calcined at 800°C increased, following sintering at $950^{\circ}\text{C}/1\text{h}$, from 0.3 to 1.9 μm for the pH 3.7 powders (Fig. 9 and 10) and from 1.0 to 2.3 μm for the pH 11 powders. For the powders calcined

Fig. 11. Effect of pH of precipitating solution on the pressed and fired densities ($950^{\circ}\text{C}/1\text{h}$) of PZT (+0.25 w/o V_2O_5).

at 750°C , the average grain size increased from 0.25 to 3.9 μm for the pH 3.7 powder, and from 0.5 to 1.7 μm for the pH 11 powder. The data show densification and grain growth rates to be significantly enhanced for the lower temperature ($750^{\circ}\text{C}/4\text{h}$ vs. $800^{\circ}\text{C}/4\text{h}$) calcined powders, reflecting the higher driving force for densification with the smaller-sized aggregates with the liquid phase-assisted sintering. Grain sizes and final microstructures developed were much influenced by the calcination conditions, reported also by Venkataramani and Biggers (18), but, significantly, also by the powder morphology developed, as a function of pH, during coprecipitation from the alkoxide precursor mixtures. With close control of the coprecipitation parameters (especially pH) combined with manipulation of the calcination conditions, therefore, controlled microstructures in sintered PZT can be achieved (at least under conditions of low temperature liquid phase-assisted sintering), which would lead to improved reproducibility of dielectric properties and aging characteristics.

Table I gives grain size and dielectric property data for the samples shown in Fig. 10 with sintered densities $\geq 95\%$ theoretical density. Measured dissipation factors were $< 2.0\%$ and dielectric constants were in the range 700-1000 at 25°C , in line with reported values for PZT (21). The increase in dielectric constant noted with grain size is similar to that reported by Okazaki (22) for small grain size ($< 4 \mu\text{m}$) PLZT samples. The observed increase in dielectric constant with grain size can be attributed to a volume decrease in the more insulating boundary phase as well as to a measured increased conduction and ease of polarization of the larger grains. This is further illustrated in Fig. 12, which compares the dielectric constant as a function of temperature for the nonfluxed PZT samples in Fig. 8 (sintered at $1280^{\circ}\text{C}/4\text{h}$) for pH conditions 3.7 and 11.0. These samples showed a marked increase in dielectric constant with average grain size in the range 10-20 μm . This is in contrast to the reported decrease in dielectric constant with grain size by Webster (23) and also by Haertling (16). For both samples in Fig. 12, loss tangents up to $\sim 200^{\circ}\text{C}$ were below 2.0%, but increased sharply on approach to the Curie points ($\sim 394^{\circ}\text{C}$). The dielectric constants also increased almost linearly up to $\sim 250^{\circ}\text{C}$ and attained values $> 10,000$ at the Curie points. The marked differences in dielectric constants between the two powders indicated the sensitivity of the final microstructure and properties to initial powder characteristics.

Conclusions

1. This study has shown that in the coprecipitation of PZT from butoxide precursors, such powder characteristics as amorphous structure, agglomerate cohesion (hardness), and size distribution were established during the coprecipitation process. Differences at this level tended to persist throughout subsequent processing, resulting in significantly different microstructure and properties.

2. The parameters which most sensitively affected coprecipitation were found to be dilution, pH, temperature, and precipitation or hydrolysis rate (controlled by H_2O addition). Low solids constant ($\sim 3\text{-}5$ v/o PbO), low temperature rise ($< 15^{\circ}\text{C}$), acidic pH ($\sim 3\text{-}4$), and high precipitation rates (25-32 ml $\text{H}_2\text{O}/\text{min}$) were found to promote

Table I. Effect of pH and calcination temperature on grain size and dielectric property of PZT

pH	Calcination (temp./t)	Grain size (μm)	Dielectric constant	Percentage disp. factor
3.7	$800^{\circ}\text{C}/4\text{h}$	1.9	760	1.2
11.0	$800^{\circ}\text{C}/4\text{h}$	2.3	880	1.0
3.7	$750^{\circ}\text{C}/4\text{h}$	3.9	930	1.1
11.0	$750^{\circ}\text{C}/4\text{h}$	1.7	700	2.0

Sintering temp: $950^{\circ}\text{C}/1\text{h}$. Dielectric data at 25°C .

smaller and more uniformly sized agglomerates. These conditions were readily achieved in the two-step blending process described.

3. As both a milling and washing medium, isopropanol/water solution (60/40 v/o) was found to promote higher fired densities and more uniform microstructures.

4. Calcination temperature and spray drying of dispersed powders were found to be important processing variables. Lower calcination temperatures were required with the basic powders to achieve equivalent microstructures.

5. Grain sizes and dielectric constants obtained with the basic (pH 11) powders were generally larger, particularly at the higher (800°C) calcination temperatures.

ABSTRACT

The radiation-induced reactions of chloromethylstyrene-based resist materials are studied by low temperature ESR and gas chromatography-mass spectrometry (GC-MS) analyses using low molecular model compounds. Low temperature ESR analyses indicate that main radiation-induced active species in the initial stage of the reaction are benzyl radicals formed through chlorine removal from chloromethylstyrene units and simultaneously produced active chlorines. The amount of the α radicals formed through α -hydrogen cleavage is less than one-tenth that of the benzyl radicals. GC-MS analyses indicate that large amounts of α radicals are produced through the subsequently occurring hydrogen abstractions by radiation-induced active chlorines. The susceptibilities of individual constituents to hydrogen abstractions are determined as 6.2 for a methylstyrene unit, 2.6 for a styrene unit, and 1 for a chloromethylstyrene unit.

Chloromethylstyrene-based resist materials, such as chloromethylated polystyrene (CMS) (1) and chlorinated poly(vinyltoluene) (CPMS) (2), provide high etch resistance to plasma and ion beams, as well as excellent resolution and high sensitivity to radiation, which are required for electron beam and deep-UV lithographies.

Gokan *et al.* explained etch resistance of metal-free organic materials under ion beam etching conditions in terms of the carbon content in a polymer (3). As for resolution, there is no rule to determine resolution capability, because resolution in cross-linking negative resists is largely influenced by swelling during development process. Recently, the radiation-induced reactions of these resist materials have been studied in order to understand high sensitivity obtained in these resists.

Tagawa *et al.* studied the reaction mechanism for polystyrene, poly(α -methylstyrene), and their chloromethyl derivatives by pulse radiolysis and laser flash photolysis (4). In their study, reactive intermediates in the cross-linking reaction were detected and the reaction mechanism was discussed from the viewpoint of transient phenomena. Harita *et al.* studied the photolysis of benzylchloride in toluene and cummene by deep-UV radiation at 313 nm as a model photochemical reaction for chlorinated poly(vinyltoluene) (5). However, the reactions taking place on individual units of a polymer in these resist materials have not been clarified yet, because they are polymeric systems.

In the present study, the radiation (deep UV and ^{60}Co γ -ray) induced reactions of chloromethylstyrene-based polymers have been studied on the basis of the radiolysis of low molecular model compounds, *i.e.*, isopropylbenzene (IPBZ) for a styrene unit, 4-methylisopropylbenzene (4-MIPBZ) for a vinyltoluene unit, and 4-chloromethylisopropylbenzene (4-CMIPBZ) for a chloromethylstyrene unit, with the intention of clarifying the reactions occurring on individual units of a polymer. Low temperature ESR analyses have been carried out to trap the radiation-induced free radicals and to determine their production yields from individual constituents in the initial stage of the reaction. Gas chromatography-mass spectrometry (GC-MS) analyses have been carried out to detect final products and to determine their relative yields. The susceptibilities of individual constituents to hydrogen abstractions by radiation-induced active species were determined from the relative final product yields. The whole features for the reaction of these resist materials are discussed in detail.

*Electrochemical Society Active Member.

Experimental

Chemicals.—Isopropylbenzene (IPBZ), 4-methylisopropylbenzene (4-MIPBZ) and 4-chloromethylisopropylbenzene (4-CMIPBZ) (*ca.* 15% *ortho*-form) were purchased from Tokyo Kasei Company and purified by distillation under reduced pressure (bp 39°C/11 mm Hg, 67°C/14 mm Hg, and 68°C/3 mm Hg, respectively). These compounds are suitable as low molecular model compounds, although they have no β -hydrogen, because β -hydrogen is not sensitive to radiation as compared with α -hydrogen (4, 6).

Methods.—Electronic absorption measurements were carried out using a Cary Model 14 recording spectrophotometer and 1 cm optical pathlength quartz absorption cells. Spectrograde ethanol was used as a solvent without further purification. The concentration of sample solutions was 10^{-3}M .

For ESR study, a JEOL JES-FE X-band spectrometer (100 kHz modulation) equipped with an ESC-10 NP cavity (Echo Electronics) was used. Irradiation was performed using an Original Hanau D₂ lamp (466 $\mu\text{W}/\text{cm}^2$) for 20 min *in vacuo*. All measurements were carried out at 77 K.

For GC-MS study, a Shimadzu AUTO GC-MS 9020 DF spectrometer equipped with a TIC GC detector and a Silicon GE SE-30 (5% on chromosorb W AW DMCS) (3 \times 2 mm) column was used. Samples (0.1 microliter) were introduced, and the column temperature was retained at 70°C for 4 min and then raised to 230°C at a rate of 8°C/min. Irradiation was carried out with a ^{60}Co γ -ray irradiation machine (4.81 \times 10⁵R) for 80h or with a Canon PLA-521 aligner equipped with a 250 Cold Mirror (40 mW/cm²) for 50 min. The relative product yields were determined by the integrated intensities of signals, assuming that ionization efficiencies are the same for all the compounds studied here.

Results

Electronic absorption spectra.—Electronic absorption spectra of the low molecular model compounds are shown in Fig. 1. Substituents, such as methyl and chloromethyl groups, enhance the optical density in the range of 260–280 nm. The chloromethyl group also enhances the optical density shorter than 260 nm; on the other hand, the methyl group decreases the optical density in these regions. From these electronic absorption spectra, UV light around 250 nm wavelength was used as a deep UV irradiation source.

ESR analyses.—In the initial stage of the reaction, low temperature ESR is an effective method for use in de-

Fig. 1. Electronic absorption spectra of isopropylbenzene IPBZ, 4-methylisopropylbenzene 4-MIPBZ, and 4-chloromethylisopropylbenzene 4-CMIPBZ.

detecting radiation-induced free radicals and in determining their amounts. ESR spectra measured at 77 K after being irradiated with deep UV are shown in Fig. 2. Some comments are given for individual compounds below.

IPBZ and 4-MIPBZ.—Both compounds showed the same featureless singlet signal of 1.7 mT width (Fig. 2c). This signal is assigned to the radical produced on the α position through α -hydrogen removal by radiation (this type radical is hereafter abbreviated as Alpha, see Fig. 3). GC-MS analyses using IPBZ or 4-MIPBZ, where Alpha products were mainly formed, indicate that the assignment of the observed signal is reasonable. However, the signal observed was somewhat different from that of irradiated polystyrene, *i.e.*, it did not show the hyperfine splittings (7). The assignment of the signals observed after being irradiated in the case of polystyrene has not been sufficiently completed and remains in an area of active research.

4-CMIPBZ.—This compound showed the same spectrum as that of CMS films (Fig. 2a and 2b) after being irradiated at 77 K. This fact indicates that 4-CMIPBZ is suitable as a low molecular model compound for a chloromethylstyrene unit.

The observed spectrum of 4-CMIPBZ (Fig. 2b) is not assigned to one radical, because the observed hyperfine splittings are not interpreted as the signal arising from one radical. In order to analyze the observed spectrum, experiments were carried out in mixtures of IPBZ or 4-MIPBZ with carbon tetrachloride. These experiments were conducted to study the interaction between

Fig. 2. Low temperature ESR spectra of deep-UV-irradiated samples. Solid line: observed spectra. Dot-dashed and dashed lines: simulated spectra.

Fig. 3. Formulas for produced radicals

radiation-induced active chlorines and the model compounds. The mixtures showed a 1:4:6:4:1 quintet-featured signal (hyperfine splitting, 1.4 mT) (Fig. 2d), while carbon tetrachloride itself showed a singlet signal of 3.0 mT width (Fig. 2e). Thus, it is concluded that the quintet-featured signal is also formed through the interaction with radiation-induced active chlorines, in addition to the signal of a radiation-induced free radical.

Based on the conducted experiments mentioned above, the observed signal was analyzed using the 1:4:6:4:1 quintet signal and the gaussian-type singlet signal, with varying their signal strength and the singlet signal width so as to simulate the observed spectrum. Consequently, the observed spectrum was explained as a broad singlet signal (dot-dashed line in Fig. 2) of 4.4 mT width and a small quintet signal (dashed line). The deconvoluted main broad signal (dot-dashed line) is assigned to the radical formed through chlorine removal from a chloromethyl group (this type radical is hereafter termed "Benzyl," see Fig. 3). Bridge observed only a broad singlet signal of 4.6 mT width from γ -irradiated toluene at 77 K and assigned it to the benzyl radical (8). The obtained result is in good agreement with his result.

From these ESR analyses, the radicals produced by radiation in the initial stage of the reaction are found to be Benzyl generated from chloromethyl substituted constituents, and Alpha from the other substituents. From the integrated intensities of measured ESR signals (Fig. 2b and 2c), the amount of Benzyl produced through chlorine removal from 4-CMIPBZ is found to be ten times larger than that of Alpha produced through α -hydrogen removal from IPBZ or 4-MIPBZ. As a result, in the initial stage of the reaction, the main active species induced by radiation in chloromethylstyrene-based resists are Benzyl and simultaneously produced active chlorines, while Alpha is negligibly little.

GC-MS analyses.—The reactions of chloromethylstyrene-based resist materials, which take place on individual constituents of a polymer, have not been clarified sufficiently, because they are polymeric systems. GC-MS analyses using low molecular model compounds of which chemical structures are close to the repeating units of polymers can give us the information on the final products and their relative yields to clarify the reactions of individual constituents.

Final products from CMS model compounds.—CMS resist materials are composed of styrene and chloromethylstyrene. Thus, mixtures of IPBZ and 4-CMIPBZ can be used as model systems for them.

Measured GC gas chromatograms for a mixture of IPBZ (1 mol) and 4-CMIPBZ (1 mol) after being irradiated with deep UV are shown in Fig. 4. The signals of the final products formed were assigned by MS analyses.

The measured chromatograms show somewhat complicated features due to the isomers that result from *ortho*-, *meta*-, and *para*-CMIPBZ forms. The final products are classified into three groups. The first group products, [6], [12], and [14], are formed through the recombination of Alpha produced from IPBZ and CMIPBZ. The second group products, [10], [11], are formed through the recombination of Benzyl produced from CMIPBZ. The third

Fig. 4. Gas chromatograms for a deep-UV-irradiated mixture of isopropylbenzene IPBZ (1 mol) and 4-chloromethylisopropylbenzene 4-CMIPBZ (1 mol).

group products, [7, 8, 9] and [13], are formed through the recombination of Alpha and Benzyl. The product [3] is formed through the hydrogen abstractions by Benzyl [Bockrath *et al.* have recently reported in detail on hydrogen abstractions by benzyl radicals (9)].

Figure 5 shows production yields for the mixture (1:1 molar ratio) as a function of deep-UV irradiation time. Nonlinear parts were observed in the products [3] and [7, 8, 9]. This is because these products are formed through a thermally induced reaction, when mixtures were introduced into a GC-MS spectrometer for analyses, as well as through a radiation-induced reaction. In order to understand the thermally induced reaction, experiments were carried out on nonirradiated samples. The products [3] and [7, 8, 9] were produced thermally from nonirradiated mixture samples; on the other hand, the other products were not produced thermally. However, each compound was thermally stable and no change could be observed when it was introduced into a GC-MS spectrometer. An explanation for this phenomenon might be an intermolecular interaction between IPBZ and 4-CMIPBZ. The relative product yields were determined from the linear parts by excluding the parts of the thermally induced products.

The mixtures were also subjected to ^{60}Co γ -ray radiation for 80h. This radiation dose is estimated to be $20 \mu\text{C}/\text{cm}^2$ in electron-beam radiation using the depth-dose function (10). The main spectrum features were almost the same as those observed in deep-UV radiation. This indicates that the γ -ray radiation-induced reaction in this system is almost the same as the deep-UV-induced reaction.

Final products from CPMS model compounds.—A resist material obtained by chlorination of anionically prepared poly(vinyltoluene) (CPMS) has more than four types of units (5, 11). However, the main constituents are vinyltoluene and chloromethylstyrene. Thus, mixtures of 4-MIPBZ and 4-CMIPBZ can be used as model systems for this resist.

Fig. 5. Irradiation time dependences of production yields in a deep UV-irradiated mixture of isopropylbenzene IPBZ (1 mol) and 4-chloromethylisopropylbenzene 4-CMIPBZ (1 mol).

Fig. 6. Gas chromatograms for a deep UV-irradiated mixture of methylisopropylbenzene MIPBZ (1 mol) and 4-chloromethylisopropylbenzene 4-CMIPBZ (1 mol).

Measured GC chromatograms for a mixture of 4-MIPBZ (1 mol) and 4-CMIPBZ (1 mol) after being irradiated with deep UV are shown in Fig. 6. The signals of the final products formed were assigned by MS analyses. The final products are classified into three groups: Alpha-Alpha recombination products [14], [16], and [18], Benzyl-Benzyl recombination product [11], and Alpha-Benzyl recombination products [13] and [17].

In this mixture system, [17] was also produced through the thermally induced reaction; on the other hand, the other products were not formed thermally. The relative yields of final products were determined, taking this phenomenon into account in the same way as the case of CMS model systems.

4-CMIPBZ concentration effects on final product yields.—Sensitivity for chloromethylstyrene-based resist materials is markedly influenced by the component ratio for chloromethylstyrene moieties. Therefore, the effects of the 4-CMIPBZ concentration on final product yields are important factors in these resists. The relationships between relative yields and 4-CMIPBZ concentration are examined (see Fig. 7).

Observed signal intensities of final products produced from irradiated IPBZ and 4-MIPBZ ($x = 0$) were very weak and usually not detected¹; whereas mixtures containing 4-CMIPBZ showed large amounts of signals after being irradiated. This result indicates that chloromethylstyrene units are highly sensitive to radiation and that styrene and vinyltoluene units are rather less sensitive to it. Addition of small amount of 4-CMIPBZ to IPBZ or 4-MIPBZ enhanced the sensitivity of mixtures to radiation remarkably. This is in good agreement with the fact that small amount of chloromethylation enhances sensitivity markedly in chloromethylstyrene-based polymers (1).

It is noted that recombination products related to Alpha are formed largely in mixture samples, although the amount of Alpha in the initial stage of the reaction is negligibly little as indicated by the low temperature ESR analyses. This is because large amounts of Alpha are produced through subsequently occurring hydrogen abstractions by radiation-induced active species. The hydrogen abstractions take place through two types of processes. One is through the hydrogen abstraction by Benzyl, and

¹The observed signal strength from IPBZ or 4-MIPBZ was negligible compared with that from 4-CMIPBZ- or 4-CMIPBZ-containing mixtures. Thus, higher measurement range of a GC-MS spectrometer was employed in order to detect the very weak signals. The results indicated that Alpha-Alpha recombination product from IPBZ or 4-MIPBZ is mainly formed with being irradiated by ^{60}Co γ -ray or deep UV. This reveals that free radicals are formed on the α position of isopropylbenzene derivatives, if the benzene rings are not substituted by highly sensitive chloromethyl groups, and that the assignment of observed ESR signals from IPBZ or 4-MIPBZ is reasonable.

Fig. 7. Relationships between relative yields of final products and concentration of 4-chloromethylisopropylbenzene 4-CMIPBZ: (a) IPBZ-4-CMIPBZ for CMS, and (b) 4-MIPBZ-4-CMIPBZ for CPMS. 4-MIPBZ was detected as a final product from 100% 4-CMIPBZ and its mixtures with IPBZ (a). On the other hand, in the case of 4-CMIPBZ mixtures with 4-MIPBZ (b), the 4-MIPBZ formation as a final product could not be discussed because of the existence 4-MIPBZ as an irradiated component.

the other is through the hydrogen abstraction by active chlorines. Active chlorines are produced equivalently to the amount of Benzyl in the initial stage of the reaction. The amount of the hydrogen abstractions by Benzyl can be calculated with the amount of the final product [3], and its amount was found to be only less than 5% of the amount of the hydrogen abstractions by radiation-induced active chlorines. Thus, it is concluded that Alpha is produced mainly by the hydrogen abstractions by radiation-induced active chlorines.

The difference between the reaction of CMS model compounds (Fig. 7a) and that of CPMS model compounds (Fig. 7b) is the susceptibilities of individual constituents to hydrogen abstractions. Detailed discussions are presented quantitatively in the following section.

Discussion

Susceptibilities of individual constituents to hydrogen abstractions.—Susceptibilities of individual constituents to the hydrogen abstractions by radiation-induced active chlorines can be determined from the final product yields in 1:1 molar ratio mixtures. The relative yields in 1:1 molar ratio mixtures for CMS and CPMS are shown in Table I. Relative yields are expressed as the total amount of recombination products (I-VI) is unity. The amount of the radicals formed from individual moieties can be calculated through relating radical recombinations. For example, the Alpha-Benzyl recombination product VI is formed from Benzyl A and Alpha C.

In the radiation-induced model reaction for CMS, the relative amounts of radicals formed through the radiation-induced and the subsequent hydrogen abstractions are as follows: Benzyl 0.99, Alpha from IPBZ 0.74, and Alpha from 4-CMIPBZ 0.28. Therefore, the ratio of the hydrogen abstraction from IPBZ to that from 4-CMIPBZ is 2.6 to 1.

In the radiation-induced model reaction for CPMS, the amount of radicals formed through the radiation-induced and through subsequent hydrogen abstractions is as follows: Benzyl 1.23, Alpha from 4-MIPBZ 0.60, and Alpha from 4-CMIPBZ 0.17. In this case, Benzyl is considered to be partly produced from 4-MIPBZ through the hydrogen abstraction process by active chlorines, because large amounts of Benzyl, not explained quantitatively, are produced. In the initial stage of the reaction, equivalent amounts of active chlorines to those of Benzyl are produced by radiation, while Alpha produced through α -hydrogen removal is extremely little, as indicated by the low temperature ESR analyses. Furthermore, in the subsequent hydrogen abstraction reactions, the hydrogen abstractions by radiation-induced Benzyl can be negligible (less than 5%), compared with those by radiation-induced active chlorines. Thus, the total amount of the radicals formed through the subsequent hydrogen abstractions by active chlorines is equivalent to that of the radiation-induced Benzyl, assuming that all the radiation-induced active chlorines contribute only to the hydrogen

Table I. Final product relative yields for 1:1 molar ratio model compound systems for CMS and CPMS, and the relative amount of the produced radicals. The relative yields are expressed, taking the total amount of final products responsible for a cross-linking reaction as unity.

Final products		Systems	CMS (R=H)	CPMS (R=CH ₃)
ALPHA - ALPHA	I		0.22 (p ²)	0.23 (p ²)
	II		0.095 (2pq)	0.043 (2pq)
	III		0.015 (q ²)	0.007 (q ²)
BENZYL - BENZYL	IV		0.32	0.51
ALPHA - BENZYL	V		0.20	0.10
	VI		0.15	0.11
Produced radicals		Systems	CMS (R=H)	CPMS (R=CH ₃)
BENZYL	A		0.99	1.23
ALPHA	B		0.74	0.60
ALPHA	C		0.28	0.17

abstractions. The data obtained in the radiation-induced model reaction for CMS confirmed this hypothesis. For example, the amount of Benzyl (0.99) is almost the same as the total amount of Alpha B and C (1.02) in a 1:1 mixture sample. Thus, it is concluded that the extra amounts of Benzyl are formed from the methyl group of 4-MIPBZ, and its amount is the difference (0.46) between the amount of Benzyl A (1.23) and the total amount of Alpha's B and C (0.77). Therefore, the hydrogen abstractions from individual moieties is 6.2 from 4-MIPBZ (3.5 parts from the α position and 2.7 parts from the methyl group) to 1 from 4-CMIPBZ. This high susceptibility of 4-MIPBZ to hydrogen abstractions, in addition to the position of chlorination (11), could give CPMS resists somewhat different characteristics from those for CMS resists.

As a result, the susceptibilities of individual constituents to the hydrogen abstractions by radiation-induced active chlorines are 6.2 for 4-MIPBZ, 2.6 for IPBZ, and 1 for 4-CMIPBZ. These obtained susceptibilities are interpreted in terms of the electron donation of the substituents. The methyl group shows +I effects; on the other hand, the chloromethyl group shows -I effect. +I effect can stabilize the intermediate complex between a benzene ring and a chlorine radical. These results obtained are in good agreement with the photolysis data for substituted toluenes in carbon tetrachloride solution (12).

Radiolysis of model compounds.—The reactions for model compounds are shown in Fig. 8. In the initial stage of the reaction, free radicals and active chlorines are produced by deep UV or high energy radiation, such as ^{60}Co γ -ray and EB. In this stage, the amount of Alpha is less than one-tenth that of Benzyl produced through the chlorine removal. This is confirmed by the low temperature ESR analyses. Thus, Alpha produced is neglected in this stage.

In the next stage of the reaction, the two types of hydrogen abstractions take place by radiation-induced active chlorines and Benzyl. The abstractions by active chlorines take place through the charge-transfer complex between a benzene ring and an active chlorine (3). In this stage, the abstractions by radiation-induced active chlorines are the major process and their amount is 20 times more than that of the abstraction by Benzyl.

In the final stage of the reaction, final products are formed through the radical recombinations among the free radicals produced by radiation and by subsequently occurring hydrogen abstractions. It is noted that relative yields of the final products formed through the Alpha

Fig. 8. Radiolysis of low molecular model compounds. R: substituents besides chloromethyl group. Cl^* : radiation-induced chlorine, Cl or Cl^- . *: For lifetime data, see Ref. (4).

cross- or home-recombinations (I, II, and III, see Table I) are nearly the same as the random collision probability for the related Alpha's; that is, the production yields of the product B-C formed through the cross-recombination between radical B and radical C is $2pq$, while the production yield of the home-recombination products B-B and C-C are p^2 and q^2 , respectively, where p and q denote the probabilities for the production of Alpha's B and C. This relationship can be seen in Table I. This fact implies that Alpha-Alpha recombination reactions take place through random collisions among Alpha's produced through hydrogen abstractions, and needs only small activation energy in this stage.

From GC-MS analyses, high energy (^{60}Co γ -ray) radiation and deep-UV radiation gave rise to the same final products with the same quantities. Thus, it was concluded that the high energy radiation-induced reactions are almost the same as the deep-UV radiation-induced reactions. Here, the high energy radiation-induced reactions are discussed in more detail.

In high energy radiation, such as electron beam, x-ray, and ^{60}Co γ -ray, ionization of organic materials is predominant in the initial stage of the reaction; on the other hand, in deep-UV radiation, excitation is predominant. This is the difference in the initial stage of both radiation-induced reactions.

In Fig. 9, high energy-induced reactions of CMIPBZ are shown as an example. Electrons produced through ionization generate Benzyl and chlorine anions through dissociative electron attachment, or generate excited CMIPBZ through geminate ion recombination. Whereas, the excited CMIPBZ generate Benzyl and chlorine radicals through homolytic splitting of covalent bonds. However, in the next stage of the reaction, both active chlorines, a chlorine anion and a chlorine radical, form the same charge-transfer complex to generate Alpha, as reported by time-resolved spectroscopic study (4). Therefore, the same final products are observed between the high energy radiation-induced reactions and the deep-UV radiation-induced reactions, in spite of the difference in the initial stage of the reaction.

Radiation-induced reaction of chloromethylstyrene-based resist materials.—On the basis of the radiolysis of model compounds, radiation-induced reactions of chloromethylstyrene-based resist materials are discussed. There are some differences to be considered between the radiation-induced reactions in polymeric materials and those in low molecular compounds. The differences arise mainly from the lifetimes and the diffusivities of free radicals. Therefore, when the radiation-induced reactions for polymeric materials are discussed compared with those for the model compounds, the lifetimes of free radicals responsible for a cross-linking reaction and the diffusion length of radiation-induced active chlorines have to be taken into account.

Tagawa *et al.* reported the lifetimes of Benzyl and the charge-transfer complex between a polymer unit and a

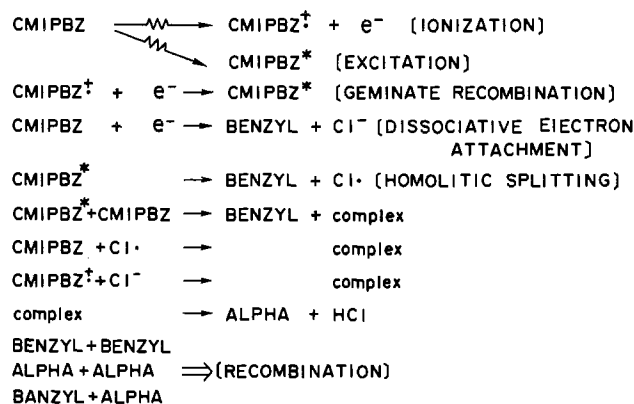

Fig. 9. High energy radiation-induced reactions of chloromethylisopropylbenzene CMIPBZ. Asterisks denote the excited states.

Fig. 10. Radiation-induced reactions of chloromethylstyrene-based resist materials.

radiation-induced active chlorine (4). Using the reported lifetimes, it can be determined which is the predominant reaction, recombination of radiation-induced Benzyl or hydrogen abstraction from polymer units through charge-transfer complexes. From their time-resolved spectroscopic data, the lifetime of Benzyl is about 20 μ s, and that of charge-transfer complexes is about 100 ns. Thus, 99.5% of Benzyl is still remained without recombination, while free radicals are formed through the subsequent hydrogen abstractions. Therefore, it is concluded that recombination of free radicals occurs after hydrogen abstraction reactions.

The other important factor is the diffusion length of radiation-induced active chlorines. This is because it is determined by the active chlorine diffusion length how closely the free radicals responsible for the cross-linking reaction are produced. Diffusion data for gases in polymers have been reported (13). Diffusivity coefficient of chlorines in polystyrene ($D = 9 \times 10^{-8}$ cm²/s at 25°C) was used to estimate the diffusion length [= $(D\tau)^{1/2}$] during hydrogen abstractions, where τ is the lifetime of the charge-transfer complex. The diffusion length is estimated as 9.5×10^{-8} cm. Thus, hydrogen abstractions by radiation-induced active chlorines extend to more than five units of a polymer. On the other hand, one Benzyl is estimated to be formed among 10-100 units of a polymer by radiation in resist materials from Charlesby's gel formation theory (14). Consequently, it is concluded that although Benzyl-Alpha recombinations are predominant in these resist materials, Alpha-Alpha and Benzyl-Benzyl recombinations cannot be neglected even in the polymeric materials, due to the large diffusion length of radiation-induced active chlorines.

Bartlett and McBride reported the disproportionation of 3,4-diphenyl-2,3,4,5-tetramethylhexane, which was formed through decomposition of azobis(2-phenyl-3-methylbutane) (15). According to their report, when large free radicals are put on Alpha, disproportionation (which would not lead to cross-linking) is considered to be important in polymeric materials compared with that in low molecular model compounds. However, in the case of the used model compounds, no ring-substituted α -methylstyrenes produced through the disproportionation of Alpha-Alpha products were observed. Furthermore, Weir and Milkie reported that the formation of C-C double bonds through disproportionation is not so predominant in ring-substituted polystyrenes (6). Therefore, the disproportionations of Alpha-Alpha products might occur, but they are not considered to be predominant in chloromethylstyrene-based polymeric materials.

The radiation-induced reactions of chloromethylstyrene-based resists are shown in Fig. 10. High sensitivity is achieved in these resists due to the hydrogen abstractions by radiation-induced active chlorines, which produce free radicals responsible for a cross-linking reaction, and the

high production yield of Benzyl. It is worthwhile to denote that the determined susceptibilities of individual constituents to hydrogen abstractions using model compounds are valid even in these polymeric materials.

Conclusion

The radiation-induced reactions of chloromethylstyrene-based resist materials have been discussed in detail, from the viewpoint of the radiolysis of low molecular model compounds of which chemical structures are close to the repeating units of the polymers. Low temperature ESR data show that main active species in the initial stage of the reaction are Benzyl radicals from chloromethyl derivatives and simultaneously produced active chlorines, while Alpha radicals induced by radiation through α -hydrogen removal are negligibly little. GC-MS data show that the hydrogen abstractions by radiation-induced active chlorines are the major process in a subsequently occurring reaction. It was found that large electron donating ring substituents increase the susceptibilities of individual constituents to the hydrogen abstractions.

Acknowledgments

The authors thank Professor Y. Hatano, Dr. Y. Shin-saka, and R. Yugeta, of Tokyo Institute of Technology, for their discussions in this study. They also thank Dr. H. Makino for affording them the chance to use the ESR spectrometer and H. Honda for her technical assistance in ESR measurements, and T. Masumoto for affording them the chance to use a Cary recording spectrophotometer.

Diffusivity and Thermal Cracking Rate of Metalorganic Gases by Chromatography

Motoyuki Suzuki* and Michio Sato

Institute of Industrial Science, University of Tokyo, Tokyo 106, Japan

ABSTRACT

Metalorganic gases such as trimethylaluminum (TMA), trimethylgallium (TMG), triethylaluminum (TEA), and triethylgallium (TEG) are often used as metal sources of chemical vapor deposition for producing epitaxial thin films of GaAs or GaAlAs. Film growth kinetics are governed by thermal cracking of those gases in a thermal boundary layer which is expected to develop on the heated substrate and also by diffusion of those gases from bulk stream into the boundary layer. Since there has been poor understanding on physicochemical properties of these gases, such as rate of thermal cracking reaction and molecular diffusion, the present work is aimed to determine these properties by means of a chromatographic technique (pulse-response analysis) developed in the field of chemical engineering. Method of moment was used to analyze chromatographic elution curves and measurements at different temperature ranges provided diffusivities (293-428 K) and thermal cracking rate coefficients (454-580 K) of the four gases in hydrogen stream.

During the last decade, metalorganic chemical vapor deposition (MOCVD) has collected wide attention because of its advantages: ease in controlling an epitaxial layer thickness and adaptability to production in large scale. This technique was first developed by Manasevit for growing GaAs epitaxial film on an insulator substrate (1). Since then, many applications of this technique have been tried to prepare devices of different compositions.

When epitaxial growth of GaAs, for instance, is tried, the growth rate of the film appears proportional to the concentration of metalorganic gas, while it is little influenced by the concentration of arsine or a substrate temperature when the same equipment and the same total gas velocity are used. Also, gas velocity has some influence on the growth rate (2). These facts suggest that supply of metalorganic gas from a bulk stream to the surface of epitaxial layer is one of the significant factors in controlling overall kinetics of the epitaxial growth. Transport phenomena involved in MOCVD have to be studied in more detail in order to determine the precise mechanisms of the growth in this arrangement. Then on the basis of this information, a rational design for the reactor becomes possible, and precise control of product layer thickness, alloy composition, and other resultant electronic characters become controllable. For the above described purpose, it is essential to know such properties of metalorganic gases as diffusivity and thermal cracking rate for an understanding of what happens near the substrate kept at a high temperature.

Trimethylaluminum (TMA), trimethylgallium (TMG), triethylaluminum (TEA), and triethylgallium (TEG) are often employed as the metal-source gases for the growth of GaAs or GaAlAs files by MOCVD method. The present work focuses on determination of the diffusivities and the thermal cracking rate coefficients of these gases in a hydrogen stream which is usually used as a carrier in MOCVD. Those properties are determined by employing chromatographic technique (Fig. 1 outlines the chromatographic experiment) which has been often used for obtaining rate parameters in a complexed system (3). Pulse of metalorganic gas was introduced in a hydrogen stream flowing in a column packed with inert glass beads kept at a constant temperature. The effluent peak from the column was detected by mass spectrometry and analyzed by the method of moment. Measurements at the low temperature ranges where thermal cracking is considered negligible provided diffusibilities of these gases, while thermal cracking rate coefficients were obtained from the higher temperature runs.

Theory of Chromatography

Metalorganic gas in hydrogen is decomposed to metal and hydrocarbon at high temperature. The overall reaction is

*Electrochemical Society Active Member.

When hydrogen exists in large excess, the reaction rate is considered first order regarding concentration of metalorganic gas. Then mass conservation of metalorganic gas in the column packed with inert glass beads leads to an equation which describes a concentration pulse introduced at the inlet of the column

$$Ez \frac{\partial^2 C}{\partial z^2} - u \frac{\partial C}{\partial z} = \epsilon k C + \epsilon \frac{\partial C}{\partial t}$$

$$z = 0 : C = M \delta(t)$$

$$z = \infty : C = 0 \quad [2]$$

where Ez represents the axial dispersion coefficient of metalorganic gas, u is the superficial velocity of a carrier gas based on the cross-sectional area of the column, ϵ is the void fraction of the column, and k is the first-order reaction rate constant. As the boundary conditions, M is the intensity of pulse introduced at the inlet of the column and $\delta(t)$ means the delta function defined as

$$\delta(t) \begin{cases} \delta(0) = \infty \\ \delta(t \neq 0) = 0 \\ \int_{-\infty}^{\infty} \delta(t) dt = 1 \end{cases} \quad [3]$$

Equation [2] can be transformed and solved in the Laplace domain, and the solution in the Laplace domain which contains three parameters (Ez , ϵ , and k) directly gives moments of the effluents peak in the time domain (3). The moments of the effluent peak are defined by the following equations.

The zeroth reduced moment, which is defined as the ratio of the amount of the unreacted sample detected at the outlet of the column and that of the sample introduced at the inlet, is calculated as

$$\mu_0 = \frac{\int_0^{\infty} C dt}{M} \quad [4]$$

Fig. 1. Chromatographic experiment

The first absolute moment is obtained as

$$\mu_1 = \frac{\int_0^\infty tC dt}{\int_0^\infty C dt} \quad [5]$$

and the second central moment as

$$\mu_2 = \frac{\int_0^\infty (t - \mu_1)^2 C dt}{\int_0^\infty C dt} \quad [6]$$

The moment solutions of the general equations, which describe the mass balance in a fixed bed reactor, have been obtained by Suzuki and Smith (3). Equation [2] is a simplified form of the general equation and the moment solution of Eq. [2] can be obtained from their work by omitting the terms related to adsorption, intraparticle diffusion, and surface reaction in the general moment solutions.

Zeroth-reduced, first-absolute and second-central moments are written as

$$\begin{aligned} \mu_0 &= \exp \left[\frac{uz}{2Ez} (q_0 - 1) \right] \\ &= \exp \left(- \frac{\epsilon z}{u} k \frac{2}{q_0 + 1} \right) \end{aligned} \quad [7]$$

$$\mu_1 = \frac{\epsilon z}{u} \frac{1}{q_0} \quad [8]$$

$$\mu_2 = \frac{2Ez\epsilon^2 z}{u^3} \frac{1}{q_0^3} \quad [9]$$

where

$$q_0 = \sqrt{1 + \frac{4Ez\epsilon k}{u^2}} \quad [10]$$

By comparison among Eq. [7]-[10] and the corresponding moments determined for varieties of conditions, parameters Ez , ϵ , and k can be obtained.

Special cases.—No reaction—diffusivity from the second moment.—If the column is kept at a low temperature, thermal cracking can be neglected. When k can be regarded as zero in Eq. [10], q_0 becomes 1 and then the zeroth moment, which represents the fractional ratio of the uncracked metalorganic gas, becomes unity. Then from the second central moment, the axial dispersion coefficient, Ez , can be obtained as

$$Ez = \frac{\mu_2(2z/u)}{(\epsilon/u)^2} \quad [11]$$

where the void fraction of the column, ϵ , is readily obtained from the first moment

$$\epsilon = \mu_1/(z/u) \quad [12]$$

Axial dispersion coefficient in a packed column may be written as (4)

$$Ez = \eta D + lu \quad [13]$$

The first term in the right side of Eq. [13] means the effect of molecular diffusion, and the second term shows the effect of convective dispersion due to the gas flow. In the case of very low gas velocity, the effect of dispersion becomes small enough and Ez approaches the constant value ηD . Diffusibility η is a parameter specific to the column determined by packing configurations. First, the measurement of η is carried out by using helium pulse in a hydrogen carrier, where molecular diffusivity is known.

Then the diffusivity of each gas is obtained from Ez determined from Eq. [11] by using Eq. [13].

Thermal cracking rate coefficient from the zeroth moment.—If the column temperature is raised, thermal cracking occurs and zeroth reduced moment becomes less than unity. Also, when the cracking rate is not too high, q_0 is calculated from Eq. [10] to be about 1.001. Then the magnitude of $[2/(q_0 + 1)]$ in Eq. [7] can be regarded as approximately 1. Then the thermal cracking rate coefficient can be obtained from semilog plots of the zeroth moments for each temperature *vs.* the residence time ze/u .

Experimental

The schematic diagram of experimental apparatus is shown in Fig. 2. A column was a copper tube 1/4 in. in outer diameter, 2m long, and packed with glass beads (Shiraki Rikagaku Company) whose average diameter was 0.5 mm. Carrier gas was pure hydrogen of research grade. Flow rate of the carrier gas was limited up to 70 cm³/min because of the excessive pressure drop of the column beyond this rate. Metalorganic gas was maintained in a stainless bubbler cooled in a constant-temperature bath and was vaporized by introducing a small amount of pure hydrogen flow. The bubbler temperature was 283 K for TEG and 273 K for TMA, TMG, and TEA. The column temperature was maintained constant by a thermostatic oven. A six-way valve was used to introduce the gas pulse whose volume was 0.30 cm³. Gas flow rate was measured by a soap flow meter situated after the column.

A needle valve splitter just behind the column was used to lead a small amount of the outlet gas into quadrupole mass spectrometer (QMS) (TE-600 Anelva Corporation), which is furnished with multiple ion selector (MIS). About 0.3 cm³/min effluent gas was led into the QMS. The chamber pressure of the QMS was about 10⁻⁶ torr.

A mass spectrometer is suitable for the present chromatographic experiment, since it has very little effective dead volume because of the high vacuum of the chamber and it also has the base line stability brought about from its principle of detection: MS detects the sample dislocated electrically at the ion source. If the amount of introduced gas and the chamber pressure are kept constant during the experimental run, MS is not influenced by the alteration of another parameter (gas velocity or temperature in the column).

In this experiment, mother peaks of metalorganic gases were scarcely detected, so that fragment peaks (CH₃⁺ of 15 amu for TMA and TMG, C₂H₅⁺ of 29 amu for TEA and TEG) were measured for determination of uncracked metalorganic gases.

When carrier gas is hydrogen, hydrocarbon is easily formed by combination of the alkyl ions, which are products of electrical cracking, and the hydrogen in vacuum chamber, and it appears as recombination peaks. Metalorganic gas and the corresponding hydrocarbon gas (CH₄ or C₂H₆) are indistinguishable by QMS only.

In thermal cracking rate measurement, Dry Ice-methanol cold trap was prepared for the purpose of

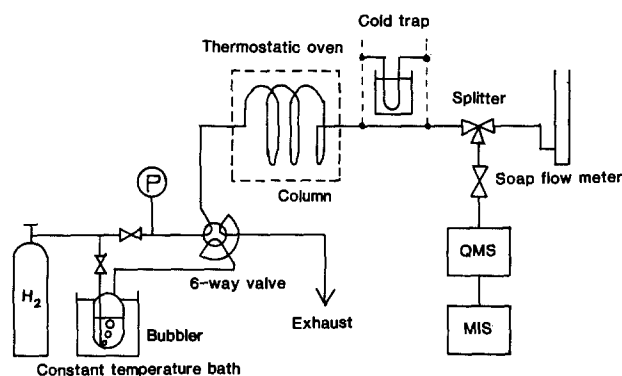

Fig. 2. Schematic diagram of experimental apparatus. Cold trap was used in thermal cracking rate measurement.

removing the uncracked metalorganic gases from the stream. The glass beads packed column (1/8 in. od, 30 cm long) was kept in the Dewar vessel filled with Dry Ice-methanol. Fragment peaks of hydrocarbon were used for quantitative determination of the extent of thermal cracking reaction.

The amount of hydrocarbon was

$$\int_0^{\infty} C dt \text{ (with cold trap)} \quad [14]$$

and the amount of total CH_3 or C_2H_5 , which represents total amount of metalorganic gas and hydrocarbon, was

$$\int_0^{\infty} C dt \text{ (without cold trap)} \quad [15]$$

The zeroth moment was defined as

$$\mu_0 = \frac{\int_0^{\infty} C dt \text{ (without cold trap)} - \int_0^{\infty} C dt \text{ (with cold trap)}}{\int_0^{\infty} C dt \text{ (without cold trap)}} \quad [16]$$

Results and Discussion

Preliminary runs.—First, temperature effects on cracking of the gases were examined from decrease of elution peak area, *i.e.*, zeroth moments. Below 450 K, no appreciable decrease of the peak area was observed, and then the diffusion measurements were performed between room temperature and 450 K. As a consequence, thermal cracking rates were obtained above 450 K until the temperature where no elution peak of metalorganic gas was detected.

Second, for determining column characteristics, helium pulse was introduced into a hydrogen stream flowing in the column and then elution curve analysis gave void fraction, ϵ , and diffusibility, η , in the column which becomes important for correcting the effect of the gas flow in calculating the molecular diffusivities of the metalorganic gases.

From the first moment of the helium peak, the void fraction of the bed was determined in good accuracy to be 0.405. This value is used for the estimation of axial dispersion coefficient of helium from the second moment of helium elution peaks as described earlier. Since molecular

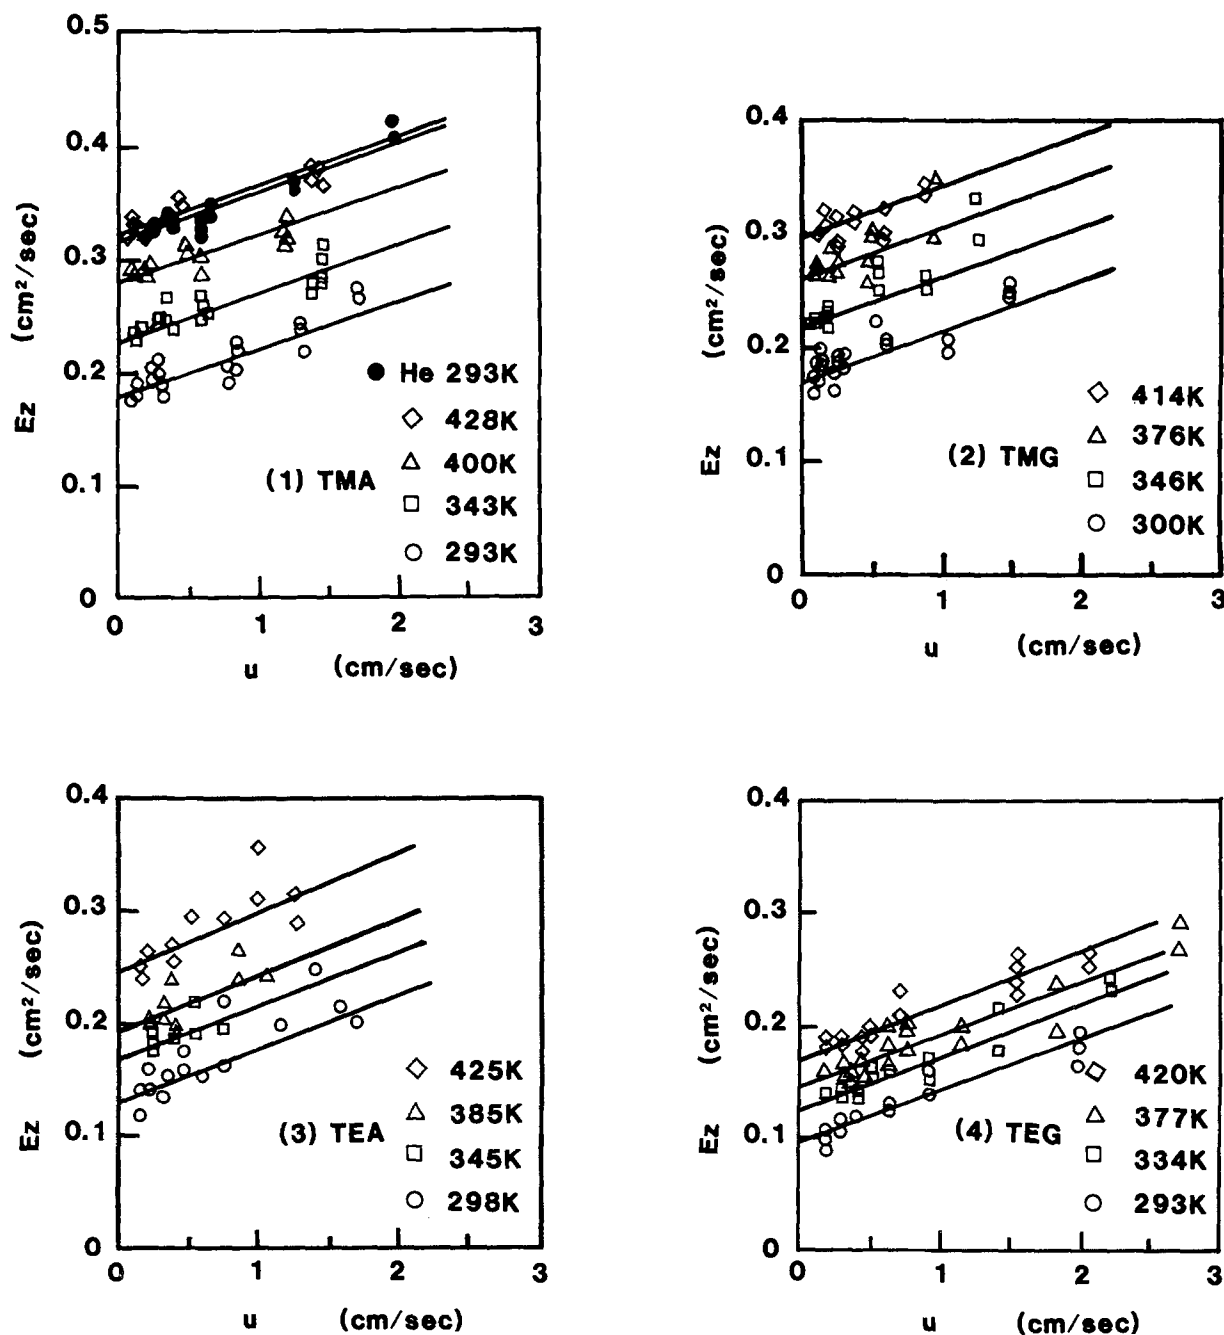

Fig. 3. Relationship between axial dispersion coefficient, E_z , and superficial velocity, u . 1: TMA: $\text{Al}(\text{CH}_3)_3$ and He. 2: TMG: $\text{Ga}(\text{CH}_3)_3$. 3: TEA: $\text{Al}(\text{C}_2\text{H}_5)_3$. 4: TEG: $\text{Ga}(\text{C}_2\text{H}_5)_3$.

diffusivity of helium in hydrogen is given as $D_{He} = 1.132 \text{ cm}^2/\text{s}$ at 298.2 K (5), from the plot shown by solid circles in Fig. 3.1, diffusibility, η , is determined as $\eta = 0.285$. Suzuki and Smith reported $\eta = 0.30$ for a similar glass beads ($d_p = 0.51 \text{ mm}$) packed column (4), which suggests that the figure given here is reasonable.

Diffusivity of metalorganic gases.—Figures 3.1-3.4 show the relationship between axial dispersion coefficient, E_z , of metalorganic gases and superficial velocity, u , at room temperature or at high temperatures to about 420 K.

Though the second moments, from which E_z is calculated, are susceptible to scattering error introduced by experimental difficulties on evaluation of tail part of the elution peaks, the reproducibility of E_z is upgraded by careful experiments at low gas velocities and repeated measurements at similar conditions. From the linear regression lines of slope, l , according to Eq. [13], the intercept at the ordinate in the figures gives diffusivity of the gas from Eq. [13] by using the diffusivity determined in the preliminary runs. Thus obtained molecular diffusivities of the four gases are shown as functions of temperature in Fig. 4. Molecular diffusivities are proportional to the 1.7 power of the absolute temperature. This tendency is quite reasonable when compared with the general equations presented for diffusivity of gas (6). Also, the magnitudes of diffusivities determined here are similar to those of the hydrocarbons whose carbon numbers are the same (propane with TMA and TMG, cyclohexane or hexane with TEA and TEG).

Fuller *et al.* (6) reported that molecular diffusivity is proportional to the value $\sqrt{1/M_1 + 1/M_2}$. Since $1/M_1$ of hydrogen is so large, molecular weight of metalorganic gas has little influence on the diffusivity. Mainly, the diffusion volume or collision diameter in H_2 has a controlling effect on the diffusivity.

In the vapor phase TMA, monomer is considered to exist in an equilibrium state with its dimer and the equilibrium constant of the dissociation is given as 2.83×10^{-3}

Fig. 4. Temperature dependency of molecular diffusivity. Metalorganic gases in hydrogen.

atm at 373.5 K (7). The TMA bubbler was kept at low temperature, and the gas pulse was steadily spread in the column; the concentration of TMA was estimated to be below $8 \times 10^{-3} \text{ mol/m}^3$ ($2 \times 10^{-3} \text{ atm}$) in the column, which is small enough to assume that dimerization is negligible.

Also, it may be reasonable to assume that the metal atom attracts the alkyl groups and that the molecular shape of metalorganic gas is globular, as the alkyl groups are distributed around the metal atom as a center. Thus, the volume of the metal has little influence on the diffusion volume. Because the bonding energy of aluminum

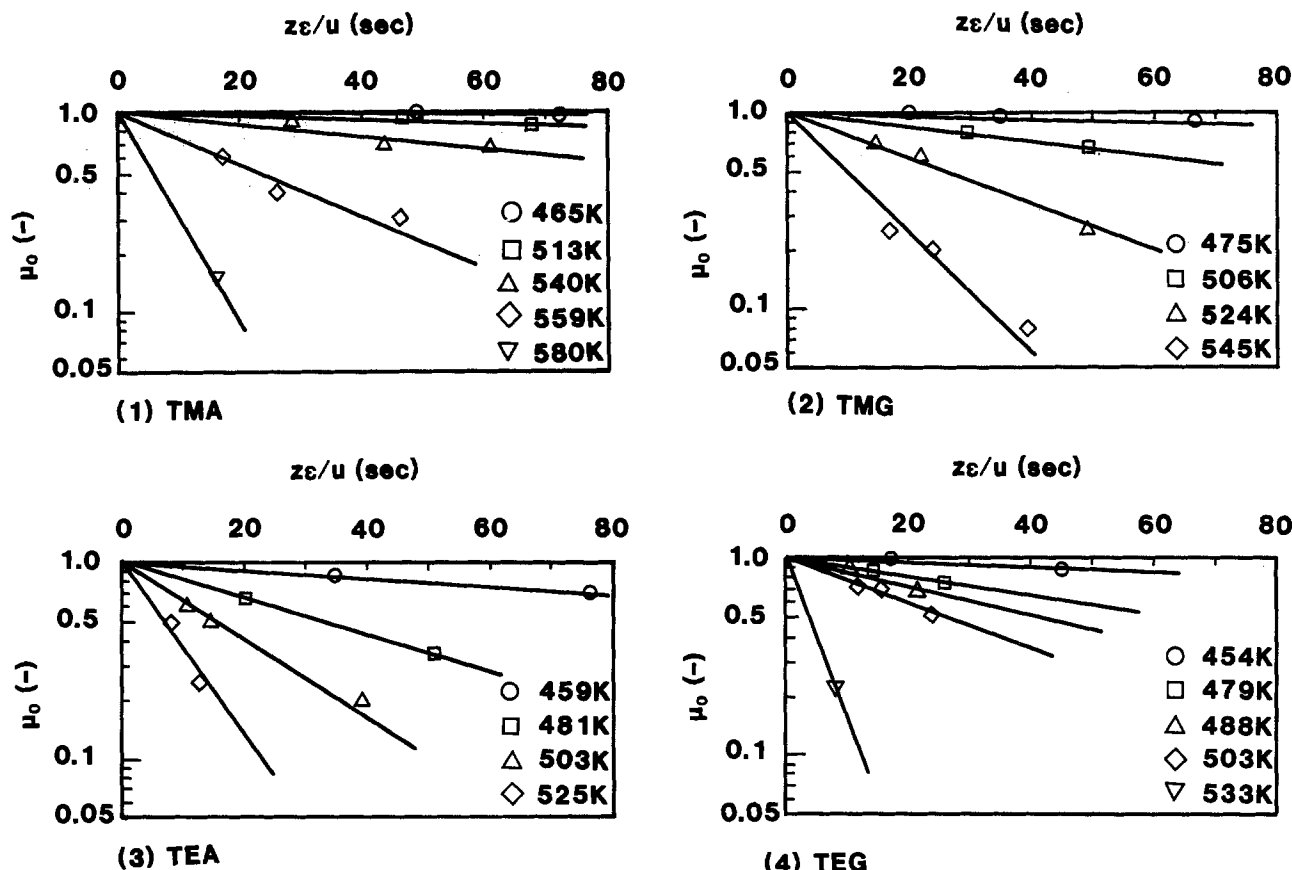

Fig. 5. Relationship between zeroth moment, μ_0 and residence time, $z\epsilon/u$. 1: TMA:Al(CH₃)₃. 2: TMG:Ga(CH₃)₃. 3: TEA:Al(C₂H₅)₃. 4: TEG:Ga(C₂H₅)₃.

Fig. 6. Arrhenius plots of thermal cracking rate constant of metalorganic gases in hydrogen.

and carbon is stronger than that of gallium (8), the ethyl groups of TEA cannot spread themselves. Thus the diffusion volume of TEA may become smaller than that of TEG, resulting in higher diffusivity of TEA.

Thermal cracking rate coefficient.—Metalorganic gas in hydrogen is decomposed to metal and hydrocarbon at higher temperatures. Hydrogen, the carrier gas of this experiment and also of ordinary MOCVD systems, is also a reactant of the thermal cracking reaction. However, it usually exists in excess enough to make it possible to assume that the reaction is first order regarding the metalorganic gas.

Glass beads are expected to be inert fillers in this experiment. In the thermal cracking experiment, metal of aluminum and gallium deposited in the column and covered the surface of the glass beads, but there was observed no difference between the reaction rate in a new column and that after many repeated runs. Then, it may be reasonable to assume that glass beads or metal surface have no influence on the cracking reaction.

Figures 5.1-5.4 show the relationship between the residence time and μ_0 , the fraction of the uncracked metalorganic gas. The linearities of these plots mean that the assumption of the first-order kinetics is reasonable. From the slope of the line, the cracking rate coefficient, k , at that temperature can be obtained by means of Eq. [7]. Temperature dependencies of the reaction rate coefficient, k , are shown by Arrhenius plot in Fig. 6.

The elementary process of this cracking reaction is not known, and in this experiment intermediate products (MR or MR_2 were expected) could not be detected by QMS. But from the slopes of the plots given in Fig. 6 using Eq. [17], the activation energy for the overall kinetics can be obtained for each reaction, and these are listed in Table I.

$$k = A \exp\left(-\frac{E_{act}}{RT}\right) \quad [17]$$

Heats of the thermal cracking reactions in concern can be calculated from the quoted data by Stone and West (8) and are included for comparison in Table I. Methyl com-

Table I. Activation energy and heat of cracking. Metalorganic gases in hydrogen

	Activation energy (kJ/mol)	Heat of cracking (kJ/mol)
TMA, [Al(CH ₃) ₃]	158.6	90.4
TMG, [Ga(CH ₃) ₃]	119.7	139.3
TEA, [Al(C ₂ H ₅) ₃]	84.5	193.3
TMG, [Ga(C ₂ H ₅) ₃]	91.6	203.3

pounds have larger activation energies and smaller heats of the cracking reaction compared with the corresponding ethyl compounds. This suggests that they are more stable than the ethyl compounds in hydrogen at higher temperatures.

Conclusion

Molecular diffusivities and thermal cracking rate coefficients were obtained by chromatographic experiment for the four metalorganic gases, trimethylaluminum, trimethylgallium, triethylaluminum, and triethylgallium, in hydrogen stream. The chromatographic method is found to be an appropriate method for the objective of those measurements. The diffusivities of these gases are of the same magnitude as the common hydrocarbons with the same carbon number. From the thermal cracking rate data, it was concluded that trimethyl compounds are more stable than the corresponding triethyl compounds. By employing these data, kinetics of growth of thin films in MOCVD reactors can be more precisely described in terms of transport processes and chemical reaction in a boundary layer developed on the thin film, which helps future progress in this field.

Reduction of Sodium Ion Density in Molybdenum-Gate MOS Devices with the Addition of Tantalum to Gate Electrodes

Shin-ichi Ohfuji* and Noboru Shiono

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839 Ono, Atsugi-shi, Kanagawa Prefecture, 243-01 Japan

ABSTRACT

The reduction mechanism of mobile ion contamination in Ta-Mo alloy gate MOS structures has been examined by varying the deposition and annealing conditions of gate metals. Mobile ion density in the gate SiO₂ for the Ta-Mo gate structures decreases drastically after forming gas annealing at 1000°C, whereas the density increases during nitrogen gas annealing. The structure and composition analysis for the Ta-Mo gate observed by x-ray diffraction, SIMS, and AES indicates that nitriding of Ta-Mo films occurs during the forming gas annealing, and the nitride, MoTa₃N (tetragonal, CrNbN-type structure), is stable even at 1000°C during annealing. These facts suggest that MoTa₃N formation at the boundaries of Mo grains, which is similar to the stuffing effect observed in TiN films, is responsible for immobilizing the sodium atoms within the gate electrodes. As a result, the diffusion of sodium from the gate electrode into the SiO₂ layers is suppressed.

With regard to the development of highly conductive and self-aligned gate electrodes and interconnection lines, molybdenum (Mo) is under active investigation as an alternative to the widely used polycrystalline silicon gate in MOS LSI's (1). In the self-aligned gate process, high temperature annealing above 900°C is necessary to activate implanted ions in the source and drain regions following gate electrode formation. This process causes the impurities sodium (Na) and potassium (K), contained in the Mo electrodes and having a concentration less than 1 ppm (2), to diffuse into the gate SiO₂ layers. This alkali ion contamination is known to result in flatband voltage shifts in MOS structures (3). It is essential to prevent this ionic Na and K contamination in the thermally grown SiO₂ layers in order to stabilize the Mo-gate MOS characteristics.

A phosphosilicate glass stabilization process (4) and an oxidation technique for silicon in the presence of chlorine and chlorine compounds (5) have been developed as methods to obtain passivated oxides. Another possible solution, high temperature annealing of Mo gate electrodes in a forming gas, has been reported to be effective in reducing this contamination (6). We have recently shown that the effect of forming gas annealing is enhanced by hydrogen doping and the addition of tantalum to Mo films (2). The Ta addition is intended to increase the amount of doped hydrogen in the films as a result of the fact that Ta has a higher hydrogen absorption property than Mo (7). It has also been shown that the Na diffusion from these specially designed gate electrodes into the gate oxides is almost entirely prevented when high temperature annealing is performed in a forming gas, although the physical origin of this effect remains unclear.

In this work, a reduction mechanism of mobile ion contamination in the Ta-Mo alloy gate MOS structures is examined by varying the deposition and annealing conditions of gate metals. Structural and compositional changes in the Ta-Mo films as a function of process conditions are measured using an x-ray diffractometer, SIMS, and AES, and are compared with the mobile ionic charge density in the gate SiO₂ measured by the triangular voltage sweep method. Metal nitride formation, which is induced by the Ta addition, is discussed as a cause for the reduction of Na ion density in the gate SiO₂.

Experimental

Ta-Mo alloy-gate MOS capacitors were fabricated on p-type (100) Si wafers of 4-6 Ω-cm resistivity. Thin gate SiO₂ was grown on the wafers in a dry O₂ ambient at 950°C to a 400Å thickness. The H-doped Ta-Mo alloy films, 3300Å thick, were co-sputtered using an RF planar magnetron sputtering apparatus with two independent Ta and Mo targets at pressure 1 × 10⁻² torr in a mixed H₂(20%) and Ar(80%) ambient for H doping. The purity of

* Electrochemical Society Active Member.

both the Mo and Ta targets was more than 99.95%. The RF power was divided between the two targets at various ratios so as to control the Ta concentration in the films from 0 to 100 atom percent (a/o).

Gate electrodes of 500 × 500 μm were defined by conventional photolithography and chemical etching using an H₃PO₄-HNO₃ solution. After patterning the gate electrodes, high temperature annealing was carried out at 1000°C in an N₂ ambient and/or a forming gas ambient (H₂:N₂ = 1:9 by volume). This annealing step also serves as an activation of implanted dopant in the source and drain regions in the self-aligned gate process for FET's. A subsequent low temperature annealing in forming gas (H₂:N₂ = 1:2) was performed at 450°C for 30 min for all samples in order to reduce the interface trap density at the Si/SiO₂ interface.

The mobile ionic charge density N_m in the MOS structures was measured by the triangular voltage sweep method (TVS) with a 50 mV/s ramp rate at 270°C. The detection limit of this method was less than 5 × 10⁹ cm⁻². The electrical resistivity of the films were determined by a four-point probe method in conjunction with thickness measurements using a Talystep (Rank Taylor Hobson). Depth distribution profiles for the Na in the MOS structures were measured by SIMS (CAMECA, IMS-3F) with a 15 kV primary O₂⁺ ion beam. The film structure was investigated using an x-ray diffractometer. The average grain size for Mo was determined from the broadening of the diffraction peaks of Mo(110), using Scherrer's equation (8).

Results and Discussion

Reduction of ionic charge density.—Figure 1 shows variations in mobile ionic charge density, N_m , and electrical resistivity of electrode films for H-doped Ta-Mo alloy gate MOS structures (denoted as "H-Ta-Mo"), after annealing in forming gas at 1000°C for 30 min, as a function of Ta concentration in the electrodes. In this case, gate electrodes of 500 × 500 μm were fabricated by depositing H-Ta-Mo films through a metal mask onto SiO₂ layers. The reason for this is that it is difficult to etch H-Ta-Mo films selectively from the SiO₂ layers when the H-Ta-Mo films contain more than 10 a/o Ta. A several atomic percent Ta addition is found to be effective in reducing N_m , whereas more than this is not very effective. Since bulk resistivity of Ta is higher than that of Mo, as shown in Fig. 1b, the electrical resistivity increases with an increase in the Ta concentration. A resistivity of 4.2 × 10⁻⁵ Ω-cm can be obtained even for a sample with as high as 20 a/o Ta. This resistivity is only four times as large as the resistivity for the samples without Ta (denoted as "H-Mo"), and this H-Ta-Mo is applicable to conductive gate electrodes.

Figure 2 shows the N_m for an Mo gate (not doped with hydrogen) and an H-Ta-Mo gate with 7 a/o Ta as a func-

Fig. 1. Mobile ionic charge density N_m (a) and electrical resistivity of electrode films (b) for H-Ta-Mo gate MOS structures after annealing in forming gas at 1000°C for 30 min as a function of Ta concentration in the electrodes.

tion of H₂ gas concentration in the H₂-N₂ annealing ambient at 1000°C for 30 min. More than 3 volume percent (v/o) H₂ is found to be required to reduce N_m in both gate structures. The H-Ta-Mo gate is more influenced by the H₂

Fig. 2. Mobile ionic charge density N_m for Mo gate and H-Ta-Mo (7 a/o Ta) gate MOS structures as a function of H₂ gas concentration in the annealing ambient at 1000°C for 30 min.

Fig. 3. Variations in mobile ionic charge density N_m for Mo gate and H-Ta-Mo (7 a/o Ta) gate as a function of annealing time t_H in forming gas at 1000°C.

concentration than the Mo gate. This indicates that H doping and Ta addition enhance the reduction effect during forming gas annealing (2).

The effect of the annealing time t_H in the forming gas at 1000°C is shown in Fig. 3 for the Mo gate and H-Ta-Mo gate (7 a/o Ta). Mobile ionic charges are undetected for the H-Ta-Mo gate. For the Mo gate, N_m is as high as 7×10^{11} cm⁻² at $t_H = 5$ min and gradually decreases with an increase in t_H . This result suggests that mobile ionic charges, which are mostly Na ions, are not diffused into the gate oxides in the H-Ta-Mo gate structures, even at the initial stage of the annealing, whereas Na contamination occurs within 5 min and is gradually reduced with an increase in t_H for Mo gate structures. The difference in N_m between the gate structures is caused by the amount of hydrogen absorbed in the films before annealing and by the Ta addition to the electrodes in the deposition process.

The following mechanisms may be proposed for the reduction effect on the mobile ionic charge density: (i) blocking of Na thermal diffusion into the SiO₂ at the metal/SiO₂ interface by an H-Ta-Mo alloy diffusion barrier, (ii) immobilization of Na contained in the gate electrodes, (iii) neutralization of Na ions in the SiO₂ layers, and (iv) gettering of Na from the SiO₂ by H-Ta-Mo films. The appropriateness of these mechanisms is next discussed.

To clarify the blocking effect [mechanism (i)], N_m has been compared for various MOS structures of an H-Ta-Mo(150Å)/Mo(3100Å) double-layered gate, an Mo(3300Å) gate, and an H-Ta-Mo(3300Å) gate after annealing in forming gas at 1000°C for 30 min. The results are shown in Table I. The blocking effect by the thin H-Ta-Mo layer is concluded to be very weak. This is because the N_m for the double-layered gate is as large as that for the Mo gate.

Figure 4 shows a variation in N_m as a function of annealing time t_N in N₂ at 1000°C for the H-Ta-Mo gate (7 a/o Ta). Subsequent annealing was carried out on several samples in forming gas at 1000°C for 30 min. More than 2×10^{11} cm⁻² of N_m , which was measured after annealing in N₂ within 20 min, is found to decrease to undetectable levels

Fig. 4. Mobile ionic charge density N_m as a function of annealing time t_N in N_2 at 1000°C for H-Ta-Mo (7 a/o Ta) gate. Several samples were subsequently annealed in forming gas at 1000°C for 30 min.

Electrode structures	N_m (cm^{-2})
Mo(3100Å) on H-Ta-Mo(150Å)	$> 2 \times 10^{11}$
Mo(3300Å)	1.3×10^{11}
H-Ta-Mo(3300Å)	Undetected ^a

^a The detection limit of N_m measurements is less than $5 \times 10^9 \text{ cm}^{-2}$.

when subsequent annealing is carried out in forming gas. This indicates that mobile ionic charge contamination in the gate oxides can be removed by annealing in forming gas. However, the reduction effect is not so remarkable when t_N is extended to 60 min. The prolonged annealing for 60 min in N_2 may have induced a change in film structures which suppresses the reduction effect. These results suggest the possibility that the removal of the mobile ionic charge contamination in the gate oxide is caused not only by the immobilization of Na in the electrodes [mechanism (ii)] but also by the gettering of Na from the SiO_2 by H-Ta-Mo films [mechanism (iv)].

Depth distribution profiles of Na for the samples examined in Fig. 4 are shown in Fig. 5. $^{23}\text{Na}^+$ intensity peaks are clearly observed in the SiO_2 region for the samples annealed only in N_2 (Fig. 5a, 5c), and are nearly independent of annealing time t_N in N_2 . For samples which were subsequently annealed in forming gas for $t_H = 30$ min, $^{23}\text{Na}^+$ intensity, normalized by $^{28}\text{Si}^+$ intensity in the SiO_2 region, decreases to 1/100 for the sample with $t_N = 5$ min (Fig. 5b) and 1/2 for the sample with $t_N = 60$ min (Fig. 5d). These re-

Fig. 5. Depth distribution profiles for $^{23}\text{Na}^+$, $^{28}\text{Si}^+$, $^{94}\text{Mo}^+$, and $^{181}\text{Ta}^+$ ions in H-Ta-Mo(3300Å)/ SiO_2 (400Å)/Si(substrate) structures. Analysis was done after annealing in N_2 at 1000°C for (a) $t_N = 5$ min, and (c) 60 min. Subsequent forming gas annealing was carried out at 1000°C for $t_H = 30$ min (b, d).

sults agree well with the N_m values measured by TVS (shown in Fig. 4), and indicate that very few Na atoms are contained in the SiO_2 when ionic charges are not detected in MOS capacitors. Therefore, the neutralization mechanism of Na ions in the SiO_2 [mechanism (iii)] can be ignored. Immobilization [mechanism (ii)] and gettering [mechanism (iv)] are still consistent with these experimental results.

Structural effects of Ta addition.—Figure 6 shows x-ray diffractometer traces for the H-Ta-Mo films with 0-100 a/o Ta after annealing in forming gas at 1000°C for 30 min. When the Ta concentration is 0 a/o, i.e., H-Mo (Fig. 6a), only Mo can be found. However, with the increase in the Ta concentration to 20 a/o (Fig. 6b and 6c), diffraction peaks for tetragonal MoTaN (CrNbN-type structure, space group $P4/nmm$) (9) appear in addition to the Mo peaks. For the films with 100 a/o Ta, i.e., H-Ta (Fig. 6d), hexagonal TaN is found instead of Ta, which is ordinarily observed after annealing in N_2 . The nitrogen in the H-Ta-Mo films was also analyzed by AES. Figure 7 shows Auger peak-to-peak heights of nitrogen (379 eV, KLL transition) in the middle depth of Mo and H-Ta-Mo films as a function of annealing time t_H in forming gas at 1000°C . The peak heights for H-Ta-Mo films are relatively higher than those for Mo films at any t_H . The nitrogen concentration in the H-Ta-Mo films, evaluated from these peak heights using sensitivity corrections for the constituent elements (10), is more than 5 a/o, whereas the concentration for Mo films is less than 2 a/o. From the results of the diffractometer traces and the AES analysis data, H doping and Ta addition are found to activate nitriding in the matrix Mo films.

Figure 8 shows Auger peak-to-peak heights of nitrogen in the middle depth of H-Ta-Mo gate electrodes as a function of annealing time t_N in N_2 at 1000°C . After annealing in N_2 , some samples were subsequently annealed in forming gas at 1000°C for 30 min. Immediately after an-

Fig. 6. nealing in N_2 , the peak heights are as low as those for Mo gate annealed in forming gas (shown in Fig. 7). However, subsequent annealing in the forming gas results in peak heights as high as those in the H-Ta-Mo gate annealed only in the forming gas (shown in Fig. 7), whereas the peak heights decrease when t_N is increased up to 60 min. This indicates that the nitriding reaction of the films proceeds remarkably when forming gas annealing is combined with Ta addition, and that nitriding occurs even on samples previously annealed in N_2 .

Mo grain growth is shown in Fig. 9, and corresponds to the samples shown in Fig. 8. Subsequent annealing in forming gas is found to increase the Mo grain size even more when the annealing time t_N in N_2 is less than 30 min. However, at $t_N = 60$ min, an increase in the Mo grain size is not observed after the subsequent annealing in forming gas. This phenomenon at $t_N = 60$ min agrees with the relatively low AES peak heights of nitrogen in the same samples shown in Fig. 8 as well as with the increased N_m shown in Fig. 4, sample (d). It is thought that large Mo grains, grown by prolonged annealing for 60 min in N_2 , suppress the nitriding of the samples due to the subsequent annealing in forming gas. This is because amorphous structures, which can be easily converted into nitrides, are almost completely eliminated from the Mo grain boundaries after prolonged annealing.

As described above, the Auger peak heights of nitrogen shown in Fig. 7 and 8 are found to agree with the ionic charge densities N_m , which change with process condi-

Fig. 8. Auger peak-to-peak heights of nitrogen (379 eV, KLL transition) in the middle depth of H-Ta-Mo gate electrodes as a function of annealing time t_N in N_2 at 1000°C . After annealing in N_2 , some samples were subsequently annealed in forming gas at 1000°C for 30 min.

Fig. 9. Average grain sizes of Mo in H-Ta-Mo gate electrodes as a function of annealing time t_N in N_2 at 1000°C . Prior to grain size measurements, same samples were subsequently annealed in forming gas at 1000°C for 30 min.

tions such as annealing time t_H in forming gas (Fig. 3) and annealing time t_N in N_2 (Fig. 4). In these figures, the relatively high N_m of more than $1 \times 10^{11} \text{ cm}^{-2}$ corresponds with the low nitrogen concentration of less than 2 a/o. On the contrary, when ionic charges are not detected in MOS structures, the nitrogen concentration in the gate electrodes reaches more than 5 a/o. These facts suggest that the reduction in N_m is significantly influenced by the structural and compositional changes in gate electrodes, which supports the immobilization mechanism taking place within the electrodes.

Effects of nitride on sodium diffusion.—The nitriding of H-Ta-Mo gate electrodes is found to be closely related to the reduction effect on the Na ion density in the gate oxide. The following effects on Na diffusion from gate electrodes into gate SiO_2 due to the nitride formation are supposed: (i) dramatic decrease in the diffusion coefficient of Na in the electrodes due to nitriding, and (ii) the capture of Na cations in the electrodes as a result of a stable nitride formation due to high electronegativity of nitrogen.

Thin metal nitride films, such as TiN (150Å thick) (11), TaN (12), and Mo-N (13), have been well known to work as diffusion barriers. A stuffing effect in grain boundaries has been proposed (14) as the mechanism for the diffusion-barrier properties of these metal nitrides. This effect is expected to be applicable to the blocking of Na diffusion in the present results, although thermal processing temperatures ($<600^\circ\text{C}$), applicable to these diffusion barriers, are lower than those in the present experiments ($900^\circ\text{--}1000^\circ\text{C}$).

Nitriding of Mo films has been reported for Mo formed by reactive sputtering in a mixture of Ar and N_2 gases (15), and for Mo annealed at $700^\circ\text{--}800^\circ\text{C}$ in an ammonia gas ambient (16) or in a mixture of H_2 and N_2 gases (16, 17). However, nitride does not form when Mo films are annealed in N_2 or in a mixture of H_2 (5%) and Ar (95%) (17) at temperatures up to 1000°C . Since the heat of dissociation of nitrogen molecules to monatoms is very high at these temperatures (113 kcal/mol) (16), the nitriding reaction between monatomic nitrogen and Mo can be ignored thermodynamically. When annealing is carried out in a forming gas, the heat of dissociation has been estimated to be reduced by half (16), which results in nitride formation, mainly $\gamma\text{-Mo}_2\text{N}$, at low temperatures of $700^\circ\text{--}800^\circ\text{C}$. As with Mo, Ta can be nitrided by annealing in forming gas but not in N_2 , as shown in Fig. 6. Therefore, H doping in

the films and/or in the annealing ambients is concluded to be effective in the nitride formation of Mo and Ta.

It has also been reported that the molybdenum nitride, formed in the processes described above, is thermally decomposed into elementary molybdenum by high temperature annealing at more than 900°C in N_2 or in a mixture of H_2 and N_2 (17-19). This agrees with the experimental results shown in Fig. 6a. However, as is shown in Fig. 6d, TaN is stable under annealing up to 1000°C . In addition, the melting point of TaN is as high as 3088°C . The formation and stability of MoTaN have been also confirmed in the samples annealed at 1000°C by x-ray diffraction, as shown in Fig. 6b and 6c. Therefore, the addition of Ta in the appropriate amount to Mo is thought to have a remarkable effect on preventing the decomposition of formed nitrides even after high temperature annealing up to 1000°C .

In molybdenum nitride gate MOS structures formed by reactive sputtering, passivation effects on ionic charge contamination have not been reported (15). This suggests that nitriding of gate electrodes is not required to reduce the contamination. The volume expansion caused by high temperature nitriding processes, which is estimated to reach to 27% in MoN from Mo (16), is thought to increase the density of Mo grain boundaries and to result in blocking Na diffusion at the boundaries.

To clarify the second mechanism in connection with electronegativity, oxygen-doped molybdenum films were examined as the gate electrodes for MOS structures. This is because oxygen has a higher electronegativity (3.5) than nitrogen (3.0) (20). Figure 10 shows N_m in the MOS structures as a function of the oxygen concentration in the electrodes. Here, the oxygen was doped by reactive sputtering of Mo in a mixture of O_2 and Ar gases. After annealing in N_2 at 1000°C for 30 min, the oxygen was converted into stable MoO_2 in the electrodes (21). With an increase in the oxygen concentration, N_m shows a tendency to increase after annealing above 800°C . This indicates that the possibility of capturing Na cations in oxygen-doped Mo films is eliminated. Similarly, the capturing of Na in H-Ta-Mo films may be eliminated.

The decrease in N_m resulting from forming gas annealing after N_2 gas annealing, shown in Fig. 4, can be ex-

Fig. 10. Mobile ionic charge density N_m for oxygen-doped Mo gate MOS structures after annealing in N_2 at $600^\circ\text{--}1000^\circ\text{C}$ for 30 min as a function of oxygen concentration in the electrodes.

plained by the blocking effect on Na diffusion, discussed above. When t_N is within 15 min, Na in the gate SiO_2 , diffused from gate electrodes by the annealing in N_2 , continues to diffuse toward the Si substrate during subsequent annealing in forming gas. In this case, an additional Na supply from the gate electrodes to the gate SiO_2 is abruptly blocked by the nitriding of the H-Ta-Mo gate. This results in a decrease in Na density in the SiO_2 . When t_N is 60 min, however, the blocking of Na diffusion is not sufficient and a relatively high density of Na remains in the SiO_2 even after the annealing in forming gas.

Conclusion

The reduction mechanism of mobile ion contamination in Ta-Mo alloy gate MOS structures is examined. The formation of tetragonal MoTaN is found in the Ta-Mo alloy gate electrodes during high temperature annealing up to 1000°C in forming gas. A possible explanation for the reduction in Na ion density in the gate SiO_2 is that the incorporated nitrogen changes the amorphous boundary structures of Mo grains to the crystalline MoTaN in the electrodes, and increases the density of the boundaries in the same way as the stuffing effect observed in TiN diffusion barrier films. These changes are believed to immobilize the Na in the electrodes and block Na diffusion from the gate electrodes into the gate SiO_2 .

ABSTRACT

The atom superposition and electron delocalization molecular orbital theory and large cluster models have been employed to study cation vacancy diffusion in α -Al₂O₃ and the bonding of α -Al₂O₃ to nickel, aluminum, and yttrium surfaces. Al³⁺ diffusion barriers in α -Al₂O₃ by the vacancy mechanism are in reasonable agreement with experiment. The barrier to Y³⁺ diffusion is predicted to be much higher. Since addition of yttrium to transition metal alloys is known to reduce the growth rate and stress convolutions in protective alumina scales, this result suggests the rate-limiting step in scale growth is cation vacancy diffusion. This may partially explain the beneficial effect of yttrium dopants on scale adhesion. The theory also predicts a very strong bonding between alumina and yttrium at the surface of the alloy. This may also be important to the adhesion phenomenon. It is also found that aluminum and yttrium atoms bond very strongly to nickel because of charge transfer from their higher lying valence orbitals to the lower lying nickel s-d band.

The essential requirement for high temperature oxidation resistant alloys is the development and maintenance of a continuous protective oxide scale on their surfaces. However, it is observed that, during cyclic heating and cooling, stresses are developed, leading to the spalling of the protective layer, thus corroding the alloy surface. It is well known that the addition of small amounts of rare-earth elements such as yttrium, zirconium, and hafnium improves the oxidation resistance of the alloy, first by decreasing the growth rate of the oxide, and second by increasing the adherence of the oxide scale to the alloy surface. Various hypotheses have been put forward to explain these beneficial effects of the rare-earth dopants. These mechanisms have been reviewed by Whittle and Stringer (1), Delaunay and Hunz (2), and Hindam and Whittle (3). It may be noted that there is an optimum amount of the rare-earth dopant necessary for obtaining optimal resistance to oxidation and optimal oxide scale adherence. In the case of yttrium, this optimum amount is about 100-300 ppm (2). The yttrium-implanted aluminum containing alloys show behavior similar to that of the cast alloys.

It is known on the basis of platinum marker studies (4) and ¹⁸O tracer studies (5) that the Al₂O₃ grains of the oxide scale grow inward into the alloy. The implication is that oxygen in some form diffuses inward along grain boundaries and aluminum oxidation takes place in the vicinity of the grain-alloy interface. Nothing is known about the details of the oxidation chemical reaction mechanism. That is, if cation vacancy migration is involved, it is not known if the cation vacancies diffuse some distance through the interfacial region prior to reduction at the grain-alloy interfacial region, or if they diffuse down from upper regions of the oxide grain boundaries for some distance prior to reduction, or if they diffuse some distance through the grains to the reduction sites at the grain-alloy interface. If such cation vacancy diffusion is unimportant, then anion vacancies might diffuse to the grain boundary region from the grain-alloy interface either through the Al₂O₃ or through the interfacial region. If the grain-alloy interfacial region is similar to the oxide grain boundary, then oxygen may diffuse all the way to the metal before being reduced. In this case, to continue inward grain growth, anion vacancy diffusion from the base of the grain through the interfacial region will occur and oxidation will take place in the interfacial region at the alloy surface. Alternatively, Al₂O₃ clusters may form in the alloy at the grain boundary-alloy interface and these would

then have to migrate to the center of the grain-alloy interface.

The present theoretical study shows that yttrium present in a nickel-aluminum alloy has the effect of preventing cation vacancy diffusion. This and the observed reduction in grain growth (1-3) implies that the rate-limiting step in the kinetics of Al₂O₃ grain formation has a mechanism involving cation vacancy diffusion.

The reduction in grain growth has the well-known beneficial effect of slowing the consumption of aluminum metal in the alloy due to spalling which occurs during cyclic heating and cooling (1-3). It is commonly hypothesized that an additional effect of reduced grain growth is a significant reduction in stresses in the scale which, when high (i.e., when no rare-earth dopant is present), cause rapid spalling. A cation vacancy migration blocking mechanism such as ours is not inconsistent with this hypothesis.

It has been suggested that the rare-earth dopants reduce interfacial void formation (1-3), although more recent studies cast doubt on the generality of this explanation (6), at least based on initial stages of scale growth. Less often considered is the possibility that void formation is a consequence of growth stresses.

The last general effect sometimes invoked to help explain rare-earth dopant effects on alumina scale adhesion to alloy surfaces centers on chemical bond strengths between the alumina and alloys and how the rare-earth elements may increase these strengths. In the present study, we find some support for this hypothesis. This comes from examining theoretically the binding energies of aluminum and yttrium metal atoms in nickel and the binding of Al₂O₃ to the alloyed surface. The calculated energies are large in each case, suggesting that the alloy is especially strong and that oxide scales should bond more strongly to yttrium on the surface of a Ni-Al-Y alloy than to nickel or aluminum.

Method of Calculation

We use the atom superposition and electron delocalization molecular orbital (ASED-MO) theory (7). This theory is based on separating the electronic charge density of a molecule or solid into a sum of rigid free atom components and a delocalized bond charge component. In a diatomic molecule (the generalization to polyatomics is straightforward), the binding energy E is exactly equal to the energy of integrating the electrostatic force on a nucleus as the two atoms come together forming the molecule (7a). The energy thus obtained for the superposition of rigid atoms, E_R , is equal to the interaction of one nucleus with the nucleus and electronic charge density of

¹ On leave from K. M. College, University of Delhi, Delhi 110007, India.

the other atom and is repulsive. The energy due to the interaction of the nucleus with the charge redistribution density, E_D , is attractive. Thus

$$E = E_R + E_D \quad [1]$$

If the electron redistribution density, which can be viewed as a bond charge density, is assumed to be made up of point charges, then the laplacian of the total energy evaluated at equilibrium is equal to the equilibrium harmonic bond stretching force constant, k_e (7a)

$$k_e = 4\pi Z_a \rho_b(a) \quad [2]$$

where Z_a is the charge of nucleus a, $\rho_b(a)$ is the atomic charge density centered on a and evaluated at nucleus b, and the laplacian is $\nabla_{R_a}^2$ when nucleus b is at the origin and nucleus a is at position R_a . Equation [2] is of the form of a classical electrostatic Poisson equation. Its derivatives contain, to good accuracy, harmonic, cubic and quartic force constants for molecules (8a, 8b) and solids (8c). In ionic molecules and solids such as aluminum and yttrium oxides, the point charge approximation is especially favorable, as shown below. In applying Eq. [1] for the total energy, E_R is easily calculated using atomic charge density functions. The bond charge density function is not available for calculating E_D , but it has been found that the total molecular orbital energy, E_{MO} , from diagonalizing a one-electron hamiltonian similar in form to the extended Hückel hamiltonian, is generally a good approximation to E_D , allowing predictions of molecular structures and reaction energy surfaces using Eq. [1] (7b). Numerous studies of molecular and surface structures and reactions have been published using the ASED-MO theory and Eq. [1]. The present paper is representative of the growing number of studies of solid-state systems using the theory. Past studies include the lattice and harmonic force constants of diamond structure carbon, silicon, germanium, and tin (8c), the lattice constant and optical properties of α -quartz (8d), the optical properties of ferrous and ferric oxides (8e) and bismuth and molybdenum oxides (8f), and the structures of defect clusters in wustite, $Fe_{1-x}O$ (8g).

In the ASED-MO theory, atomic valence orbital parameters are based on standard values,² modified by increasing cation and decreasing anion valence orbital ionization potentials to yield charge transfers in diatomic fragments approximating those from Pauling's ionicity and electronegativities relationship. Cation valence orbital exponents are for +1 charge. Oxygen anion valence orbital exponents are decreased by 0.5 a.u., which allows the theory to produce reasonable diatomic AlO and YO equilibrium bond lengths in this study. Parameters thus chosen are in Table I, and calculated diatomic properties are in Table II. It may be noted from Table II that the classical electrostatic Poisson equation, Eq. [2], does a good job of predicting the force constants of AlO and YO, which is additional support for the choice of oxygen valence orbital exponents.

Oxide and Alloy Model

For modeling cation diffusion in the scale, a 72-atom cluster model of bulk α - Al_2O_3 , shown in Fig. 1, is used. It consists of five nearly close-packed oxygen anion layers and four aluminum cation layers sandwiched between

² Valence orbital ionization potentials from Ref. (9a); valence orbital Slater exponents from Ref. (9b).

Table II. Calculated bond lengths (R_e), harmonic force constants (k_e), and dissociation energies (D_e) for AlO and YO^a

Molecule	R_e (Å)	k_e (mdyn/Å)		D_e (eV)
AlO	1.64 (1.62)	4.67 ^b	5.85 ^c (5.67)	4.95 (5.03)
YO	1.84 (1.79)	5.13 ^b	7.03 ^c (5.80)	8.66 (7.39)

^a Numbers in parentheses are the experimental values taken from Ref. (18).

^b From total energy calculation, Eq. [1].

^c From Poisson equation, Eq. [2].

them. Al³⁺ ions are shown on lines perpendicular to the close-packed planes of oxygen ions. The X's indicate the positions where these lines intersect the oxygen planes. α - Al_2O_3 belongs to the R $\bar{3}c$ space group, and the lattice is rhombohedrally centered hexagonal with $a = 4.763\text{Å}$ and $c = 13.003\text{Å}$ (10). Each aluminum cation is coordinated to six oxygen anions in a distorted octahedron. Three anions are at a distance of 1.93Å from the central cation and form a large triangle with 2.87Å edges, and the other three anions are at a distance of 1.89Å and form a small triangle with 2.52Å edges. Each anion is approximately tetrahedrally coordinated to four cations. In α - Al_2O_3 , two-thirds of the distorted octahedral sites are occupied by aluminum cations and the remainder are unoccupied interstices.

It will be seen that all of our oxide cluster models are charged. This results in proper molecular orbital occupations corresponding to the formal oxidation states of the cations and anions in the clusters. Since electronic structures in the ASED-MO theory depend only on atom valence orbital ionization potentials and orbital symmetries, exponents, and overlap, and not explicitly on electron repulsions, these extra charges do not enter into the calculation of E_R or the E_{MO} approximation to E_D .

We first model the cation vacancy diffusion by a vacancy migration, parallel to the C axis. For this, consider the tube of oxygen triangles shown in Fig. 2, through which the cations diffuse downward from the point marked a to the point marked e. This motion is segmented into three parts: (i) motion from a to b is studied with a cation vacancy at c; (ii) motion from b to c is studied with a cation vacancy at a; and (iii) motion from c to e is studied with a cation vacancy at f. Points a, c, and f represent the normal lattice sites of aluminum cations; points b and d show the centers of the small and large oxygen triangles, respectively; and point e represents an unoccupied octahedral interstice.

Calculations for diffusion along the C axis direction are performed both with and without lattice relaxations about aluminum cation vacancies and yttrium cation substitutions. Additional calculations modeling diffusion perpendicular to the C axis without lattice relaxation are also made using a wider 94-atom cluster. Additional calculations allow an estimate of the vacancy formation energy.

For modeling the binding of the oxide to a metal substrate, we have chosen a two-layer thick cluster of ten nickel atoms, with seven atoms in the top layer, representing the Ni(111) surface (Fig. 3). In alloy models, the top central atom is replaced by Al and Y, whose positions are relaxed. In treating the bonding of small oxide clusters to the metal surface, the oxide cluster is kept rigid and its height is variationally optimized.

Table I. Parameters used in the calculations. Principal quantum number (n). Slater exponents (ζ) in atomic units, coefficients (c), and ionization potentials (IP) in electron volts

Atom	s			p			d					
	n	ζ	IP	n	ζ	IP	n	c_1	ζ_1	c_2	ζ_2	IP

Fig. 1. $Al_{18}O_{54}^{54-}$ cluster model of $\alpha-Al_2O_3$ used in the theoretical calculations.

Our metal atom clusters are high spin, meaning each d band molecular orbital is occupied by at least one electron. Thus, while lower levels are doubly occupied, some upper ones are singly occupied. The result is that the clusters have spin magnetic moments approximating bulk values. It may also be noted that these are initial state calculations and do not include shake-up and relaxation shifts evident in photoemission studies of the electronic structure. Such phenomena are unimportant to chemical bond strengths and molecular structures analyzed in this paper.

Results

Cation vacancy diffusion and oxide grain growth.—We plot the variation of E , E_R , and E_{MO} as a function of the dif-

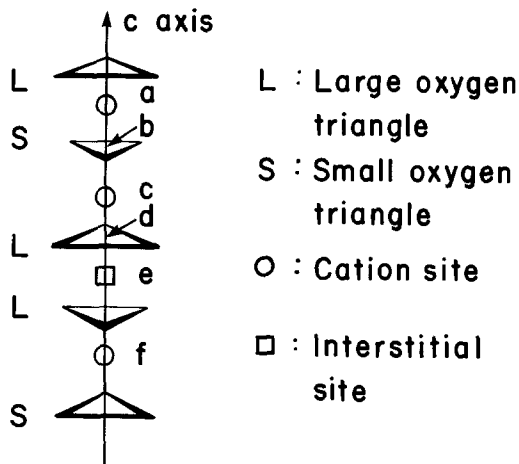

Fig. 2. Sites traversed in the cluster model of Fig. 1 by migrating Al^{3+} and Y^{3+} cations during Al^{3+} cation vacancy migration.

Fig. 3. Cluster model of the Ni(111) surface

fusion distance of Al^{3+} cation through the oxygen network without relaxation of the lattice in Fig. 4. As the cation moves towards the center of the small oxygen triangles (point b), the molecular orbital energy (E_{MO}) decreases but the two-body repulsion energy (E_R) increases much more rapidly, with the result that the total energy (E) is much less stable at point b than that for the lattice site of the cation (point a). The calculated diffusion barrier at point b is 4.6 eV. When the cation is at b, the cation vacancy becomes a split vacancy, one-half at a and one-half at c. As the cation moves down further towards point c, the total energy decreases and becomes minimum on reaching c.

Fig. 4. Dependence of total energy, E , and its components, E_R and E_{MO} , as an Al^{3+} cation moves through the cluster model according to the scheme in Fig. 2. Motion from a to c represents vacancy motion from c to a. Motion from c to e is with the vacancy at f.

During its subsequent motion from c to d, the center of the large oxygen triangle, the stabilization in E_{MO} is only marginally less than the destabilization in E_R . This produces a diffusion barrier of only 0.3 eV at d. As the Al^{3+} cation moves further towards point e, the unoccupied octahedral interstice, the molecular orbital energy becomes more stable, whereas the two-body energy becomes less stable, producing a diffusion barrier of 0.9 eV at point e. Thus the maximum barrier height for the diffusion of the cation during its motion from a to e is 4.6 eV, and this is while passing through the small oxygen triangles. Our calculated diffusion barrier might appear to be consistent with the experimental value of 4.9 eV determined for the diffusion of aluminum cations in polycrystalline Al_2O_3 by Paladino and Kingery (11). However, it must be remembered that this experimental barrier includes the vacancy formation energy, assuming the diffusion is by the vacancy diffusion mechanism. Within the unrelaxed model, we calculate a vacancy formation energy of 4.7 eV and Dienes *et al.* (12) determine a value of 9.1 eV using a pairwise potential method including a polarization energy term and lattice relaxation about the defect. The procedure employed here and also by Dienes *et al.* for determining the Al^{3+} vacancy formation energy takes into account the energy for removing a bulk-coordinated Al^{3+} ion and placing it on the surface. Dienes *et al.* found a vacancy migration barrier along the C axis of 6.6 eV with the lattice relaxed. Thus, the result of adding the formation energies and migration energies is 9.3 eV in our work without lattice relaxation and 15.7 eV in the work of Dienes *et al.* including lattice relaxation. Both overestimate the experimental value of 4.9 eV. It should be remembered that it is unlikely that one will find the results of calculations based on a quantum mechanical model and those based on a parameterized classical model for a solid in agreement. The Dienes *et al.* method appears to severely overestimate the diffusion barrier for Al^{3+} ion. The present result, a bit closer, does not include lattice relaxation. When we allow the oxygen anions making up a small triangle to relax against a fixed surrounding cation environment, then the Al^{3+} vacancy diffusion barrier reduces to 0.6 eV. The relaxation amounts to a 0.2\AA increase in the distance between the center and vertices of the small triangle. When this energy is added to 4.7 eV, the cation vacancy formation energy, the total is 5.3 eV, which compares favorably with the experimental value of 4.9 eV. Vacancy migration in other directions may also be possible. Two pathways perpendicular to the C axis were examined and yielded barriers of 7.0 and 3.8 eV. The 7.0 eV transition state was along a path through an interstitial site. For this pathway, relaxation produced no stabilization. The other pathway takes the cation through an oxygen triangle, which is larger than the small triangle discussed above. No relaxation in this site was made, but because of the larger size of this triangle the relaxation energy is expected to be no more than a few tenths of an electron volt. From these results, it appears that migration along the C axis is favored over the other direction. Let us now consider the diffusion of the Y^{3+} cation along the C axis in the $\alpha-Al_2O_3$ lattice. Consider its motion again from point a to point e, which is the same diffusion pathway used for the Al^{3+} cation. The variations in E , E_R , and E_{MO} are graphed in Fig. 5. For the unrelaxed lattice model, the calculated diffusion barrier for the Y^{3+} ion to pass through the small oxygen triangle is 26.5 eV, that for crossing the large oxygen triangle is 6.4 eV, and that for passing through the octahedral interstice is only 0.3 eV. In a lattice relaxation calculation for Y^{3+} in the center of the small triangle, the Y-O distances increase by 0.3\AA and the barrier to reach this position drops to 7.5 eV. These results show that there is a very large increase in the diffusion barriers for the Y^{3+} ion passing through the lattice along the C axis, compared to the values calculated for Al^{3+} ion diffusion as discussed above. Most of this difference is due to the large ionic radius of the Y^{3+} ion (0.93\AA) as compared to that for the Al^{3+} ion (0.50\AA). In the framework of ASED-MO theory, the large nuclear charge of Y

Fig. 5. As in Fig. 4, but for Y^{3+} and Al^{3+} vacancy pair diffusion

(39) compared to Al (13) increases the two-body repulsion energy considerably and this is mainly responsible for the high Y^{3+} diffusion barriers on crossing the oxygen triangles. In the octahedral interstice, however, the two-body repulsion energy is small, which gives rise to lower barrier at this site.

As discussed in the opening of this paper, cation vacancy migration may be, although the mechanistic details have not yet been deduced experimentally, the rate-limiting step in the grain and hence protective-scale growth rate. The mechanism of growth within an individual oxide grain may be illustrated by considering a schematic packing of the metal alloy (M), aluminum (Al), and oxygen (O), as shown in Fig. 6. There will be excess O_2 at the grain surface due to rapid short-circuit diffusion. This will lead to cation vacancies at the grain surface which may be associated with O^{1-} anions or perhaps O_2 mole-

Fig. 6. Schematic view of a cross section of an alumina grain bonded to a metal alloy. Aluminum cation vacancies at the alumina surface are due to excess oxygen.

cules, either of which will be reduced during oxide growth. A cation vacancy may be viewed as carrying a charge of +3, but in the bulk the charges are actually holes in oxygen 2p band. When vacancies with accompanying holes in the O 2p band reach the metal alloy surface, they are reduced and metal atoms fill the vacancies and are themselves oxidized, as shown schematically in Fig. 7 and 8. As the process continues, voids begin to form at the interface, but these can be filled by metallic aluminum and oxide rebonding to the void bottoms as structure and kinetic factors allow, but some voids may never be filled. During this process of reduction of vacancies at the metal-oxide interface, yttrium will be introduced to the interfacial region, but, its diffusion barrier being high compared to aluminum, it will block cation vacancy diffusion through the interface. The consequent reduction in oxide growth within the scale will decrease internal strains which lead to the convoluted grain morphologies associated with poor adhesion as shown by Golightly *et al.* (13, 14).

Bonding of yttrium and aluminum oxide to nickel.—Because of the high diffusion barrier of a Y^{3+} and Al^{3+} vacancy pair in Al_2O_3 , it may be that Y^{3+} never enters the oxide but forms a monolayer of cations sandwiched between the alloy and the first anion layer of the oxide grains. Nevertheless, we have modeled the effects of Y^{3+} when fully coordinated to oxygen anions in the first layer of oxide bonded to the alloy.

Our model consists of $[AlO_6]^{6-}$ and $[YO_6]^{6-}$ binding on the center of the top of Ni_{10} cluster. We obtain comparable binding energies for both (Table III). These oxide clusters are structured to be superimposable in bulk Al_2O_3 , and the triangular face (edge length of 2.52\AA) bonds nearly in registry with the threefold hollow sites of the surface spaced 2.48\AA apart. The difference in energy for $[AlO_6]^{6-}$ bonded to threefold sites with atoms or hollows in the second nickel layer is only 0.02 eV , so the former sites are used throughout this study. The clusters are given charges of -6 , so that the surface is oxidized by three electrons. The binding energies are so close to one another for $[AlO_6]^{6-}$ and $[YO_6]^{6-}$ clusters that we conclude that the oxide adhesion bond to the surface is not affected by the presence of yttrium in the oxide should it penetrate the first layer of anions. When the central Ni atom is removed, representing the metal vacancy site formed when Al or Y enter a vacancy site in the oxide, the respective $[AlO_6]^{6-}$ and $[YO_6]^{6-}$ binding energies to the surface are both increased about the same amount (Table III). While these energies are higher, reflecting the increased bonding ability of partially coordinated Ni atoms surrounding the vacancy, they are again comparable in magnitude.

Bonding of aluminum and yttrium atoms in nickel.—The alloy surface is expected to contain, in addition to Ni, some Al and Y atoms. We calculate binding energies about two and three times larger for Al and Y, respectively, compared to Ni in the center of a Ni_9 cluster. As

Fig. 7. Schematic view of cation vacancy migration through an alumina grain to the alloy substrate.

Fig. 8. Electronic structure leading to vacancy reduction at the alumina-alloy interface.

may be seen in Table III, these results are about the same when metal cation parameters are used, and thus are parameter insensitive. The large binding energy of Al is consistent with $\sim 1.75\text{ eV}$ enthalpy of formation of Al-Ni alloys in the limit of low Al concentration (15).

There are two separable contributions to consider for adatom adsorption energies. One, which is quite strong for all three, is the binding stabilization resulting from the adatom s orbital mixing with the Ni_9 cluster s band. The second occurs only for Al and Y adatoms and involves charge transfer to the Ni_9 band. These two effects are clearly visible in Fig. 9. The charge-transfer interaction may be a general feature of tenacious alloys.

^a Results using free atom parameters. Based on Table I, decrease all IP by 1 eV for Ni; decrease all ζ by 0.3 and all IP by 2 eV for Y; $\zeta_s = 1.3724$, $\zeta_p = 1.352$, and decrease all IP by 2 eV for Al.

Bonding of alumina to the alloy.—We have modeled the bonding of alumina to alloys both low in aluminum and yttrium concentration at the interface and high. For the low concentration case, we find [AlO₆]⁶⁻ binds to Ni₁₀, Ni₉Al, and Ni₉Y with the respective energies 4.0, 4.0, and 5.8 eV (Table III). For the high concentration case, we find [AlO₆]⁶⁻ binds to Al₁₀ and Y₁₀ hexagonally-packed bulk-superimposable clusters with respective energies of 4.8 and 12.8 eV (Table IV). These results imply that the presence of yttrium on the surface of the alloy at monolayer coverage will greatly strengthen the bond between the oxide grain and the alloy. As shown in Fig. 10, the stabilization of the lowest asymmetry orbital of the O 2p band by the lowest asymmetry orbital of the Ni 4s band dominates the interfacial bond. The strong bond in the yttrium case is a result of the mixing of its high lying empty d orbitals with the O 2p band orbitals, stabilizing many of them by a small amount. The strengths of the oxide cluster bonds to Al and Y are consistent with the high standard heats of formation of α -Al₂O₃ and Y₂O₃, 17.5 and 18.2 eV, respectively (15). The standard heat of formation of NiO is only 2.5 eV (16). Thus the combination of strong Al-Ni and Y-Ni bonds and great stability of Al-O and Y-O bonds are likely to be important to the adherence of the oxide to the alloy.

Other models for the interfacial bond strength may also be considered. The [MO₆]⁶⁻ (M = Al,Y) clusters oxidize the surface on bonding to it. It might be thought that a more appropriate model is [MO₆]⁹⁻ representing an oxide layer bonding by means of its nonbonding electrons to the alloy surface. A similar model has been employed to discuss the bonding between [AlO₆]⁹⁻ and Fe, Ni, Cu, and Ag atoms (17). We find that [AlO₆]⁹⁻ binds much more weakly to Ni₁₀ (0.2 eV) and does not bind at all to Ni₉Al and Ni₉Y. This is expected because the [AlO₆]⁹⁻ cluster is closed shell and the metal clusters are nearly d¹⁰, also closed-shell systems. The [AlO₆]⁶⁻ cluster, which serves to oxidize the metal surface, is a more reasonable model and results in strong bond formation. It is likely that this inability of the stoichiometric oxide to bind to the alloy serves to help prevent the closing of voids that form at the oxide-alloy interface. Only short-circuit oxygen diffusion into an interfacial void or cation vacancy migration to the surface of the oxide facing the void or metal flow into the void will allow the void to close.

Table IV. Binding energy (BE) of AlO₆⁶⁻ with Al₁₀ and Y₁₀ cluster models. Heights of oxygens [*h*(O)] and central metal atom [*h*(M)] are optimized to the nearest 0.05Å

Cluster	BE (eV)	<i>h</i> (O)	<i>h</i> (M)

Y ₁₀	12.8	0.45	-0.90

Fig. 10. Molecular orbital energy level correlation diagram showing bonding stabilizations at the alumina-nickel interface.

Conclusion

We find that Y³⁺ cations, once they are incorporated at monolayer levels in the oxide metal interface, cannot diffuse into the oxide and block oxide growth by the cation vacancy diffusion mechanism. If cation diffusion is the rate-limiting growth mechanism, then this may serve to retard void formation at the interface and rapid grain growth, which would lead to convoluted morphologies in response to growth stresses. This conclusion, derived from our theoretical treatment of diffusion, supports suggestions of Golightly *et al.* (13, 14) based on observations of a reduction of interfacial void formation, the development of columnar oxide grain growth on alloys doped with yttrium, and a reduction of scale-growth rate on the yttrium-doped alloy.

We also find that alumina bonds very strongly to yttrium when at the surface of the alloy. If adhesion failures involve rupture of Y-O bonds at the interface, then this may be important to adhesion. Interestingly, we find aluminum and yttrium bind very strongly in nickel as alloying elements. This extra strength is a result of a charge-transfer interaction and is likely to be a general explanation for the high strengths of many alloys.

The Effects of Thermal History during Growth on O Precipitation in Czochralski Silicon

Monsanto Electronic Materials Company, St. Louis, Missouri 63167

ABSTRACT

High oxygen wafers from 100 mm diam Si crystals grown by the Czochralski process, but subjected to three different thermal histories in an experimental puller, were examined by Wright etching, transmission electron microscopy, and Fourier transform infrared spectroscopy after wafer heat-treatments at 775°, 1050°, 775° + 1050°, and 1320° + 775° + 1050°C. Only wafers near the seed end of each ingot were used, thus minimizing differences in parameters other than thermal history. The observations show that defect morphology and O precipitate number density (not total O precipitation) after the one- and two-step heat-treatments depend on thermal history in the puller. In particular, 775°C heated wafers which spent less than an hour in the puller below 1000°C show number densities down by more than a factor of 100 from those which spent longer. On the other hand, the observations indicate that effects of puller thermal history are erased with a short 1320°C anneal, or typical VLSI multistep pretreatments which enhance bulk oxygen precipitation. In addition, the results suggest two possible complications for simple models of oxygen precipitation. These are that 500°C annealing can be much more effective than 775°C annealing for nucleating oxygen precipitates, contrary to model predictions, and that critical sizes for precipitate dissolution at 1050°C can be much larger than predicted by classical calculations.

Oxygen in Czochralski-grown silicon crystals plays an important role in device performance. After certain thermal treatments, it can have such negative effects as the formation of "thermal" (1) and "new" (2) donors, or such positive effects as the formation of bulk defects which act as gettering sites for metallic impurities and native point defects (3).

During crystal growth, the silicon crystal receives not only its specified oxygen allotment, but also its first thermal annealing treatment. This annealing treatment introduces oxygen donors and precipitate nuclei which can determine precipitation behavior during subsequent wafer heat-treatments. Previous investigators have reported precipitation behavior differing with position along the length of a 3 in. diam crystal even in regions with similar oxygen content (4), but the roles of puller thermal history and those of other factors associated with position in the ingot were not separated. In related work, Tsuya *et al.* (5) found that extended annealing in the puller enhanced the rate of precipitation and the number density of defects in the middle of a 35 cm long ingot. Independently, Nakanishi *et al.* (6) have demonstrated that defect density after a 1050°C wafer heat-treatment can be decreased, and the defect radial distribution modified, by rapid cooling of a 3 in. diam ingot after crystallization. However, no detailed study of the effects specifically of puller thermal history after a wide variety of heat-treatments was available.

The goal of this study was to assess (for 100 mm diam crystals) the dependence on puller thermal history of defect type, precipitate number density, and total oxygen

precipitation after a variety of wafer heat-treatments. Instead of using position in the ingot for indirect control of thermal history, position in the ingot was held constant and only thermal history was modified. To be specific, silicon crystals were cooled by three different methods: (i) quenching in air, (ii) shielding the growing crystal from heat radiated by the hot melt, and (iii) gradual cooling of the ingot in direct view of the melt. The results which follow support many of the observations cited above. In addition, they indicate that the strongest effects of puller history involve defect type and precipitate number density, not total precipitation, and that those effects are most obvious after precipitation in a single low temperature step (*e.g.*, 775°C). However, the strong puller effects observed conflict markedly with predictions from a simple semiempirical model for oxygen precipitation. Possible explanations of this are discussed as well.

Experimental

Nine 100 mm diam boron-doped [100] silicon crystals grown in an experimental puller with 18-22 Ω-cm resistivity and different oxygen levels were used. Six of these crystals were grown for about 2h, plucked from the crystal puller, and then allowed to cool to room temperature. These crystals, which will be referred to as Quench crystals, were pulled sequentially from the same melt. Another crystal, which will be referred to here as the Shield crystal, was grown for 10h in a crystal puller fitted with a shroud suspended directly above the melt, which surrounded and shielded the pulled crystal from the hot melt below. For comparison, two unshielded crystals grown for a similar time were also used. These crystals, for con-

Fig. 1. Thermal profiles in the crystal puller. Estimated time spent in each 100°C temperature interval, based on optical pyrometer measurements, for seed-end material from ingots with three different thermal histories.

venience, will be called Ramp crystals. Figure 1 shows histograms of the time per degree centigrade spent in the crystal puller by seed-end silicon from each process. These profiles were inferred from optical pyrometer measurements on the ingot exterior during crystal growth. Note that the thermal history of the Quench crystals is similar to what one might expect for material from the bottom end of a Ramp ingot.

Slices cut with (110) or (100) orientation from the first 10 cm of each of the nine crystals were subjected to a variety of annealing treatments. The treatments (and their abbreviations) are: 16h at 775°C in N₂ (L), 24h at 1050°C in N₂ (H), and 16h at 775°C followed by 16h at 1050°C (LH) in N₂. To assess the possibility of erasing puller history effects with a high temperature heat-treatment, the LH heat-treatment was also performed after a 3h "dispersing" heat-treatment at 1320°C (DLH) in argon. The two precipitation temperatures in these treatments, 775° and 1050°C, were chosen because the combination of these two is known to facilitate efficient precipitation in Czochralski crystals.

Before and after the annealing treatments, the concentration of oxygen was inferred from FTIR absorption coefficient (α) measurements using the DIN relationship: $O/[cm^3] = 2.45 \times 10^{17} \alpha [cm^{-1}]$. Carbon in all wafers was below FTIR detectability ($< 3 \times 10^{15} [cm^3]$). Optical microscope characterization was done after a 20 min Wright etch to verify defect uniformity. Several 3 mm disks (typically four) from the center of each of the 20 wafers for this study were examined in the TEM. Defect types, precipitate sizes, and precipitate number densities were determined from TEM observations. Although Wright etching did not distinguish precipitates from other defects, in cases where defects were large enough to result in distinct etch pits, the optical observations qualitatively supported TEM density determinations over a larger sampled volume. Finally, some wafers with each puller history were subjected to a denuding treatment (7). This involved a denuding step at 1150°C, a multistep annealing treatment in the 500°-800°C temperature range, and 8h annealing steps at 900° and 1050°C, to allow residual puller effects on denuded zone depth after a lengthy treatment process to be assessed.

Results

Table I summarizes the comparative data on Shield, Ramp, and Quench material which had oxygen concentration near 18 ppma. It includes information on initial carbon and oxygen concentrations and thermal history in the puller as well as interstitial oxygen concentrations, defect types, precipitate number densities, and precipitate sizes after the heat-treatments described above. Figure 2 shows TEM micrographs of some of the defect population types referred to in Table I.

The consistency between IR and TEM observations should be addressed first. Figure 3 shows a log-log plot

of precipitated oxygen (initial minus final) per precipitate vs. precipitate size. These data cluster along a line of slope 2, as expected if precipitates above a few hundred angstroms in size are platelets which grow laterally, but not in thickness, as has been suggested previously (8). If we assume the density of oxygen in the precipitates to be typical of silica minerals (e.g., 5×10^{22} [O/cm³]), then the volume-averaged thickness of these precipitates is around 60Å. Such thicknesses appear consistent with some TEM edge-on precipitate observations (9). Thus we have reason to believe that oxygen precipitation is the primary operating process, and that we can get some idea of the number of oxygen atoms per defect as a function of precipitate size from the above correlation.

Concerning the overall effects of wafer thermal history, we find very little of the total oxygen precipitated after individual 775°C or 1050°C wafer heat-treatments, but a sizeable fraction (e.g., 70%) precipitated after 775° + 1050°C treatments, regardless of prior history. In the specimens with a single wafer heat-treatment, we find a much lower number density of defects after 1050° than after 775°C. This was expected, and probably results because much smaller nuclei are able to survive and grow at 775° than at 1050°C (10). Unexpected, however, was the slight decrease in defect density for Ramp and Shield material in going from 775° to 775° + 1050°C treatments. It is certainly plausible that the 1050°C treatment redissolves some of the precipitates which had not grown large enough during the 775°C treatment to survive higher temperature. However, one might expect (as we show in the discussion) that defects large enough to be detected in the TEM after the 775°C treatment would not dissolve at 1050°C.

Fig. 2. a: Defects in Ramp crystals after 775°C wafer heat-treatment. Dipoles and tiny precipitates were found in the Ramp as well as in the Shield wafers; only precipitates in Quench material. b: Stacking faults and tiny precipitates (arrowed) in Shield wafers after 775°C + 1050°C treatment. c: Defects in Ramp crystals after 775°C + 1050°C. d: A punched-out dislocation in a Quench wafer after 775°C + 1050°C. e: Precipitate dislocation complex in a 1050°C Shield crystal. This type of defect was also found in 1050°C Ramp wafers. f: Defects in a Shield crystal after the 1320°C + 775°C + 1050°C treatment. Similarly treated Ramp and Quench wafers also contained these defect types.

Concerning different puller histories, the most striking differences in precipitate number density occur after single-wafer heat-treatments. The relative absence of detectable defects in approximately 10^{-7} cm³ of Quench material after the 1050°C treatment is consistent with the observation by Nakanishi *et al.* (6) that densities after such annealing in Quench material can be down from those in Ramp/Shield material by several orders of magnitude. This may be easy to understand, since the 1050°C heat-

treatment is an unlikely source of precipitate nuclei itself. A similar drastic reduction in number density going from Ramp/Shield to Quench wafers (in this case, by nearly two orders of magnitude) is observed after the 775°C treatment, although this time it is unexpected since 775°C is considered to be a very effective nucleation temperature (10). The trend to lower number densities in quench material after the 775°C + 1050°C treatment is also present, although not as large. However, both Ramp and Shield material show number densities similar to that of the Quench material if they have been first put through a 1320°C “dispersing” heat-treatment. This provides evidence that the Quench differences are in fact due to puller thermal history, and are not otherwise intrinsic to the crystals. Differences in precipitate number density of smaller than a factor of 10 between ingots might also result from thermal history differences. However, since such differences exist between ingots after the 3h “dispersing” anneal, intrinsic ingot differences may be responsible as well.

Defect types are in general correlated with the size of precipitates, with few lattice deformation effects (*e.g.*, punched-out loops, dislocation complexes) associated with defects in the 100-200Å size range. But there are also unexplained differences, especially after the two-step heat-treatment. The most drastic is the much larger diversity of defects in Ramp as compared to Shield wafers. That thermal history is the cause, as opposed to subtle intrinsic differences, is this time supported by the similarity of defect types (in all crystals) observed in wafers which have undergone a 1320°C treatment prior to the two-step anneal.

Discussion

The results above confirm that precipitate number density and type (but not necessarily total oxygen precipitation) after one or two wafer heat-treatments can be strongly dependent on prior thermal history in the puller. Along the length of a single ingot, these effects may be offset by axial impurity and point defect profiles (4) which are present as well. The results also confirm that the effects of thermal history can be erased to a large extent by a short wafer heat-treatment at 1320°C, and that puller history may have little effect on denuded zone depths after a multistep denuding treatment which includes temperatures below 800°C.

The results also provided a few surprises. The first concerns the loss of detectable precipitates in 775°C-treated wafers after a subsequent 1050°C anneal. Critical radius calculations (*e.g.*, 11, 12) predict that precipitates with more than 60-100 oxygen atoms should be stable at 1050°C, and yet Fig. 3 suggests that many of the precipitates “lost” after the 1050°C anneal probably contained more than 10^4 atoms of oxygen. Even if they did not, the defects certainly were detectable in the TEM in darkfield images at rather low magnifications (*e.g.*, 50,000 times). Between 10^3 and 10^4 atoms is probably a lower limit for detectability for equidimensional precipitates under the observing conditions, and hence a large discrepancy exists. The problem may lie with the assumption of spheres in critical radius calculations. If many of the defects are very small in one or more directions (*e.g.*, as disks or rods), then their surface area and propensity to dissolve may increase. Of course, their effective size (longest linear dimension) for TEM detection would also increase. The “small dislocation loop contrast” associated with many of the defects in the 775°C material (Fig. 2a) and the observations by Bourret *et al.* (13) and others of rodlike defects which are unstable when too large suggest further that shape effects may be quite important in nucleation models.

A second surprise was the strong effect of puller history on defects after a 16h wafer treatment at 775°C. Figure 4 compares measurements of precipitate number density after the 775°C treatment with predictions of the nucleation model of Inoue *et al.* (10-12). Their model is based on observations after LH-type heat-treatments, which indicate that the number of detectable precipitates is propor-

Fig. 3. Oxygen atoms per precipitate (O_p/N_p) vs. mean precipitate size (maximum projected dimension L). Data from Table I are plotted here along with a least squares power law fit (linear on log-log) which suggests two-dimensional growth for precipitates larger than 0.03 μ m in size. Vertical bars reflect IR and precipitate number density uncertainties, and have been considered in the fitting process. The horizontal bars do not represent uncertainties in mean size, but do indicate relative limits on the range of precipitate sizes observed in each specimen type.

Fig. 4. Theoretical vs. observed number densities after a 16h, 775°C heat-treatment. The curves show precipitates per cubic centimeter as a function of processing time. Nucleation rates were calculated with the algorithm of Inoue *et al.* (10) using numbers recommended by Rogers *et al.* (12). Total number densities were determined by convoluting those rates with the growth thermal history (Fig. 1) followed by a 16h 775°C heat-treatment. Observed number densities are from Table I.

tional (for small changes in interstitial oxygen concentration) to the time spent at various temperatures in the 600°-900°C range. As can be seen, the number of precipitates predicted after the 775°C anneal for all material is near that observed for the Quench crystal. This suggests relatively short puller histories for the material used to calibrate the model. More importantly, the modeled nucleation rate curve [*cf.* Ref. (12)] peaks at 700°C with a full width at half-maximum of 100°C. Thus a 6h thermal history in the puller between 400° and 1000°C (*i.e.*, the Shield/Ramp puller treatments) should have increased the number of observed precipitates by 30%, instead of the observed 18,000%.

Ingot position, initial oxygen concentration, initial carbon concentration, but not thermal history, were the same for the Quench and Ramp/Shield material examined. Since the differences between Quench and Ramp/Shield number densities are removed by a 3h 1320°C "dispersing" treatment, they almost certainly arise from differences in thermal history. In subsequent work (15), this conclusion has been confirmed by TEM/etching observations on Quench wafers which indicate that 3h pretreatments at 500° or 600°C are adequate to bring the 16h, 775°C precipitate number densities in Quench wafers up to those found in Ramp/Shield wafers. Taken in the context of the single-stage nucleation model of Inoue *et al.* (10), this would imply nucleation rates below 700°C that are at least three orders of magnitude higher than rates predicted by the model. Reconciliation of these observations with those of Inoue *et al.*, especially concerning the temperature dependence of nucleation rate, appears to require that the critical-density term in the nucleation equation be dependent on prior history. This problem with a steady-state critical-density term has already been mentioned in the discussion by Osaka *et al.* (11) of an "induction time" for nucleation in quenched materials, and appears to be due to the kinetic stability of clusters with only a few oxygen atoms (14) and the existence of a site in the lattice able to trap its first oxygen only at temperatures below 700°C (15). A precipitation model which considers these issues may be important for modeling low temperature history effects.

Conclusion

A systematic study of the effects of thermal history during the growth of 100 mm Czochralski silicon ingots is reported. It shows that puller thermal history, if separated from other axial effects in the ingot, can play a strong role in the type of defects and number density of precipitates (but not necessarily the total oxygen precipitated) after one- or two-wafer heat-treatments. In particular, the study of precipitate number density differences after a single 775°C heat-treatment provides evidence for a low temperature process enabling precipitate nucleation at rates much higher than predicted from the model of Inoue *et al.* The observations also call into question the relevance of classical critical radius calculations in such models. On the other hand, differences due to puller thermal history from the point of view of device manufacture do not survive intentional low temperature annealing or multistep intrinsic gettering schemes which add additional processing in the 500°-800°C temperature range. Effects of puller thermal history may also be completely erased by a short 1320°C heat-treatment.

Structural Effects on a Submicron Trench Process

Daeje Chin,* Sang H. Dhong,* and Glenn J. Long

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Recently, silicon trenches have been widely used for device isolation or three-dimensional capacitors in dynamic memories. In this work, trenches with submicron openings have been fabricated and several structure-dependent effects were discovered. A reactive ion etching rate in the vertical direction inside a trench decreases significantly as the aspect ratio (depth/width) becomes larger. A bottle-shaped profile due to undercutting starts to appear with trenches whose openings are smaller than a micrometer and becomes worse as the width decreases. A film thickness on sidewalls for refilling trenches shows no strong dependence on the structural aspect when chemically vapor deposited at low pressure.

Isolation technology using silicon trenches is employed in high-speed bipolar integrated circuits (1, 2) and in latchup-free CMOS devices (3). A high density MOS dynamic RAM cell utilizes trench sidewalls to increase storage capacitance (4). Three steps are involved in a silicon trench process: reactive ion etching of Si substrate, refilling with dielectric materials, and planarization. Technical constraints include: (i) no void remains inside a trench after refilled; (ii) defect density is low at sidewalls and corners; and (iii) a dielectric layer can be deposited uniformly.

As lithographic technology improves, the trench opening width is expected to shrink, while the depth is kept the same or even larger in dynamic memories to maintain a minimum storage capacitance. Currently the minimum feature size definable by lithography, however, is about 1 μm or slightly less by advanced optics and 0.5 μm by an electron beam. By making features smaller than the lithographic limit, this work aims at investigating potential problems in a submicron trench process in the future, particularly the reactive ion etching of silicon substrates with small mask openings and chemical vapor deposition into narrow and deep trenches.

Experiments

On p-type wafers, 100 nm nitride and 600 nm polysilicon layers were sequentially deposited. An optical lithographic step was done to create patterns on the polysilicon layer with different linewidths, as shown in Fig. 1a. After etched vertically by reactive ion etching (RIE) with a photoresist mask, the polysilicon film was oxidized at 1100°C. The film thickness after oxide was grown was 1.1 μm , and the oxide shape was round near the edges, as shown in Fig. 1b. Oxide grown laterally from the polysilicon edges was about 0.4 μm thick, and this shrank the original polysilicon openings by 0.8 μm , creating openings smaller than the lithographic limit. The nitride layer preventing the Si substrate from being oxidized was removed by RIE in CF_4 , and then silicon trenches were formed by reactive ion etching in a mixture of CCl_2F_2 and O_2 using the oxide layer as a mask after a precleaning step using CCl_2F_2 and Ar. The etch rate of silicon was approximately 92 nm/min, and the selectivity to oxide was over 15 in this experiment. In order to study refilling, an oxide layer (75 nm) was deposited into 8 μm deep trenches by a chemical vapor deposition at atmospheric pressure (APCVD), followed by deposition of a polysilicon layer (150 nm) at 400 mtorr (LPCVD).

Results and Discussion

Cross sections of silicon trenches with various etching times are shown in SEM's of Fig. 2. The initial openings measured from Fig. 2a were 2.5, 1.3, 0.9, 0.7, 0.45, 0.3, and 0.2 μm , respectively. These widths, however, slightly decreased as the RIE continued because of deposition of a polymer layer on sidewalls (5), which will be discussed below. The depth of a wide trench, when plotted with respect to etching time in Fig. 3a, linearly increases, while

that of a narrow one increases with a slower rate. The trench depths of 0.2 μm wide line and a square (0.3 \times 0.3 μm), for instance, were shorter by about 1 and 3.2 μm , respectively, than a trench wider than 2 μm by the time it becomes 4.7 μm deep. This two- or three-dimensional phenomenon was more pronounced as the etching pro-

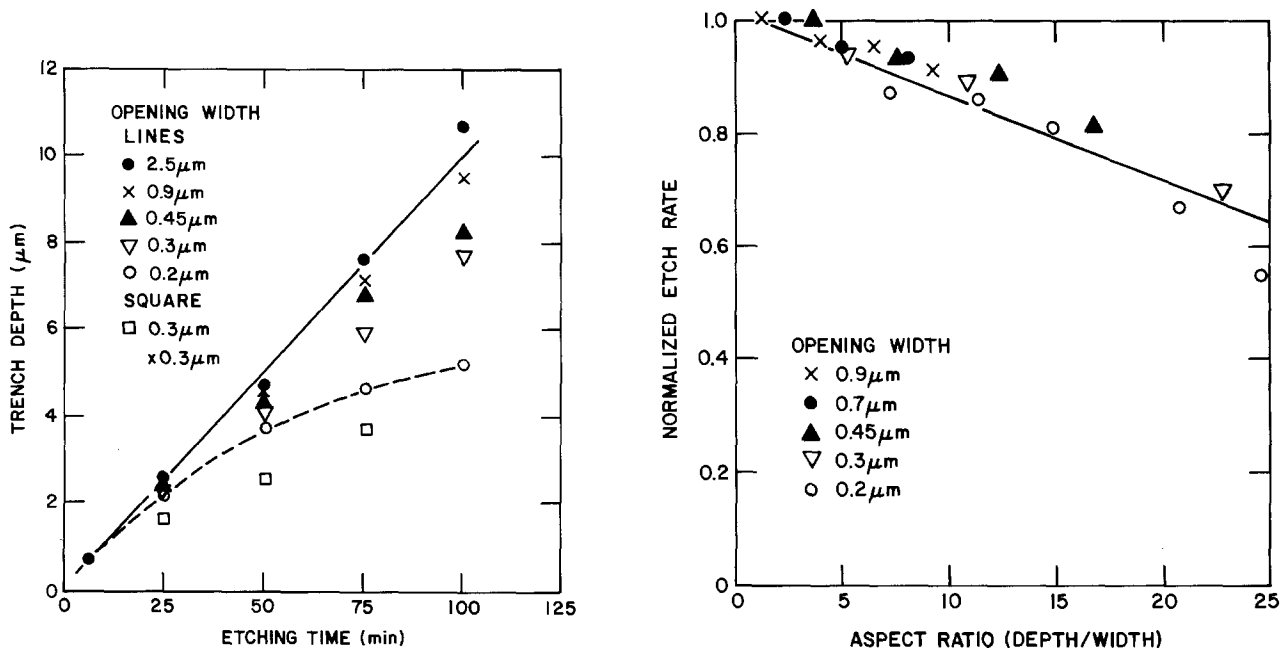

Fig. 3. Structural effects of a silicon RIE. a (left): Trench depth vs. etching time. b (right): Normalized etching rate vs. aspect ratio

ceeded or as the opening was a small square rather than a line. In particular, the depth decrease of the square hole is about twice as large as that of the line trench with the same width.

Figure 3b shows a plot of the silicon etch rate vs. the aspect ratio (width/depth) of the two-dimensional trenches, in which the etch rate decreases almost linearly as the aspect ratio increases and it is solely determined by the aspect ratio regardless of the opening sizes. The etch rate E with width W and depth D was obtained empirically as

$$E(W/L) = \left(1 - 0.16 \frac{W}{L}\right) E_w \quad [1]$$

where E_w represents the etch rate at a trench wide enough not be affected by the two-dimensional effect. It should be noted that the depth and width are changing continuously as etching goes on. In calculating the etch rate and the aspect ratio in Fig. 3b, therefore, the average depth between two consecutive time steps was chosen. However, the initial width measured from Fig. 2b was used because the deposited polymer material reduces the width. This is done to avoid measurement errors of the narrow trench openings, and it also seems more practical in determining trench dimensions on a mask level.

There may be several reasons responsible for the two- and three-dimensional phenomena on the deep-trench RIE. In this paper, a diverging electric field inside a trench is considered to qualitatively explain the two-dimensional effect. The electric field across a sheath near a powered electrode due to a self-bias in an RIE system is mostly perpendicular to a silicon substrate because the sheath width is much smaller than the electrode size. The field within a trench, however, should diverge because the silicon surface is at a constant potential. Some of the ions entering the trench through its opening, consequently, are captured at the sidewalls, and therefore fewer of them can arrive at the trench bottom. In this particular process used involving a mixture of $\text{CCl}_2\text{F}_2 + \text{O}_2$, the polymer material deposited on the trench sidewalls reduces the trench opening significantly. Therefore, this diverging field effect becomes more pronounced. Although no precise relationship between the etch rate and the ion flux has been reported yet, the etch rate is known to be greatly enhanced by the ion bombardment (6). It is, therefore, not difficult to conceive that the etch rate at the trench bottom should be reduced due to the fewer number of ions bombarding the bottom surface. The linear dependence on the aspect ratio may be derived from

this diverging field associated with the two-dimensional structure.

Figure 4 shows some of the trenches in Fig. 2b after all polymer layers (about 80 nm thick) were removed in buffered HF. The thickness of the polymer layer increases initially but saturates as the etching goes on. This phenomenon actually helps tapering the sidewall slope for ease of refilling, as seen in wide trenches. The polymer layer, however, together with the two- or three-dimensional effect described earlier, results in pointed bottoms when the opening is 0.5 μm or smaller. In Fig. 4, significant undercutting was also noticed in trenches with 1 μm or smaller width, which results in a bottle-shaped trench. The length of the narrow bottle neck is approximately equal to the opening width, and clearly depends on the shape of the oxide mask. The narrowest trench in Fig. 4, for an example, has an asymmetric mask whose steeper angle at the right side creates undercutting at a deeper location at the left side. From these observations, it was conjectured that ions deflecting from the oxide-mask edges are responsible for the undercutting. The round shape of oxide edges resulting from lateral oxidation of the polysilicon layer may have enhanced such ion deflection in the present experiment. Since mask edges during RIE are always subjected to a facet effect causing a round shape (5), a layer thicker than the opening width may be desirable to avoid such undercutting. This bottle shape makes it difficult to refill without a void, and sharp corners at the bottoms are prone to defect generation in subsequent hot processing steps. These are major concerns related to reliability in a submicron trench process.

In Fig. 5, the initial opening of a trench before deposition of 75 nm oxide was about 1 μm . Then it shrank to

Fig. 4. Trenches after the polymer layer on sidewalls was removed in BHF.

Fig. 5. A trench (1 μm wide and 8 μm deep) after the APCVD oxide and LPCVD polysilicon were deposited. The SEM's show (a) the top and (b) the bottom of the trench.

0.55 μm after 150 nm polysilicon was deposited. The thickness of the polysilicon layer changes very little with depth, even for a trench with an aspect ratio as large as 20, while the oxide thickness becomes less than half at the bottom. This may be attributed to the fact that the mean-free path of a gas molecule, inversely proportional to pressure, is smaller than 1 μm at 1 atm, but larger than 100 μm at 400 mtorr (7). As a result, it is concluded that LPCVD is necessary to deposit dielectric layers uniformly inside trenches with large aspect ratios.

Conclusions

Trenches with openings as small as 0.2 μm have been successfully made by oxidizing a polysilicon layer after its being patterned by optical lithography. Several structure-dependent effects were found. The silicon etch

rate drops significantly as the trench opening becomes smaller. This may cause problems if there are many different trench sizes. Undercutting also appears below 1 μm width, and otherwise on vertical and tapering sidewalls. These technical problems must be considered in optimizing any submicron trench process. Low pressure chemical vapor deposition into trenches, however, is less sensitive to their structures than atmospheric pressure CVD, and it is necessary for successful refilling in a trench process.

Determination of Conversion Factor for Infrared Measurement of Oxygen in Silicon

T. Iizuka, S. Takasu,* M. Tajima, T. Arai, T. Nozaki, N. Inoue,* and M. Watanabe*

Japan Electronic Industry Development Association, Kikaishinkokaikan, Shibakoen 3-5-8, Minato-ku, Tokyo 105, Japan

ABSTRACT

A reliable conversion factor for the infrared absorptiometry of oxygen in silicon has been determined by round-robin infrared measurement followed by charged particle activation analysis with the $^{16}\text{O}(^3\text{He},p)^{18}\text{F}$ reaction. As for the round-robin samples, 70 dislocation-free CZ silicon wafers with oxygen contents ranging from 3 to 20×10^{17} at.-cm $^{-3}$ and thicknesses of 2, 1, and 0.5 mm were carefully prepared by five organizations. A good linear relationship has been obtained between the absorption coefficient and the oxygen content. The relationship is expressed as [oxygen concentration (at.-cm $^{-3}$)] = $(3.03 \pm 0.02) \times 10^{17} \times$ [absorption coefficient (cm $^{-1}$)].

Oxygen in Czochralski (CZ) grown silicon crystals is known to be an important impurity in connection with defect control and wafer deformation. Oxygen concentration in silicon wafers is determined by infrared absorption at 9 μm due to the localized vibrational mode of the interstitial oxygen. The conversion factor correlating the infrared absorption coefficient to the oxygen content is obtained by the use of some analytical method which gives absolute oxygen concentration, such as vacuum fusion or activation analysis. Since Kaiser and Keck first determined this calibration relationship, several different conversion factors have been reported and used (1-7). Thus, oxygen concentration values for a given silicon wafer reported by different organizations frequently show considerable disagreement. In order to improve this situation, a working committee was organized in the Japan Electronic Industry Development Association (JEIDA) in 1979. The committee decided to determine highly reliable conversion factor using carefully prepared silicon crystals.

*Electrochemical Society Active Member.

This is a report on the newly determined conversion factor obtained by round-robin measurement of infrared absorption at 9 μm followed by activation analysis of the total oxygen in silicon. The work continued from October 1979 to November 1982. The following organizations participated: Electrotechnical Laboratory; Hitachi Limited; Institute of Physical and Chemical Research; Komatsu Electronic Metals; Matsushita Corporation; Mitsubishi Electronic; Nippon Telegraph and Telephone Corporation; Musashino Electrical Communication Laboratory; NEC Corporation; Nippon Silicon; Osaka Titanium; Shin-Etsu Handotai; The University of Tokyo; The University of Tsukuba; Toshiba Corporation; VSLI Cooperative Laboratory; Monsanto Corporation; Nicolet Japan; and Wacker Chemitronic.¹

Experimental

Sample preparation.—Dislocation-free, low carbon (100) CZ silicon crystals of 70-100 mm diam were pre-

¹Monsanto, Nicolet, and Wacker participated from the middle of the round-robin.

pared by Komatsu Electronic Metals, Musashino Electrical Communication Laboratory, Nippon Silicon, Osaka Titanium, and Shin-Etsu Handotai. The oxygen contents of these crystals ranged from 3 to 20×10^{17} at.-cm⁻³, which were obtained using a tentative conversion factor of 3.0×10^{17} at.-cm⁻², and their resistivities were more than 10 Ω-cm. In order to investigate the effect of the wafer thickness on the infrared measurement, a set of wafers 2, 1, and 0.5 mm thick were so taken from an adjacent portion of each ingot so as to assure its containing nearly the same concentration of oxygen. Both sides of the wafers were mirror-polished to a surface flatness of better than 3 μm for the infrared measurement. Thus, 70 wafers (26 of 2 mm, 22 of 1 mm, and 22 of 0.5 mm thickness) with different growth histories were prepared for this investigation. Reference samples with the same thicknesses and surface finish were prepared by float-zone method.

Infrared measurement.—In order to obtain the infrared absorption coefficient of the samples as accurately and reproducibly as possible by the round-robin measurement, the following measurement procedures were recommended by the committee. Each organization was requested to undertake the measurement following the practices shown in Table I and to take into account other recommendations considering the variety of the apparatus used.

Apparatus.—Dispersive, as well as Fourier transformation-type, spectrometers are used. In case of dispersive spectrometers, the double-beam type has an advantage of applying the difference method. Transmittance accuracy is the most important performance in the measurement. The transmittance error must not exceed 1% of the percentage transmission scale, and, therefore, it was decided that the transmittance accuracy of the spectrometer in each organization should be checked by the use of a chopper or specially prepared ND filter. The chopper passes 10-90% (10% interval) of incident beam, while the ND filters pass 72, 61, and 30% of incident beam at 1100 cm⁻¹, respectively. An example of instrumental accuracy is shown in Fig. 1, revealing the error as much as 2% before adjustment but below 0.4% after adjustment, the latter being the best accuracy one can expect for a grating spectrometer.

Procedure.—In case of a dispersive spectrometer, the difference method with the oxygen-free reference specimen in the reference beam is superior to the air reference method for accurate determination of the absorption coefficient. The transmittance mode is recommended because it is more convenient for calculating the absorption coefficient for the specimens with large surface reflection than is the absorbance mode. A Fourier transform spectrometer is substantially a single-beam type. Differential transmittance or absorbance spectra are calculated from reference and sample spectra. All measurements are performed at room temperature. Slight temperature variations do not affect the accuracy. Before the measurement, verification of 0 and 100% transmission must be performed. The holders for sample and reference must prevent any source radiation from bypassing the specimen. Transmittance spectrum is taken from 1300 to 900 cm⁻¹,

Table I. Recommended practices for infrared measurement

Item		Recommended
Spectrometer	Type	Dispersive or FTIR
	Path	Double-path (single-path)
	Accuracy	1% of the percentage T scale
	Mode	Transmittance T (absorbance)
Measurement	Reference	Difference method (air reference)
	Scan range	1300-900 cm ⁻¹
	Blank check	100%; 0%
	Resolution	Good enough to resolve the 9 μm absorption band (FWHM: 38 cm ⁻¹)
	Temperature	Room temperature

Fig. 1. Example of instrumental accuracy (grating spectrometer, air reference method using a chopper with the transmittance of 10-90%).

which is wide enough to examine the background spectrum. Measurement conditions must be so selected as to assure required resolution; the full width at half maximum (FWHM) of the oxygen absorption band should be no more than 38 cm⁻¹ in transmittance (32 cm⁻¹ in absorbance).

Typical measurement conditions for a grating spectrometer are a resolution of 4 cm⁻¹, a scan rate of less than 1 cm⁻¹/s, a pen response of 2s of time full scale deflection. Repeating measurements (at least two) and taking their average improves the accuracy.

Typical measurement conditions for Fourier transform spectrometer are resolution of 4 cm⁻¹ and accumulation of 100 times.

The size of the measured area (beam size) depends on the respective spectrometer. Typical sizes are 5 × 15 mm² and 15 mm diam.

The round-robin measurement was performed on the 70 samples by 16 organizations. Examples of measured spectra following the recommended practices on 2, 1, and 0.5 mm thick samples are shown in Fig. 2. A 0.5 mm-thick sample shows considerable interference fringes due to multiple internal reflection. The uniqueness of the base line and absorption peak is lost by the interference fringe. The simplest way to eliminate the interference fringe is to reduce the resolution. The FWHM and peak absorbance values of the oxygen absorption band do not show detectable change if the resolution is better than 6 cm⁻¹.

Fig. 2. Examples of measured spectra of differential transmittance for 2, 1, and 0.5 mm thick samples containing 8.2×10^{17} at.-cm⁻³ of oxygen. Measurements were performed following the recommended practices with the resolution of 2 cm⁻¹. Base lines are also shown.

Calculation.—The transmittance measured by the air reference method for normal incidence considering multiple reflection is expressed by

$$T_{\text{air}} = \frac{(1 - R)^2 \exp(-\alpha d)}{1 - R^2 \exp(-2\alpha d)} \quad [1]$$

where R is the reflectivity, α is the absorption coefficient, and d is the sample thickness. Absorption coefficient consists of α_o (due to oxygen), α_f (free carrier), and α_l (lattice vibration). The α_o and α_f terms are negligibly small in FZ reference specimen. Differential transmittance is given as

$$T_{\text{diff}} = \frac{T_{\text{samp,air}}}{T_{\text{ref,air}}} \quad [2]$$

Differential transmittance of the absorption peak and background are

$$T_{\text{diff,peak}} = \frac{T_{\text{samp}}}{T_{\text{ref}}} = \frac{\{1 - R^2 \exp(-2\alpha_1 d)\} \exp\{-(\alpha_f + \alpha_o)d\}}{1 - R^2 \exp\{-2(\alpha_1 + \alpha_f + \alpha_o)d\}} \quad [3]$$

$$T_{\text{diff,bg}} = \frac{\{1 - R^2 \exp(-2\alpha_1 d)\} \exp(-\alpha_f d)}{1 - R^2 \exp\{-2(\alpha_1 + \alpha_f)d\}} \quad [4]$$

respectively, where sample thickness and reference thickness are assumed to be equal. Thickness agreement to within 10 μm does not introduce the error in the absorption coefficient determination. The reflectivity and lattice vibrational absorption coefficient at the oxygen absorption peak, used in the present calculation, are

$$R = 0.30$$

and

$$\alpha_l = 0.85 \text{ cm}^{-1}$$

The base line is used to obtain the differential transmittance of the background (Eq. [4]). The base line is approximated by a straight line on a differential transmittance spectrum between 1300 and 900 cm^{-1} , as shown in Fig. 2. The $\alpha_f + \alpha_o$ and α_f values are separately determined from Eq. [3] and [4], and their difference gives the oxygen absorption coefficient α_o .

For present samples, the effect of free carrier absorption is negligibly small.² Therefore, the relative transmittance of the oxygen absorption band with respect to the base line is expressed as

$$T_{\text{rel}} = \frac{T_{\text{diff,peak}}}{T_{\text{diff,bg}}} = \frac{1 - R^2 \exp(-2\alpha_1 d)}{1 - R^2 \exp\{-2(\alpha_1 + \alpha_o)d\}} \exp(-\alpha_o d) \quad [5]$$

Conventionally, the following equation is used for rough estimation of oxygen concentration

$$T_{\text{rel}} = \exp(-\alpha'_o d) \quad [6]$$

The α'_o term corresponds to the absorption coefficient which does not include the multiple reflection effect. The relationship between T_{rel} and α_o and that between α'_o and α_o are given in Fig. 3 and 4, respectively. These were distributed to each organization in the round-robin measurement, where the relationship between α'_o and α_o is given in a table form with an α_o interval of 0.02 cm^{-1} .

The recommended procedure for obtaining the absorption coefficient of oxygen, α_o , is summarized as follows: (i) measure the differential transmittance (absorbance) spectrum using the FZ reference specimen; (ii) draw base line on the spectrum between 1300 and 900 cm^{-1} ; (iii) cal-

²The value of the free carrier absorption, α_f , is less than 0.1 cm^{-1} for most samples. Two samples show the highest value of 0.4 cm^{-1} . The maximum error of T_{rel} in Eq. [5] caused by this α_f value is only 1%.

Fig. 3. Relationship between the relative transmittance of the oxygen absorption band, T_{rel} , and the absorption coefficient due to oxygen, α_o . (Refer to Eq. [5].) Curves are plotted for the sample thickness of 0.5, 1, and 2 mm.

Fig. 4. Relationship between the α'_o value determined by Eq. [6] and the absorption coefficient due to oxygen, α_o . (Refer to Eq. [5] and [6].) Curves are plotted for the sample thickness of 0.5, 1, and 2 mm.

culate T_{rel} (Eq. [5]) or α'_o (Eq. [6]); (iv) obtain α_o using Fig. 3 or 4.

Charged particle activation analysis.—After the infrared measurement, the 22 wafers 1 mm thick were analyzed for oxygen by charged particle activation analysis with the $^{16}\text{O}(^3\text{He,p})^{18}\text{F}$ reaction (^{18}F : 110m, β^+ , no γ). The sample was bombarded with ^3He particles (18 MeV, about 2 μA) for 20 min behind aluminum foil (30 μm thick) in the cyclotron of the Institute of Physical and Chemical Research. The surface layer ($23 \pm 2 \mu\text{m}$) of the bombarded wafer was etched with HF-HNO₃ solution for complete removal of the surface oxygen effect. After 1h from the end of the bombardment, the sample wafer was placed directly on a Ge(Li) detector, and the positron annihilation radiation was measured for 200s. The measurement was repeated several times at about 1h intervals to give the decay curve, which indicated the absence of any notable positron activity other than ^{18}F . As for the activation standard, a quartz plate was used with an aluminum

cover (20 μm), in which the ^3He particle loses its energy equally as in the sample surface removed by the etching. Within each cyclotron machine time period, usually eight such plates were bombarded in order to check the reproducibility. The analysis of each silicon sample was repeated at least twice. Samples for which the results of the two analyses deviated more than 5% from each other were analyzed once again. When the three analyses gave no satisfactory results, a fourth analysis was undertaken. At the same time, one assigned sample was analyzed in every machine times, in order to ascertain the reproducibility of the result.

Since the ^{18}F activity in the infrared reference sample was so weak as to be masked by the radiation of ^{31}Si β -ray, it was measured after chemical separation. The sample was bombarded with a higher beam current for a longer time, and then pulverized and dissolved in a NaOH solution containing F^- carrier (15 mmol). After silicon was removed from the solution by precipitation, the fluorine was collected as $\text{CaF}_2\text{-CaCO}_3$ coprecipitate, distilled, and precipitated as BaSiF_6 . The annihilation radiation from the BaSiF_6 was measured by a NaI detector, and the absence of bremsstrahlung was checked. The carrier recovery was measured by alkali titration.

Results and Discussion

From the results of activation analysis, some values showing considerable deviations were eliminated when the reason of the deviation could be understood. The other values were averaged to give the final results for the total oxygen concentration; they are shown in Table II. The infrared reference wafer was found to contain $(1.3 \pm 0.4) \times 10^{15}$ at.-cm $^{-3}$ oxygen. This value can be legitimately ignored in our succeeding calculations.

Of all the methods for quantitative determination of oxygen in CZ silicon, the nondestructive activation analysis with the $^{16}\text{O}(^3\text{He,p})^{18}\text{F}$ reaction can at present be regarded as the most accurate because of the following three reasons: (i) freedom from the surface oxygen effect and oxygen contamination in the analytical process; (ii) capability of repeated analysis for a single sample and no need of

chemical separation, in which any possible loss of oxygen should be taken into account; and (iii) requirement of only relative measurements of the bombardment data (beam current and time) and the induced ^{18}F activity for the sample and activation standard of quartz, which is of well-defined stoichiometry.

In vacuum fusion, some correction for surface oxygen is indispensable. This introduces a considerable uncertainty in the final result, especially for a sample of relatively low oxygen content. By the ^3He activation analysis with chemical separation of the ^{18}F , we have actually obtained a result of as low as $(2.3 \pm 0.5) \times 10^{14}$ at.-cm $^{-3}$ oxygen for a specially prepared FZ silicon. The surface oxygen effect thus proved to be eliminated completely by etching after bombardment. Modern instrumental methods available for the oxygen analysis (e.g., secondary ion mass spectroscopy) are likely to be interfered with by residual oxygen in the apparatus and have need of some suitable standard, which is difficult to prepare. In photon activation analysis with the $^{16}\text{O}(\gamma,n)^{15}\text{O}$ reaction, the ^{15}O (122s half-life) should usually be separated very quickly after the surface etching (6). It is natural that the result of this analysis inevitably involves more uncertainty than the result of our analysis. Our method, when carried out carefully, can be thought to give the most reliable result with the smallest systematic error of all the methods available for the present analysis.

In the results of our analysis, however, the following two kinds of uncertainty should be taken into account: (i) error in the analytical process, mainly in the measurement of the sample-to-standard ratio for the bombardment data and for the ^{18}F activity; and (ii) uncertainty due to some inhomogeneous distribution of oxygen in the sample. The first kind of uncertainty can be estimated to be about 4%, about 3%, and under 3% for oxygen concentrations of under 5×10^{17} , $5\text{--}10 \times 10^{17}$, and over 10×10^{17} at.-cm $^{-3}$, respectively. As for the sample inhomogeneity, it is easily understood from the excitation function for the $^{16}\text{O}(^3\text{He,p})^{18}\text{F}$ reaction and the range-energy relations of charged particles that oxygen only in the depth region of less than 200 μm from the bombarded surface is sensitive

to our analysis (8). Thus, the most sensitive part in the original sample changed in each analysis due to the surface etching in the preceding analysis and to some fluctuation of the bombarded portion of the sample. Actually, we experienced considerable scatter (5-10%) in the results of repeated analysis for several samples. Most samples, however, gave well reproducible results, as is exemplified by an assigned sample (no. 16 in Table II) analyzed every machine time to give the values of 8.84, 8.74, 8.77, 8.87, and 8.91×10^{17} at.-cm⁻³.

The effect of instrumental error of infrared measurement on the error in determining the absorption coefficient is negligible for the following reasons. Transmittance error of 2% is not unlikely for grating-type spectrometers, as shown in Fig. 1. However, the transmittance error generally changes slowly with transmittance. Maximum transmittance, corresponding to the background transmittance (Eq. [4]), ranges from 53% (0.5 mm thick) to 44% (2 mm thick). The minimum transmittance corresponding to the oxygen absorption band (Eq. [3]) varies from 47% (0.5 mm thick and 3×10^{17} at.-cm⁻³) to 11% (2 mm thick and 20×10^{17} at.-cm⁻³). Within this transmittance range, the differential transmittance error is expected to be within 0.5% if the air reference transmittance error is within 1% for 0-100% transmittance and varies slowly with the transmittance. Therefore, the transmittance error of 1% does not cause a noticeable error in the determination of the absorption coefficient.

The reported absorption coefficients sometimes showed considerable scattering, although the infrared measurement had been expected to be fairly precise and most reported values actually agreed with one another. Mean values over all the reported absorption coefficients were calculated for the individual wafers, together with their standard deviations. The standard deviations were then averaged over all the samples belonging to the same thickness to give the mean standard deviation. The total numbers of the reported data for each sample thickness are shown in Table III together with the numbers and percentages of the data deviating more than 10% from the mean values and also with the mean standard deviation. The mean standard deviation is regarded as the measure of precision in the infrared measurement, and is seen to become better with the sample thickness in the three thicknesses tested. The standard deviation of the 1 mm-thick data is only slightly larger than that of the 2 mm-

Table III. Scattering in the reported absorption coefficient

Sample thickness (mm)		2	1	0.5
Total number of reported values		434	267	263
Values with more than 10% deviation	Number	94	96	123
	Percentage	22	36	47
Mean standard deviation (%)		10	14	32

thick data. The standard deviation of 0.5 mm-thick data is noticeably larger than that for the 1 and 2 mm-thick data, showing that samples of this thickness are not adequate for accurate oxygen-content determination.

The mean absorption coefficients are shown in Table II for the individual samples. Each set of three samples cut from adjacent positions of each ingot but with the different thicknesses was expected to give nearly the same absorption coefficient. Actually, however, the mean absorption coefficient for a 2 mm sample is sometimes found to differ by more than 10% from that for the corresponding 1 mm sample, as shown in Fig. 5. This is probably due to the oxygen inhomogeneity in such samples. In order to keep the 2 mm samples for future use as infrared standard samples, the 1 mm samples were used in the activation analysis. Because of this and the only slightly larger mean standard deviation for the 1 mm samples than for the 2 mm samples, it is thought to be better to calculate the infrared conversion factor from the absorption coefficients for the 1 mm samples than from those of the 2 mm samples.

About half of the organizations used infrared spectrometers of Fourier transformation type and the others of the dispersive type. No significant difference in the round-robin measurement results due to the difference of the spectrometer type was observed (Fig. 6 and 7). In order to get the absorption coefficient more accurately, it can be recommended to exclude some of the data. A few organizations reported values invariably larger or smaller by more than 10% than the mean values. Hereafter, a reported absorption coefficient is expressed as α_{ijk} , where $i = 1, 2, 3$ is for 2, 1, and 0.5 mm thickness, respectively, j is a sample number for each thickness, and k is an organization number. The number of data (absorption coefficients) for a particular sample is n_{ij} , which is a number of organization measuring the sample. The mean absorption

Fig. 5. Difference of infrared absorption coefficient for 2, 1, and 0.5 mm samples

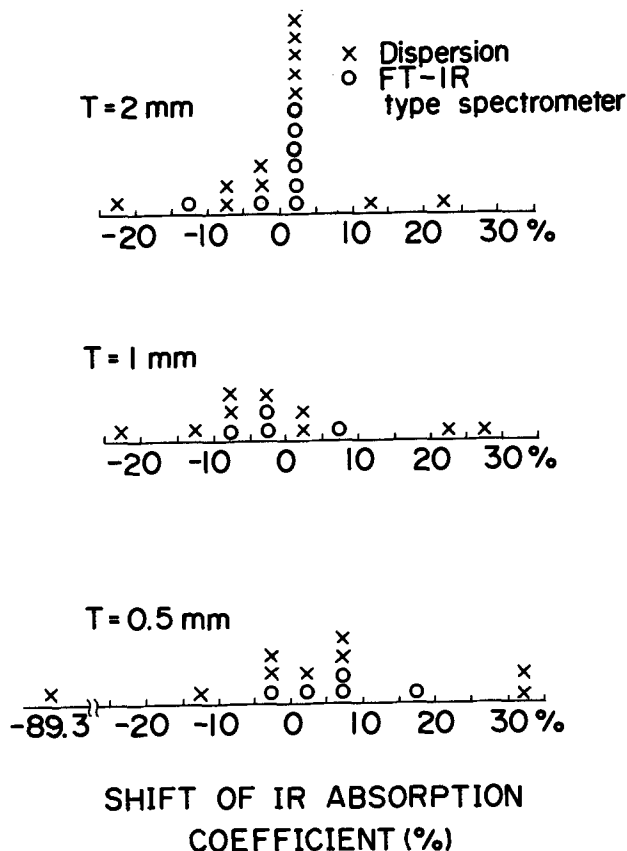

Fig. 6. Shift of mean infrared absorption coefficient of the laboratories.

coefficient for the particular sample is given by

$$\bar{\alpha}_{ij} = \frac{1}{n_{ij}} \sum_k \alpha_{ijk} \quad [7]$$

The absorption coefficients scatter around $\bar{\alpha}_{ij}$, and some of them deviate more than 10%. Table III shows the total number of data, $n_i = \sum_j n_{ij}$ for 2, 1, and 0.5 mm thick samples. It also shows the number of data which deviated more than 10% from $\bar{\alpha}_{ij}$. The percentage of such data decreases with increasing sample thickness. This means the reproducibility of infrared measurement is better for thicker samples. The standard deviation of data for a particular sample, σ_{ij} , is expressed by

$$\sigma_{ij} = \left\{ \frac{1}{n_{ij} - 1} \sum_k \left(\frac{\alpha_{ijk} - \bar{\alpha}_{ij}}{\bar{\alpha}_{ij}} \right)^2 \right\}^{1/2} \quad [8]$$

and then the mean standard deviation is given by

$$\sigma_i = \frac{1}{N_i} \sum_j \sigma_{ij} \quad [9]$$

where N_i is a number of 2, 1, or 0.5 mm-thick samples. The reproducibility of infrared measurements for 1 mm samples is not best, but is not so bad as is a case of 0.5 mm samples, as shown in Table III.

A few organizations reported values invariably larger or smaller by more than 10% than the mean values. The following two kinds of organization-dependent scatterings were considered in the reported absorption coefficients. The first one, X_{ik} , is a shift of the mean absorption coefficient for a particular organization

$$X_{ik} = \frac{1}{n_{ik}} \sum_j \left(\frac{\alpha_{ijk} - \bar{\alpha}_{ij}}{\bar{\alpha}_{ij}} \right) \quad [10]$$

where n_{ik} is the total number of samples with a given thickness, i , measured by the organization in question, k . The second one, Y_{ik} , is the scattering of the data of the particular organizations around the shifted mean

Fig. 7. Scattering of infrared absorption coefficient around the shifted mean absorption coefficient.

$$Y_{ik} = \left\{ \frac{1}{n_{ik}} \sum_j \left(\frac{\alpha_{ijk} - \bar{\alpha}_{ij}}{\bar{\alpha}_{ij}} - X_{ik} \right)^2 \right\}^{1/2} \quad [11]$$

These X_{ik} and Y_{ik} are shown in Fig. 6 and 7, respectively. In the scattering around the shifted mean, no marked difference is found between the data of those few organizations which reported invariably deviated data and those of the other organizations. From this fact, the use of samples with accurately known absorption coefficients as interlaboratory infrared standards is seen to be highly recommendable.

The least squares method is the most conventional way to investigate the correlation between the two groups of data. By this method, the relationship between the absorption coefficient, α , and oxygen concentration, C , is expressed by

$$C = f\alpha + g \quad [12]$$

The f and g values are mathematically determined. According to Beer's law, however, the relationship between α and C should be given by

$$C = f\alpha \quad [13]$$

where f is called conversion factor. If we used the least squares method for the present data, the g term in Eq. [12] does not necessarily go to zero. The physical meaning of the g term is ambiguous. Therefore, the conversion factor for a particular sample with a thickness, i , and sample number, j , is not determined by the least squares method but by the relationship in Eq. [13]

$$f_{ij} = C_{ij}/\alpha_{ij} \quad [14]$$

Since we have assumed $C_{ij} = C_{2j}$, Eq. [14] is rewritten as

$$f_{ij} = C_{2j}/\alpha_{ij} \quad [15]$$

The mean absorption coefficient $\bar{\alpha}_{ij}$ and corresponding conversion factor f_{ij} are shown in Table II. The mean conversion factor f_i , the standard deviation σ_i^f , and the standard error ϵ_i are expressed as

$$f_i = \frac{1}{N_i} \sum_j f_{ij} \quad [16]$$

Table IV. Conversion factor

Sample thickness (mm)	Data exclusion ^a	Conversion factor ($\times 10^{17} \text{ cm}^{-2}$)		
		Mean value (f_i)	Standard deviation ($\sigma_i^{(f)}$)	Standard error (ϵ_i)
2	No	3.015	0.224	0.048
2	Yes	3.036	0.228	0.049
1	No	2.973	0.089	0.019
1	Yes	3.030	0.110	0.023
0.5	No	3.157	0.328	0.070
0.5	Yes	3.143	0.373	0.080

^a Infrared absorption coefficient data deviating more than 10% from the mean values are excluded (yes), are not excluded (no).

$$\sigma_i^{(f)} = \left\{ \frac{1}{N_i - 1} \sum_j (f_{ij} - f_i)^2 \right\}^{1/2} \quad [17]$$

$$\epsilon_i = \sigma_i^{(f)} / N_i \quad [18]$$

These values are summarized in Table IV. As shown in the table, the conversion coefficient depends on a choice of data. The committee members have agreed that the most reliable conversion factor is obtained from the results of 1 mm samples with the data exclusion. Therefore, the conversion factor has been determined to be $(3.03 \pm 0.02) \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$. The value of the conversion factor is believed to be quite reliable because the present value agrees remarkably with recent independent investigations. Yatsurugi *et al.* reported the value of $3.0 \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$ by using charged particle activation (4), Li *et al.* reported $(3.1 \pm 0.05) \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$ by inert gas fusion and $(3.1 \pm 0.2) \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$ by charged particle activation (5), and Rath *et al.* reported $(3.0 \pm 0.2) \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$ by photon activation (6) and $(3.0 \pm 0.25) \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$ by charged particle activation (7).

In Fig. 8, the mean absorption coefficients with their standard deviations for the results of 1 mm samples with the data exclusion are plotted against the oxygen concentration. All of the absorption coefficients lie on the straight line within their standard deviations. It should be noted that the 2 mm-thick sample measurement gives the same conversion factor (3.036) as the 1 mm-thick sample measurement. The measurement on 0.5 mm-thick samples, however, gives a little larger conversion factor than those of 2 and 1 mm-thick samples. In other words, it gives a lower oxygen content. The conversion factor determined here is obtained from the as-grown crystals and as-received wafers. Figure 8 implies that very small portions of oxygen, if any, are precipitated in our samples even at higher oxygen concentration ranges, because no significant deviation of the obtained absorption coefficient from the linear relationship is observed.

The use of the standard samples with accurately known oxygen concentration is quite helpful for improving the accuracy of the infrared absorption analysis. Many sets of standard samples are now under preparation at JEIDA. The oxygen concentrations were determined by infrared measurement using the present 2 mm-thick samples as calibration standards. Each set consists of three samples with high, medium, and low levels of oxygen concentrations and one reference sample. The oxygen concentrations of respective samples are in the range of 10.2-10.7, 7.8-9.1, 5.4-6.3, and $<0.1 \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$. The maximum error in oxygen concentration is estimated to be less than $\pm 5 \times 10^{16} \text{ at}\cdot\text{cm}^{-2}$. Details of the preparation of the standard samples will be reported elsewhere. These samples, we believe, are highly useful also for the re-examination of our conversion factor by various groups in the world with various techniques.

Summary and Conclusion

1. Seventy samples with the oxygen concentration of $2.7\text{-}21 \times 10^{17} \text{ at}\cdot\text{cm}^{-2}$ and 2, 1, and 0.5 mm thick were carefully prepared by five organizations.

Fig. 8. Oxygen concentration vs. mean infrared absorption coefficient of 1 mm sample after data exclusion. The standard deviation is shown for each infrared data.

2. A round-robin measurement of the infrared absorption due to the interstitial oxygen at room temperature was carried out by 16 organizations with 20 spectrometers. The total oxygen content was determined by charged particle activation analysis.

3. A good linear relationship has been obtained between the infrared absorption coefficient and oxygen content from the results of 22 samples with 1 mm thickness. The relationship is given as: [oxygen concentration ($\text{at}\cdot\text{cm}^{-3}$)] = $(3.03 \pm 0.02) \times 10^{17} \times$ [absorption coefficient (cm^{-1})].

4. There is no essential difference between the results by Fourier transformation-type infrared spectrometers and those by dispersive-type spectrometers.

5. The analysis of the round-robin measurement shows that the use of the standard samples with known oxygen content is quite helpful for determining the oxygen content accurately by the infrared absorption and for suppressing interlaboratory discrepancies.

Interface Charges at the Back Surface of Seeded, Recrystallized Silicon Films

T. I. Kamins*

Hewlett-Packard Laboratories, Palo Alto, California 94304

ABSTRACT

Interface charges at the back of seeded, recrystallized silicon films on insulating oxide layers were investigated and compared to those at the back of unseeded films. Both the fixed charge density and the interface trap density were found to be appreciably lower for the seeded devices than for unseeded devices. A recrystallization technique which melted the silicon film a minimum number of times produced the lowest interface charge densities. The differences between seeded and unseeded structures may be related to the higher charge densities expected for grain orientations other than {100} or to traps located at the grain boundaries near the back surface of the silicon film.

Control of charges at the Si-SiO₂ interfaces in metal-oxide-semiconductor transistors has long been a source of concern for reliable and reproducible device fabrication. In silicon-on-insulator (SOI) structures, an additional Si-SiO₂ interface is present below the thin silicon film. Charges at the underlying interface can influence the behavior of MOS transistors in the film. n-Channel transistors are especially affected because a positive charge can induce an inversion layer near the back interface in parallel with the desired front-channel transistor. For thin films, a space-charge region induced by interface charges at the back surface can influence the characteristics of p-channel transistors also. In more advanced structures, the channel to be controlled by the gate may be located at the back interface. In this case, accurate control of the interface charges there is critical to the basic device performance.

Several recent reports have discussed the interface charges beneath recrystallized silicon films (1-3). In all these cases, however, the recrystallized film was large-grain polycrystalline silicon, rather than single-crystal silicon. The fixed charge density at the back interface was found to be about $1 \times 10^{11} \text{ cm}^{-2}$, under optimum conditions, and considerably higher if the materials and processing were not carefully controlled. This value is much higher than that found for Si-SiO₂ interfaces formed on bulk single-crystal silicon wafers. The difference can be related to two dominant effects. First, the silicon film is composed of grains of several different orientations. The important crystal orientations other than {100} have higher fixed charge densities than do {100}-oriented silicon, so a polycrystalline film is expected to have a higher fixed charge density than does a single-crystal film. Second, grain boundaries in the silicon film near the interface can contribute states which increase the effective interface charge.

The present study investigated the interface charges beneath single-crystal silicon films formed by laterally seeding the recrystallization so that grain-boundary-free, {100}-oriented single-crystal films were obtained. The fixed-charge density Q_f^B and the interface-trap density D_{it}^B were investigated by measuring both the high frequency and quasistatic capacitance-voltage characteristics. These structures were compared to unseeded devices fabricated simultaneously.

Experimental Device Structure

To probe the interface characteristics at the back of the recrystallized silicon film, the present experiment used an inverted capacitor structure in which the "gate" voltage was applied to heavily doped regions of an n-type substrate wafer, and the depletion region extended into a lightly doped, recrystallized silicon film above an oxide thermally grown on the "gate" wafer. Thus, the interface at the back of the recrystallized silicon film was probed.

Because of the limited lateral propagation of high quality, single-crystal recrystallization, a structure containing

a number of parallel stripes of silicon-on-insulator material was used (Fig. 1). The unseeded structures needed for comparison were simultaneously fabricated using the same mask set by omitting the seeding mask. The mask contained 13 parallel SOI stripes, each about 21 μm wide, separated by seed regions about 9 μm wide. Most of the area under the oxide stripes was implanted with phosphorus to act as a heavily doped counterelectrode. However, to avoid dopant migration from the substrate into the film during recrystallization, the heavily doped regions were confined under the SOI stripes and away from the seeding regions.

After recrystallization, the seeding regions were sealed by a thick local oxide so that the major part of the capacitance was contributed by recrystallized regions over the gate oxide and heavily doped regions of the substrate. The final structure contained about $1.6 \times 10^{-3} \text{ cm}^2$ of gate oxide, $9.5 \times 10^{-4} \text{ cm}^2$ of field oxide over the seed, and $6.3 \times 10^{-4} \text{ cm}^2$ of slightly thicker field oxide adjacent to the seed, but outside the buried-layer region.

The seeded wafers were lightly doped, n-type, {100}-oriented wafers with [100]-aligned flats. Some of the unseeded wafers were also lightly doped, while others were heavily doped to allow more direct comparison with previous experiments. Bulk control wafers were also included.

Device Fabrication Details

Phosphorus was first implanted into selected regions of the seeded wafers and the lightly doped unseeded wafers through a thin oxide. After the implant was annealed and the thin oxide was removed, a 200 nm-thick gate oxide was grown at 1000°C in a chlorine containing, dry oxygen ambient. This type of oxide beneath the silicon film was found in our previous experiments to produce the lowest back interface charge density. On the seeded wafers, the seed windows were then opened by etching the oxide between the heavily doped regions, and a 550 nm thick layer of LPCVD polysilicon was deposited at 625°C. This layer was implanted with boron to produce an average dopant concentration of about $2 \times 10^{16} \text{ cm}^{-3}$ after it was redistributed during recrystallization.

Stabilization layers were then formed; a 64 nm thick LPCVD oxide deposited at 900°C was placed over the seed regions, and a 6 nm thermal oxide was grown over

Fig. 1. Schematic cross section of seeded capacitor structure

*Electrochemical Society Active Member.

the SOI regions. Both regions were further covered with 6 nm of LPCVD silicon nitride deposited at 700°C. This patterned stabilization layer allowed more power to be absorbed in the seed regions, which lose energy rapidly to the substrate through the seed windows and, consequently, require more energy to melt the silicon film.

To recrystallize the films, an argon-ion laser was rastered across the wafer while the substrate was externally heated to about 500°C. On some seeded wafers a $20 \times 60 \mu\text{m}$ elliptical beam was swept parallel to the long axis of the beam and stepped by $6 \mu\text{m}$ perpendicular to the long axis between scans ("shuttle beam"). On other seeded wafers the elliptical beam was swept at 45° to its long axis, with a step of $29 \mu\text{m}$ between scans ("slanted beam") (4). In both cases, the scan was parallel to the SOI stripes. The unseeded structures were recrystallized with a circular beam which melted a region about $40 \mu\text{m}$ across, and the beam was stepped by about $20 \mu\text{m}$ between scans. The beam swept across the wafer at $20 \text{ cm}\cdot\text{s}^{-1}$ in all cases.

After the stabilization layers were removed, the silicon in the seed regions and areas outside the device was oxidized through its entire thickness by local oxidation using a nitride mask. Phosphorus was implanted into the back of each wafer to ensure ohmic contact, and several heat cycles simulated a complete transistor fabrication process. Contact to the recrystallized silicon film was made by depositing and defining an Al/2%Si layer, and the device fabrication was completed with a 450°C anneal in a hydrogen ambient for 30 min.

Results

High-frequency C-V characteristics.—High frequency (1 MHz), capacitance-voltage characteristics were measured on all wafers. The flatband voltage was found after a negative bias-temperature stress, and the corresponding fixed charge density was calculated. No measurable mobile ion drift was observed on any of the recrystallized wafers.

The complex structure used to obtain seeded devices in these experiments impeded extraction of a quantitative value of the fixed charge density directly from the high frequency C-V data. Although the contributions to the capacitance from the gate and field oxides and that resulting from the finite doping in the gate (substrate wafer) can be separated, the gradual transition region between gate and field oxide cannot readily be analyzed. Because of the long periphery of the gate-oxide region, the contribution of this transition region to the total capacitance is not negligible, complicating determination of the flatband voltage. However, the relative values of fixed charge density calculated from the flatband voltage allow a semiquantitative comparison between the different structures in this experiment.

To compare seeded and unseeded structures, we assume the back-side fixed charge density of the unseeded structures to have the value of $1 \times 10^{11} \text{ cm}^{-2}$ repeatedly found in this laboratory with a simpler capacitor structure covered with the same stabilization layers during recrystallization. This assumption produces consistent results.

The seeded wafers recrystallized with the slanted beam can be compared most directly with the unseeded wafers containing an n^+ buried layer in a lightly doped substrate. In both cases, the silicon was melted about two times. The primary difference is the presence or absence of seeding windows in the underlying oxide, so that the field-oxide capacitance is very slightly different.

In the seeded devices recrystallized with the slanted beam, the indicated fixed charge density was about $6.6 \times 10^{10} \text{ cm}^{-2}$ lower than for the unseeded wafers, suggesting a fixed charge density of about $3 \times 10^{10} \text{ cm}^{-2}$. The seeded structures recrystallized with the shuttle beam generally indicated a higher fixed charge density than did those recrystallized with the slanted beam. The fixed charge density with the shuttle beam was $6.4 \times 10^{10} \text{ cm}^{-2}$ for the lower laser power, and somewhat higher for the higher power.

The fixed charge density indicated for the bulk wafers was about $1 \times 10^{10} \text{ cm}^{-2}$. This is consistent with the value of $1.6 \times 10^{10} \text{ cm}^{-2}$ obtained on bulk wafers in recent experiments with the simpler capacitor structure, suggesting that this method of interpreting the data is reasonable. These values are consistent with those obtained in normal MOS transistor processing on bulk wafers.

To obtain further semiquantitative information about the differences between seeded and unseeded structures in a manner that minimizes the effect of the device structure, the maximum slope was determined for each C-V characteristic and normalized by the total capacitance change.

The normalized slope for the seeded structures recrystallized with the slanted beam is $0.24 \pm 0.01 \text{ V}^{-1}$, while that for the corresponding unseeded structures is $0.19 \pm 0.02 \text{ V}^{-1}$. The other seeded structures also had greater slopes than did the unseeded structures, indicating that the interface trap density is lower in seeded structures.

The voltage corresponding to the intersection of the tangent to the curve with the maximum capacitance is influenced both by the fixed charge density and the interface trap density. It was $2.03 \pm 0.13 \text{ V}$ for the seeded structures recrystallized with the slanted beam and $2.58 \pm 0.14 \text{ V}$ for the unseeded devices, corresponding to a charge difference of $6 \times 10^{10} \text{ cm}^{-2}$ between the two structures.

After correcting for the field-oxide regions, the effective dopant concentration in the seeded films was calculated to be $2 \times 10^{16} \text{ cm}^{-3}$, in good agreement with the value expected from the amount of implanted dopant. The oxide thicknesses calculated are also consistent with the values measured directly.

The maximum high frequency capacitance appears to be the same for the seeded and unseeded structures, but the minimum capacitance is about 3% greater for the unseeded structure. This could be related to expansion of the depletion region into the film being limited by defect levels in the unseeded structure or by loss of dopant from the seeded film to the substrate during recrystallization. It is unlikely that the defect levels increase the effective carrier concentration.

Quasistatic C-V measurements.—Comparison of quasistatic and high frequency C-V characteristics also shows a significant difference in the interface trap density between seeded and unseeded structures (Fig. 2a and 2b, respectively). As the film is being depleted, no difference can be resolved between the high frequency and quasistatic characteristics for the seeded structure, while a clear difference is seen for the unseeded structure.

Figure 3 shows that the minimum in the quasistatic curve is broader and shallower for the unseeded structure

Fig. 2. High frequency and quasistatic capacitance-voltage characteristics of (a) seeded structure recrystallized with the slanted beam and (b) unseeded structure with an n^+ buried layer in a lightly doped substrate. Voltage is that applied to the recrystallized film (i.e., the negative of the "gate" voltage applied to the wafer).

Fig. 3. Quasistatic capacitance-voltage characteristics of seeded and unseeded structures.

than for the seeded structure. This difference is consistent with the different slopes of the high frequency C-V characteristics noted above.

The major difference in the shape of the quasistatic characteristics of the two devices occurs during the transition from the accumulation region to the minimum capacitance. The region from the minimum to inversion is similar in the two cases, with primarily a parallel shift of approximately 0.9V, corresponding to a difference in the integrated number of traps of about $9.5 \times 10^{10} \text{ cm}^{-2}$. If the traps were uniformly distributed across the gap from accumulation to weak inversion (about $30 kT/q = 0.77 \text{ eV}$), the trap density would be about $1.2 \times 10^{11} \text{ cm}^{-2} \text{ eV}^{-1}$ higher in the unseeded structure than in the seeded structure. A nonuniform distribution would lead to a lower minimum trap density.

The width of the quasistatic characteristic was also significantly greater for the unseeded structure than for the seeded structure. The widths of the capacitance minimum (FWHM) are 3.34V for the unseeded structure and 2.86V for the seeded structure, corresponding to a charge difference of about $5 \times 10^{10} \text{ cm}^{-2}$ contained within a 0.6 eV wide region of the bandgap. The width of the calculated C-V characteristic was about 2.76V, close to that in the seeded structure.

The minimum values of the interface trap density computed using the conventional data-reduction program are useful for comparison of the different devices. Although their values may not be accurate because of lateral non-uniformities in the device structure used, the structure should influence all the devices in the same manner, so the differences are related to the seeding and recrystallization conditions. The minimum values indicated by the data-reduction program are used for convenience in this comparison. They are $(1.2 \pm 0.5) \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ for the seeded devices recrystallized with the slanted beam and $(11.9 \pm 2.5) \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ for the unseeded wafers with the n^+ buried layer. The minimum value occurs slightly above midgap.

As with the fixed charge density, the shuttle beam produced seeded material with a higher interface trap density than did the slanted beam (although it was still lower than in the unseeded structures). This higher density may be related to the repeated melting and recrystallization caused by the small step size used with the shuttle beam. The effect appears to be significantly more detrimental at the higher laser power. This is consistent with our previous observations on simpler capacitor structures that the interface charge densities were higher with the shuttle beam than with the slanted beam.

Little difference is seen between the unseeded devices with an n^+ buried layer and those on an n^+ wafer, again consistent with the dominant differences being caused by the seeding and consequent single-crystal growth. When different powers were used with the unseeded structures, no significant differences in the interface trap density

were seen; any effect is probably hidden by the defects in the unseeded structure itself.

Discussion

Two effects are expected to cause higher interface charges in an unseeded structure than in a seeded structure. First, the unseeded devices contain a large number of grains with crystal orientations other than {100}; these other orientations are expected to have higher interface charge densities. Second, traps at the grain boundaries can contribute to the measured charges. As the depletion region extends into the unseeded material, the charge state of some of the grain-boundary traps must be changed, so that more voltage is required for formation of an inversion layer. This causes dispersion in the C-V characteristic. In addition, the discrete location of the grain boundaries can cause dispersion because of the resulting lateral nonuniformity; *i.e.*, a higher voltage is required to invert the region near the grain boundary than that away from the grain boundary. These effects cannot readily be separated.

Lateral nonuniformities arising from the device structure with adjacent gate-oxide and field-oxide regions should affect the C-V characteristics similarly for both structures. Therefore, the differences seen between seeded and unseeded devices appear to be related to the different charge densities at or near the back surface of the recrystallized silicon films. The value found for the seeded structures may be limited by the resolution of the measuring system.

Conclusions

Both the fixed charge density and the interface trap density at the back of seeded, recrystallized silicon films on insulating oxide layers are significantly lower than those in unseeded devices. A recrystallization technique which melts the silicon film a minimum number of times produces the lowest interface charge.

From the flatband voltage observed during high-frequency C-V measurements, the difference in fixed charge density between optimum seeded and unseeded structures was found to be about $6 \times 10^{10} \text{ cm}^{-2}$. Differences in the slopes of the high frequency characteristics suggested that the interface trap densities were different also. Quasistatic C-V measurements indicated a minimum interface trap density of about $1.2 \times 10^{10} \text{ cm}^{-2}$ for the seeded structures, and $1.2 \times 10^{11} \text{ cm}^{-2}$ for the unseeded devices. The difference in integrated interface trap densities between seeded and unseeded structures is about $5 \times 10^{10} \text{ cm}^{-2}$ over a 0.6 eV portion of the bandgap and $1.0 \times 10^{11} \text{ cm}^{-2}$ over 0.8 eV.

Seeded films remelted a number of times had higher interface charge densities, but these were still less than in unseeded films. Higher laser powers also appeared to be detrimental.

The differences between seeded and unseeded structures may be related to the higher charge densities expected for grain orientations other than {100} and to traps located at the grain boundaries near the back surface of the silicon film. Quantitative values of the interface charge density distributions could not be confidently determined because of the laterally nonuniform nature of the structure used to obtain seeded material.

ABSTRACT

InGaAs photodetectors for the 1.7-2.0 μm region have been fabricated by LPE growth of InGaAs layers on intermediate layers of InAsP on an InP substrate. p-n Junctions were formed either by Zn diffusion into an n-type In_xGa_{1-x}As layer or by epitaxial growth of a p-type layer of In_xGa_{1-x}As doped with Mn. The effect of threading dislocations on minority carrier lifetime is analyzed on the basis of minority carrier diffusion length data obtained by fitting a computer model to the experimentally observed quantum efficiency.

In_xGa_{1-x}As_yP_{1-y} lattice matched to InP is currently the preferred materials system for the fabrication of light sources and detectors for optical communications. The maximum wavelength accommodated in this system is 1.65 μm , corresponding to the bandgap of Ga_{0.47}In_{0.53}As, and thus it encompasses the wavelength region of minimum total loss of silica-based fiber optical waveguides (1). Although for such fibers the position of this minimum is not likely to shift much farther into the infrared, small adjustments in the most desirable wavelength of transmission beyond 1.7 μm may become necessary in the future. This paper reports on the fabrication of a photodetector that covers the 1.7-2.0 μm region (2). The detector is fabricated in the In_xGa_{1-x}As ternary system (0.53 < x < 0.70) on InP substrates by liquid phase epitaxy (LPE). To accommodate the lattice mismatch, InAs_yP_{1-y} step-graded layers have been grown between the substrate and the active region. The In-As-P ternary system was chosen because it is easy to step grade and can also act as a window on the active region if the detector is illuminated from the substrate side.

Experimental and Results

The present work was preceded by the determination of the phase diagrams of both the In-Ga-As (3) and the In-As-P (4) ternary systems. The respective solidus and liquidus isotherms for several temperatures were generated by the aid of the regular solution approximation in conjunction with extended data from across the solidus composition of each ternary system. The extended solidus and liquidus data sets were acquired by growing by LPE multiple epitaxial layers using step grading techniques (3). For the present work, saturation temperature for the In-Ga-As melts was 650°C. In-As-P melts were saturated at slightly higher temperatures.

The possibility of growing by LPE an InGaAs layer on intermediate layers of InAsP on an InP substrate is demonstrated in Fig. 1. This pattern shows clearly seven of the eight expected peaks from a single InGaAs epitaxial layer grown on two intermediate, step-graded layers of InAsP on a (111)B InP substrate. The InGaAs layer is approximately 3 μm thick and the InAsP layers are each approximately 5 μm thick. The copper K_{α2} peak of the InGaAs layer is overlapping with the copper K_{α1} peak of the top-most InAsP layer. As indicated in Fig. 1, the compositions

of the InAs_yP_{1-y} layers are y = 0.057 and 0.095 and the composition of the In_xGa_{1-x}As layer is x = 0.62. The overall lattice mismatch between the InP substrate and the InGaAs layer shown in Fig. 1 is calculated to be 0.57%. The lattice mismatch between the top InAsP step-graded layer and the InGaAs layer shown in Fig. 1 is calculated to be 0.27%. In later growth runs, the lattice mismatch between the top two epitaxial layers was successfully decreased to the resolution of our x-ray diffractometer, which is 0.10%.

Etch pit density (EPD) studies were performed on the mismatched InGaAs epitaxial layer by etching for 5-30s in AB etch at room temperature. The revealed defect density in all cases tested exceeded 10⁶ cm⁻². This high EPD is attributed to the large mismatch between adjoining epitaxial layers and to some extent to the (111) orientation of the epitaxial layer.

The In_xGa_{1-x}As undoped n-type epitaxial layer was characterized by Hall data from an epitaxial layer grown on a semi-insulating substrate and C-V measurement data on a junction. These data show consistently a carrier concentration of n = 4 × 10¹⁵ cm⁻³. The Hall data result in a mobility of μ = 9100 cm²/V-s for x = 0.54. Devices were fabricated either by Zn diffusion into an n-type In_xGa_{1-x}As layer or by epitaxial growth of a p-type layer

of $\text{In}_x\text{Ga}_{1-x}\text{As}$ doped with Mn, as illustrated in Fig. 2a and 2b, respectively. Zn diffusion was performed either by sealed ampul diffusion or by plating with Zn followed by diffusion on a strip heater. The Zn-diffused material was characterized by Hall data resulting in typically $p = 5 \times 10^{18} \text{ cm}^{-3}$ and $\mu = 73 \text{ cm}^2/\text{V}\cdot\text{s}$. For Mn-doped growth, Mn was added to the melt at the ratio 1.0-1.5 mg/g-In. For a ratio of 1.2 mg/g-In in Mn-doped material, the net hole concentration and Hall mobility were $p = 3 \times 10^{19} \text{ cm}^{-3}$ and $\mu = 17 \text{ cm}^2/\text{V}\cdot\text{s}$.

The devices were characterized by I-V characteristics and spectral response. Representative I-V characteristics are shown in Fig. 3 and 4. For the I-V light and dark currents, reverse bias breakdown became increasingly soft as lattice mismatch increased. For Zn-diffused $\text{In}_x\text{Ga}_{1-x}\text{As}$ junctions of compositions of $x = 0.545, 0.58, \text{ and } 0.625$, open-circuit voltages were 0.21, 0.18, and 0.14V, respectively, and peak quantum efficiencies were 0.662, 0.628, and 0.226, respectively. The quantum efficiency spectra of these three devices are depicted in Fig. 5. Mn-doping $\text{In}_x\text{Ga}_{1-x}\text{As}$ junctions of compositions of $x = 0.54, 0.59, \text{ and } 0.69$ had peak quantum efficiencies of 0.265, 0.202, and 0.059. For the Mn-doped $\text{In}_x\text{Ga}_{1-x}\text{As}$ photodetector of composition $x = 0.69$, the quantum efficiency was fairly flat to 1.9 μm and dissipated thereafter to 2.0 μm as viewed in Fig. 6.

Analysis and Discussion

The difference in the quantum efficiencies between the Zn-doped and the Mn-doped $\text{In}_x\text{Ga}_{1-x}\text{As}$ photodetectors may be attributed to several causes. The order-of-mag-

nitude-higher doping concentration of Mn explains the lower mobility and quantum efficiencies because of a reduction of the minority carrier lifetime due to increased scattering effects. With lower Mn doping, higher quantum efficiencies can be expected. On the other hand, because the electrical p-n junction is separated from the metallurgical junction in the Zn-diffused devices, quantum efficiencies are improved (5, 6). Furthermore, in agreement with the higher mobility of the Zn-diffused epitaxial layers and in view of the fact that the field generated by the doping gradient guides minority carriers toward the collecting junction, the Zn-diffused devices have higher efficiencies.

The density of misfit dislocations depends to a large extent on the lattice misfit strain between adjacent mismatched epitaxial layers or between a mismatched epitaxial layer and the adjacent substrate. Furthermore, these dislocations tend to bend into the epitaxial layers, creating "inclined" or "threading" dislocations that can transmit the impact of the lattice misfit into the bulk of the epitaxial layer and thus contribute to a degradation of the layer properties (7). The direct relationship between an increased lattice mismatch, an increase in misfit dislocation density, and a decrease in device performance has been reported in several lattice-mismatched ternary systems (8-10). In view of these observations, an analysis of the known lattice mismatch and corresponding device

quantum efficiencies for the In_xGa_{1-x}As photodetectors described in this paper is appropriate.

The quantum efficiency spectra of the Zn-diffused devices were fitted on the basis of a homojunction model for solar cells (11). A computer algorithm performed the fit by finding optimum values of the diffusion lengths of the minority carriers and junction depth. An example of this fit is shown in Fig. 7 for the Zn-diffused In_{0.58}Ga_{0.42}As detector. The fit is not perfect, since the model itself is meant to be only a first approximation of a diffused junction. Furthermore, the model requires estimated values for wavelength-dependent parameters such as the absorption coefficient and the reflectance. The modeling results indicated that the quantum efficiency spectra were fairly insensitive to the minority carrier hole diffusion length on the n-type side of the electrical junction. This insensitivity can be expected if most of the absorption takes place near the surface of the device.

Under these circumstances, the minority carrier lifetime, τ_n , of the electrons in the p-type side of the electrical junction can be calculated on the basis of the modeling results by the relationship of $\tau_n = L_n^2/D_n$, where D_n is the electron diffusion coefficient and L_n is the electron diffusion length. Also, the threading dislocation density can be calculated from the derived expression (12)

Fig. 5. Quantum efficiency spectra of three Zn-diffused In_xGa_{1-x}As photodetectors.

$$\frac{\eta}{\eta_0} \approx (1 + \Pi^2 L_n^2 \rho_d)^{-1}$$

where ρ_d is the threading dislocation density, η_0 is the peak quantum efficiency in the absence of dislocations, and η is the peak quantum efficiency in the presence of

Fig. 7. Quantum efficiency experimental data and the fitted model for a Zn-diffused In_{0.58}Ga_{0.42}As photodetector.

Fig. 8. Minority carrier lifetime vs. misfit dislocation of Zn-diffused $\text{In}_x\text{Ga}_{1-x}\text{As}$ photodetectors.

dislocations. By allowing η_0 to be 70% (13, 14), η to be the peak value for each of the Zn-diffused devices, and L_n to be the corresponding values deduced from the fitting procedures, the threading dislocation density can be estimated for each device. Figure 8 indicates the relationship between the computed minority carrier lifetimes and their corresponding estimated dislocation densities for the Zn-diffused devices of the present work. Figure 8 thus indicates the estimated trend of the effects of threading dislocation density on the minority carrier lifetime. Similar work with p-type GaAs (7) is also presented in Fig. 8 for comparison.

On the basis of the analysis resulting in Fig. 8, the decrease in lifetime due to the increase in misfit dislocations in $\text{In}_x\text{Ga}_{1-x}\text{As}$ appears to be less critical than the decrease in lifetime due to the increase in defect density in GaAs specifically and other materials (Ge, Si, GaP, and AlGaAs) in general (7). This difference in part reflects the fact that devices with short diffusion lengths are less sensitive to a moderate dislocation density than devices with long diffusion lengths. This difference can also be attributed to the differences in the nature of the defects in those other materials and as well to the presence of step-graded layers used in the present study. Improved electrical performance of mismatched material due to the presence of step-graded layers included to relieve mismatch strain has been noted in GaAsSb photodiodes (8) and in $\text{In}_x\text{Ga}_{1-x}\text{As}$ layers grown on GaAs substrates (9). This effect has also been noted in the present work, as can be observed in Fig. 9. This figure shows the responsivities of $\text{In}_{0.58}\text{Ga}_{0.42}\text{As}$ homojunction photodiodes both with and without intermediate step-graded layers of $\text{InAs}_y\text{P}_{1-y}$. Both devices were Zn diffused and otherwise identical except for the presence of the intermediate step-graded layers. The device with the intermediate step-graded layers has more than twice the responsivity of the device with a single mismatched layer. Thus, although increased threading dislocations due to lattice-mismatched material cause a serious decrease in efficiency of the device de-

scribed in the present work, the introduction of intermediate step-graded epitaxial layers has made it possible to produce by LPE InGaAs photodetectors for the 1.7-2.0 μm spectral region.

Gettering of Carbon and Oxygen in Silicon Processing

W. E. Bailey,* R. A. Bowling,* and K. E. Bean*

Texas Instruments, Incorporated, Dallas, Texas 75265

ABSTRACT

The control of carbon and oxygen is of great importance in today's silicon materials and device processing, and it will become a critical parameter in the immediate future for VLSI device processing. Although considerable technology and some understanding are available today in the control of oxygen in silicon materials through processing, there is little technology and even less understanding of carbon control in silicon wafer processing. We have determined, for high carbon content silicon, that carbon can be gettered to damage sites such as dislocations, stacking faults, and/or wafer surfaces, thus creating a carbon-denuded zone in epitaxial silicon, as well as in bulk Czochralski silicon substrates. The gettering effects of carbon have been investigated using controlled time, temperature, and ambient gas thermal anneals. The characterization of these materials was carried out using chemical etches, Fourier transform infrared spectroscopy, and scanning Auger microprobe analysis.

The control of oxygen and carbon in Czochralski (CZ) silicon is the subject of a great number of recent studies because of its importance in defect formation and gettering of impurities. Intrinsic gettering can be used to remove unwanted impurities from device active regions (1-5); thus, the control of oxygen and its effects on intrinsic gettering have been particularly examined (1, 2, 5-16). Intrinsic gettering has been found to retard material slip (17-18), reduce slip formation (19), control epitaxial stacking fault formation (20), reduce p-n junction leakage currents, and improve MOS generation lifetimes (21-23). Oxygen donors can significantly alter silicon electrical properties (24). Interstitial oxygen and small oxygen clusters can strengthen wafers to prevent process-induced warpage (25, 26). The effects of carbon on both oxygen precipitation and oxygen donor formation have also been often investigated (1, 3, 24, 27-32), but not with as much success of definitive behavior as for oxygen. Pinizzotto and Marks (5) concluded that both the initial carbon and oxygen concentrations affect the final measured oxygen solubility in silicon, that carbon is involved in precipitate nucleation, but not in precipitate growth, and that carbon content does not strongly affect oxygen precipitation in high oxygen silicon (> 30 ppm), but does control the oxygen precipitation in low oxygen content silicon (< 25 ppm). In this paper, the role of carbon in high carbon-content silicon is examined (32, 33).

Experimental

In these experiments, (100) p-type, 5-20 Ω -cm silicon wafers with various levels of carbon were used to study effects introduced during the processing of VLSI devices and epitaxial silicon deposition. The samples were within an oxygen concentration range of 1.25×10^{18} cm^{-3} (25 ppm) to 1.7×10^{18} cm^{-3} (34 ppm), which is considered to be a useful range to achieve intrinsic gettering effects. A heat-treatment sequence was picked to simulate current VLSI processing and to provide denuded substrates for epitaxial deposition. The heat cycles were three separate anneals of 1100°C, in nitrogen, for 2h to out-diffuse oxygen (anneal 1), of 650°C, in nitrogen, for 20h to begin nucleation (anneal 2), and of 1000°C, in oxygen, for 20h to simulate precipitate growth during processing (anneal 3). Push-pull rates between each cycle were 20 cm/min, with the two high temperature cycles being ramped up from 850°C after the push cycle, and ramped down to 850°C prior to the pull cycle.

CZ Single-Crystal Silicon Wafers

Carbon and oxygen.—Carbon and oxygen measurements were made using a Nicolet MX-ECO FTIR spectrometer. The measurements of substitutional carbon and interstitial oxygen in silicon were based on ASTM Methods F-121-76 and F-123-74 as refined by Vidrine (34). In this work, the materials used were of a production nature obtained from several silicon wafer vendors, each sub-

strate being single-side polished with various types of back-side treatments particular to each vendor. The values of carbon and oxygen are relative to repeated measurements on the same wafer, but are not intended to be absolute in magnitude. Figure 1 shows differences in the FTIR traces due to the various back-side surfaces as produced by four different vendors, A, B, C, and D. Traces A and D are from wafers that have been acid etched to relieve stress caused by sawing and lapping processes during wafer production, while traces B and C are from wafers that received a caustic etch as part of the vendors' standard processes. The differences in the curves are caused by changes in scattering and internal reflection of the infrared beam due to the texture of the back side of the wafers. All four wafers were then back-side polished to remove the texture of the relief etches. Major differences in the background of the FTIR traces were removed, as shown by a superposition of all four back-side polished wafer FTIR traces, A', B', C', D', in Fig. 1.

The plots in Fig. 2 show the behavior of interstitial oxygen for silicon material with low carbon (< 0.2 ppm) as a function of the three-step anneal described in the Experimental section. The initial data points are the interstitial oxygen concentrations of the as-received wafers, after crystal growth and vendor resistivity stabilization anneals, but prior to any further heat-treatments. The other points are after the cumulative anneals to the step designated. The oxygen reduction during the third anneal step is shown to be dependent on the initial oxygen concentration as previously reported by Pinizzotto and Marks (5).

Fig. 1. FTIR traces of silicon wafers from different wafer vendors, A, B, C, and D, with various types of back-side texture. A and B are acid etched by vendors; C and D are caustic etched by vendors. Also shown are FTIR traces of silicon wafers from the same four vendors, but with a back-side polish; all four traces, A', B', C', and D', are superimposed.

Fig. 2. The change of interstitial oxygen concentration in bulk CZ silicon wafers as a function of the three-step anneal for <0.2 ppm carbon wafers; data from FTIR measurements with carbon below the detection limits in each case.

Figures 3 and 4 give the changes in interstitial oxygen and substitutional carbon, respectively, for high carbon (> 2 ppm) concentration wafers. The change in substitutional carbon, in this case, is linear with respect to the initial concentration of carbon. This is shown in Fig. 5, which is a plot of the differences between the initial carbon and final carbon concentrations shown in Fig. 4 vs. the initial carbon content for those wafers. The points of this plot fit well, within experimental error, to a straight line. This observation of linearity, however, may be oxygen concentration dependent as reported by Pinizzotto and Marks (5). The change in interstitial oxygen with respect to the initial oxygen concentration is similar to the curves in Fig. 2 for low carbon wafers. This change has been previously shown to follow a straight line (2). The main difference between low and high carbon, shown in Fig. 2 and 3, is that the high carbon wafers had approxi-

Fig. 3. The change of interstitial oxygen content in >2.0 ppm carbon content silicon wafers as a function of the three-step anneal; data from FTIR measurements. Initial carbon concentrations in ppm for wafers 0 through 9, respectively, were 3.18, 3.09, 3.58, 6.18, 5.41, 5.43, 1.95, 2.75, 2.64, and 2.02.

Fig. 4. The change in substitutional carbon content in 24-30 ppm oxygen content silicon wafers as a function of the three-step anneal; data from FTIR measurements. Initial oxygen concentrations in ppm for wafers 0 through 9, respectively, were 29.03, 29.35, 28.97, 24.71, 25.15, 25.02, 27.64, 27.25, 26.76, and 27.47.

mately 5 ppm greater change in interstitial oxygen for a given initial oxygen content than the low carbon material. All materials represented in Fig. 2, 3, and 4 were received from the same vendor, with the higher carbon levels being achieved by intentional doping by the vendor of the molten silicon with carbon.

Dislocation and defect analyses.—The CZ-grown single-crystal wafers intentionally doped with carbon from non-detectable limits to greater than 5 ppm were processed using the three-cycle heat-treatment. The bulk of each wafer was examined using a variation of the groove-and-etch method described by McDonald and Goetzberger (35). A 5 min Wright-Jenkins dislocation etch (36) was used to display precipitated sites within a $35 \mu\text{m}$ deep cylindrical groove. Inspection of the groove using an optical microscope with Nomarski interference contrast revealed a clear denuded area approximately $10\text{-}20 \mu\text{m}$ deep. Standard stacking faults and dislocation loops associated with oxygen precipitation appeared at the bottom of the

Fig. 5. Plot of the differences between the initial carbon and final carbon concentrations for wafers in Fig. 4 vs. the initial carbon content for those wafers. The correlation coefficient for the least squares best fit line to the data is 0.936.

Fig. 6. Optical photograph of (A) normal (100) bulk stacking faults, and (B) c pits as found in high carbon concentration silicon.

groove and were oriented along $\langle 110 \rangle$ directions. In the higher carbon samples, a new defect, which we call "c pits," also appears. Its axis of symmetry is oriented 45° to the $\langle 110 \rangle$ direction defined by the bulk stacking faults. Several such c pits are shown in relationship to bulk stacking faults in Fig. 6. The parallel, vertical lines in the figure are groove artifacts due to the polishing wheel used to prepare the cylindrical groove. This new c pit defect has been found to occur singly or in pairs; the c pits shown in Fig. 6 are all in pairs. Recently, Matlock (4) also noted these new defects in high carbon silicon wafers used for processing 64K DRAM devices. Extended time anneals were performed on the low carbon silicon and have not, in any instance, created the c pit defects observed on the high carbon samples.

Figure 7 is a transmission electron micrograph (TEM) image of an area of a high carbon wafer containing c pits and a bulk stacking fault. The stacking fault, which runs horizontally across the picture, and several of the 45° c pit dislocations are shown in the (100) sample plane. The stacking fault, which lies in the (111) plane, defines the (011) plane. The 45° c pit dislocation can be visualized as

Fig. 7. TEM micrograph from an area of high carbon in silicon after three-step anneal, showing a stacking (horizontal across the micrograph) and several c pits (diagonal across the micrograph).

Fig. 8. TEM micrograph of four pairs of c pits in high carbon silicon

lying in the (101) plane and projected onto the (100) plane at 45° with respect to the projection of the stacking fault on the (100) plane. Figure 8 is another TEM image of a high carbon content wafer showing a higher density of these c pits, in this case, four pairs.

Subsequent examination of the heat-treated high carbon grooved samples using a JEOL JAMP-3 scanning Auger electron microscope has revealed low levels of atomic carbon in the upper $10\text{--}20\ \mu\text{m}$ of the groove and in clear areas around the defects in the bottom of the groove. The concentration of carbon at the dislocation sites, both c pits and bulk stacking faults, was found to be from two to six times greater than in the bulk of the wafer. Typical Auger results for one sample are shown in Table I. This gettering of carbon to sinks and nearby wafer surfaces has been previously proposed (27, 37, 38), but not experimentally verified, in CZ single-crystal silicon wafers or in epitaxial silicon films. Standard carbon wafers having the same heat-treatments were not found by Auger analysis to exhibit this difference in carbon levels. In each case, the Auger spectrometer electron beam spot size was focused to approximately $2000\ \text{\AA}$ diam and line rastered on the defect or bulk defect-free area (clear area) over a distance of about $1\ \mu\text{m}$. Argon ion sputtering was used to remove surface contaminants and sputter into the defect or bulk clear area. Analyses were made at 1 min sputter intervals to monitor the progress of the sputtering. The Auger data presented are for depths, given in sputter minutes, at which no significant changes in the carbon, oxygen, or silicon levels were noted over several minutes of sputtering. This typically ranged from 5 to 10 min of sputtering. This was taken to be the point at which most surface contamination, which might be largely carbon, has been removed. 1 min of sputtering has been empiri-

cally determined, for our system, to correspond to approximately 150Å depth in the silicon wafer. The Auger system base pressure before sputtering was typically $5-8 \times 10^{-10}$ torr, pressure during argon ion sputtering while using a Kratos Minibeam-II differentially pumped ion sputter gun was about 5×10^{-8} torr, and pressures during Auger analyses were usually from 1×10^{-9} to 5×10^{-9} torr. The tabulated Auger data are given as typical examples of the data obtained from multiple samples of each type.

Gettering of Carbon in Epitaxial Silicon

Chemically vapor deposited epitaxial silicon was grown on (100) silicon substrates with low (< 0.1 ppm), normal (< 0.5 ppm), and high (> 1.0 ppm) carbon concentrations in the bulk crystal. Epitaxy was also grown on normal carbon concentration substrates with known carbon surface contamination (from the substrate holder) in specific areas of the wafer, as well as on high carbon substrates. In all cases of epitaxial silicon over areas of high carbon, defect-denuded regions were observed around stacking faults in the epitaxial film. Figure 9 is a phase contrast photograph of such a region which shows the denuding or gettering effect of damage around the stacking fault in the epitaxial film on a high carbon wafer. This denudation occurs as a result of the epitaxial deposition process only; no further heat-treatments or surface treatments were necessary to observe this phenomenon. Large dislocations, with precipitates, are observed at the corners of the stacking fault. Auger analyses of the corners of the stacking fault, a clear denuded area around the stacking fault, and a clear area away from the stacking fault showed the precipitates to contain a high concentration of carbon, with much less carbon being observable in the clear areas. Heavy metals, which are also expected to be associated with these corner precipitates, and the denuding region were not observed by Auger, probably because of the 0.5% or higher detection limits of scanning Auger spectroscopy for such metals. Slightly higher carbon was observed for a clear area away from the stacking fault as compared to the clear denuded area near the stacking fault. These areas are designated A, B, and C in Fig. 9, and the Auger data for these areas are summarized in Table II. Another example of this gettering process in epitaxial films is shown in Fig. 10. Scanning Auger analysis results for the area of one of the stacking faults in Fig. 10 showed little or no carbon in the zone around the stacking fault as compared to 20% or more carbon in the stacking fault. Auger analyses of the defects around the clear denuded area and clear areas around those defects revealed no measurable differences in carbon levels between these two areas. Figure 11 is an optical phase con-

trast photograph of a cleaved cross section of a heat-treated epitaxial film on a high carbon substrate. The cleaved sample was Wright-Jenkins etched, but was not polished. It clearly shows a typical oxygen precipitation denuded region beneath the junction of the epitaxial layer; the surface itself does show a number of defects. The denuded region in the sample is about 20 μm deep.

Discussion

Interstitial oxygen measurements indicate less than 2 ppm total change in oxygen concentration during the 1100° and 650°C anneal with usually a 15-25 ppm reduc-

Fig. 10. Epitaxial stacking faults on high carbon silicon showing denuded areas due to the epitaxial CVD processing only.

tion in oxygen concentration during the final 1000°C anneal. The initial interstitial oxygen concentration of all samples ranged from about 24 to 32 ppm. Significant changes in substitutional carbon levels occurred only during the 1000°C growth cycle.

Gosele and Tan have speculated on the coprecipitation of carbon and self-interstitials to enhance the diffusivity of carbon in silicon (39). They have concluded that carbon either migrates rapidly via a complex involving an intrinsic point defect (I) or has a fast diffusing component via interstitial carbon (C_i). The two methods are illustrated as follows, where C_s is substitutional carbon

and

This association of carbon atoms with self-interstitials leads to nuclei for microdefect formation; hence, the influence of carbon would depend upon the concentration of self-interstitials present. New donors created in CZ silicon at 650°C are considered to be oxygen precipitates with nuclei provided by carbon. Tajima *et al.* (40) have shown that the density of new donors can be affected by either high carbon concentrations or extended 470°C anneal cycles which precede a 650°C anneal. Thus oxygen precipitation is governed by the thermal history of the wafers, and knowledge of the thermal behavior of microdefects at lower temperatures is indispensable if one is to understand the complete system of nucleation and growth of defects (41). Also, the control of carbon concentration in silicon will be necessary to achieve proper control and understanding of oxygen precipitation and gettering.

ABSTRACT

This paper describes the design of a proximity effect test structure and electrical test method for estimating the magnitude of proximity effects in electron-beam lithography. The test structure consists of a van der Pauw cross resistor for measuring sheet resistance, a bridge resistor for measuring electrical linewidth, and a second bridge resistor simulating a close line-space environment for measuring electrical linewidth where proximity exposure effects from nearby patterns may be encountered. In this experiment, test structures were delineated in aluminum on silicon wafers using electron-beam exposure and wet chemical etching. Electrical measurements from these test structures are compared to optical measurements to verify the measurement method. In addition, results from the test structures are used to estimate the parameters for the gaussian model commonly used for proximity correction.

Proximity effects in electron-beam (E-beam) lithography are the additional exposure in the resist due to electron scattering in regions not addressed by the electron beam (1-3). This scattering of electrons in the resist and additional patterns in close proximity to that being exposed. In both cases, linewidth control for fine-line patterns with high packing density will deteriorate. The magnitude of proximity effects in the exposed resist depends on the beam voltage, beam diameter, resist material, resist thickness, and substrate material. In general, for linewidth and line-to-line spacings of less than $2 \mu\text{m}$, proximity effects can have significant effect on the resultant linewidths (4, 5).

Theoretical models and Monte Carlo simulations are the basis for much of the understanding of proximity effects and for predicting the magnitude of these effects on linewidth control (6, 7). However, detailed experimental data for comparison to calculated values are limited by time and by the complexity of obtaining accurate linewidth measurements of resist profiles on wafer.

This paper describes an electrical technique for determining the magnitude of proximity exposure on linewidth control. An electrical test structure and a test method were developed for the rapid and precise determination of linewidth of an E-beam-exposed pattern from samples simulating a dense line-space environment. Electrical linewidth measurements were compared to optical linewidth measurements to verify the magnitude of the proximity effects. In addition, a practical application for the measurements from the test structure for proximity correction was investigated.

Proximity Effect Test Structure

The proximity effect test structure (PETS) is an extension of the cross-bridge sheet resistor (8). A PETS, shown in Fig. 1, consists of a van der Pauw cross resistor, an upper bridge resistor, and a lower bridge resistor with proximity inducing bars of width T separated from the bridge resistor at a spacing S . The cross-bridge resistor allows electrical measurements of the linewidth of a conducting layer and is sensitive to small variations in linewidth (9). Hence, the PETS allows for the electrical measurement of linewidth differences between bridge resistors with and without proximity inducing bars. This linewidth difference is the result of proximity effects from electron scattering registered in the resist of the lower bridge.

The PETS can be tested electrically to determine sheet resistance (R_s), top linewidth (W_t), and bottom linewidth (W_b). Sheet resistance of the conducting layer is deter-

mined at the cross resistor connected to probe pads 2, 3, 7, and 8. Current I_c is forced between two probe pads, and voltage drop V_c is measured at the other two probe pads. R_s is calculated by the van der Pauw method (10) where

$$R_s = (\pi/\ln 2)(V_c/I_c) \quad [1]$$

W_t is determined at the upper bridge resistor

$$W_t = R_s L_t (I_o/V_t) \quad [2]$$

where V_t is the voltage drop measured at probe pads 1 and 2 for a current I_o forced between probe pads 9 and 4. L_t is the center-to-center design length of the top bridge resistor. Similarly, W_b is determined at the lower bridge resistor

$$W_b = R_s L_b (I_o/V_b) \quad [3]$$

Fig. 1. Proximity effect test structures

*Electrochemical Society Active Member.

where V_b is the voltage drop measured between probe pads 7 and 6 for I_0 forced between probe pads 9 and 4. L_b is the center-to-center design length of the bottom bridge resistor.

To minimize differences in the electrical measurement due to variations in the current supply, V_t and V_b are measured for the same current I_0 forced between probe pads 4 and 9. Assuming that $L_t = L_b$ and that the upper and lower linewidths do not vary over the distance separating the two bridges, W_b is equal to W_t . Differences between the two lines are the result of the presence of the proximity inducing bars. Magnitude of this difference is

$$\Delta W = W_b - W_t \quad [4]$$

For practical test structure design, a small correction to ΔW is necessary because the length of the proximity inducing bars is always less than L_b . As shown in Fig. 2, the length, A , of the right side of the proximity inducing bar must be less than L_b to avoid shorting the taps to the probe pads. To calculate the correct ΔW , let R_b , the resistance of the lower bridge, be

$$R_b = V_b/I_0 = (R_1 + R_2) \quad [5]$$

where the sum $(R_1 + R_2)$ is the total resistance between the midlines of the two voltage taps. In terms of sheet resistance R_s , the resistances R_1 and R_2 are

$$R_1 = R_s A / (W + \Delta W) \quad [6]$$

$$R_2 = R_s (L_b - A) / W \quad [7]$$

where W is the width without proximity effects. Assuming $W = W_t$, combining Eq. [6] and [7] into Eq. [5] and solving for ΔW

$$\Delta W = \frac{A}{\frac{R_b}{R_s} - \frac{L_b - A}{W_t}} - W_t \quad [8]$$

Note that, if $A = L_b$, Eq. [8] is identical to Eq. [4].

As the space S between the bridge resistor and the proximity inducing bars diminishes, proximity effects as well as process variations can lead to the incomplete resolution of these line pairs, resulting in bridging between the bars and the bridge resistor. To identify and exclude these faulty structures, an electrical continuity test between probe pads 5 and 7 is conducted prior to any measurements.

Experiment

An evaluation of the performance of the test structure and test method was conducted with the design, fabrication, and measurements on test samples. A test chip was developed for fabrication by an E-beam system. Six PETS having a single proximity inducing bar (left) with drawn line-to-line spacings (S) of 1, 1.5, 2, 2.5, 3, and 4 μm and five PETS with two proximity bars (one on each side) with spacings of 1, 1.5, 2, 2.5, and 3 μm were included on the test chip. A control structure with no proximity bar was included for establishing the accuracy and precision of the measurement technique. Design dimensions are for $W_t = W_b = 5 \mu\text{m}$, $L_b = L_t = 200 \mu\text{m}$, $T = 2 \mu\text{m}$, and $A = 190 \mu\text{m}$.

A 50 mm diam silicon wafer was thermally oxidized to obtain an oxide thickness of 500 nm. Aluminum was then

evaporated onto the wafer to a thickness of 220 nm. The wafer was then coated with approximately 400 nm of a positive resist, AZ1350J, and baked at 90°C for 30 min. A commercial vector-scan E-beam system exposed a 5×5 array of the test chip on the wafer. Operating conditions with the gaussian beam system were 20 keV beam voltage, 0.2 μm beam diameter, 10 nA beam current, and a varying dwell time depending on the feature sizes.

After exposure, the resist was flood exposed with UV for 30s and then developed. A negative image pattern of the E-beam exposure can be obtained using this technique (11). Final patterns were delineated in the aluminum by wet chemical etching.

Measurements were obtained using a computer-controlled wafer prober and dc parametric test system. The test system included a digital current source with micro-ampere resolution and a digital voltmeter with microvolt resolution. Typical measurement time for each PETS is 4s. Precision of the test system for measuring nominal 5 μm linewidth was determined to be better than 0.002 μm (1σ) based upon 60 repeated measurements of one cross-bridge test structure.

Results

Experimental results are summarized in Table I. Each value is an average of 25 measurements on a wafer. The maximum standard deviation is less than or equal to 0.06 μm . The average sheet resistance and linewidth (without proximity) across the wafer are 0.156 Ω/\square and 3.71 μm , respectively. The magnitude of proximity effects as a function of S for the two-sided PETS and the one-sided PETS are shown in rows 1 and 2, respectively. As expected, the magnitude of proximity effects corresponding to the smallest spacing is largest. These results are in qualitative agreement with that expected from the exposure of photosensitive materials having a finite exposure threshold. Also, the average ΔW as measured from the two-sided PETS is twice that from the single-sided PETS, as would be expected. The average linewidth differences for the "control" structure is zero. This assures that systematic spatial nonuniformities are not responsible for the measured linewidth differences. Similar results have been obtained from other wafers using another E-beam system and process.

In order to verify the magnitude of the electrically measured values, optical linewidth measurements were performed on one chip in the center of the wafer. The optical measurement system used was a bright-field incident-light image scanning optical microscope employing a 1.4W krypton ion laser illumination source at a wavelength of 530 nm (12). This system illuminates a 30-50 μm radius area, which in turn is imaged onto a stationary scanning slit. The upper and lower bridge resistor widths for a set of two-sided PETS with spacings of 1.5, 2, 2.5, and 3 μm were measured optically. The linewidth difference between the upper and lower bridge resistors from optical measurements on each device and the correspond-

ing electrical linewidth differences are shown in Table II. The results of the comparison are in sufficient quantitative agreement (within one standard deviation of the electrical measurements) to verify the magnitude of the proximity effects measured electrically.

Proximity Correction

An electrical test structure can also serve as a tool for determining inputs to computer programs to correct for proximity effects during E-beam writing. Computer programs have been developed based upon the two-gaussian proximity function (4) defined as

$$f(r) = C_1 \exp(-r^2/S_1^2) + C_2 \exp(-r^2/S_2^2) \quad [9]$$

where r is the distance from the center of an electron beam, and C_1 , C_2 , S_1 , and S_2 are gaussian parameters. The first term of the function models the forward-scattered electrons and the second term models the back-scattered electrons. This proximity function represents the exposure intensity distribution in the resist due to a beam of electrons incident at $r = 0$. Monte Carlo simulations of E-beam exposure have shown that the gaussian model serves as a good approximation for the back-scattered electron distribution from the silicon substrate (13). However, the determination of the gaussian parameters for varying process conditions remains a difficulty for this model. A number of techniques for acquiring the gaussian parameters have been proposed (14-16). They require microscopic inspections and an unavoidable degree of subjective judgment regarding exposure and development. An alternative method for determining the gaussian parameters based upon electrical data from the test structures is now described.

The method can be used to obtain an optimum set of gaussian parameters from a least squares search by comparing the calculated results from the model to the measured results from the PETS. First, an initial estimate of the gaussian parameters based upon published data and the knowledge of the materials and process conditions is made. With these parameters and the gaussian model (Eq. [9]), the exposure intensity distribution or dose in the resist at point p due to the area exposure of A_1 and A_2 , as shown in Fig. 3, can be determined. A_1 represents a portion of the bridge resistor and A_2 represents a portion of the proximity bar. The dose at point p is the cumulative effect of exposure of A_1 and A_2 and can be calculated as

$$\text{Dose}(p) = \sum_{i=1}^2 \int f(r) dA_i \quad [10]$$

The integral of $f(r)$ can be approximated by error functions following the approach outlined in Ref. (17). The region of interest is between the bridge and the proximity bar where electron scattering during exposures of the proximity bar will shift the patterned bridge edge. Using Eq. [10], the dose as a function of position along the X axis as well as for different spacings of the proximity bar can be calculated.

Figure 4 shows an example of a plot of the exposure intensity distribution curve for the four spacings of the proximity bar ($S = 1.5, 2, 2.5,$ and $3 \mu\text{m}$). In addition, the

$$\text{Dose}(p) = \sum_{i=1}^2 \int f(r) dA_i$$

Fig. 3 Exposed pattern or geometry

exposure intensity distribution curve corresponding to an isolated line with no proximity bar is also shown. As would be expected, the presence of a proximity bar increases the total exposure received in the bridge resistor. In effect, the bridge edges shift to the right by a small amount for a given exposure level.

Since the measured data were obtained from developed resist and etched wafers, the effect of resist development on this model must be considered. As described earlier, the AZ resist was processed to provide a negative image of the exposed pattern. Thus, following development, resist area not exposed to the electron beam is removed. Using the threshold energy density model (6), the developed image in the resist can be determined given the threshold energy density or critical dose, D_c . The estimation of D_c will be described shortly. Because all the exposed patterns on a wafer were developed at the same time, the value of D_c is the same for different spacings of the proximity bar and can be used to extrapolate the predicted shift in the bridge edge from the exposure intensity distribution curves. Figure 5 is an expansion of Fig. 4 around the bridge edge to illustrate how the bridge edges (X_c) are determined for the different spacings. To briefly summarize, with an initial set of gaussian parameters, the gaussian model was used to calculate the exposure intensity distribution curves for the exposed patterns as a function of the spacing of the proximity bars. From these curves and an estimate of D_c , the magnitude of proximity effects for different spacings of the proximity bars can be determined.

As shown in Fig. 5, D_c is determined as the intersection of the point X_c to the exposure intensity curve with no

Fig. 4. Exposure intensity distribution curves for different spacings

Fig. 5. Electron dose distribution as a function of spacing of proximity strips.

proximity bar. X_s is the location of the right edge of the bridge resistor following resist development. X_c was estimated to be $1.85 \mu\text{m}$ from the center of the bridge resistor based upon the averaged measured electrical linewidth with no proximity bar. Because of the uncertainty introduced by the wafer etching process on this estimate, small variations about this estimate were considered and are described below. Also, since the initial set of gaussian parameters is an estimate, other sets of parameters which are independent small variations of each of the initial parameters are also used to calculate the curves. In this experiment, 625 sets of gaussian parameters were used to determine the values of the X_s for the different spacings.

In the least squares search, the criterion for determining the optimum set of parameters is that set which minimizes the least squares error (LSE). LSE is defined as

$$\text{LSE}(X_c) = \sum_s (\Delta W_s - \Delta X_s)^2 \quad [11]$$

where

$$\begin{aligned} S &= 1.5, 2, 2.5, 3 \mu\text{m} \\ X_c &= 1.85 \pm m(0.05) \mu\text{m} \\ m &= 0, 1, 2 \end{aligned}$$

where ΔW_s is the measured results from the PETS, ΔX_s is the calculated data from the exposure intensity curves and is defined as $(X_s - X_c)$, and S denotes the spacings of the proximity bar. As mentioned earlier, due to the uncertainty introduction by the wet etching process, X_c is varied about the initial value of $1.85 \mu\text{m}$ in $0.05 \mu\text{m}$ steps. Equation [11] thus solves for the LSE values for each of the 625 sets of gaussian parameters and for each of the five values of X_c for each set of gaussian parameters. The set of gaussian parameters that resulted in the minimum least squares error for the exposure and development conditions used in this experiment is $C_1 = 0.637$, $C_2 =$

0.242 , $S_1 = 0.277$, and $S_2 = 2.332$ at $X_c = 1.85 \mu\text{m}$. The value of X_c determined by this method is in agreement with that previously obtained from independent electrical measurements. The average minimum LSE value obtained from these calculations was $0.008 \mu\text{m}$. Both the magnitude of the LSE value and the close agreement between the calculated and measured X_c values indicate that the gaussian parameters extracted from this procedure are sufficient to model the proximity effects for the process described.

Conclusion

The proximity effect test structure provides a rapid and precise method for measuring the magnitude of proximity effects due to electron scattering in the course of direct-write E-beam lithography. This electrical measurement technique provides an alternative to optical measurements for determining effective linewidth in a dense circuit environment and for evaluation of proximity correction algorithms. The results from the test structure can also be used to determine the gaussian parameters for proximity correction.

Phosphorus Diffusion Using Spin-On Phosphosilicate-Glass Source and Halogen Lamps

Juri Kato and Yoshiteru Ono

Suwa Seikosha Company, Limited, Fujimi Plant, 281 Fujimi, Fujimi-Machi, Suwa-Gun, Nagano-Ken 399-02, Japan

ABSTRACT

Formation of phosphorus-diffused layers using spin-on phosphosilicate glass (SOPSG) source and rapid isothermal halogen lamp annealing (HLA) were investigated with respect to sheet resistivities, junction depths, carrier concentrations, and contact resistances. Higher HLA temperature and SOPSG phosphorus weight percent results in lower average resistivities (sheet resistivity \times junction depth). With a 1205°C, 2s HLA using 37.5 w/o SOPSG, a shallow junction (junction depth = 0.23 μm) with low resistivity (37.7 Ω/\square) was achieved. Carrier concentration profiles of phosphorus-diffused layers formed by 1205°C HLA using 37.5 w/o SOPSG have very abrupt shapes and can be expressed by a function of x/\sqrt{t} , where x is the depth and t is the HLA soak time. They have almost the same maximum carrier concentration and the same contact resistance as the phosphorus-doped layer formed by ^{31}P ion implantation and HLA.

We have been studying the application of halogen lamp annealing (HLA) technologies (1-5) to VLSI fabrication processing. The scaling down of electronic device dimensions requires shallower junctions and lower sheet resistivities. In order to achieve these, ion implantation technology and predeposition solid-state diffusion technology have been most frequently employed in the VLSI fabrication processing. Formation of phosphorus-diffused layers using spin-on phosphosilicate glass (SOPSG) source and halogen lamp rapid isothermal processing is a new solid-state diffusion technology (6-8). From a practical viewpoint, this diffusion technology has advantages due to the low cost fabrication equipment and simple cassette-to-cassette single wafer processing. The predeposition solid-state diffusion excludes the enhance diffusion which seems to take place during the initial portion of the rapid heating of ion-implanted silicon yet leaves the matrix free of extended effects (9). This paper describes the basic characteristics of the predeposition solid-state phosphorus diffusion technology using SOPSG and HLA, such as sheet resistivities, junction depths, carrier concentrations, and Al [2 weight percent (w/o)]Si-N-type silicon contact resistances.

Experimental Procedure

Czochralski-grown P-type silicon crystals of (100) orientation, 6-9 $\Omega\text{-cm}$, were used for the experiments. The 4-in.-diam wafers were chemically and mechanically polished on one side. The wafers were dipped in dilute HF solution to remove the native oxide and were 3500 rpm spin coated with 1500Å phosphosilicate glass using OCD.¹ After having baked the wafers at 250°C for 60 min, they were heated for a few seconds using halogen lamps in nitrogen gas at atmospheric pressure. A 1205°C, 6s soak time HLA was carried out using 4.5, 9.0, 16.5, or 37.5 w/o SOPSG. Also, a 1205°C, 2, 6, 15, or 30s soak time HLA was carried out using 37.5 w/o SOPSG. The temperatures of HLA's were measured by a Chromel-Alumel thermocouple attached to the bottom surface of the wafer. The rise times of HLA's were 6s throughout this study. Sheet resistivities were measured by means of the four-probe method. Junction depths and carrier concentration profiles were obtained by the spreading resistance method. Contact resistances were measured by four-terminal test structure (10), which allows a direct kelvin measurement of interfacial contact resistance.

Results and Discussion

Figure 1 shows the junction depths and sheet resistivities of phosphorus-diffused layers which were formed by the new diffusion technology as a function of phosphorus weight percent $[\text{P}_2\text{O}_5/(\text{SiO}_2 + \text{P}_2\text{O}_5)]$ of the spin-on phosphosilicate glass (SOPSG). A 1205°C, 6s halogen

lamp rapid isothermal processing (HLA) was carried out as shown in Fig. 1. To obtain a slip line free mass produced wafer, about 1200°C is the maximum temperature (3) of halogen lamp rapid isothermal processing which can be allowed. The sheet resistivities and junction depths depend much on the phosphorus weight percent of SOPSG. As the phosphorus weight percent increases, the sheet resistivities decrease and junction depths increase. The higher phosphorus weight percent SOPSG also results in a lower average resistivity (sheet resistivity \times junction depth), and a minimum average resistivity of 867 $\mu\Omega\text{-cm}$ is achieved at 37.5 w/o phosphorus.

Figure 2 shows the sheet resistivities and junction depths of the phosphorus-diffused layers as a function of HLA temperature for a soak time of 6s and a phosphorus weight percent SOPSG of 37.5. Figure 2 determines the maximum HLA cycle which causes little diffusion of the phosphorus dopant from SOPSG. A 1000°C, 6s HLA causes a little diffusion from the 37.5 w/o SOPSG. This is almost the same annealing condition that causes phosphorus diffusion from high dose ^{31}P ion-implanted layers (3). The higher HLA temperature results in the lower average resistivity. In order to achieve shallower junctions and lower sheet resistivities, higher phosphorus weight percent SOPSG and higher HLA temperature are preferable. With a 1205°C, 2s HLA using 37.5 w/o SOPSG, phosphorus-diffused layers which had 0.23 μm junction depth and 37.7 Ω/\square sheet resistivity were achieved.

Figure 3 shows the sheet resistivities and junction depth relationships measured for phosphorus-diffused layers formed by 37.5 w/o SOPSG and a 1205°C, 2, 6, 15, or 30s halogen lamp rapid isothermal processing. For constant phosphorus weight percent and HLA temperature,

Fig. 1. Sheet resistivities and junction depths of phosphorus-diffused layers as a function of phosphorus weight percent.

¹ OCD is spin-on glass made by Tokyo Ohka Kogyo Company, Limited.

Fig. 2. Sheet resistivities and junction depths of phosphorus-diffused layers as a function of HLA temperature.

the sheet resistivities are inversely proportional to the junction depths. This means that the average resistivity of the phosphorus-diffused layer is constant irrespective of the HLA soak time.

Figure 4 shows the electrical active dopant concentration profiles of phosphorus-diffused layers formed by 37.5 w/o SOPSG and 1205°C HLA as a function of normalized distance x/\sqrt{t} ($\text{\AA}\cdot\text{s}^{-1/2}$), where x is the depth and t is the HLA soak time to 2, 6, 15, or 30s. These profiles are almost coincident with each other. This means that the phosphorus diffusivity in silicon is independent of soak time or depth. This characteristic is the same as that of phosphorus-diffused layers formed by 900°C furnace annealing (10 ~ 240 min) (12). The profiles of Fig. 4 have a flat region near the surface and drop abruptly without any kink. Profiles without kinks are also observed in the phosphorus-diffused layers formed by high temperature (> 1050°C) furnace annealing (13). These results lead to the conclusion that the qualitative profile shaping diffu-

Fig. 4. Electrical active dopant concentration profiles of phosphorus-diffused layers formed by 1205°C HLA using 37.5 w/o SOPSG, as a function of reduced distance $x\sqrt{t}$.

sion mechanisms at high temperature are the same in halogen lamp annealing for a few seconds and in furnace annealing for tens of minutes. The low average resistivity of the phosphorus-diffused layers formed by 1205°C HLA using 37.5 w/o SOPSG is not only due to the absence of a tail but also to the high maximum carrier concentration.

Figure 5 shows the electrical active dopant concentration profiles of phosphorus-diffused layers. The open-square sample was formed by a 1208°C, 2s HLA using 37.5 w/o SOPSG. The open-circle sample was heated with 37.5 w/o SOPSG for 30 min at 800°C in nitrogen gas at atmospheric pressure after the 1208°C, 2s HLA. An 800°C, 30

Fig. 5. Electrical active dopant concentration profiles of phosphorus-diffused layers. Those represented by the open squares are formed by 1208°C, 2s HLA using 37.5 w/o SOPSG. Those presented by the open circles are formed by 800°C 30 min FA after 1208°C, 2s HLA using 37.5 w/o SOPSG.

min furnace annealing (FA) reduces the maximum carrier concentration and increases the sheet resistivity. Also, the FA increases the tail of the carrier profile and increases the average resistivity. Figure 5 indicates that the rapid cooling of the silicon wafer is important to get the higher maximum carrier concentration and the absence of kink. The closed square in Fig. 5 indicates the maximum carrier concentration of the phosphorus-diffused layers formed by ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 ion implantation followed by HLA (800°C 6s or 1000°C 6s). The closed circle in Fig. 5 indicates the maximum carrier concentration of the phosphorus-diffused layers formed by ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 ion implantation followed by FA (900°C 30 min, 1000°C 30 min, or 1050°C 30 min).

While HLA or FA temperature changes, the maximum carrier concentration does not change for both ion-implanted layers, respectively. The difference of the maximum carrier concentration between ^{31}P ion-implanted layers annealed by HLA and by FA is due to the rapid isothermal annealing effect (4, 14, 15). Figure 5 indicates that rapid annealing effect of high maximum carrier concentration exists for both thermal diffusion from SOPSG and ion implantation. The difference of the maximum carrier concentration between HLA sample and FA sample is almost the same for both thermal diffusion from SOPSG and ion implantation, and a 1208°C HLA with 37.5 w/o SOPSG has almost the same maximum carrier concentration as that formed by ^{31}P ion implantation and HLA. This result suggests that the rapid annealing effect at high maximum carrier concentration of both ion-implanted and thermal-diffused layers may be due mainly to the rapid cooling of the wafer.

Relative surface carrier concentrations are assured by measuring contact resistance, too. Figure 6 shows Al(2 w/o)Si/phosphorus-diffused silicon contact resistances as a function of annealing temperature for three types of phosphorus-diffused layers. The sintering was carried out at 450°C for 20 min in H_2 forming gas. The electrical measurements were performed on phosphorus-diffused silicon having contact windows of $4 \times 4 \mu\text{m}$. Contact resistance depends on electrical active phosphorus dopant concentrations (16), and the higher electrical active phosphorus dopant concentration has the lower contact resistance. In Fig. 6, the closed circles represent contact resistance of Al(2 w/o)Si/phosphorus-diffused layer formed by 37.5 w/o SOPSG and a 6s soak time HLA (1065° , 1150° ,

Fig. 6. Contact resistances of three types of phosphorus-diffused layers as a function of isothermal heating temperatures. That represented by the closed circles is formed by HLA using 37.5 w/o SOPSG. That represented by the open circles is formed by ion implantation and HLA. That represented by the open triangles is formed by ion implantation and FA.

1215°C). Before being spin coated with SOPSG, the wafer was implanted with ^{31}P (40 keV, $3 \times 10^{12} \text{ cm}^{-2}$) in order to prevent Al penetration. The open circles represent the contact resistance measurement of phosphorus-diffused layers formed by implanting ^{31}P (40 keV, $4 \times 10^{15} \text{ cm}^{-2}$) through 400\AA SiO_2 followed by a 6s soak time HLA (980° , 1050° , 1150°C). The open triangles stand for implanted ^{31}P (40 keV, $4 \times 10^{15} \text{ cm}^{-2}$) through 400\AA SiO_2 followed by a 30 min FA (900° , 950°C). The contact resistances of the ion-implanted layers followed by HLA are independent of annealing temperatures and have the lowest contact resistances ($< 10\Omega$). The contact resistances of the ion-implanted layers followed by FA are not so much dependent on annealing temperatures and have slightly higher contact resistances compared to HLA samples. The contact resistances of phosphorus-diffused layers formed by SOPSG and HLA depend much on the HLA temperatures. Above 1200°C , halogen lamp rapid isothermal processing with 37.5 w/o SOPSG results in the same contact resistance as for the ^{31}P ion-implanted layers followed by HLA. The measured contact resistances are consistent with the phosphorus carrier concentrations.

Summary

The sheet resistivities and junction depths of phosphorus-diffused layers formed by SOPSG and HLA depend not only on HLA temperature, but also on SOPSG phosphorus weight percent. The highest HLA temperature using the highest phosphorus weight percent SOPSG results in the lowest average resistivity. With a 1205°C , 2s HLA using 37.5 w/o SOPSG, a shallow junction ($x_j = 0.23 \mu\text{m}$) with low resistivity ($37.7 \Omega/\square$) was achieved. The carrier concentration profiles of phosphorus-diffused layers formed by 1205°C HLA using 37.5 w/o SOPSG have very abrupt shapes without kinks and can be expressed by a function of x/\sqrt{t} , where x is the depth and t is the HLA soak time. They have almost the same maximum carrier concentration and the same contact resistance as that formed by ^{31}P ion implantation and HLA.

Acknowledgments

We would like to thank Mr. Mizuno, General Manager, Dr. Iwamatsu, Manager, Mr. Ichikawa, Chief Engineer, Mr. Asahina, Chief Engineer, and Mr. Furuhashi, of Suwa Seikosha Company, Limited, Fujimi Plant, for their helpful discussion and cooperation in this study.

Thermodynamic Comparison of InGaAsP Vapor Phase Epitaxy by Chloride, Hydride, and Metalorganic-Chloride Methods

M. Yoshida and H. Watanabe

NEC Corporation, Fundamental Research Laboratories, Miyazaki 4-chome, Miyamae, Kawasaki 213, Japan

ABSTRACT

A thermodynamic comparison of composition controllability is made between three InGaAsP vapor phase epitaxial (VPE) methods: namely, chloride, hydride, and the newly proposed metal organic (MO)-chloride VPE processes for the growth of an alloy lattice matched to InP and emitting at $1.3 \mu\text{m}$. In order to discuss the dynamic aspects of an open-flow system, the calculated model includes a completeness factor, e , for the reaction between a liquid metal source and gas phase, and a saturation factor, s , for the metal source with a Group V element. It is shown that control of the temperatures to within 2.4°C makes it possible to keep the lattice mismatch less than 3×10^{-4} in all three VPE systems. Control of the flow rates to within 1.2% in both chloride and hydride VPE systems and to within 0.3% in the MO-chloride system are sufficient for that purpose. It is found that the alloy composition varies greatly with e and s . A decrease in either e by 0.4% or s by 3.4% produces a lattice mismatch of 3×10^{-4} .

Quaternary alloys of $\text{In}_{1-x}\text{Ga}_x\text{As}_y\text{P}_{1-y}$ have received increasing attention as materials for many semiconductor devices. The alloys lattice matched to InP are important both for microwave devices and for sources and detectors of light in the $1.0\text{--}1.7 \mu\text{m}$ wavelength range. The alloys lattice matched to GaAs are expected to be used for light sources in the visible wavelength range.

These alloys have been grown by liquid phase epitaxy (LPE), chloride transport vapor phase epitaxy (CTVPE), metal organic vapor phase epitaxy (MOVPE), and molecular beam epitaxy (MBE). However, it is difficult to grow InGaAsP with some of these techniques. LPE cannot prevent compositional inhomogeneity (1). With MBE, it is difficult to control the P/As ratio; also, one needs a special pumping system for volatile phosphorus vapor (2). In contrast to these two methods, uniform InGaAsP layers except for the alloys in the miscibility gaps (3-5) can be grown by CTVPE (6) and low pressure MOVPE (7). In MOVPE, the composition of III-V alloys is independent of the growth temperature in some cases (8), and x and y in $\text{In}_{1-x}\text{Ga}_x\text{As}_y\text{P}_{1-y}$ are controlled independently by the $\text{Ga}/(\text{Ga} + \text{In})$ and $\text{As}/(\text{As} + \text{P})$ ratios in the vapor phase, respectively (9). However, one cannot control x and y separately in CTVPE since not only x , but also y varies with the $\text{Ga}/(\text{Ga} + \text{In})$ ratio in the vapor phase (10). Therefore, there is much interest in how the composition of InGaAsP grown by CTVPE varies with the growth parameters. To know these variations in alloy composition is important both for growing a particular alloy of InGaAsP and for controlling the alloy composition to increase a device yield. In this paper, VPE means CTVPE.

There have been chloride and hydride VPE methods since the early years of III-V materials research. In addition to these, a new VPE method using Group III metal organics and Group V trichlorides (MO-chloride VPE) has been proposed (11). The purest compound semiconductor has been grown by chloride VPE. The hydride VPE system has shown its advantage for alloy growth, and the MO-chloride VPE process is of great advantage to the productivity and the safety since it is free from heterogeneous liquid-vapor source reactions and fatally toxic Group V hydrides.

The purpose of this paper is to compare thermodynamic composition controllabilities of the three InGaAsP VPE methods. The comparison is made by calculating the variations in alloy composition with the growth parameters. In order to discuss the dynamic aspects of an open-flow system, a completeness factor for the reaction between a metal source and gas phase (12) and a saturation factor for the metal source with a Group V element are introduced into the thermodynamic model.

VPE Growth Systems

Figures 1a-1c show schematic diagrams of the three InGaAsP VPE systems. Hot-wall reactors are used to

form reactants for growth and to avoid deposition of III-V compounds upstream from the substrate. The reaction rates for the decomposition of AsCl_3 , PCl_3 , AsH_3 , PH_3 , TEG, and TEI may be kinetically limited; however, the decomposition will be considered to be complete.

In the chloride system, a four-barrel reactant formation region is arranged. In each barrel, the Group V trichloride reacts with H_2 to form HCl and the Group V element, which is absorbed into the Group III metal source. Undecomposed AsCl_3 (13) is not considered since it is a problem only when the source temperature is too low and the flow rate is too high. When each source is saturated with

Fig. 1. Schematic diagrams of InGaAsP VPE systems. a: For a chloride VPE system. b: For a hydride VPE system. c: For a MO-chloride VPE system. AsCl_3 , PCl_3 , TEG, and TEI are carried by H_2 flows passing through them. A chloride system has four metal sources covered with III-V crusts. A hydride system has two metal sources. A MO-chloride system has no liquid metal source.

the Group V element and covered with the thin III-V crust, the chloride VPE system is in a steady-state condition for growth (14). There are four sources: the Ga metal saturated with As and covered with a GaAs crust; the Ga metal with P and GaP; the In metal with As and InAs; and the In metal with P and InP. The Group III chloride is formed by the reaction between HCl and the III-V crust in each barrel. A dilution H₂ flow is added between the source region and the growth region. The incompleteness of the reaction between the source and the gas phase due to incomplete mixing in the gas phase, and the unsaturation of the source with the Group V element due to depletion of the Group V element during the heat-up, are problems associated with this VPE system. The kinetic process at the source surface is considered to be complete because an etching reaction in a chloride system is mass-transport limited at the temperature considered. To increase the completeness of mixing in the gas phase, one can make the flow rate in the source region low and enlarge the source region. However, the low flow rate causes the back-diffusion of HCl produced downstream from the substrate, and the large source makes the unsaturation more serious. Therefore, it is impossible to make the source reaction and the source saturation complete simultaneously. The four source temperatures are chosen to be equal in the following calculation for the sake of simplicity.

In the hydride system, a two-barrel Group III chloride formation region is arranged. One barrel contains Ga, and the other contains In. HCl in and H₂ carrier flow reacts with the Group III metal source and converts it to the Group III chloride in each barrel. The incompleteness of the source reaction similar to that in the chloride system is a problem associated with this VPE system. The surface of the source can be enlarged to complete the mixing of the gas phase during contact to the source. However, the slow saturation of the In source with InCl (15) presents a serious problem. Therefore, the incomplete source reaction should be considered. The Group V hydrides carried by a dilution H₂ flow are decomposed to form the Group V elements. It is shown that PH₃ does not so readily decompose even in a hot-wall system (16). However, the incomplete decomposition of the Group V hydrides is not considered since the longer residence time for the decomposition reaction is expected to make the decomposition perfect. The two source temperatures are chosen to be equal, again for the sake of simplicity.

In the MO-chloride system, a single-barrel reactant formation region is arranged. The Group III organics [for example, triethylgallium (TEG) and triethylindium (TEI)] are used instead of the Group III metals. It is shown that trimethylgallium (TMG) does not readily pyrolyze (17). However, it decomposes perfectly in H₂ at temperatures above 600°C in a hot-wall open-flow system (18). TEG (18) and TEI (19) also decompose perfectly at temperatures above 500°C. Therefore, the metal organics are like metals in the vapor phase when they are introduced into a hot region. The Group V trichlorides are also decomposed perfectly as is the case in the chloride system. Hence, in the mixing region the Group III chlorides and the Group V elements are formed. An excess of the number of Group III atoms over the number of chlorine atoms causes deposition of III-V compounds in the mixing region. This deposition depletes the Group V elements in the growth region. Contrary to the above, when the number of chlorine atoms greatly exceeds the number of Group III atoms, etching takes place. A III/V ratio sufficient not to deposit III-V compounds in the mixing region and not to etch a substrate is chosen. The temperature of the mixing region is kept high enough to eliminate the wall deposition. The MO-chloride system is defined to be an ideal chloride system with $e = s = 1$ with other AsCl₃ and PCl₃ introduced between the source and the substrate (20).

Thermodynamic Calculation Procedure

Preparation of reactants for growth reaction.—Chloride system.—In each barrel, the species other than III-

V(solid), H₂, HCl, III Cl, III Cl₃, V₄, and V₂ (III = Ga or In, V = As or P) are assumed to be nonexistent since the Group V trichloride, Group V hydride, and chlorine are negligible in a state of equilibrium at temperatures between 600° and 900°C (21, 22). The reactions in each source region are

and proceed under constant atmospheric pressure (1 atm). The numbers of hydrogen and chlorine atoms in the vapor phase are kept at n_{H}^0 and n_{Cl}^0 (n_{H}^0 is the number of supplied H atoms, and n_{Cl}^0 the number of supplied Cl atoms) since there are no other phases containing hydrogen and/or chlorine atoms. The number of Group V atoms in the vapor phase is also kept at n_{V}^0 (the number of supplied Group V atoms), since the Group V element acts as if it passes through this region when the thickness of the crust and the amount of the Group III metal saturated with the Group V element are unchanged. The partial pressures of six species are obtained from three equilibrium equations and three equations for the conservation of total pressure, $c (= n_{\text{Cl}}^0/n_{\text{H}}^0)$, and $b (= n_{\text{V}}^0/n_{\text{H}}^0)$.

A completeness factor for the source reaction, e ($0 < e \leq 1$), is introduced assuming that $1 - e$ of the gas flow passes above the source metal without any reaction with it. A saturation factor for the Group III source, s ($s \leq 1$), is introduced assuming that s of the Group V element passes through the source region. The other $1 - s$ of the Group V element is absorbed into the source; that is, the number of Group V atoms in the vapor phase is kept at sn_{V}^0 (then $b = sn_{\text{V}}^0/n_{\text{H}}^0$). This assumption is valid only when the source is covered with a crust. Therefore, s should not be much smaller than 1.

Since stoichiometric III-V compounds are deposited, the difference between the number of Group III and Group V atoms, $n_{\text{III}} - n_{\text{V}}$, is kept constant throughout the growth process. Hence, we get c and $d [= (n_{\text{III}} - n_{\text{V}})/n_{\text{H}}]$ as constants in the growth region

$$c = \frac{3 \sum_{i=1}^4 F_{\text{H}_2(i)} \left(\frac{P_{\text{VCl}_3^0}}{1 - P_{\text{VCl}_3^0}} \right)_i}{2 \sum_{i=1}^5 F_{\text{H}_2(i)}} \quad [1]$$

where F is the flow rate and P^0 vapor pressure (in atmospheres)

$$d = \frac{2 \sum_{i=1}^4 e_i F_{\text{H}_2(i)} \left(\frac{P_{\text{III Cl}} + P_{\text{III Cl}_3}}{2P_{\text{H}_2} + P_{\text{HCl}}} \right)_i - \sum_{h=15}^4 s_h F_{\text{H}_2(i)} \left(\frac{P_{\text{VCl}_3^0}}{1 - P_{\text{VCl}_3^0}} \right)_i}{2 \sum_{i=1}^5 F_{\text{H}_2(i)}} \quad [2]$$

where P is the equilibrium partial pressure in each source region (in atmospheres), and 1-5 denote the relation to the barrels containing Ga-As, Ga-P, In-As, In-P, and the dilution line, respectively.

Hydride system.—The following are reactions in each source region

As in the chloride system, two equilibrium equations and two equations for the conservation of total pressure and c give the partial pressures of four species.

The completeness factor for the source reaction similar to that in the chloride system is introduced. The Group V hydrides are assumed to convert to arsenic and phosphorus perfectly in a state of equilibrium. Hence the constants c and d in the growth region are

$$c = \frac{\sum_{i=1}^2 F_{HCl}(i)}{2 \sum_{i=1}^3 F_{H_2}(i) + \sum_{i=1}^2 F_{HCl}(i) + 3(F_{AsH_3} + F_{PH_3})} \quad [3]$$

$$d = \frac{\sum_{i=1}^2 e_i [2 F_{H_2}(i) + F_{HCl}(i)] \left(\frac{P_{III Cl} + P_{III Cl_3}}{2P_{H_2} + P_{HCl}} \right)_i - (F_{AsH_3} + F_{PH_3})}{2 \sum_{i=1}^3 F_{H_2}(i) + \sum_{i=1}^2 F_{HCl}(i) + 3(F_{AsH_3} + F_{PH_3})} \quad [4]$$

where 1, 2, and 3 denote the relation to the barrels containing Ga and In, and the dilution line, respectively.

MO-chloride system.—As has been mentioned, the triethyl Group III compounds and the Group V trichlorides are perfectly decomposed in the mixing region

or

The produced hydrocarbons are completely ignored in the equilibrium system since the reverse reactions to form triethyl Group III compounds do not proceed. When no deposition occurs in the mixing region, the reactions are

We get c and d in the growth region only from the input gas flow rate data

$$c = \frac{3 \sum_{i=3}^4 F_{H_2}(i) \left(\frac{P_{VCl_3^0}}{1 - P_{VCl_3^0}} \right)_i}{2 \sum_{i=1}^5 F_{H_2}(i)} \quad [5]$$

$$d = \frac{\sum_{i=1}^2 F_{H_2}(i) \left(\frac{P_{MO^0}}{1 - P_{MO^0}} \right)_i - \sum_{i=3}^4 F_{H_2}(i) \left(\frac{P_{VCl_3^0}}{1 - P_{VCl_3^0}} \right)_i}{2 \sum_{i=1}^5 F_{H_2}(i)} \quad [6]$$

where 1-5 denote the relations to the TEG, TEI, AsCl₃, PCl₃, and dilution lines, respectively.

In_{1-x}Ga_xAs_yP_{1-y} growth.—The growth takes place through the same process in the three VPE systems. In the growth region, the following species are considered: For the surface of grown layer, GaP, GaAs, InAs, and InP in a solid solution, and for the vapor phase, H₂, HCl, GaCl, GaCl₃, InCl, InCl₃, As₄, As₂, P₄, P₂, As₃P, As₂P₂, AsP₃, and AsP. The reactions are reactions [A]-[L] listed in Table I.

According to Koukitu and Seki (23), the activities of the binary III-V components in the In_{1-x}Ga_xAs_yP_{1-y} alloy system, a_{GaAs} , etc., are

$$a_{GaAs} = \gamma_{GaAs} \frac{m + (1 - m)(x + y) - \sqrt{[m + (1 - m)(x + y)]^2 - 4(1 - m)xy}}{2(1 - m)} \quad [7]$$

$$a_{GaP} = \gamma_{GaP} (x - a_{GaAs}/\gamma_{GaAs}) \quad [8]$$

$$a_{InAs} = \gamma_{InAs} (y - a_{GaAs}/\gamma_{GaAs}) \quad [9]$$

$$a_{InP} = \gamma_{InP} (1 - x - y + a_{GaAs}/\gamma_{GaAs}) \quad [10]$$

where

$$m = \frac{K_B K_D}{K_A K_C} \frac{\gamma_{GaAs} \gamma_{InP}}{\gamma_{GaP} \gamma_{InAs}}$$

K_i is the equilibrium constant of the reaction i , and γ_j the activity coefficient of the j component. The activity coefficients are given theoretically (24) as

$$kT \ln \gamma_{GaAs} = \alpha_{InP-GaP} (1 - x)(1 - y)(1 - 2x) + \alpha_{InAs-GaAs} (1 - x)[(1 - x)y + x(1 - y)] + \alpha_{InP-InAs} (1 - x)(1 - y)(1 - 2y) + \alpha_{GaP-GaAs} (1 - y)[(1 - x)y + x(1 - y)]$$

etc., where the α 's are the interaction parameters.

The equations for the conservation of total pressure (1 atm), c , and d are given as follows

$$P_{H_2} + P_{HCl} + P_{GaCl} + P_{GaCl_3} + P_{InCl} + P_{InCl_3} + \sum P_{V_4} + \sum P_{V_2} = 1 \quad [11]$$

$$\frac{P_{HCl} + P_{GaCl} + P_{InCl} + 3(P_{GaCl_3} + P_{InCl_3})}{2P_{H_2} + P_{HCl}} = c \quad [12]$$

$$\frac{P_{GaCl} + P_{GaCl_3} + P_{InCl} + P_{InCl_3} - (4\sum P_{V_4} + 2\sum P_{V_2})}{2P_{H_2} + P_{HCl}} = d \quad [13]$$

where

$$\sum P_{V_4} = P_{As_4} + P_{As_3P} + P_{As_2P_2} + P_{AsP_3} + P_{P_4}$$

$$\sum P_{V_2} = P_{As_2} + P_{AsP} + P_{P_2}$$

From Eq. [7]-[13] and the 11 equilibrium equations for the reactions [A]-[C] and [E]-[L], the partial pressures of 14 species are obtained (see Appendix).

The composition of the grown In_{1-x}Ga_xAs_yP_{1-y} alloy is calculated with an iterative procedure. The differences in both x and y between the assumed alloy balanced with

Table I. Equilibrium constants for reactions

	Reaction	log ₁₀ K	Ref.
[A]	GaP + HCl ⇌ GaCl + 1/4 P ₄ + 1/2 H ₂	5.05 - 6.00 × 10 ³ /T	(25)

[C]	InAs + HCl ⇌ InCl + 1/4 As ₄ + 1/2 H ₂	5.84 - 5.63 × 10 ³ /T	(26)
[D]	InP + HCl ⇌ InCl + 1/4 P ₄ + 1/2 H ₂	5.81 - 5.04 × 10 ³ /T	(27)
[E]	GaCl + 2HCl ⇌ GaCl ₃ + H ₂	-6.68 + 8.61 × 10 ³ /T	(28)
[F]	InCl + 2HCl ⇌ InCl ₃ + H ₂	-3.42 + 4.84 × 10 ³ /T	(29)
[G]	1/2 As ₄ ⇌ As ₂	3.76 - 6.67 × 10 ³ /T	(26)
[H]	1/2 P ₄ ⇌ P ₂	3.97 - 5.94 × 10 ³ /T	(27)
[I]	3/4 As ₄ + 1/4 P ₄ ⇌ As ₃ P	0	
[J]	1/2 As ₄ + 1/2 P ₄ ⇌ As ₂ P ₂	0	
[K]	1/4 As ₄ + 3/4 P ₄ ⇌ AsP ₃	0	
[L]	1/2 As ₂ + 1/2 P ₂ ⇌ AsP	0	
[M]	Ga + HCl ⇌ GaCl + 1/2 H ₂	2.93 - 1.29 × 10 ³ /T	(27)
[N]	In + HCl ⇌ InCl + 1/2 H ₂	2.36 - 0.42 × 10 ³ /T	(27)

the vapor phase and the deposited alloy from the vapor phase are made smaller than 1×10^{-5} . Note that the composition is independent of the activity of the substrate surface prior to growth. The composition is determined only from the conservation of In, Ga, As, and P. The vapor phase is balanced with the surface just grown from it.

Thermodynamical data.—The equilibrium constants of reactions are listed in Table I (25-29) in the form of $\log_{10} K = A + B/T$. The standard free energies of formation for the As-P complexes are assumed as

$$\Delta G_{\text{As}_4 - m\text{P}_m}^0 = \frac{4 - m}{4} \Delta G_{\text{As}_4}^0 + \frac{m}{4} \Delta G_{\text{P}_4}^0 \quad (m = 1, 2, 3)$$

$$\Delta G_{\text{As}_2\text{P}}^0 = \frac{1}{2} \Delta G_{\text{As}_2}^0 + \frac{1}{2} \Delta G_{\text{P}_2}^0$$

That is, the equilibrium constants for the reactions [I]-[L] are supposed to be 1 at any temperature. The selection of the values for the equilibrium constants A-D (23) and the above assumption for the constants I-L make the calculations best fit to the experimental data (10, 30, 31). The selection of the values for the constants E-H affects the calculations little. [The comparison was made between the data in Ref. (25-29) and (32), the assumption for the constants I-L, and the nonexistence of As-P complexes ($K_{I-L} = 0$).] The interaction parameters are listed in Table II (33).

Data for growth systems.—The vapor pressures of materials in the containers are 0.01 atm for AsCl_3 at 18°C, TEG at 30°C, TEI at 74°C, and 0.05 atm for PCl_3 at 2°C. Tentatively, the imaginary Cl atom gas flow rate in each system is set at 0.03 standard-liter/min. This value corresponds to a flow rate of H_2 passing through AsCl_3 of 0.99 standard-liter/min and an HCl flow rate of 0.03 standard-liter/min. In the MO-chloride system, the III/V ratio is set at 2.9 to avoid deposition in the mixing region. The V/III ratio in the hydride system is set at ~ 1 ($[\text{VH}_3]/[\text{HCl}] = 1$) (30, 34), which differs from the ratio of about 0.4 in the chloride and MO-chloride systems. The effect of V/III ratio on the composition controllability will be discussed below. A source temperature of 800°C and a growth temperature of 700°C are selected. The selected source temperature is $\sim 50^\circ\text{C}$ lower than that temperature in the experimental hydride VPE system so as not to make the unsaturation in the chloride system serious (35).

Table II. Interaction parameters for ternary III-V systems (33)

System	α (cal/mol)
InP-GaP	3500

MO-chloride	$F_{\text{H}_2}(\text{TEG})$	0.12472	0.12126	0.10803	0.08954
	$F_{\text{H}_2}(\text{TEI})$	2.74628	2.74974	2.76297	2.78146
	$F_{\text{H}_2}(\text{AsCl}_3)$	0.24167	0.23484	0.20554	0.14781
	$F_{\text{H}_2}(\text{PCl}_3)$	0.14362	0.14493	0.15055	0.16163

Under the conditions above and $e = s = 1$, the flow rates for the growth of $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$, which is lattice matched to InP and emitting at 1.3 μm , were calculated with various dilution flow rates. The flow rate data are listed in Table III. $F_{\text{H}_2}(\text{AsCl}_3 \rightarrow \text{Ga})$ is the flow rate of H_2 passing through AsCl_3 and over a Ga source, $F_{\text{HCl}}(\text{Ga})$ the HCl flow rate over a Ga source, F_{AsH_3} the AsH_3 flow rate, and $F_{\text{H}_2}(\text{TEG})$ the flow rate of H_2 passing through TEG. As the dilution H_2 flow rate increases, the Cl/H ratio in the vapor phase decreases. Figure 2 shows the variation in alloy composition from $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$ with the increase in either flow rate by 3% or temperature by 3°C as a function of the Cl/H ratio in the hydride system. The solid lines denote the variations in x , and the broken lines denote the variations in y . The Cl/H ratio does not greatly affect the variations in x and y caused by the increase in the growth parameters, though it changes the vapor composition for the growth of a particular solid composition. Therefore, the likely dilution flow rate of 1 standard-liter/min is selected as the standard for the comparison of composition controllability. Under this dilution flow rate, the Cl/H ratios and thermodynamic growth rates of $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$ are 1.1×10^{-2} and 6.1×10^{-5} mol/min in the chloride system, 5.0×10^{-3} and 1.4×10^{-4} mol/min in the hydride system, and 3.5×10^{-3} and 6.8×10^{-5} mol/min in the MO-chloride system.

Results

The calculated variations in alloy composition with the increase in the flow rate by 3% and the temperature by 3°C are shown on X-Y planes for $\text{In}_{1-x}\text{Ga}_x\text{As}_y\text{P}_{1-y}$ in Fig. 3a for the chloride VPE system, in Fig. 3b for the hydride VPE system, and in Fig. 3c for the MO-chloride VPE system, where $e = s = 1$. The solid arrows show the variations with the flow rates, and the thin arrows show the variations with the temperatures. Two solid lines and two broken lines parallel to the line lattice matching to InP represent lattice mismatches (without any consideration for the lattice distortion), $|\Delta a/a_0|$, of 1×10^{-3} and 3×10^{-4} , respectively. The notations in Fig. 3 are the same as in Table III. A short arrow is equivalent to good composition controllability. The length of the arrow perpendicular to the line lattice matching to InP and reaching to the line with a lattice mismatch of 3×10^{-4} is 0.004 on the X-Y plane. The variations in the chloride and hydride systems are comparable in the length. However, some of the variations in the MO-chloride system are much larger than the others.

Figure 4 shows the variation in alloy composition with the completeness factor, and Fig. 5 shows the variation with the saturation factor. An incompleteness of 1% pro-

Fig. 2. Variation in alloy composition with the increase in either flow rate by 3% or temperature by 3°C as a function of the Cl/H ratio in a hydride VPE system. Solid lines and broken lines show Δx 's and Δy 's, respectively.

(b) Hydride VPE

(c) MO-chloride VPE

duces a lattice mismatch of 8×10^{-4} , and an unsaturation of 5% produces one of 4.4×10^{-4} .

Because the relation between the variation in alloy composition and the change in the growth parameters for $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$ is nearly linear, Fig. 3-5 can be summarized in Table IV, where the lengths of the variations on the X-Y plane and the required accuracies for a length of variation of 0.004 (proportional to the reciprocal of the length of variation) are listed. The required accuracies are greater than 2.4°C in the temperatures in all three VPE systems and greater than 1.2% in the flow rates in both chloride and hydride systems. Precise flow rate control to within 0.3% is needed in the MO-chloride system. The compositional accuracy stated above also requires control of the completeness factor to within 0.3% in the chloride system and 0.4% in the hydride system and of the saturation factor to within 3.4% in the chloride system.

Discussion

The constituent partial pressures (P_{GaCl} , P_{InCl} , P_{As_4} , P_{P_4}) can be changed independently only in the hydride sys-

Fig. 3. Variation from $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$ on an X-Y plane. a: For chloride VPE. b: For hydride VPE. c: For MO-chloride VPE. Flow rates and temperatures increase by 3% and 3°C, respectively. A line lattice matching to InP is shown. Solid lines and broken lines show lattice mismatches of 1×10^{-3} and 3×10^{-4} , respectively.

tem. In the chloride system, the partial pressures of GaCl and As_4 , for example, are changed simultaneously due to the change in $F_{\text{H}_2}(\text{AsCl}_3 \rightarrow \text{Ga})$. In the MO-chloride system, the change in the constituent material flow rates (F_{TEG} , F_{TEI} , F_{AsCl_3} , F_{PCl_3}) causes changes in both the constituent partial pressures and the HCl partial pressure. Therefore, the hydride system is discussed first to see the effect of the GaCl, InCl, As_4 , and P_4 partial pressures on the alloy composition.

Effect of constituent partial pressures.—It is shown in Fig. 3b that the variations in alloy composition with $F_{\text{HCl}}(\text{Ga})$ and F_{PH_3} go in the Ga-P direction and the variations with $F_{\text{HCl}}(\text{In})$ and F_{AsH_3} go in the In-As direction. The calculated solid-vapor composition curves for ternary III-V compounds in the hydride VPE system are shown in Fig. 6a and 6b to explain these directions. The above data were used for the calculation. It is seen that increases in As- and Ga-related partial pressures cause decreases in x and y, respectively. The interaction parameters make the solid-vapor curves S-shaped. However, the selection of the values for the equilibrium constants plays

Fig. 4. Variation from $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$ with the completeness factor, e , in chloride and hydride systems.

a more important role in determining the direction of the variation in alloy composition.

Effect of incomplete source reactions.—Figure 4 shows that the incomplete source reactions cause the variations in the Ga-P direction in the hydride system ($V/\text{III} \approx 1$) and in the Ga-As direction in the chloride system ($V/\text{III} \approx 0.4$). Since each source reaction has the same completeness factor, the $\text{Ga}/(\text{Ga} + \text{In})$ ratio in the vapor phase is unchanged. (The total Group III chloride partial pressure decreases to $e\%$.) A decrease in the completeness factor results in a much greater increase in the HCl partial pressure and thus causes a large variation in the alloy composition. Therefore, the incompleteness of the source reaction is analogous to an increase in the HCl partial pressure.

Fig. 5. Variation from $\text{In}_{0.74}\text{Ga}_{0.26}\text{As}_{0.55}\text{P}_{0.45}$ with the saturation factor, s , in a chloride system.

Effect of flow rates in chloride and MO-chloride systems.—The discussion on the direction of the variation in alloy composition in the hydride system can be applied to the chloride and MO-chloride systems. In the chloride system, the alloy composition changes in the III-V-rich side with the VCl_3 flow rate over the group III source, except for $F_{\text{H}_2}(\text{AsCl}_3 \rightarrow \text{Ga})$, whose increase results in the variation going in the Ga-P direction because of the increase in the GaCl partial pressure.

In the MO-chloride system, it is rather complicated to foresee the variation in alloy composition with the flow rates because the partial pressure of HCl greatly changes with the flow rates. The MO-chloride system is more like the chloride system ($V/\text{III} = 0.35$). Therefore, the variation in alloy composition goes in the Ga-As direction with the

H ₂ (PCl ₃)	0.0368	0.3%

^a Length of the variation from In_{0.74}Ga_{0.26}As_{0.55}P_{0.45} on a X-Y plane with the change in the temperature by 3°C, the flow rate by 3%, e by 1%, or s by 5%.

^b Required accuracy for a length of variation of 0.004. This is comparable to a lattice mismatch of 3×10^{-4} when the variation is perpendicular to the line lattice matching to InP.

HCl partial pressure. An increase in either TEG or TEI flow rate decreases the HCl partial pressure. Hence, the increase in the TEI flow rate causes the large variation in the In-P direction as a consequence of the addition of the In-As direction and the In-P direction (opposite to the Ga-As direction). Because the TEG flow rate is much smaller than the VCl₃ flow rate, an increase in the TEG flow rate by 3% decreases the HCl partial pressure little. Therefore, the variation with the TEG flow rate is about the same as that with F_{HCl}(Ga) in the hydride system. The variation in alloy composition with either AsCl₃ or PCl₃ flow rate shows the effect of the increase in the HCl partial pressure. Each variation goes in the Ga direction.

Effect of unsaturation of sources.—The total Group V partial pressure decreases with the unsaturation of the sources. The As/(As + P) ratio in the vapor phase is unchanged since each source has the same saturation factor. The variation in the Ga-P direction with decreasing saturation factor is seen in Fig. 5. In the real chloride VPE system, the saturation factors are different from one another. Probably, an In source covered with an InAs crust has the smallest saturation factor, considering the solubility of III-V compounds in Group III liquids (36).

Effect of source temperature.—The variation in alloy composition with the source temperature goes in the Ga-P direction only in the chloride system. The Ga/Cl and In/Cl ratios increase to a maximum value of 1 as the source temperature increases. Since the In/Cl ratio (> 0.9) is larger than the Ga/Cl ratio (≈ 0.8), the GaCl partial pressure increases more than the InCl partial pressure, which causes the variation in the Ga-P direction. As is well known, the hydride system is less sensitive to the source temperature than the chloride system because the III/Cl ratio in the hydride system is more than 0.98 and fully saturated. Since all of the Group III organics are converted to the Group III chlorides, the III/Cl ratio is independent of the mixing temperature in the MO-chloride system.

Effect of growth temperature.—Because of the similarity of the growth process in the three VPE systems, the variations in alloy composition with the growth temperature are comparable to one another. The difference in the di-

Fig. 7. Variation in alloy composition from In_{0.74}Ga_{0.26}As_{0.55}P_{0.45} with the increase in either flow rate by 3% or temperature by 3°C as a function of the V/III ratio in a hydride VPE system. Solid lines show Δx 's, and broken lines show Δy 's.

rection of the variation between the hydride system and the chloride and MO-chloride systems arises from the difference in the V/III ratio. As shown in Fig. 7, the variation with the growth temperature goes in the Ga-As direction also in the hydride system at a V/III ratio of 0.4. This variation goes in the Ga-P direction at V/III ratios above 0.6. The other variations in alloy composition do not change their direction with the V/III ratio. The values of the variations are affected a little by the V/III ratio.

Summary

A thermodynamic comparison of composition controllability was made between the chloride, hydride, and newly proposed MO-chloride InGaAsP VPE systems for the growth of an alloy lattice matched to InP and emitting at 1.3 μ m. In order to discuss the dynamic aspects of the VPE methods, the calculated model includes a completeness factor for the reaction between a source metal and gas phase and a saturation factor for the metal source with a Group V element.

Control of the temperatures to within 2.4°C in all three VPE systems and of the flow rates to within 1.2% in both chloride and hydride systems are enough to make the length of variation on the X-Y plane less than 0.004 (a length which produces a lattice mismatch of 3×10^{-4} at the maximum). In the MO-chloride system, more precise control of the flow rates to within 0.3% is needed. It is found that the completeness and saturation factors greatly affect the alloy composition. Control of the completeness factor to within 0.3% in the chloride system and to within 0.4% in the hydride system and control of the saturation factor to within 3.4% in the chloride system are also required to keep the alloy composition in a circle with a radius of 0.004 on the X-Y plane.

APPENDIX

Equilibrium Eq. [B] and [C] give

$$P_{\text{GaCl}} + P_{\text{InCl}} = h_1 P_{\text{GaCl}} \quad [\text{A-1}]$$

where

$$h_1 = 1 + (K_C/K_B)(a_{\text{InAs}}/a_{\text{GaAs}})$$

Equilibrium Eq. [E] and [F] give

$$P_{\text{GaCl}_3} + P_{\text{InCl}_3} = h_3 P_{\text{GaCl}_3} \quad [\text{A-2}]$$

where

$$h_3 = 1 + (K_{\text{F}}K_{\text{C}}/K_{\text{E}}K_{\text{B}})(a_{\text{InAs}}/a_{\text{GaAs}})$$

Equilibrium Eq. [A], [B], and [I]-[K] give

$$P_{\text{As}_4} + P_{\text{As}_3\text{P}} + P_{\text{As}_2\text{P}_2} + P_{\text{AsP}_3} + P_{\text{P}_4} = h_4 P_{\text{As}_4} \quad [\text{A-3}]$$

where

$$h_4 = 1 + K_{\text{I}}z + K_{\text{J}}z^2 + K_{\text{K}}z^3 + z^4$$

and

$$z = (K_{\text{A}}/K_{\text{B}})(a_{\text{GaP}}/a_{\text{GaAs}})$$

Equilibrium Eq. [G], [H], and [L] give

$$P_{\text{As}_2} + P_{\text{AsP}} + P_{\text{P}_2} = h_2 P_{\text{As}_2} \quad [\text{A-4}]$$

where

$$h_2 = 1 + K_{\text{L}}(K_{\text{H}}/K_{\text{G}})^{1/2}z + (K_{\text{H}}/K_{\text{G}})z^2$$

Substitution of Eq. [A-1]-[A-4] in Eq. [11]-[13] gives

$$P_{\text{H}_2} + P_{\text{HCl}} + h_1 P_{\text{GaCl}} + h_3 P_{\text{GaCl}_3} + h_4 P_{\text{As}_4} + h_2 P_{\text{As}_2} = 1 \quad [\text{A-5}]$$

$$2cP_{\text{H}_2} + (c-1)P_{\text{HCl}} - h_1 P_{\text{GaCl}} - 3h_3 P_{\text{GaCl}_3} = 0 \quad [\text{A-6}]$$

$$2dP_{\text{H}_2} + dP_{\text{HCl}} - h_1 P_{\text{GaCl}} - h_3 P_{\text{GaCl}_3} + 4h_4 P_{\text{As}_4} + 2h_2 P_{\text{As}_2} = 0 \quad [\text{A-7}]$$

Thus Eq. [E] and [A-6] give

$$P_{\text{GaCl}}(1) = \frac{2cP_{\text{H}_2} + (c-1)P_{\text{HCl}}}{h_1 + 3h_3 K_{\text{E}} P_{\text{HCl}}^2 / P_{\text{H}_2}} \quad [\text{A-8}]$$

Equations [G], [A-5], and [A-7] give

$$P_{\text{As}_4}^{1/2} = \frac{-3h_2 K_{\text{G}} + \sqrt{9h_2^2 K_{\text{G}}^2 + 20 h_4 [1 - (2d+1)P_{\text{H}_2} - (d+1)P_{\text{HCl}}]}}{10 h_4} = g(P_{\text{H}_2}, P_{\text{HCl}}) \quad [\text{A-9}]$$

Then substitution of Eq. [G] and [A-9] into Eq. [A-5] gives

$$P_{\text{GaCl}}(2) = \frac{1 - P_{\text{H}_2} - P_{\text{HCl}} - h_4 g^2(P_{\text{H}_2}, P_{\text{HCl}}) - h_2 K_{\text{G}} g(P_{\text{H}_2}, P_{\text{HCl}})}{h_1 + h_3 K_{\text{E}} P_{\text{HCl}}^2 / P_{\text{H}_2}} \quad [\text{A-10}]$$

Equations [B] and [A-9] give

$$P_{\text{GaCl}}(3) = K_{\text{B}} a_{\text{GaAs}} P_{\text{HCl}} / [g(P_{\text{H}_2}, P_{\text{HCl}}) P_{\text{H}_2}]^{1/2} \quad [\text{A-11}]$$

A set of P_{H_2} and P_{HCl} when $P_{\text{GaCl}}(1) = P_{\text{GaCl}}(2) = P_{\text{GaCl}}(3)$ gives a solution.

N-CuInS₂/Sulfide-Polysulfide Electrochemical Photovoltaic Cells

Michael A. Russak and Charles Creter

Grumman Aerospace Corporation, Research and Development Center, Bethpage, New York 11714

ABSTRACT

Large-grained photovoltaic n-CuInS₂ was prepared by directional solidification. The as-grown material had doping levels of $\sim 6 \times 10^{16} \text{ cm}^{-3}$, a minority carrier diffusion length of $\sim 1 \mu\text{m}$, and a maximum efficiency of 6.4% in a sulfide-polysulfide electrolyte under simulated AM2 conditions. CuInS₂ thin films were also made by an elemental vacuum evaporation technique with observed efficiencies of 2%. These electrodes had high doping densities ($\geq 10^{17}$), short diffusion lengths ($\sim 0.05 \mu\text{m}$), and recombination dominated I-V behavior.

Photoelectrochemical conversion systems that utilize narrow bandgap (1.3-1.7 eV) thin film II-VI materials with sulfide/polysulfide (SPS) containing electrolytes have been investigated quite extensively in recent years (1-5). While solar conversion efficiencies in the range of 7-8% have been obtained with these materials, the long-term output stability of the II-VI/SPS systems remains questionable.

Conversely, I-III-VI₂ compounds, which are ternary analogues of the II-VI materials, have received considerably less study in SPS electrolytes, and reported efficiencies are much lower than for the II-VI compounds, especially for thin film electrodes (6-8). However, the most notable feature of these materials is their outstanding output stability (6-8). While high quality materials are more difficult to produce in the ternary system, their potential for very stable cells justifies further investigation of them. It is also interesting to note that when S and Se are combined with Cu and In to form CuInS_{2-x}Se_{2(1-x)} solid solutions, direct bandgap, high absorptivity materials with bandgaps in the range of 1.0-1.5 eV can be obtained (9). This presents optimization possibilities for a given electrode/electrolyte system similar to those found in the CdSe_{1-x}Te_x ternary system (4, 5).

P-CuInS₂ has been successfully used in solid-state thin film photovoltaic cells with CdS or Cd_xZn_{1-x}S to achieve efficiencies greater than 10% with very high current outputs. However, the voltage output of these cells is low (10). This is also the case for CuInS₂ used in concert with a SPS electrolyte (8). This reflects the fact that the bandgap of this material is narrow (*i.e.*, 1.0 eV). In a photoelectrochemical cell, a material with a bandgap closer to 1.5 eV, such as CuInS₂, should provide maximum photovoltaic performance (11).

In this paper, we report results with n-CuInS₂ in the form of directionally solidified, large-grained, polycrystalline material and vacuum-evaporated thin films as photoanodes in a SPS electrolyte.

Experimental

Stoichiometric amounts of high purity (5N⁺ or 6N) Cu, In, and S were reacted in an evacuated quartz tube at $\sim 1100^\circ\text{C}$ for 36h to form CuInS₂. The material was subsequently removed, crushed to ~ 200 mesh, and used as the starting material for directional solidification processing. A boron nitride growth ampul (1 cm diam \times 7.5 cm length) was filled with the CuInS₂ powder and supported within an evacuated ceramic tube. The details of the ampul are shown in Fig. 1. Directional solidification was performed using the Bridgman-Stockbarger method in a high temperature apparatus (12). The apparatus consisted of a three-zone furnace, capable of translating at velocities of from 0.01 to 50 cm/h and had an upper limit temperature of 1600°C . For the solidification of CuInS₂, a hot zone temperature of 1150°C ($\sim 100^\circ\text{C}$ greater than the melting point of CuInS₂) was used and a linear gradient of $\sim 60^\circ\text{C}/\text{cm}$ was employed. The ampul was held stationary and the furnace moved at ~ 0.02 cm/h.

After processing, the ampul was sliced perpendicular to the direction of solidification to form disk-shaped samples for electrode fabrication. Evaporated indium was

used to make an ohmic contact and silver-filled epoxy was used to connect a copper wire to the material.

A triple-source vacuum evaporation system, the construction details of which have been reported previously (5), was used to make the CuInS₂ thin films on titanium substrates. The system had resistive heated elemental sources, a tungsten dimple boat for copper, and Al₂O₃ crucibles for indium and sulfur, arranged in parallel with baffles between them. The power to each source was controlled by a microprocessor-driven feedback controller activated by an oscillating quartz crystal monitor which drove a SCR power supply. The key feature of the evaporation system was a tubular shielding arrangement of the crystal monitors whereby no interference between deposition sources was registered. Substrate heating was supplied by a copper block substrate holder, into which cartridge-type heaters and a thermocouple were inserted. X-ray diffraction analysis was performed using a diffractometer with Cu K α radiation. Quantitative compositional data were obtained using a wavelength dispersive electron microprobe at the Solar Energy Research Institute (SERI, Golden, Colorado).

Photoelectrochemical measurements were made using a standard potentiostatic test setup. I-V traces were obtained in an aqueous 2.5M Na₂S-1M S-1M KOH electrolyte using a platinum counterelectrode and a saturated calomel reference electrode. Electrodes were chemically etched in 25% HNO₃, and when photoetching was done a dilute HCl:HNO₃ etchant was used (13).

Fig. 1. High temperature schematic ampul for directional solidification.

White light measurements were obtained using a simulated AM2 spectrum provided by a W-I ELH lamp mounted in a dichroic parabolic reflector (14). A 0.25m grating monochromator with 1 kW Xe light source was used with a light chopper and lock-in detection to obtain monochromatic I-V curves and action spectra. All light intensities were measured with a calibrated thermopile detector.

Results and Discussion

The material that was synthesized in the quartz tubes was single-phase CuInS_2 with the chalcopyrite structure as shown in Table I. The resultant directionally solidified material had excellent compositional uniformity over the middle 1.8 cm of the sample, as shown in Fig. 2. The material was n-type as formed and required no further annealing or doping. It was also polycrystalline, with an irregular grain structure having some grains as large as several millimeters in length. X-ray diffraction analysis of the electrode surface indicated the material was single-phase CuInS_2 with a slight 112 growth orientation. Electrodes which had been mounted, polished, chemically etched, and then photoetched were evaluated photoelectrochemically. The best performance was obtained after photoetching, as shown in Fig. 3, for the electrode with the highest output observed. The efficiency of the other electrodes cut from this sample after similar optimization were 2.8, 3.6, and 5.4%. The spectral response (at zero bias) of the electrode from Fig. 3 is shown in Fig. 4. While the quantum yield of the optimized electrode is uniformly high (ϕ external ~ 0.7) across this spectrum (the dropoff at $\lambda < 550$ nm is due to electrolyte absorption), some subbandgap photoresponse is present. As a result, determination of the bandgap of this material by taking the onset of photocurrent to indicate the interband transition energy as well as a plot of the square of the photocurrent vs. the light energy near the bandedge (i.e., J_{ph}^2 vs. $h\nu$) (15, 16) yielded a value of ~ 1.48 eV (see Fig. 5), which is almost 0.5 eV lower than that reported in the literature (9, 17-20). This subbandgap response may be indicative of intrinsic defect states in the material which give rise to optical transitions with less than full bandgap energy light (21, 22).

At the low light intensities used to generate the action spectrum (i.e., $I \leq 1$ mW/cm²), electrode kinetics are not rate limiting and the semiconductor-electrolyte interface may be treated as a Schottky barrier. The Gartner model can then be used to determine optical and electronic parameters of the semiconductor from spectral photocurrent data taken in reverse bias (i.e., at potentials anodic of the dark rest potential in photoelectrochemical systems) (23).

Majority carrier density (N) and minority carrier diffusion length (L_p) can be determined using this model from a plot of $\ln(1 - \phi)$ vs. $(V_{FB} - V_a)^{1/2}$, where ϕ is the monochromatic quantum yield, V_a is the applied reverse bias voltage, and V_{FB} is the flatband potential provided the absorption coefficient (α) is known (23). Using monochro-

matic I-V traces obtained at 800 nm and $\alpha = 4.6 \times 10^4$ cm⁻¹ (20), the above-mentioned analysis yielded the following values: $N = 6.8 \times 10^{16}$ cm⁻³ and $L_p = 0.8$ μm . It is likely that the good L_p value for this material is responsible for its superior I-V performance as compared to the results reported in Ref. (7) for CuInS_2 with $L_p \sim 0.2$ μm . Direct measurement of the resistivity through the thickness of this disk electrode yielded a value of 5 $\Omega\text{-cm}$. Using this value, a majority carrier mobility of ~ 18 cm²/V-s was calculated.

Fig. 5. J^2 vs. $h\nu$ plot for determination of bandgap for directionally solidified CuInS_2 material.

It has been shown by several workers that the Gartner model can be further used to determine V_{FB} , provided certain conditions are satisfied (15, 16, 24). Specifically, if monochromatic I-V data are taken at a wavelength of relatively weak absorption so that $\alpha L_p < 1$ and $\alpha W_0 < 1$, where W_0 is the width of the space-charge layer in the semiconductor, a quadratic relation between Φ (or J) exists such that $J^2 \propto V_a - V_{FB}$. V_{FB} may then be obtained by extrapolation of the J^2 vs. V_a plot to $J = 0$. In the present case (800 nm) for $N = 6.8 \times 10^{16} \text{ cm}^{-3}$, $W_0 = 0.116 \mu\text{m}$, and $\alpha W_0 < 1$, however, because α is large, the product $\alpha L_p > 1$, so the use of this model becomes somewhat questionable. Even so, a plot of J^2 at 800 nm as a function of V_a is linear, as shown in Fig. 6. The V_{FB} value of -1.5 V vs. SCE obtained from this extrapolation was in agreement with the value of -1.52 V vs. SCE obtained by noting the onset of photocurrent with high intensity chopped white light (25). So, while the above-mentioned assumptions are not rigorously met, the J^2 vs. V_a relationship still holds and a good value for V_{FB} can be obtained. This V_{FB} value is slightly lower than that of -1.54 V vs. SCE reported by Mirovsky *et al.* (7), also determined using the Gartner model, but is probably within experimental variability in view of the fact that different SPS electrolytes were used.

Initially, considerable difficulty was encountered in producing good quality CuInS_2 thin films by the elemental evaporation process, because the Cu source tended to overheat the S source, which made the S deposition rate erratic. Placement of a ceramic baffle between these two sources significantly improved the situation.

In CuInS_2 , which is not extrinsically doped, the carrier type is determined by the Cu/In ratio as well as the

Fig. 6. Monochromatic J^2 vs. reverse bias plot for flatband determination of CuInS_2 in $2.5\text{M Na}_2\text{S}$, 1M S , 1M KOH electrolyte.

S/metal ratio. In producing thin films of CuInS_2 by the elemental evaporation technique, n- and p-type films could be made by adjusting the Cu/In ratio. If $\text{Cu/In} > 1$, p-type films resulted, and if $\text{Cu/In} < 1$, n-type films were made. It should be noted that in all cases the S rate was held at a slight excess over stoichiometry (nominal composition of $\text{CuInS}_{2.1}$), because nonuniform and poorly adhering films resulted if the films were made too sulfur deficient. The p-type films exhibited very little photovoltaic activity in SPS electrolyte, which is consistent with results reported previously with p-type CuInS_2 (7).

The most consistent results in terms of obtaining single-phase n- CuInS_2 films were achieved using substrate temperatures between 350° and 400°C and running the evaporator with a slight excess of In. The x-ray diffraction pattern of a film produced with these processing conditions is presented in the last column of Table I. It is difficult to determine conclusively if the thin film has the chalcopyrite or sphalerite structure, due to the weakness of the 213, 105 reflection, which belongs to the chalcopyrite structure alone. It is interesting to note that while the microstructure of this type of film, shown in Fig. 7, appears columnar, the x-ray diffraction pattern does not indicate a growth texture. This is in contrast to CdSe thin films grown by elemental evaporation in the same temperature regime, where similar microstructures are accompanied by a strong 001 growth texture (26, 27). These results imply that there is a random orientation of crystallites within the columns in Fig. 7. This would provide higher grain boundary recombinations for carriers going through the film than in a textured microstructure. This is probably one factor limiting the performance of the n- CuInS_2 thin films at present.

The compositional uniformity of these films was found to be quite good, as indicated by the EPMA line scan shown in Fig. 8. The excess In in this film is evident in this microprobe scan. The average composition of the film was 23.07% Cu, 26.38% In, and 50.44% S. Although not detected in the film's x-ray diffraction pattern, the formation of some In-S or In-O compound, or CuIn_5S_8 , might have occurred (28, 29).

A 30 min heat-treatment at 200°C in air followed by photoetching and rinsing in 1M KCN was found to optimize the photovoltaic output of this type of thin film. Figure 9 presents the photovoltaic output of a CuInS_2 thin film electrode and demonstrates how postdeposition treatment improves the I-V performance of the heat-treated electrode. Even though the photoetch treatment significantly improves the performance, the I-V curve still has a recombination-dominated shape in forward bias. While the dark current is very low in forward bias, the photocurrent still drops off rapidly (30). The action spectrum of this electrode, which was only somewhat modified by photoetching, shows significant subbandgap response, as seen in Fig. 10. The major effect of photo-

Fig. 9. Photovoltaic performance of CuInS_2 thin film electrode before (solid line) and after (broken line) photoetch/KCN treatment.

etching is seen in the improvement of the red response of the electrode and in the maximum external quantum yield which improves from ~ 15 to $\sim 50\%$. In analyzing these films, it became obvious that they are far from optimized. There are probably several major efficiency limiting mechanisms present, *e.g.*, poor electronic properties, kinetic limitations, surface states, and/or bulk defect states.

Application of the Gartner model analysis to the thin film material indicated $N = 6.2 \times 10^{17} \text{ cm}^{-3}$ and $L_p = 0.05$

Fig. 10. Action spectrum of CuInS_2 thin film electrode before (solid line) and after (broken line) photoetching showing significant sub-bandgap photoresponse.

Table II. Effect of temperature on photovoltaic output of a CuInS_2 thin film electrode (simulated AM2 conditions)

20	0.40	12.0	0.29	1.9
60	0.41	12.3	0.32	2.1

μm . Because reliable resistivity measurements could not be made due to contact difficulties, the mobility was not calculated. However, the high N value is not surprising, due to the excess In found in the film. The low L_p value is consistent with poor photovoltaic output. Calculation of the film depletion width (W_0) based on the measured N value and a built-in potential (V_B) of 0.7V from the relation $W_0 = (\epsilon\epsilon_0 V_B / qN)^{1/2}$ where ϵ is the dielectric constant of CuInS_2 which was taken to be 11 (31), $\epsilon_0 = 8.86 \times 10^{-14}$ F/cm, and $q = 1.602 \times 10^{-19}$ C, yields $W_0 = 380\text{\AA}$. Such a thin W_0 should minimize field-assisted collection, especially in forward bias, and bulk collection would be poor due to the low L_p value. This interpretation is supported by the recombination-dominated curve shape seen in forward bias as well as the falloff in collection efficiency found at the red end of the spectrum (Fig. 10), where carriers are generated deeper into the film and must rely on diffusion for collection (27).

In order to evaluate the effect of electrode kinetics on the I-V performance of the thin film material, a series of monochromatic I-V curves (550, 700, and 800 nm) was taken at temperatures between 20° and 60°C using lock-in detection at 30 Hz. Significant effects have been reported in this temperature regime for CuInS_2 (6, 7). Monochromatic I-V data were used so that spectral information could be obtained and dark currents eliminated. Very little temperature dependence was found as a function of wavelength or voltage, indicating that, at least for the light intensities employed ($< 1 \text{ mW/cm}^2$), kinetics are not the major efficiency limiting factor. This contention was further supported by white light measurements at 75 mW/cm^2 in the same temperature range. Here, about a 10% increase in efficiency, due mostly to an improvement to fill factor, was seen in going from 20° to 60°C. The photovoltaic output parameters of the electrode at 20° and 60°C are presented in Table II. It is not surprising that there is little temperature dependence seen at these low efficiency levels, considering the large actual surface area of the electrode (Fig. 7) and small diffusion length of this material.

The output stability of the CuInS_2 materials produced in this work was quite good. The electrode whose I-V trace is shown in Fig. 3 was run at maximum power at a current density of 20 mA/cm^2 (*i.e.*, $2 \times \text{AM2}$ intensity) for a total of 10,000 C/cm², with a slight increase in efficiency from 6.4 to 6.6%. The thin film electrode of Fig. 9 was run at maximum power at 10 mA/cm^2 for a total of 5000 C/cm², with a slight decrease in output of from 1.8 to 1.7%.

Summary

It has been shown that photovoltaically active, large-grained n- CuInS_2 can be prepared by the directional solidification of prereacted CuInS_2 starting material. The best electrode fabricated from the as-grown material had a minority carrier diffusion length of $\sim 1 \mu\text{m}$, excellent output stability in SPS electrolyte, and a simulated AM2 efficiency of 6.4%. CuInS_2 thin films were also produced by elemental vacuum evaporation, and results were more variable. These electrodes, when optimized, exhibited only modest efficiency levels ($\sim 2\%$) and recombination-dominated I-V curve shapes. Analysis of monochromatic I-V data indicated that the films had high doping densities ($N \geq 10^{17}$) and short effective diffusion lengths ($L_p \sim 0.05 \mu\text{m}$).

Thermal Oxidation of Silicon in Dry Oxygen

Accurate Determination of the Kinetic Rate Constants

Hisham Z. Massoud*¹ and James D. Plummer*

ABSTRACT

Based upon the linear-parabolic growth model of silicon oxidation, accurate kinetic rate constants are determined for (100), (111), and (110) silicon oxidized in dry oxygen in the 800°-1000°C range. The oxide growth was monitored by high temperature automated *in situ* ellipsometry. It is shown that fitting the maximum number of oxidation data points to a linear-parabolic relationship yields accurate oxidation rate constants that are unique to the oxidation process as described in the Deal-Grove model, and not just good empirical fitting parameters. This approach is denoted the "optimum X_i technique." Both linear and parabolic rate constants exhibit a break in their activation energies at 950°C. This behavior is discussed and interpreted in terms of the viscoelastic properties of SiO₂.

The thermal oxidation of silicon in the thin regime (< 500Å) is of vital importance to VLSI device designers because thin layers of SiO₂ are exclusively used as the gate dielectric for high performance MOS devices. In early studies of the growth kinetics of silicon dioxide in dry oxygen, it has been observed that the oxidation rate, in the early stages (< 250Å) of SiO₂ growth, is faster than described by the linear-parabolic growth relationship (1). This observation was later confirmed by a number of investigations [e.g., Ref. (2)]. In a quantitative study of the oxidation-rate enhancement in the thin regime (to be published in forthcoming papers), accurate values of the ox-

idation rate constants were needed in calculating the magnitude of the rate enhancement. Some discrepancies, however, exist in the reported values of the linear and parabolic rate constants (2). In this paper, the techniques commonly used to determine these constants from oxidation data are analyzed, an alternative method is introduced, and all methods are compared. The approach that yields physically meaningful results is then applied to a large body of oxidation data obtained using high temperature *in situ* ellipsometry. The results are then explained in terms of the potentially important role played by the viscoelastic properties of SiO₂ (3) in determining the oxidation rate constants.

The Thermal Oxidation of Silicon

The growth kinetics of thermal layers of silicon dioxide on silicon were successfully modeled by Deal and Grove

*Electrochemical Society Active Member.

²Present address: Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514.

(1), using a simple linear-parabolic relationship. This model was derived by considering three fluxes of oxidizing species to be in steady state: the flux of oxidant from the gas ambient to the gas-SiO₂ interface, the diffusive flux of oxidant through the SiO₂ film, and the flux representing the consumption of oxidant at the Si-SiO₂ interface by the oxidation reaction. In this description, the oxidation rate was expressed as

$$\frac{dX_{ox}}{dt} = \frac{B}{2X_{ox} + A} \quad [1]$$

where X_{ox} is the oxide thickness, and B and B/A are the parabolic and linear constants, respectively. The parabolic rate constant is directly proportional to the product of the diffusion coefficient and solubility of the oxidizing species in the oxide, whereas the linear rate constant is a function of the solubility of the oxygen species in the SiO₂ and the surface-reaction rate constant. It is important to note that this relation represents a "steady-state" description of the oxidation process wherein B and B/A are both time- and thickness-independent parameters; this corresponds to constant values for the diffusion coefficient and solubility of the oxidizing species in the oxide and for the surface-reaction rate constant. The fit of oxidation data over a wide range of temperatures and growth ambients—with values for the linear and parabolic rate constants which are only temperature dependent—would appear to support these assumptions (1, 4, 5). The relationship between oxide thickness X_{ox} and oxidation time t_{ox} is obtained by integrating Eq. [1] to yield

$$(X_{ox}^2 - X_i^2) + A(X_{ox} - X_i) = Bt_{ox} \quad [2]$$

or

$$X_{ox}^2 + AX_{ox} = B(t_{ox} + \tau) \quad [3]$$

where X_i is the oxide thickness at $t_{ox} = 0$, and τ is a correction parameter for the presence of any initial oxide X_i . From Eq. [2] and [3], the relationship between X_i and τ is

$$\tau = \frac{X_i^2 + AX_i}{B} \quad [4]$$

These parameters have also been used to account for the fast initial oxidation rate observed at the onset of silicon oxidation in dry oxygen (1). In this case, the fit to the oxidation data using the linear-parabolic model is only true for oxides thicker than X_c and oxidation times longer than t_c , as shown in Fig. 1 (1, 2).

Experimental Procedure

The use of automated ellipsometry reduces the time required for a single measurement of the ellipsometric parameters ψ and Δ to, typically, a few tens of milliseconds.

Fig. 1. The fit of the linear-parabolic relationship to oxidation data in dry oxygen. Parameters X_i and τ are defined as the intercepts at $t_{ox} = 0$ and $X_{ox} = 0$, respectively. Data point (X_c, t_c) denotes the onset of linear-parabolic kinetics.

Such a reduction in time makes automated ellipsometry an effective technique for studying the kinetics of physical and chemical processes on the surface of solids and liquids. It is especially suited to the study of oxide-growth kinetics in the initial stages of oxidation in dry oxygen where the growth rate is particularly high (1). The automated ellipsometry system used in this study was adapted to high temperature operation by van der Meulen and Hien (6) from the ellipsometric thickness analyzer (ETA) developed at the IBM Thomas J. Watson Research Center by Hauge and Dill (7). This system permits *in situ* monitoring of oxide growth at high temperatures.

Single-crystal, CZ-pulled, lightly doped with 1×10^{15} cm⁻³ phosphorus or boron, (100), (111), and (110) silicon wafers were used in this study. To investigate doping effects on oxidation, some wafers were doped using POCl₃ predeposition and subsequent drive-in to obtain surface concentrations of 1.8×10^{20} and 3.2×10^{20} cm⁻³. The pre-oxidation cleaning sequence consisted of H₂O₂-based solutions of NH₄OH and HCl with appropriate DI water rinses followed by a dip in dilute HF and a final DI rinse. The wafers were dried using nitrogen and immediately loaded in the oxidation tube in an argon ambient. Details of the operation of the automated ellipsometry system and the optical properties of Si and SiO₂ at high temperatures are described elsewhere (6).

The native-oxide thickness was measured *in situ* at the oxidation temperature at the onset of every oxidation run. Its thickness ranged between 7 (on lightly doped samples) and 22 Å (on heavily doped samples). After the background-intensity measurement, 33 data points were taken for every oxidation experiment over the thickness range of 0-600 Å. Thickness reproducibility from run to run was better than 2%.

Accurate modeling of the oxide growth kinetics, based on an understanding of the physical mechanisms involved, requires a complete characterization of the experimental conditions affecting oxide growth at the onset of oxidation in dry oxygen. As a result, the effects of growth temperature, partial pressure of oxygen in the oxidizing ambient, silicon orientation, and substrate doping on oxidation in the thin regime were investigated. A complete set of silicon-dioxide growth data (X_{ox} vs. t_{ox}) for (100), (111), and (110) silicon doped with phosphorus at 1×10^{15} , 1.8×10^{20} , and 3.2×10^{20} cm⁻³ in dry oxygen-argon mixtures corresponding to oxygen partial pressures of 1.0, 0.1, and 0.01 atm was obtained (8). An example is shown in Fig. 2 for lightly doped (100) silicon oxidized in dry oxygen.

Determination of the Oxidation Rate Constants

Accurate modeling of thermal oxidation in the thin regime necessitates a comprehensive body of experimental data to differentiate between proposed models or define new ones. In any study of the early stages of oxidation, it is important to define the onset of linear-parabolic kinetics.

Fig. 2. Oxide thickness vs. oxidation time for (100)-oriented lightly doped silicon oxidized in dry oxygen in the 800°-1000°C range.

Fig. 3. Differences in some of the reported values of the linear (left), and the parabolic (right) rate constants for the oxidation of silicon in dry oxygen (1, 3, 8).

ics accurately, which, in turn, requires an equally accurate estimation of the oxidation rate constants in the linear and parabolic regimes. Details of the physical, chemical, and electrochemical mechanisms that may affect the oxidation process have not been fully identified. For example, the transport of oxidizing species through the oxide is modeled by the diffusion of neutral molecules of oxygen, using a simple diffusion constant, and the oxidation reaction is expressed in terms of a single rate constant. Little information is available regarding the interaction and influence of point defects, stress, and electric field in the oxide on the transport of oxidant species through it.

In comparison to B and B/A defined in the general oxidation relationship, other rate constants can be determined by fitting the oxidation data to a polynomial expression in the form of

$$t_{\text{ox}} = a_0 + a_1 X_{\text{ox}} + a_2 X_{\text{ox}}^2 + \dots \quad [5]$$

where the constant coefficients, a_0, a_1, a_2, \dots , are fitting parameters obtained when the error in the fit is lower than some allowable limit. It is important to note that, although these constants may result in a good empirical fit to the oxidation data over a limited thickness range, insight into the oxidation process based on such fitting constants could be misleading. In contrast, the linear-parabolic model is based upon physically meaningful constants. To the extent that this model can fit experimental data, it provides insight into the physical mechanisms present during thermal oxidation. Consequently, this analysis is based on the description of silicon oxidation by linear-parabolic kinetics. A survey of the results of oxidation studies, however, would indicate some discrepancies in the reported values of the linear and parabolic rate constants (2). Some of these results (1, 5, 9) are reproduced in Fig. 3, where it can be seen that substantial variations in B and B/A were obtained, particularly at lower temperatures. Such differences stem from variations in the techniques and fitting parameters used in calculating the rate constants, and will be discussed later. These differences in oxidation rate constants introduce large uncertainties in the magnitude of oxidation-rate enhance-

ment in the thin regime. Being interested in the physical mechanisms responsible for the "anomalous" thin-regime kinetics, accurate values of B and B/A were necessary to determine accurately the end of the thin regime and the onset of linear-parabolic kinetics. For these reasons, an evaluation of the methods used to determine B and B/A was undertaken.

In this section, the techniques used to determine the oxidation rate constants are discussed, and a novel method is introduced to obtain constants that are representative of the oxidation process as defined by the linear-parabolic model and not merely empirical fitting parameters.

Determination of the rate constants based on X_1 .—By dividing both sides of Eq. [2] by $(X_{\text{ox}} - X_1)$, the linear-parabolic relationship can be rewritten as

$$(X_{\text{ox}} + X_1) = B \frac{t_{\text{ox}}}{(X_{\text{ox}} - X_1)} - A \quad [6]$$

For thickness-time data that fit the linear-parabolic model, a plot of $(X_{\text{ox}} + X_1)$ vs. $t_{\text{ox}}/(X_{\text{ox}} - X_1)$ should result in a straight line whose slope is B and intercept at $t_{\text{ox}}/(X_{\text{ox}} - X_1) = 0$ is $-A$. The value of X_1 used to generate this plot is obtained by estimating the intersection of the extrapolation of the linear-parabolic relationship with the thickness axis, as seen in Fig. 1 (1).

Determination of the rate constants based on τ .—By dividing both sides of Eq. [3] by X_{ox} , the linear-parabolic relationship can be rewritten as

$$X_{\text{ox}} = B \frac{(t_{\text{ox}} + \tau)}{X_{\text{ox}}} - A \quad [7]$$

A plot of X_{ox} vs. $(t_{\text{ox}} + \tau)/X_{\text{ox}}$ should again result in a straight line whose slope is B and intercept at $(t_{\text{ox}} + \tau)/X_{\text{ox}} = 0$ is $-A$. The value of τ used to generate this plot is also obtained by estimating the intersection of the extrapolation of the linear-parabolic relationship with the time axis, as shown in Fig. 1 (1).

It should be noted that, in the two above equivalent methods, the values of X_1 and τ are estimated approximately and are used as fitting parameters.

Determination of the rate constants based on X_c and t_c .—This approach eliminates the need for a fitting parameter and is based on the assumption that the oxidation data fit a linear-parabolic relationship beyond the fast initial regime. If X_c and t_c are the oxide thickness and oxidation time at or beyond the onset of linear-parabolic kinetics, then

$$(X_{ox}^2 - X_c^2) + A(X_{ox} - X_c) = B(t_{ox} - t_c) \quad [8]$$

for any set of oxide thickness X_{ox} and oxidation time t_{ox} , such that $X_{ox} > X_c$ and $t_{ox} > t_c$. A plot of $(X_{ox} + X_c)$ vs. $(t_{ox} - t_c)/(X_{ox} - X_c)$ should yield a straight line with a slope equal to B and an intercept equal to $-A$. This method is equivalent to shifting the thickness and time axes to a point (X_c, t_c) on the linear-parabolic portion of the data.

The onset of linear-parabolic kinetics can be determined by calculating the error in fitting the oxidation data, starting from a point (X_s, t_s) to the largest data point (X_f, t_f) , to a linear-parabolic expression. If the starting point is smaller than (X_c, t_c) , the error is large, and the values obtained for B and B/A are lower and higher than their true values, respectively. If the starting point, however, is equal to or larger than (X_c, t_c) , the error reaches a minimum and stays at that value, and the oxidation rate constants remain unchanged, as illustrated in Fig. 4. This analysis is based on the assumptions of steady-state and thickness-independent rate constants. This method was first introduced by Irene and van der Meulen (2) in a study of the discrepancies in the reported values of the rate constants for the oxidation of silicon in dry oxygen.

Determination of the rate constants based on $(dX_{ox}/dt)^{-1}$.—In this method, the oxidation rate is obtained numerically or graphically from the growth data. The dependence of the inverse of the oxidation rate on oxide thickness is found by inverting Eq. [1] as

$$\left(\frac{dX_{ox}}{dt}\right)^{-1} = \left(\frac{2}{B}\right) X_{ox} + \left(\frac{A}{B}\right) \quad [9]$$

A plot of $(dX_{ox}/dt)^{-1}$ vs. X_{ox} , therefore, results in a straight line whose slope is $(2/B)$ and intercept at $X_{ox} = 0$ is (A/B) . This method was used by Hopper *et al.* (10) in discussing the results of the oxidation of (111) silicon in the 700°-950°C range in various oxygen partial pressures.

Comparison.—The methods based on X_i or τ depend on an estimate of either parameter which is normally made by examining the oxidation data, such as that shown in Fig. 1. The accuracy with which the rate constants are determined is dependent on the value of X_i or τ , as will be discussed in the following section. No fitting parameter is required in the (X_c, t_c) or the inverse-rate method; in

Table I. Reported values of X_i used to determine the oxidation rate constants (1965-1982)

Workers	$X_i(\text{Å})$
Deal and Grove (1)	230 ± 30
Hess and Deal (8)	160 ± 40
Lie <i>et al.</i> (3)	40 ± 0

both, the rate constants obtained should be unique, provided the data can be described by the linear-parabolic model. The process of differentiation, however, requires a large number of closely spaced data points to avoid errors resulting from interpolation.

Optimum X_i Technique

In a study of the oxidation of (111)-oriented silicon in dry oxygen (1), Deal and Grove used the τ method to calculate the rate constants. Based on the different values of τ obtained in the 700°-1200°C range, corresponding values of X_i were calculated using Eq. [4], and a constant value of 230Å resulted. The value of X_i used in the determination of rate constants, however, has not been the same over the years, as demonstrated in Table I. The trend towards decreasing values of X_i reflects the interest in fitting data covering the growth of thinner oxides.

In this section, it will be demonstrated that values of the linear and parabolic oxidation rate constants determined from oxidation data depend on the value of X_i used in the analysis. An optimum X_i technique is introduced, wherein the value of X_i is obtained by maximizing the number of data points (X_{ox}, t_{ox}) that fit a linear-parabolic expression, and this optimum value is referred to as $X_{i(opt)}$. It will also be shown that the rate constants obtained using $X_{i(opt)}$ are the same as those obtained by the inverse-rate method, which, as discussed earlier, does not require any fitting parameters.

The oxidation data of (100) silicon oxidized in dry oxygen at 1000°C is used, as an example typical of all temperatures and orientations, in plotting $(X_{ox} + X_i)$ vs. $t_{ox}/(X_{ox} - X_i)$ for different values of X_i , as shown in Fig. 5. It can be seen that an optimum value of X_i exists for which the number of data points fitting a straight line (*i.e.*, a linear-parabolic relationship) is maximum. The thickness X_c above which the growth can be modeled as linear-parabolic is a strong function of X_i , and is at minimum in the case of the optimum X_i . For oxides thinner than X_c , the data deviate sharply from a straight line because of the fast initial-oxidation regime. For oxides thicker than X_c , a straight-line plot of $(X_{ox} + X_i)$ vs. $t_{ox}/(X_{ox} - X_i)$ is obtained for a range of values of X_i around the optimum value. The following observations are apparent from the figure.

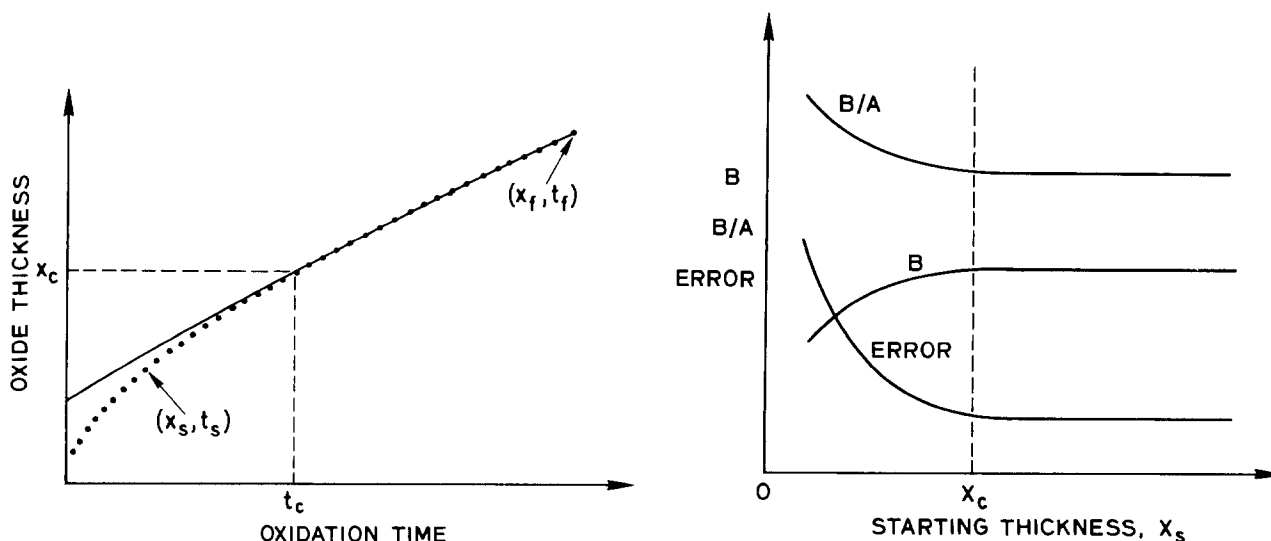

Fig. 4. The (X_c, t_c) method showing dependence of the linear and parabolic rate constants and the error in the fit to oxidation data on the position of the starting point (X_s, t_s) with respect to (X_c, t_c) .

Fig. 5. Effect of the value of X_i on (a, left) the linear and parabolic rate constants as seen from the slope and intercept of the straight-line fit in a $(X_{ox} + X_i)$ vs. $t_{ox}/(X_{ox} - X_i)$ plot, and (b, right) the fit to the oxidation of (100) silicon at 1000°C in dry oxygen.

1. The straight-line plot obtained for $X_i = X_{i(a)} > X_{i(opt)}$ is steeper than that obtained for $X_i = X_{i(opt)}$; therefore, B is larger and B/A is smaller than the rate constants obtained with $X_{i(opt)}$. This is seen from the change in slope and intercept of the two plots. The linear-parabolic relationship fits the data beyond $X_{c(a)}$, where $X_{c(a)} > X_{c(opt)}$, as in Fig. 5b.

2. The straight-line plot obtained for $X_i = X_{i(a)} < X_{i(opt)}$ is less steep than that obtained for $X_i = X_{i(opt)}$ and, as a result, B is smaller and B/A is larger than the rate constants obtained with $X_{i(opt)}$. This is also seen from the change in slope and intercept of the two plots. In this case, the linear-parabolic relationship and the (X_{ox}, t_{ox}) data intersect at point P. The thickness $X_{c(b)}$, beyond which the linear-parabolic expression fits the data, is also larger than $X_{c(opt)}$.

This observed behavior was found to be qualitatively the same for all other orientations and at all temperatures. It should be noted that such results were only made possible because of the closely spaced data points obtained by automated ellipsometry.

Having established that the oxidation rate constants depend on the value of the parameter X_i , it is important to estimate quantitatively the deviation in the rate constants from their optimum values due to different values of X_i . For this purpose, B and B/A are obtained by applying the optimum X_i method to the $X_{ox} - t_{ox}$ data points of (100) silicon oxidized in dry oxygen at 1000°C. This is illustrated in Fig. 6, where plots of $(X_{ox} + X_i)$ vs. $t_{ox}/(X_{ox} - X_i)$ are shown for X_i values in the 100-140Å range in steps of 10Å. It can be observed that the maximum number of data points that fit a straight line corresponds to X_i approximately equal to 120Å. Similar plots were obtained for different values of X_i around 120Å in increments of 2.5Å, and it was found, by comparing plots, that the maximum

number of data points that fit the straight-line portion of the plot corresponds to $X_i = 117.5\text{Å}$. From the slope and intercept of this plot, the optimum rate constants obtained are

$$B = 28,500 \text{ Å}^2/\text{min}$$

and

$$B/A = 8.66 \text{ Å}/\text{min}$$

It can also be observed in Fig. 6 that values of X_i other than the optimum will also result in a straight-line fit for data points corresponding to thicker oxides from which the linear and parabolic rate constants could be determined. Modeling oxide growth with these values of B and B/A would result in small errors in fitting the data. The error in the rate constants themselves, however, can be rather large, and attempts to identify the physical processes involved might also be in error. Table II summarizes the values obtained for the rate constants when using values of X_i other than the optimum value in the example shown in Fig. 5 and 6. It can be seen that, for $X_i = 140\text{Å}$, the deviations in B and B/A from their values determined with $X_{i(opt)}$ are approximately 30 and 10%, respectively; here, X_i is only 22.5Å away from the optimum 117.5Å.

It is, therefore, concluded that variations in the parameter X_i can result in substantial deviations in the obtained oxidation rate constants. It is shown next why this optimum technique should be used.

A plot of the thickness dependence of the inverse of the oxidation rate for (100) silicon oxidized in dry oxygen at 1000°C is shown in Fig. 7. There are the same data shown in Fig. 5 and 6. The oxidation rate was obtained by numerical differentiation of the oxide-growth data points using a five-point parabolic-fit routine (11). It can be seen that the linear-parabolic relationship (corresponding to the straight-line portion) applies beyond the fast initial oxidation regime ($\sim 350\text{Å}$). The rate constants obtained from the slope and intercept of this straight-line fit are

$$B = 28,600 \text{ Å}^2/\text{min}$$

and

$$B/A = 8.65 \text{ Å}/\text{min}$$

Fig. 6. Effect of the values of X_i on the oxidation rate constants obtained from plots of $(X_{ox} + X_i)$ vs. $t_{ox}/(X_{ox} - X_i)$ for $X_i = 100, 110, 120, 130,$ and 140Å .

the same as those obtained using the optimum X_i technique.

The inverse-oxidation-rate method yields the linear and parabolic rate constants relevant to the description of the oxidation process by the linear-parabolic model, because it does not require any additional fitting parameters. This assumes that the oxidation process is accurately described by this model. It has also been shown that identical results are obtained if the optimum X_i is used in the determination of the oxidation rate constants by plotting $(X_{ox} + X_i)$ vs. $t_{ox}/(X_{ox} - X_i)$ and fitting the maximum number of data points to the straight-line portion of the plot. The added advantage of the optimum X_i method is that no differentiation is required and, therefore, no accuracy is lost as a result of the inherently noisy differentiation process. The accuracy of both of these techniques depends, however, on the availability of a dense data set which can only be provided by *in situ* ellipsometry techniques. These findings confirm the conclusions of Irene and van der Meulen (2) in comparing the methods of analysis of SiO_2 film growth data.

Oxidation Rate Constants of Lightly Doped Silicon

In this investigation, (100)-, (111)-, and (110)-oriented lightly doped silicon wafers were oxidized in dry oxygen up to a thickness of $\sim 600\text{\AA}$. The growth was monitored by a high temperature automated *in situ* ellipsometer. The linear and parabolic rate constants were determined by increasing X_i by 2.5\AA steps until its optimum value, corresponding to the maximum number of data points fitting the linear-parabolic relationship, was reached. Table III summarizes the results obtained at five temperatures in the 800°-1000°C range; the values of $X_{i(\text{opt})}$ are also shown. It can be seen that, for (100) and (111) orientations, $X_{i(\text{opt})}$ decreases with temperature and is nearly constant for (110).

Parabolic rate constant.—The parabolic rate constants of (100)-, (111)-, and (110)-oriented lightly doped silicon oxidized in dry oxygen are plotted in Fig. 8. The values obtained by the $X_{i(\text{opt})}$ technique are plotted at 800°, 850°, 900°, 950°C, and 1000°C. Results plotted at 1100° and 1200°C are obtained by applying the same method to published oxidation data (5). These published data were not obtained using *in situ* ellipsometry and, therefore, larger

Fig. 8. Parabolic rate constant for the oxidation of (100)-, (111)-, and (110)-oriented lightly doped silicon in dry oxygen in the 800°-1000°C range.

error bars would be expected for the rate constants at 1100° and 1200°C. It can be seen that the parabolic rate constant exhibits a break in its activation energy between 950° and 1000°C. Above this temperature, it is independent of substrate orientation and has an activation energy of 1.0 ± 0.2 eV for both (100) and (111). At lower temperatures, B is dependent on the orientation of the underlying substrate and has low temperature activation energies of 2.22, 1.71, and 1.70 eV for (100), (111), and (110), respectively. These low temperature activation energies are asymptotic values obtained by a least squares fit to the lowest temperature data points to an Arrhenius expression. The dependence of the parabolic rate constant on substrate orientation in the low temperature range was observed by Irene (12) while studying the effects of trace amounts of water on the oxidation of silicon in dry oxygen in the 800°-1000°C range. The orientation dependence of B (12) is the same as observed in this work.

Deal and Grove (1) reported an orientation-independent parabolic rate constant with a single activation energy of 1.23 eV for the oxidation of (100)- and (111)-oriented silicon in dry oxygen in the 700°-1200°C range, which is close to the 1.2 eV activation energy of oxygen diffusion through fused silica. Pliskin (4) also observed the parabolic rate constant to be independent of substrate orientation at temperatures as low as 910°C. Irene and van der Meulen (2) reported a single activation energy of 2.3 eV when oxidizing (100)-oriented silicon in dry oxygen in the 780°-980°C range.

Table III. Linear and parabolic rate constants and the optimum value of X_i for the oxidation of (100)-, (111)-, and (110)-oriented lightly doped silicon in dry oxygen in the 800°-1000°C range

In more recent oxidation studies, a break in the activation energy of both the parabolic and linear rate constants was observed and reported. Irene and Dong (13) observed that the activation energy of the parabolic rate constant for the oxidation of (100)-oriented silicon in ultradry oxygen (< 1 ppm H₂O) changed from 1.3 eV in the 980°-1150°C range to 2.1 eV in the 780°-1000°C range. For the oxidation of (100)- and (111)-oriented silicon in dry oxygen in the 800°-1000°C range, these activation energies were found to be 1.40 and 1.78 eV for temperatures higher and lower than 900°C, respectively (5). Values of the parabolic rate constant reported in Ref. (13) at 780°, 893°, and 980°C fall on the solid line in Fig. 8.

The low temperature activation energy of *B* obtained in this study is in agreement with values reported for (100) (2, 13) and (111) (5). The high temperature activation energy is also in agreement with the (100) value (13). As concluded in Ref. (13), disagreements in published values of the parabolic rate constant are, therefore, confirmed here to be the result of studying different temperature ranges where the activation energy is different.

Linear rate constant.—The linear rate constants obtained for (100)-, (111)-, and (110)-oriented lightly doped silicon oxidized in dry oxygen are plotted in Fig. 9. The values obtained using $X_{1(100)}$ are plotted at 800°, 850°, 900°, 950°, and 1000°C. Values plotted at 1100° and 1200°C are the result of applying the same technique to oxidation data in the literature (1, 5). It should be pointed out here that the error margins at 1100° and 1200°C are large ($\pm 20\%$) because the data are sparse, values of the quantity *A* are small, and any slight error in the straight-line fit will result in a small error in the extracted value of *B* and a large error in that of *B/A*. For example, the 1200°C data nearly fit a parabolic growth law, which mathematically corresponds to a linear-parabolic relationship where *A* is very small and, consequently, *B/A* is very large.

The linear rate constant also exhibits a break point in its activation energy at approximately the same temperature as the parabolic rate constant; however, the direction of the break is opposite to that of *B* (the high temperature range has a larger activation energy than does the low

temperature range). At low temperatures, activation energies of 1.76, 1.74, and 2.10 eV were observed for (100), (111), and (110), respectively. As for the parabolic rate constant, these low temperature activation energies are obtained by a least squares fit of the lowest temperature data points to an Arrhenius expression. The (100) and (111) orientations have nearly the same slope, and the average ratio between the linear rate constants of the two orientations $(B/A)_{111}:(B/A)_{100}$ is 2.18. At high temperatures, the activation energy is 2.75 ± 0.22 eV for both (100) and (111).

The activation energy of the linear rate constant was originally reported to be 2.0 eV for the oxidation of (100)- and (111)-oriented silicon in dry oxygen (1). This value is similar to the Si-Si bond breaking energy of 1.83 eV, which supports the suggestion that the rate-limiting step in the linear regime is the reaction of oxygen and silicon at the Si-SiO₂ interface. The ratio between the linear rate constants of the two orientations $(B/A)_{111}:(B/A)_{100}$ was found to be 1.68. Irene and van der Meulen (2) reported an activation energy of 1.5 eV for the oxidation of (100)-oriented silicon in dry oxygen in the 780°-980°C range and concluded that oxygen-oxygen bond breaking is important in linear kinetics.

Breaks in the activation energy of the linear rate constant have also been discussed in the literature. In the oxidation of (100)-oriented silicon, a change from 2.2 eV in the 980°-1150°C range to 1.6 eV in the 780°-1000°C range in the activation energy of *B/A* was reported (13). A break was also observed in the linear rate constant, but it was less pronounced than that observed in the parabolic rate constant (5). The observed activation energy was 1.87-1.89 eV. Values of the linear rate constant reported by Irene and Dong (13) nearly fall on the solid line in Fig. 9.

The low temperature activation energy of *B/A* obtained in this study is similar to the (100) reported value (2, 13); however, at higher temperatures, it is larger than those obtained in earlier studies (5, 13). Here again the discrepancy in published values of the rate constants is the result of studying different temperature ranges with different activation energies.

The temperature dependence of the linear and parabolic rate constants suggests that they could be fitted to expressions of the forms

$$B = 1/[K_1 \exp(+E_1/kT) + K_2 \exp(+E_2/kT)]$$

and

$$B/A = C_1 \exp(-E_1/kT) + C_2 \exp(-E_2/kT)$$

The use of the above expressions, however, resulted in large errors in the fit of the data points in comparison to fitting them to a single activation-energy expression in designated temperature ranges. Minimum errors in the fitting to such single activation-energy expressions were obtained by choosing 1000°C as the break temperature. The results of such fits are as follows

$$B = \begin{cases} 1.70 \text{ E } 13 \exp(-2.22 \text{ eV}/kT) & (100) \\ 1.34 \text{ E } 11 \exp(-1.71 \text{ eV}/kT) & (111) \\ 3.73 \text{ E } 10 \exp(-1.63 \text{ eV}/kT) & (110) \end{cases} \quad T < 1000^\circ\text{C}$$

$$B = \begin{cases} 1.31 \text{ E } 07 \exp(-0.68 \text{ eV}/kT) & (100) \\ 2.56 \text{ E } 07 \exp(-0.76 \text{ eV}/kT) & (111) \end{cases} \quad T > 1000^\circ\text{C}$$

and

$$B/A = \begin{cases} 7.35 \text{ E } 07 \exp(-1.76 \text{ eV}/kT) & (100) \\ 1.33 \text{ E } 08 \exp(-1.74 \text{ eV}/kT) & (111) \\ 4.73 \text{ E } 09 \exp(-2.10 \text{ eV}/kT) & (110) \end{cases} \quad T < 1000^\circ\text{C}$$

$$B/A = \begin{cases} 3.53 \text{ E } 13 \exp(-3.20 \text{ eV}/kT) & (100) \\ 6.50 \text{ E } 12 \exp(-2.95 \text{ eV}/kT) & (111) \end{cases} \quad T > 1000^\circ\text{C}$$

where *B* is in square angstroms per minute and *B/A* is in angstroms per minute. The above expressions were obtained by a least squares fit of the rate constants to an Arrhenius expression for temperatures above and below 1000°C. It should be remembered that such data

Fig. 9. Linear rate constant for the oxidation of (100)-, (111)-, and (110)-oriented lightly doped silicon in dry oxygen in the 800°-1000°C range.

consisted of a relatively small number of data points, which reflects itself in correspondingly large error bars for the linear and parabolic rate constants at temperatures higher than 1000°C.

When the results of this study are compared with previous studies, as shown in Fig. 3 for example, it is noticed that some differences exist. It should be first pointed out that all of the data obtained in this study were for oxides thinner than 1000Å. The B and B/A values obtained in this study do not all agree with earlier values, which were largely obtained from the analysis of thicker oxides and less dense data sets (1, 5, 9). Such differences could result in errors when predicting the oxide growth for very thick oxides (several thousand angstroms) when using the B and B/A values obtained in this study. The values of B and B/A obtained in this work agree with the results of Irene and van der Meulen (2) and Irene and Dong (13) because of the use of closely spaced data sets and an optimized method for the determination of the rate constants. Of great interest here is that, in Ref. (2) and (13), the oxide growth was studied up to 1100Å. The results of this study should, therefore, be used with caution when modeling oxide growth for oxides thicker than 1100Å. Differences between thin and thick values of the oxidation rate constants, if confirmed by further experiments, may suggest that B and B/A are indeed thickness-dependent rate constants. Such experiments are needed to quantify the differences, which, if true, would be a strong evidence for changes in the properties of the growing oxide affecting the rate constants.

Discussion

Breaks in the activation energies of the parabolic and linear rate constants (Fig. 8 and 9) indicate that B and B/A are composite rate constants rather than kinetically simple single-activated steps. Other interpretations of a temperature-dependent activation energy are possible. A break in the activation energy of a rate constant could be analyzed by assuming that more than one kinetic step is involved. According to the direction of the break, these steps could occur at the same time (in parallel) or one after the other (in series). The direction of the break in the parabolic rate constant is an example of two simple steps occurring in series, while the break in the activation energy of the linear rate constant is an indication of two parallel processes. The direction of the curvature in the Arrhenius plots of the linear rate constant gives strong support for the interface mechanism to be occurring by the reaction of silicon with two oxidant species, molecular and atomic oxygen (14). This description of the interface reaction was proposed by Ghez and van der Meulen (15) to explain the less-than-linear pressure dependence of the linear rate constant. Figure 10 illustrates the temperature behavior of a composite process consisting of two activated steps with different activation energies occurring either in series or in parallel. The resulting process is limited in the series case by the slower mechanism, and dominated in the parallel case by the faster.

Another possible interpretation of the behavior of the linear and parabolic rate constants with temperature is to assume that the same physical mechanism is present at all temperatures but that it is affected by some other temperature-dependent process. In a revised model of thermal oxidation, Irene (3) proposed that high temperature oxidant transport is dominated by the classical mechanism of thermal diffusion through the oxide, while low temperature transport is dominated by a flux of oxidizing species in micropores. The effect of stress in thermal SiO₂ during growth and the influence of the viscoelastic properties of the oxide on the transport and reaction of the oxidant species through the oxide and at the Si-SiO₂ interface are proposed as one such mechanism. A revised expression for the linear rate constant that takes into account the rate of viscous flow in the oxide has been formulated (2). Viscous flow is known to occur in SiO₂ films on silicon at 960°C (16, 17), which is close to where the parabolic rate constant changes from its high

Fig. 10. Example of a composite rate constant consisting of two processes with different activation energies occurring either in series or in parallel.

temperature low activation orientation-independent behavior to its low temperature high activation orientation-dependent behavior in Fig. 8. Below 960°C, the oxide does not experience significant viscous flow and is expected to be in a high state of stress. If the transport process of the oxidant species is stress-dependent, then the magnitude and activation energy of B should reflect the influence of substrate orientation on oxide stress. All three orientations have different values of B in the low temperature range; however, (111) and (110) have similar activation energies, which may indicate that, at low temperatures, the state of stress in the oxide may be similar for these two orientations. Above 960°C, the silicon-dioxide layer experiences viscous flow and the stress is relieved. Transport of the oxidant species then proceeds with a lower activation energy. The oxide then bears no signature of the underlying substrate, and the parabolic rate constant is independent of orientation; its magnitude and activation energy are the same for all orientations.

The behavior of the linear rate constant can also be explained by considering the effect of oxide stress on the oxidation reaction at the Si-SiO₂ interface. In the low temperature range, the Si-Si bond breaking energy is lowered by stress in the silicon-dioxide layer. The activation energies of (100) and (111) indicate that the stress in the oxide is similar for these two orientations. The atomic arrangement of silicon atoms at the Si-SiO₂ interface is different for these orientations, but the resultant activation energy for linear kinetics is the same. The (110) orientation has a higher activation energy, which may again be a combined result of the interaction of oxide stress and the details of the silicon-oxygen reaction at the interface. In the high temperature range, the oxide has experienced viscous flow, stress is accordingly greatly reduced, and the Si-Si bond breaking energy must be supplied thermally. This explains the greater activation energy at high temperatures where, despite the inaccuracy in the extracted rate constants, the values of B/A for (100) and (111) are similar. This suggests that the activation energy for the oxygen-silicon reaction is the same for these orientations and is much higher than values previously reported.

The rather abrupt change in behavior of the rate constants at 960°C may be the result of the large activation energy (5.29-7.68 eV) of the viscosity of vitreous silica (18). This implies essentially that no measurable flow occurs below 960°C and that it is practically complete above 960°C.

The fit of the linear-parabolic model to oxidation data beyond the fast initial regime indicates that B and B/A

can be considered constant, in a first-order analysis, over a wide range of oxide thicknesses. Some of the discrepancies between values of the rate constants obtained in this study and earlier studies may suggest a thickness dependence in B and B/A , as discussed earlier. The thin oxide regime which is not well modeled by constant B and B/A is the subject of forthcoming papers (19, 20) where the same dense oxidation data sets are analyzed to resolve some of the physical mechanisms present in the early stages of oxidation in dry oxygen.

Conclusions

The techniques used to determine the linear and parabolic rate constants have been reviewed and compared. The optimum X_i technique, wherein the maximum number of data points are fitted to a linear-parabolic expression, was shown to result in unique values for these constants as defined in the Deal-Grove model. It has also been shown that such values of the rate constants have physically relevant information about the oxidation process as described by the linear-parabolic model. Applying this technique to the oxidation data obtained in this study and those published in the literature resulted in activation energies of the rate constants that changed with temperature. Viscous flow occurs in SiO_2 at the same temperature where a break appears in the Arrhenius-type plots of the rate constants. The viscoelastic properties of the oxide and possible additional transport mechanisms in the oxide were discussed as possible physical mechanisms in interpreting the results.

Isotope Studies of Fe-18Cr-3Mo (100) Oxidation Using Raman Spectroscopy

J. C. Hamilton* and R. J. Anderson

Sandia National Laboratories, Livermore, California 94550

ABSTRACT

Raman spectra have been obtained for chromia and iron-chromium spinels grown on an Fe-18Cr-3Mo (100) surface by exposure to oxygen 16, oxygen 18, and a mixture of the two isotopes, at 700°C and 1.3×10^{-4} Pa total pressure. Raman spectroscopy has been combined with ion bombardment to profile the isotopically tagged compounds produced during sequential oxidation in the two isotopes. We conclude that growth of spinel and chromia on this surface occurs predominantly by cation diffusion. Mixing of isotopes by diffusion within the oxide scale during these oxidations was minimal. Mixing of isotopes during ion sputtering was not an impediment to the Raman analysis.

Many experimental techniques are routinely used to determine the predominant transport mechanisms involved in scale growth during high temperature corrosion. The simplest and oldest technique is the placement of inert markers at the surface before corrosion occurs. By noting the position of the marker within the scale after high temperature exposure, it is possible to determine whether scale growth occurs by cation or anion diffusion. Alternatively, sequential exposure to isotopes such as ^{18}O and ^{16}O allows study of the location of these tagged atoms within the oxide scale. For thick scales, this is commonly done using nuclear reactions (1-3). These techniques provide a qualitative picture of the mechanisms responsible for scale growth.

In the case of thinner scales, an alternate technique is appropriate. Sputter ion mass spectroscopy (SIMS) is used to determine the position of isotopically tagged atoms in a scale. The sample is mounted in a vacuum

*Electrochemical Society Active Member.

chamber, and an ion beam is used to sputter atoms from the surface. A fraction of the sputtered atoms are ionized and are detected using a quadrupole mass analyzer. Using this technique with ^{16}O and ^{18}O , uranium oxidation (4) and anodization of tantalum (5) have been studied. More recently, molecular fragments such as $\text{Cr}^{18}\text{O}_2^-$ have been detected with SIMS in studies of chromium oxidation (6-8).

In this paper, we report a new technique using isotopic tagging of scale constituents in conjunction with ion bombardment and Raman spectroscopy. This approach allows depth profiling of the chemical and isotopic composition of the scale. Raman spectroscopy has previously been demonstrated as a probe of oxide composition providing data at temperatures up to 1000°C (9, 10). Raman spectroscopy has been used with ion bombardment to depth profile oxide scales (11, 12). In this paper, we describe oxidation experiments on an Fe-18Cr-3Mo (100) crystal using ^{16}O and ^{18}O isotopes. Raman spectroscopy

was used to determine whether initial oxidation proceeded by anion or cation diffusion in this system.

Experimental

The Fe-18Cr-3Mo single crystal used in this study was oriented to within $1/2^\circ$ of the (100) face, polished, and mounted in a Varian sample holder on an ultrahigh-vacuum manipulator. Provision for temperature measurement and control during annealing and oxidation was provided by attaching a Chromel-Alumel thermocouple to the front face of the sample and mounting a resistive heater behind the sample. The sample was mounted in a vacuum chamber with a base pressure in the 10^{-8} Pa range. A Kratos Minibeam I ion gun, operated in a dynamic mode, was used for ion sputtering to remove oxides and to clean the sample. The ion gun was used in conjunction with Raman scattering to determine the isotopically tagged compounds present through the scale.

Raman spectra were collected using the 488 nm line from a Spectra Physics Model 165 argon ion laser, a SPEX Triplemate triple spectrograph, and a Tracor Northern diode array. The light from the argon laser was focused to a line approximately $50 \mu\text{m} \times 2 \text{mm}$ on the single-crystal sample, producing an estimated power density of about 1 kW/cm^2 . Since the sample was highly reflecting, only a very small fraction of this incident power was absorbed. An $f/2$ lens was used to collect the light scattered for analysis by the spectrograph and diode array. The spectrum was integrated for 200s and the characteristic background of the diode array subsequently subtracted. Each pixel on the diode array corresponded to about one wave number dispersion. The resolution was limited largely by the diode array intensifier which produced a full width at half-maximum of about 5 pixels. Thus, the resolution of the system was about 5 cm^{-1} .

All oxidations reported in this paper were performed at 700°C in 1.3×10^{-4} Pa oxygen. Prior to oxidation the sample was sputtered until Auger spectroscopy showed the bulk composition at the surface. The sample was then annealed for 20 min at 937°C , cooled to 700°C , and oxidized.

Results

Hamilton and Anderson reported that during oxidation of this alloy, the first oxide to appear on the surface was a spinel (13). Auger measurements indicated the presence of iron and chromium in the spinel. For longer oxidation times, chromia was formed. These oxides grew reproducibly if standardized sample cleaning and annealing procedures were used.

We grew iron-chromium spinel and chromia on the Fe-18Cr-3Mo single crystal using 5 and 20 min oxygen exposures, respectively. Exposures were performed at 1.3×10^{-4} Pa in naturally occurring oxygen (99.76% ^{16}O) and in oxygen 18. Figure 1 shows the Raman spectra of spinels grown in natural oxygen (hereafter referred to as oxygen 16) and in oxygen 18. The major spinel peak which appears at 662 cm^{-1} for oxygen 16 spinel is shifted to 628 cm^{-1} when the compound is grown using oxygen 18. These two spectra clearly demonstrate the isotope effect on the Raman peak position. The position of the peak is approximated by the formula

$$\text{shift}(^{18}\text{O}) = \text{shift}(^{16}\text{O}) (16/18)^{1/2}$$

as would be expected from a simple classical model of the vibrational frequency for an oxygen atom attached to an infinitely massive atom. Using this formula the calculated position of the spinel peak with oxygen 18 is 624 cm^{-1} . If the reduced mass for an oxygen and a chromium atom is used, the calculated position of the spinel peak with oxygen 18 becomes 633 cm^{-1} . We conclude that the normal mode giving rise to this scattering peak involves large displacements of the oxygen atoms relative to those of the chromium and iron atoms.

Isotopically substituted spectra were also obtained for chromia. Figure 2 shows the Raman spectra obtained after 20 min exposures at 1.3×10^{-4} Pa. The largest

Fig. 1. Raman spectra of iron-chromium spinels grown on Fe-18Cr-3Mo (100) by 5 min exposures to 1.3×10^{-4} Pa oxygen at 700°C . Oxides were grown using oxygen 16 and oxygen 18, respectively.

chromia peak is shifted from 549 to 520 cm^{-1} when oxygen 18 is substituted for oxygen 16. A smaller chromia peak is shifted from 347 to 332 cm^{-1} when oxygen 18 is substituted for oxygen 16. The peak at 302 cm^{-1} is little shifted by isotope substitution. It appears that the modes at 549 cm^{-1} (A_{1g}) and 347 cm^{-1} (E_g) involve large displacements of the oxygen atoms relative to those of chromium, whereas the mode at 302 cm^{-1} (A_{1g}) involves very small displacements of the oxygen atoms.

Fig. 2. Raman spectra of chromia grown on Fe-18Cr-3Mo (100) by 20 min exposures to 1.3×10^{-4} Pa oxygen at 700°C . Oxides were grown using oxygen 16 and oxygen 18, respectively.

The spectra shown in Fig. 1 and 2 demonstrate that Raman spectroscopy can easily distinguish chromia and iron-chromium spinels grown using oxygen 16 from those grown using oxygen 18. The Raman spectra of oxides grown in mixed oxygen 16 and oxygen 18 are also of interest. Oxides grown under these conditions should have both oxygen isotopes randomly substituted within the lattice. A randomly substituted oxide could also be produced by sequential exposures to oxygen 18 and oxygen 16 if lattice diffusion or other mixing processes occurred during the experiment. We were particularly interested in the Raman spectrum of the mixed oxide, since knowing this spectrum would allow us to determine if mixing occurred in later experiments involving sequential exposure to two oxygen isotopes.

Exposures to mixed oxygen isotopes were accomplished by admitting oxygen 18 to a partial pressure of 6.7×10^{-5} Pa and then adding oxygen 16 to a total pressure of 1.3×10^{-4} Pa. Gases were admitted using Varian variable leak valves, and the total pressure was monitored with an ion gauge. Since the partial pressures of the two isotopes were not monitored simultaneously, it is not possible to be sure of the resulting isotope ratio, although we believe it was close to 1:1. Figure 3 shows the Raman spectra obtained after 5 and 20 min exposures to this mixture. Table I presents the observed peak positions and full widths at half-maximum for the spinel and chromia grown in single isotopes and in the mixture. The effect of a randomly substituted lattice is to produce a Raman shift intermediate between those of oxides grown with single isotopes of O^{16} and O^{18} . The peaks are also somewhat broadened for the randomly substituted lattice. We conclude that the phonon modes involve significant motions of a number of oxygen atoms.

Our next set of experiments involved sequential exposures to the different oxygen isotopes. Raman spectroscopy

Table I. Peak positions and widths

Compound	^{16}O (cm $^{-1}$)	$^{16}O + ^{18}O$ (cm $^{-1}$)	^{18}O (cm $^{-1}$)
Spinel	662 (26 + 1)	650 (31 + 1)	628 (25 + 1)
Chromia	302 (21 + 3)	302 (23 + 3)	301 (18 + 3)
	347 (11 + 3)	341 (19 + 3)	332 (17 + 3)
	549 (14 + 1)	541 (26 + 1)	520 (14 + 1)

Peak positions and observed full widths at half maxima are given. The FWHM include about 5 cm $^{-1}$ of instrumental broadening attributable largely to the diode array. Estimated error limits are given for the FWHM.

copy was combined with ion bombardment in order to depth profile the oxide layer. This combination of techniques has been described in previous publications (11, 12). The depth probed by Raman spectroscopy varies tremendously depending upon the optical absorption of the sample. For highly absorbing samples, the incident beam penetrates only a short distance and the depth probed is small. For transparent or translucent samples, the depth probed is determined by the overlap of the focusing volumes of the lenses used for incident and scattered light. For such materials, the depth probed may be many microns. Optical absorption data has been published for Fe_2O_3 , Fe_3O_4 , and Cr_2O_3 (14, 15); however, we have been unable to locate absorption data for iron-chromium spinels. For 488 nm light in Fe_2O_3 , the absorption coefficient is about 1.8×10^5 cm $^{-1}$ (14). In Fe_3O_4 , the absorption coefficient is about 2×10^4 cm $^{-1}$ (14), and in Cr_2O_3 , the absorption coefficient is about 2×10^4 cm $^{-1}$ (15). In all cases, these absorption coefficients were interpolated from small published plots with consequent large uncertainties. From these absorption coefficients, we estimate probe depths of 50 nm for Fe_2O_3 and 500 nm for Fe_3O_4 and Cr_2O_3 . Experiments performed on oxidized chromium samples in our laboratory suggest a probe depth of about 100 nm for Cr_2O_3 (16).

Based upon these estimates of depth probed, it would seem likely that Raman spectroscopy would sample the entirety of these thin oxide films. However, we note that the absorption coefficients for Cr_2O_3 and Fe_2O_3 change very rapidly with wavelength in the vicinity of 488 nm. Furthermore, our samples likely contain small quantities of other phases in solution (e.g., some Fe_2O_3 in solution in Cr_2O_3). The electronic structure and thus the absorption coefficients of these solids would be expected to be very sensitive to such impurities. For these reasons, and since the absorption coefficient of the spinel is unknown, we are reluctant to attribute quantitative significance to relative peak heights in the Raman spectra published here.

An advantage of the ion bombardment plus Raman spectroscopy technique is that spectra appear to be little affected by beam effects such as reduction or mixing of oxide layers, presumably because the depth probed by Raman spectroscopy is much larger than that damaged by the ion beam (typically tens of angstroms). This insensitivity to lattice damage is a major advantage for chemical characterization. A spinel layer was grown by exposing the sample to oxygen 18 for 4 min, followed by oxygen 16 for 4 min all at 1.3×10^{-4} Pa and 700°C. A Raman spectrum was obtained for the oxidized sample. The sample was then ion bombarded for 2 min, removing about 2 nm of the oxide, and another Raman spectrum was obtained. Additional spectra were obtained after 4, 6, 10, and 16 min of cumulative bombardment time. These spectra are shown in Fig. 4. The major feature seen in the spectra from the oxidized alloy is a peak characteristic of the oxygen 16 spinel. There is also a smaller peak characteristic of the oxygen 18 spinel. After 2 min of sputtering, the oxygen 16 and oxygen 18 spinel peaks are nearly equal in size. Longer sputtering times remove more of the oxygen 16 spinel, until after 10 min of sputtering little or no oxygen 16 spinel is apparent in the spectrum. We conclude that the oxide as grown consisted of an inner layer of oxygen 18 spinel and an outer layer of oxygen 16 spi-

Fig. 3. Raman spectra of iron-chromium spinel and chromia grown on Fe-18Cr-3Mo (100) by 5 and 20 min exposures, respectively, to 1.3×10^{-4} Pa oxygen at 700°C. Oxides were grown in a mixture of oxygen 16 and oxygen 18 with approximately equal proportions of each isotope.

Fig. 4. Raman spectra obtained after various ion bombardment times from an oxide grown on Fe-18Cr-3Mo (100). Oxides were grown by sequential exposure to oxygen 18, then oxygen 16, each for 4 min at 1.3×10^{-4} Pa and 700°C. Spectra are labeled with bombardment time.

nel. The thickness of the outer oxygen 16 spinel is about 4 nm, based on a sputtering rate measured for identical sputtering parameters using an anodized tantalum standard.

In the last exposure reported here, chromia was grown on this alloy by exposing the sample to oxygen 18 for 10 min followed by oxygen 16 for 10 min both at 1.3×10^{-4} Pa and 700°C. Figure 5 shows Raman spectra obtained after 0, 10, 20, and 30 min of cumulative bombardment time. The oxidized alloy shows a Raman spectra with peaks from oxygen 16 chromia and oxygen 18 chromia. The two peaks are comparable in size, although the oxygen 16 chromia peak is a little larger. After 10 min of ion bombardment, only the oxygen 18 chromia peak remains.

Conclusions

The spectra shown in Fig. 1 and 2 clearly demonstrate that oxygen isotope shifts in the Raman scattering from chromia and iron-chromium spinels allow differentiation of oxides grown in oxygen 16 from those grown in oxygen 18. It is also possible to distinguish oxides which are randomly substituted with a mixture of the two isotopes from oxides grown with either isotope alone.

We have combined Raman spectroscopy with ion bombardment to profile the isotopic composition of oxide films grown during sequential exposures to oxygen 18 and oxygen 16 at high temperatures. For both spinels and chromia grown at 700°C in 1.3×10^{-4} Pa oxygen, the predominant mechanism of oxide growth on single crystals of Fe-18Cr-3Mo appears to be cation diffusion of chromium through the oxide. Mixing of the isotopes during ion bombardment appears not to be a problem with Raman analysis, although it complicates SIMS analysis unless molecular ions are detected (7). We see no evidence for interdiffusion of the oxygen isotopes during these exposures. There is no evidence for short-circuit diffusion of oxygen through these films, a result which is perhaps not surprising since the films are quite thin and relatively homogeneous. For such thin films, stresses

Fig. 5. Raman spectra obtained after various ion bombardment times from an oxide grown on Fe-18Cr-3Mo (100). Oxides were grown by sequential exposure to oxygen 18, then oxygen 16, each for 10 min at 1.3×10^{-4} Pa and 700°C. Spectra are labeled with bombardment time.

occurring during growth probably are not sufficient to produce oxide cracking. Furthermore, the use of single-crystal samples should reduce grain boundary effects resulting in a more homogeneous oxide.

Preparation and Properties of Amorphous Boron Nitride Films by Molecular Flow Chemical Vapor Deposition

Katsumitsu Nakamura

Department of Chemistry, College of Humanities and Sciences, Nihon University, Sakurajohsui Setagaya-ku, Tokyo 156, Japan

ABSTRACT

A new chemical vapor deposition method of thin film in molecular flow region (MF-CVD) is proposed, and is applied to the preparation of boron nitride films using ammonia and decaborane reaction gases. It is found that the composition of the films can be closely controlled by regulating the pressure of source gases and stoichiometric boron nitride films deposited at $\text{NH}_3/\text{B}_{10}\text{H}_{14} \geq 20$ at the substrate temperature of 850°C. From the chemical shift of boron $\text{K}\alpha_2$ peak in the x-ray fluorescence spectra, the BN_x films having the composition $x < 0.75$ are mixture of boron and boron nitride. X-ray diffraction study indicates that the films are amorphous. The optical properties of the boron nitride films are also clarified. The energy of the direct allowed transition is estimated to be 5.90 eV.

Boron nitride has properties such as being electrically insulating, chemically inert, thermally stable, resistant to corrosion, and having desirable mechanical properties, and is considered to be one of wide bandgap semiconductors. Potential applications of boron nitride films have been proposed such as high temperature dielectrics (1), heat-dissipation coatings (2), passivation layers (3), diffusion sources of boron (4), and sodium barriers (3). Since boron nitride is highly transparent to x-rays, it can also be used in the fabrication of mask for x-ray lithography (5). Its unique crystal structure and physical properties induce a great deal of scientific and technological interest.

Boron nitride films have been prepared by the reaction of boron trichloride with ammonia at 250° ~ 1200°C (6-9), by the reaction of diborane with ammonia at 250° ~ 1250°C (3, 4, 6, 11), by the reaction of these gases in a plasma (12-14), by pyrolysis of borazine and trichloroborazine at 300° ~ 650° (15) and 1100°C (16), and by sputtering at 250° ~ 900°C (17, 18).

In many reports, boron nitride films deposition have been carried out by the general CVD, which is considered to take place at the thermal equilibrium condition in stagnant layer. Accordingly, boron nitride deposited by the CVD has nearly stoichiometric composition.

Here, we propose a new method in which CVD is carried out at the pressure of molecular flow region ($< 10^{-3}$ torr). We call this method molecular flow chemical vapor deposition (MF-CVD). In this method, the composition of compound films is easily controlled by controlling the component ratio of source gases. Boron nitride films were prepared by MF-CVD using the reaction of decaborane with ammonia. The composition of the films are analyzed by electron probe x-ray microanalysis (EPMA) and electron spectroscopy for chemical analysis (ESCA). Dependences of the gas ratio and substrate temperature on the film composition are investigated. The optical properties of the films are studied in the ultraviolet, visible, and infrared spectral regions.

Experimental

Figure 1 shows a schematic diagram of the apparatus used for the deposition of boron nitride films. The vacuum chamber is evacuated by an oil diffusion pump and a rotary pump system, and ultimate pressure is 2×10^{-7} torr.

Sapphire and silicon were used as the substrates. The substrates were fixed on the tungsten sheet (0.05 mm thick) and were heated from 300° to 1200°C by resistant

heating of the tungsten, as described in the previous paper (19). A tantalum sheet, which was cut into a wedge shape in order to induce the temperature gradient on the substrate, was also used as a substrate. By this method, we obtained the samples of various temperatures between 300° and 800°C using one run. The temperatures of the sapphire and silicon substrates were estimated from that of the tungsten heater, which was determined by an optical pyrometer and thermocouple. The relation between the temperature of the substrate and that of the heater had been obtained. Three points of tantalum substrate temperatures were measured by using thermocouples welded on the substrate surface.

The decaborane was introduced into the growth chamber at 2×10^{-5} torr through the variable leak valve (19), and then the ammonia was introduced at between 2×10^{-5} and 8×10^{-4} torr. The vacuum valve was throttled to maintain the pressure gradient between the growth chamber and the diffusion pump. The pressure was measured by a B-A-type ionization gauge. These pressures were measured as a corresponding nitrogen pressure. We varied the deposition time from 30 to 300 min, depending on the gas pressure and the substrate temperature. The conditions of the film deposition are summarized in Table I.

Fig. 1. Schematic diagram of the apparatus for deposition of boron nitride films by MF-CVD.

Table I. Experimental condition data

Decaborane	2×10^{-5} torr
Ammonia	2×10^{-5} - 8×10^{-4} torr
$\text{NH}_3/\text{B}_{10}\text{H}_{14}$	1-40
Temperature	300°-1150°C
Time	30-300 min
Substrate	Sapphire, Ta, Si

The crystal structures of the films obtained were studied by an x-ray diffraction method. The optical transmission and reflection spectra of the films on sapphire were measured in the wavelength range of 200-2500 nm using a spectrophotometer MPS-50 (Shimadzu). In the transmission and reflection measurements, an uncoated sapphire and an evaporated aluminum film were used as the references, respectively. The absorption coefficient of the films were calculated from the measured transmittance and reflectance. Infrared transmission and refraction spectra of the films deposited on the high resistive silicon wafers were measured in the wavelength range of 2.5-50 μm using an infrared spectrophotometer, DS-701G (Jasco).

The composition of the films was estimated from the x-ray fluorescence intensities of boron and nitrogen measured by EPMA using EMX-SE (Shimadzu). Measurements were carried out at 7 kV acceleration voltage, 0.1 μA sample current, and 100 μm beam diameter by using the lead stearate as a spectral crystal. Since the penetration depth of primary electron was about 6000 \AA , the thicknesses of the films used for analysis were less than 6000 \AA . The intensities of the boron and nitrogen x-ray fluorescence were corrected by those of the standard boron nitride sample. As the films deposited were highly resistive, beryllium was deposited on the sample surface to avoid charge up. The wavelength of x-ray fluorescence of boron $\text{K}\alpha_2$ was 67.5-68.5 \AA , and that of nitrogen $\text{K}\alpha_2$ was 32 \AA . The ESCA spectra of boron- and boron nitride-deposited films are measured by an HP5950 ESCA spectrometer (Hewlett-Packard) with Al $\text{K}\alpha$ (1487 eV).

Results and Discussion

Structure and optical properties of the films.—The color of the films change continuously from black-brown to colorless with the increase of the ammonia pressure. The x-ray diffraction analyses indicate that all the films obtained are amorphous.

The absorption coefficients of a colorless and transparent film in the ultraviolet spectral region are shown in Fig. 2 as a function of incident photon energy. The absorption coefficient α near the absorption edge for direct allowed transition is described as a function of photon energy $h\nu$ as,

$$\alpha h\nu \propto (h\nu - E_g)^{1/2} \quad [1]$$

where E_g is the optical bandgap energy. The variation of $(\alpha h\nu)^2$ with incident photon energy for the boron nitride film is shown in Fig. 3. The figure shows that the boron nitride obtained is a semiconductor having a direct energy gap. The energy gap, E_g , is estimated to be 5.90 eV by the extrapolation of the linear part to the horizontal axis in the figure. This value is larger than the value of 5.80 eV reported by Sano (3) and Zunger (18).

Figure 4 shows the infrared transmission spectra of the films deposited on the silicon substrate at 300°, 400°, 500°, and 700°C with the molar ratio of source gases $\text{NH}_3/\text{B}_{10}\text{H}_{14} = 15$. The four absorption bands are seen in the spectrum of the film deposited at 300°C. These correspond to NH stretching (3200 cm^{-1}) (19, 20), BH stretching (2500 cm^{-1}) (20), and antisymmetric and symmetric NH_3 deformation mode (1550 cm^{-1} , 1405 cm^{-1}) (19). Above 500°C, the absorption due to the BN lattice vibration appears at 1380 and 800 cm^{-1} (21), and that due to the BH and NH stretching vibration disappears. Figure 5 shows the infrared transmission and reflection spectra of the film deposited at 1000°C. The characteristic absorption and reflection band of boron nitride are found at 1380 and 800 cm^{-1} and 1565 and 800 cm^{-1} , respectively.

Fig. 2. The adsorption coefficient of the stoichiometric boron nitride film near absorption edge as a function of incident photon energy.

We can conclude from IR spectra the following. The films deposited at 300°C due to the reaction of decaborane with ammonia still contain B—H and N—H bonds. A B—N bond is, remarkably, formed at 400°C. The film deposited at 500°C is substantially boron nitride. The temperature of 700°C is enough to produce boron nitride because the spectrum of the film deposited at 700°C is almost the same as that of the film deposited at 1000°C.

Analysis of the films by EPMA and ESCA.—The composition of the films was determined from the peak area ratio of boron $\text{K}\alpha_2$ and nitrogen $\text{K}\alpha_2$. Typical peak

Fig. 3. The absorption edge fitted to direct allowed transition

Fig. 4. The effect of substrate temperature on the infrared transmission spectra.

profiles of boron $K\alpha_2$ and nitrogen $K\alpha_2$ of boron and boron nitride films deposited are shown in Fig. 6. The chemical shift of $K\alpha_2$ peak of boron in boron nitride is estimated to be 1.0\AA . The chemical shift of nitrogen $K\alpha_2$ is less than 0.2\AA and is smaller than that of boron.

In Fig. 7 and 8, the dependence of the peak wavelength, the center wavelength at half-maximum and the full width at half maximum (FWHM) of the boron $K\alpha_2$ and nitrogen $K\alpha_2$, on the composition of the films are shown.

The shift of the peak wavelength of boron $K\alpha_2$ from 67.5\AA to 68.5\AA implies the decrease of the gap between the $1s$ and $2p$ energy levels in the boron atom. In order to understand this chemical shift, detailed knowledge of the electronic structure of boron and boron nitride is re-

quired. These electronic structures have been studied experimentally by ESCA (24, 25), AES (26), x-ray emission measurements (27), and, theoretically, by the band structure calculation for boron (28, 29) and boron nitride (30, 31). By adding the energy of boron $K\alpha_2$ 183.7 eV (67.5\AA) in the boron film to the valence band energy of boron 8.43 eV (25), we can obtain 192 eV for the boron $1s$ energy level in the boron film. We can also obtain 194 eV

Fig. 8. The effect of composition ratio of boron nitride film on the wavelength of $N K\alpha_2$; symbols correspond to those in Fig. 7.

for the boron 1s and 400.5 eV for nitrogen 1s by adding the energy of boron $K\alpha_2$ 181 eV (68.5Å) and the nitrogen $K\alpha_2$ 387.5 eV (32Å) in the boron nitride films to the valence band energy of boron nitride, 13 eV (28).

The ESCA spectra for the boron film and the stoichiometric boron nitride film are shown in Fig. 9. In the spectrum shown in part a, the peaks at 192 and 285 eV correspond to boron 1s and carbon 1s, respectively. This carbon peak can be due to carbon impurities in the film or absorbed carbon on the surface. In the spectrum shown in part b, the peaks at 193 and 401 eV correspond to boron 1s and nitrogen 1s, respectively. The spectrum shown in part c shows the valence band (0-50 eV) of the boron nitride films. The peak of 23.0 eV corresponds to nitrogen 2s. The broad peak of 12.7 eV marks the 2p electrons of boron and nitrogen. Since these values agree in the value given above 13 eV, an x-ray emission mechanism, we considered, seems reasonable.

The chemical shift of boron $K\alpha_2$ is in agreement with the value reported by Grusserbaure (32), where the chemical shifts of boron $K\alpha_2$ for the several boron compounds (BN, B_2O_3 , B_4C , BP) were measured by EPMA. The shift is explained by the localization of electron due to the difference in electron negativities.

It is found from Fig.7 that the chemical shift of boron $K\alpha_2$ changes continuously in the nonstoichiometry composition region from boron to boron nitride. However, above the composition $N/B = 0.75$, the chemical shift of boron $K\alpha_2$ is not seen. It is considered that the electronic structure of boron nitride film with the composition $N/B = 0.75$ will be nearly the same structure as that of stoichiometric boron nitride. The FWHM of boron $K\alpha_2$ peak increases with an increase of the composition. It has a maximum value of 2.95Å at about $N/B = 0.5$ and then decreases to 2.0Å at $N/B = 1.0$. The increase of the FWHM is considered to be caused by superposition of the boron $K\alpha_2$ of boron and that of boron nitride. The dependences of the composition of the film on the peak wavelength and the FWHM of the nitrogen $K\alpha_2$ are shown in Fig. 8.

Fig. 9. The ESCA spectra for boron and boron nitride

These dependences are smaller than those of boron $K\alpha_2$. This fact suggests that nitrogen atoms included in the films are always bound with boron atoms. According to these facts, we can conclude that the deposited films are considered to be the mixture of boron and boron nitride in the nonstoichiometric composition region.

The reaction process.—The dependence of the composition of the films on the substrate temperature is shown in Fig. 10 at temperatures between 300° and 1200°C. The temperature dependence of the composition when the pressure ratio of the reaction gases $NH_3/B_{10}H_{14} = 20$ is stronger than that when $NH_3/B_{10}H_{14} = 1$. When $NH_3/B_{10}H_{14} = 20$, the nitrogen content in the films increases with increasing substrate temperature in the temperature range 350°-850°C, and then decreases gently. As the intensity of boron and nitrogen x-ray fluorescence is proportional to the amount of the boron and nitrogen per unit area, the deposition rates of boron and nitrogen are given by dividing the x-ray fluorescence intensity of boron and nitrogen by the deposition time. The temperature dependences of the deposition rate of boron and nitrogen are shown in Fig. 11.

Nitrogen atoms cannot stay on the substrate surface without bonding boron atoms. The dependence of nitrogen deposition rate normalized by the boron deposition rate on the substrate temperature is shown in Fig. 12. The figure shows that the deposition rate is determined by the kinetic process which indicates the increase of nitrogen bound to boron at temperatures between 350° and 850°C. The nitrogen bonding to boron can decrease with an increase of temperature to above 850°C, because the substrate temperature's increasing shortens the residence time of nitrogen on the surface. The reaction of nitrogen with boron requires enough residence time of nitrogen on the deposition surface. The relation between the loga-

Fig. 10. The composition ratio of boron nitride as a function of substrate temperature.

Fig. 11. The deposition rate of boron and nitrogen as a function of substrate temperature.

Fig. 12. Normalized deposition rate of nitrogen by deposition rate of boron as a function of substrate temperature.

rithm of nitrogen deposition rate and the reciprocal absolute temperature is shown in Fig. 13. We obtain the activation energy of this reaction 6.3 and 0.4 kcal/mol at temperatures above and below 850°, respectively. The activation energy of 6.3 kcal/mol is based on the reaction of boron with nitrogen atoms. However, detailed information on this small activation energy is unknown.

At constant decaborane pressure of 2×10^{-5} torr and substrate temperature of 850° and 550°C, the dependence of the film composition on the ammonia pressure at the pressure range of $2 \times 10^{-5} - 8 \times 10^{-4}$ torr is shown in Fig. 14. It is found from the figure that, at the substrate temperature of 850°C, the composition increases with the increase of ammonia pressure up to $NH_3/B_{10}H_{14} = 20$ and then saturates at $N/B = 1.0$.

In general, the amount of the decaborane and ammonia molecule impinging onto the substrate surface, S , is given from the gas dynamics as

$$S = P(Mw/2\pi RT_g) = 5.8 \times 10^{-2} P(Mw/T_g)^{1/2} \quad (\text{g/cm}^2) \quad [2]$$

where P is the gas partial pressure in torr, Mw the molecular weight, R the gas constant, and T_g is the gas temperature considered to be at room temperature (*i.e.*, $T_g =$

Fig. 13. Logarithm of nitrogen deposition rate as a function of reciprocal absolute temperature.

Fig. 14. The effect of ammonia pressure on composition ratio of boron nitride at the constant decaborane pressure 2×10^{-5} torr and substrate temperatures 600° and 850°C.

300 K). By using the Avogadro number, Eq. [2] is rewritten to give the number of impingement molecules, ν , as

$$\nu = 3.5 \times 10^{22} P / (Mw/T)^{1/2} \quad (\text{molecule/cm}^2\text{-s}) \quad [3]$$

When $P = 2 \times 10^{-5}$ torr, $Mw = 122$, and $T_g = 300$ K are substituted in Eq. [3] in the case of decaborane, $\nu_{B_{10}H_{14}} = 3.7 \times 10^{15}$ molecule/cm²-s is obtained. In the case of ammonia, substituting the value of $Mw = 17$ and $T_g = 300$ K in Eq. [3] yields the equation $\nu_{NH_3} = 4.9 \times 10^{20} P$ molecule/cm²-s. The compositions of the films are shown in Fig. 15 as a function of the partial pressure of ammonia together with the ν_{NH_3} at the constant $\nu_{B_{10}H_{14}} = 3.7 \times 10^{15}$ molecule/cm²-s and the substrate temperatures of 600° and 850°C. At the substrate temperature of 850°C, the composition of the films increases with increasing ammonia partial pressure, P_{NH_3} , and the stoichiometric composition is completed above $P_{NH_3} = 4 \times 10^{-4}$ torr, which is $\nu_{NH_3}/\nu_{B_{10}H_{14}} = 54$. In the case of 600°C, the composition at the $P_{NH_3} = 6 \times 10^{-4}$ torr will be essentially much larger than the value of 0.6 obtained in the present study, and stoichiometric composition will be completed at about $P_{NH_3} = 7 \times 10^{-4}$ torr, which is $\nu_{NH_3}/\nu_{B_{10}H_{14}} = 100$. Therefore, it is found that the stoichiometric boron nitride deposits when the ratio of impingement frequency of nitrogen and boron atoms, ν_N/ν_B , is larger than 5.4 and 10 at the substrate temperatures of 850° and 600°C, respectively.

Fig. 15. Composition of boron nitride as a function of ν_{NH_3} at the constant $\nu_{B_{10}H_{14}}$.

The compositions of the films are determined by the impingement frequency ratio of decaborane and ammonia in the nonstoichiometric composition region.

Conclusion

A new CVD method in the molecular flow region is proposed to deposit boron nitride films using the reaction of decaborane with ammonia. At substrate temperatures between 300° and 1200°C, the deposition films are amorphous. Infrared spectra of the films deposited above 700°C shown the characteristic absorption of boron nitride. The optical bandgap is estimated to be 5.90 eV from the optical absorption measurements. It is found from the chemical shift of boron $K\alpha_2$ wavelength that the films of nonstoichiometric composition below the atomic ratio N/B = 0.75 are a mixture of boron and boron nitride. It is also found from the relationship between the pressure ratio of ammonia to decaborane and the film composition that the composition of the films is proportional to the partial pressure ratio at high temperatures. Therefore, the stoichiometric boron nitride films can easily deposit by this method, which is easy to control because composition is determined by the ratio of impingement frequency of source gases onto the substrate surface in all composition regions. This new deposition method must be useful for other compound materials.

Acknowledgments

The author would like to thank Professor K. Yoshimura and A. Itoh for suggesting this study and for their continuous encouragement. He wishes to express his thanks to S. Nakagawa, S. Misawa, and Dr. S. Gonda for helpful contributions and support of this work. Numerous valuable and stimulating discussions with Professor A. Amano, Dr. S. Yoshida, and Dr. F. Shinoki are also acknowledged with many thanks. He is also grateful to T. Asano for a critical reading of the manuscript.

ABSTRACT

This paper reports on the passivating properties of PCVD silicon nitride obtained from the gas mixtures $N_2 + SiH_4$ diluted in Ar (SiH_4/Ar) and $N_2 + SiH_4$ diluted in He (SiH_4/He). Ellipsometric data, Auger data, IR data, mechanical stress, pinholes, and electrical data are presented. The stability of the hydrogen bonds in the silicon nitride is evaluated by low temperature annealing. By comparison of the properties of nitrides made from $N_2 + SiH_4/He$ and $N_2 + SiH_4/Ar$, it is concluded that the former one yields more uniform films, less critical to deposition temperature, while the latter process behaves better for passivating purposes. On the other hand, it is shown that the carrier gas (He or Ar) has a marked influence on the properties of the films, especially on the hydrogen content. It is found that both PCVD nitrides are best described as $Si_xN_yH_zO_t$.

Undoubtedly, the major advantage of PCVD techniques is the low temperature processing involved. Thus, the most important application of PCVD silicon nitride is the passivation of integrated circuits. In this application, the deposition temperature is at most 350°C. Therefore, we examined silicon nitride films deposited at 150°, 200°, and 300°C. A capacitively coupled parallel plate PCVD reactor, manufactured by L.F.E., Incorporated (Model PND-301), has been used for the depositions. A schematic diagram of this apparatus has been given elsewhere (1).

Among the different possible gas mixtures, we used diluted silane (as a safety precaution) and nitrogen. Nitrogen was preferred to ammonia, because it leads to silicon nitride films with a lower hydrogen content. SiH_4 was diluted up to 1.75% in commonly used Ar (SiH_4/Ar) or in He (SiH_4/He). He was used because it was mentioned in the literature (2) that films deposited with SiH_4/He show more uniform properties.

A review of the literature on PCVD silicon nitrides shows that a major part of the work has been done on nitride films deposited by mixtures of SiH_4 and NH_3 . It is also found that the properties of the nitride films not only depend on the gases, but also on the actual reactor configuration used. This explains why some of the results reported here are not fully comparable to previous work on a L.F.E. reactor reported by Dun *et al.* (3). Dun premixes the gases SiH_4 and N_2 , while our equipment configuration consists of a separated gas inlet system.

We found, for both SiH_4/Ar and SiH_4/He gas mixtures, the resulting nitride films to be Si rich and become even more Si rich as deposition temperature increases. This is in agreement with results obtained by Maeda *et al.* (1) in the same L.F.E. reactor. However, Maeda did not examine the influence of different carrier gases. This Si dependency on deposition temperature will be explained by the fact that PCVD silicon nitrides have no fixed stoichiometry, so that they are best described as $Si_xN_yH_zO_t$. From this formula, a consistent definition for the Si/N ratio will be derived.

As our goal was the investigation of the dependence of the passivation properties of silicon nitride on the deposition parameters, we focused our experiments on pinhole detection, step coverage, and low temperature annealing. The purpose of annealing is to investigate how strongly hydrogen is bonded to Si, because in passivation applications H should not escape from the nitride and penetrate

into the underlying circuits. If this should happen, failure of the circuits might occur.

Experimental Techniques and Results

It is well known that the composition of the nitride films depends on the deposition parameters. Two thicknesses of nitride films were evaluated: thin films of about 100 nm were deposited on 2 in. bare silicon wafers for ellipsometric and Auger measurements, while film thicknesses of 500 nm were used for IR, mechanical stress, pinhole, and electrical measurements. As deposition parameters for all films made, we used an RF power (W) of 100W at a frequency of 13.56 MHz, a total pressure (P) of 2700 mtorr for both gas mixtures SiH_4/Ar and SiH_4/He , a N_2/SiH_4 ratio of 1.55 in the case of SiH_4/Ar or 3.05 in the case of SiH_4/He , and deposition temperatures (T) increasing from 150° to 300°C. We did not examine the influence of W and P , as this was already done by previous authors (1, 3). In this way, we obtained a refractive index (n) of 2.0 for $Si_xN_yH_zO_t$ (Ar) and 2.3 for $Si_xN_yH_zO_t$ (He) at $T = 275^\circ C$. These different refractive indexes could be tolerated, first because the aim of this evaluation was to compare changes of (structural) properties related to deposition temperature for both gas mixtures, SiH_4/Ar and SiH_4/He , and, second, because a refractive index of 2.0 does not mean a stoichiometric film due to the incorporation of oxygen and hydrogen in the film, as will be discussed later. Nevertheless, the measurement of n may be considered as a simple criterion to check the deposition conditions. Ellipsometric measurements with an automatic Gaertner ellipsometer (wavelength 632.8 nm, angle of incidence 70°) also give us an idea of the uniformity of the deposited layers. In Table I, we have summarized the uniformity of n and thickness t of the silicon nitride films. It is seen that both gas systems (SiH_4/Ar and SiH_4/He) produce acceptably uniform films, but SiH_4/He leads to somewhat more uniform films. In Fig. 1, the refractive index n and the growth rate G vs. the deposition temperature T are presented. It is seen that n increases with T , while G nearly becomes independent of T in the case of He but increases with T in the case of Ar.

As mentioned above, an important feature of the assessment of silicon nitride deposits is knowledge of how strongly H is bonded to Si. To investigate this, the H content was measured by infrared transmission spectros-

copy. Measurements were done before and after low temperature annealing at 300°C using an automatic dispersive, double beam ratio, recording IR spectrophotometer (Perkin-Elmer Model 1420). This annealing at 300°C , on the one hand, simulates possible further low temperature processing of devices coated with PCVD silicon nitride and, on the other hand, will accelerate the outdiffusion of H which might occur at lower temperatures. To obtain the total atomic percent of H and the amounts of N-H and Si-H bonds, we used the calibration values of Lanford and Rand (4). Therefore, a realistic value of $2.7 \text{ g}/\text{cm}^3$ for the density of the films has been assumed. In Fig. 2, the total atomic percent H is shown vs. deposition temperature T for different annealing times (3 and 10h). In Fig. 3, the percent N-H bonds are shown vs. T for different annealing times. First it is seen that in the case of unannealed films, the amount of H decreases with increasing T . The amount of H is smaller in the case of Ar (18-15%) than in the case of He (27-19%). Annealing for 3 and 10h reduces this H content, but the effect is far more pronounced for SiH_4/He than for SiH_4/Ar . In the latter case, only minor changes are detected. This probably means that H is less tightly bonded in the case of SiH_4/He and diffuses out of the films more easily. This is in accordance with the fact that these films seem to be more po-

rous (see AES results). We may conclude that one has to be aware of the fact that H may escape from silicon nitride films, especially in the case of films made by SiH_4/He . Furthermore, it follows from Fig. 3 that there is a remarkable change in the amount of N-H bonds with changes in deposition temperature and annealing. The amount of N-H bonds decreases both with annealing time and with increasing deposition temperature T . By comparing Fig. 2b and 3b, we see that, in the case of SiH_4/Ar , the amount of Si-H bonds increases, due to annealing time and increasing deposition temperature, in such a way that the total amount of hydrogen stays more or less the same (the sum of N-H and Si-H bonds is used to obtain the total H content).

To get some insight into the composition of the deposited films, we used Auger electron spectroscopy (AES). The different atomic percents of Si, N, and O were measured on Physical Electronics 590 AES. The Auger data were corrected with the atomic H content obtained from IR spectroscopy. In Fig. 4, the atomic percents of Si, N, O, and H are plotted vs. the deposition temperature T . The amount of oxygen ($\geq 2\%$) is within the detectability range of Auger analysis and may not be neglected. As reported by Dun *et al.* (3), we believe the large amounts of oxygen (10%) at low temperatures ($\leq 175^{\circ}\text{C}$) are due to the moisture released from the inner wall of the reactor by the plasma.

From the above considerations, it follows that PCVD nitrides have to be described by the formula $\text{Si}_x\text{N}_y\text{H}_z\text{O}$. A possible molecular structure may be as follows

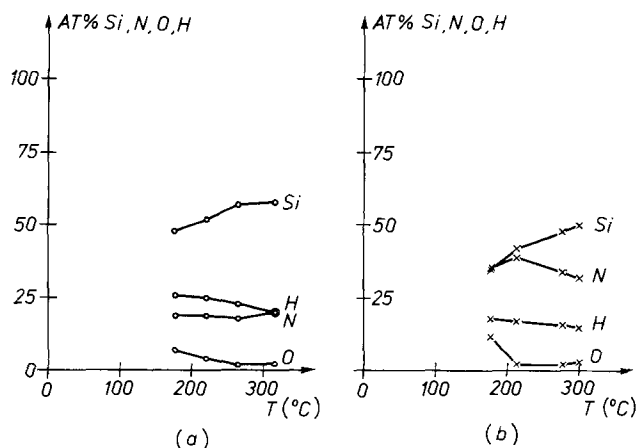

Fig. 4. Atomic percent Si, N, O, H as a function of deposition temperature. a: for SiH_4/He . b: for SiH_4/Ar . o: SiH_4/He . x: SiH_4/Ar .

where we assume that N-N bonds may be neglected and that only Si-N, Si-H, N-H, and Si-O bonds have to be taken into account (N-O bonds were not detected by IR spectroscopy). Therefore, we correct the Si/N ratio used by Dun *et al.* (3) as follows

$$\frac{\text{Si}}{\text{N}} = \frac{[\text{Si a/o}] + 1/4 [\text{H}_\text{N} \text{ a/o}]}{[\text{N a/o}] + 2/3 [\text{O a/o}] + 1/3 [\text{H}_\text{Si} \text{ a/o}]}$$

where the atomic percent (a/o) N-H bonds (H_N) and Si-H bonds (H_Si) are taken into account. For a stoichiometric structure, this ratio always equals 0.75. A value larger than 0.75 must most probably be associated with $\equiv\text{Si}-\text{Si}\equiv$ bonds. In other words, Si/N ratios larger than 0.75 indicate the incorporation of excess Si in the nitrides. In Fig. 5, Si/N vs. deposition temperature is plotted. All films are Si rich, especially in the case of He nitrides, and become even more Si rich as T increases. This is in accordance with the fact that the refractive index n also increases with T (Fig. 1). Indeed, the refractive index may be correlated with the ratio Si/N (1, 5). An increasing Si/N ratio will show an increasing refractive index. However, a refractive index $n = 2.0$ does not necessarily mean stoichiometric silicon nitride Si_3N_4 . As discussed above, we always found films with a composition $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ with $x \neq y \neq z \neq t \neq 0$, and, as is seen from Fig. 1, $n = 2.0$ may be obtained.

Another interesting feature is the sputter rate s of the $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ films under a 2 keV argon bombardment. This sputter rate s (Table II) gives an idea of the density of the films. As a reference value for s , the measured sputter rate of stoichiometric LPCVD Si_3N_4 is included. It follows from Table II that $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ (He) has a high value of s and therefore is porous, while $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ (Ar) deposited at 300°C has the lowest value of s and therefore has the largest density.

Pinholes are another important criterion for characterizing silicon nitride films. In order to measure this feature, Si wafers with 500 nm Al on top were coated with 500 nm nitride and afterwards etched in a 5% NaOH solution for 4 min. The measured pinhole density is shown in Table III. As could be expected, the pinhole density decreases as T increases. At 150°C, $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ (He) behaves better than $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ (Ar), but at 300°C both gas mixtures (SiH_4/He and SiH_4/Ar) produce films of about the same quality. It has to be remarked that, in the case of Ar, a deposition temperature of 300°C is a necessity to obtain good quality films. Although we estimated that the films made with SiH_4/He were more porous, from the point of view of pinholes, both gas systems are about equal.

To investigate the step coverage, we examined the ability of PCVD silicon nitride to cover entirely a gold wire bond on an Al bonding path of an IC. This may be considered as an extreme test case for step coverage. The samples were etched in a 5% NaOH solution. SEM analysis revealed that in the case of the low temperature nitrides, the Al etchant penetrated under the Au bonding balls and etched the Al away. This effect was far less pronounced for nitrides deposited at 300°C. For both gas systems (SiH_4/Ar and SiH_4/He), a rather good protection of the bonding paths was obtained. Nevertheless, nitrides made out of SiH_4/He behaved somewhat better.

It is established that the stability and the step coverage of films are related to the mechanical stress of the films. We therefore evaluated the mechanical stress of silicon nitride films deposited on bare Si wafers. The stress was determined by an interference technique (6). The results for the nitride films made under different deposition conditions are shown in Fig. 6. It is seen that films made with Ar have a compressive stress and show no clear correlation with the deposition temperature T . The measured value of the compressive stress ($2.5 \times 10^8 \text{ N}/\text{m}^2$) is acceptable (7, 8) from the point of view of mechanical stability. On the other hand, films made with He show a clear dependence on T , going from compressive to slightly tensile at 300°C. Pinhole experiments indicated that films at 300°C have to be preferred, which means that $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ made with He should have a somewhat better mechanical stability due to its lower mechanical stress compared to $\text{Si}_x\text{N}_y\text{H}_z\text{O}_t$ deposited with Ar. This is in agreement with the fact that, although both nitrides afforded good protec-

Fig. 6. Stress as a function of deposition temperature. o: SiH_4/He . x: SiH_4/Ar .

tion of the Al bonding paths, fewer failures were detected in the case of He.

Electrical measurements of dielectric constant and of dielectric losses on 500 nm $\text{Si}_x\text{N}_y\text{H}_z\text{O}_w$ capacitors made at 300°C with Al electrodes showed that He nitrides behaved similarly to Ar nitrides. The measurements were performed on a HP 4274A multifrequency LCR meter. Both nitride films have a dielectric constant (ϵ) between 7 and 8 comparable to the bulk value of 7.5. The loss factor ($\tan \delta$) is smaller than 0.2% and nearly constant over the frequency range 100 Hz-100 kHz. The measured breakdown strength (E_b) is 5 MV/cm. This corresponds to the fact that nitrides deposited at 300°C have practically no pinholes, and have a good step coverage, provided the nitrides have a thickness of at least 500 nm. In other words, a thickness of 500 nm for silicon nitride is a necessity. These features, especially the fact of its low loss factor, make PCVD silicon nitride also an attractive isolator for thin film capacitors.

Conclusions

We may conclude from studies of PCVD $\text{Si}_x\text{N}_y\text{H}_z\text{O}_w$ made at different deposition temperatures, using two types of carrier gases (He and Ar) for SiH_4 , that low temperature nitrides (150°-200°C) are less dense and contain more hydrogen than nitrides made at 300°C. SiH_4 diluted in He gives more uniform films and is less critical to deposition temperature, but the release of hydrogen by a low temperature annealing is more pronounced in this case.

As for optimum device protection, a low pinhole density and an acceptably small mechanical stress in the passivation layer are needed; only nitrides made at 300°C are suitable for this purpose. The disadvantage of nitrides made with SiH_4/He is that the hydrogen content is higher

and is easily released by low temperature processing (for instance, an annealing at 300°C), which cannot be tolerated in a number of applications. Apart from this fact, both high deposition temperature nitrides (300°C) have similar and quite acceptable electrical, mechanical, and pinhole performances.

Acknowledgments

Special thanks are expressed to R. Vlaeminck and R. van den Berghe (Bell Telephone, Ghent), who took care of the AES measurements, and to M. Petit (Bell Telephone, Ghent) for his assistance in the IR spectroscopy. The authors also wish to thank F. Vervaeke (Ghent State University) for valuable and helpful discussions.

Complex Plane and ^7Li NMR Studies of Arsenic Sulfide-Based Lithium Glasses

Steven J. Visco, Peter J. Spellane, and John H. Kennedy*

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

The glass forming region of the $\text{LiI-Li}_2\text{S-As}_2\text{S}_3$ system was explored as a function of lithium ion concentration. The most conductive base glass attainable was $\text{Li}_2\text{S-2As}_2\text{S}_3$, and with this glass, up to 45 mole percent LiI could be added. Ionic conductivity was measured using complex plane techniques with room temperature conductivity reaching $2.9 \times 10^{-5} \text{ S-cm}^{-1}$ for 0.45-LiI-0.18 Li_2S -0.37 As_2S_3 . NMR linewidth data were fit to the Hendrickson-Bray equation, and activation energies were obtained. All glasses showed a low activation energy process which was attributed to a local motion. Only the more conductive 30-40% LiI glasses showed a second, higher activation energy process which correlated well with activation energies from conductivity measurements.

There has been a substantial amount of research effort devoted to finding suitable lithium electrolytes, but the search for crystalline lithium electrolytes has not been entirely successful. However, there have been recent exciting advances in the development of lithium ion conductive glasses (1-15). Various glasses have been synthesized (such as $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ and $\text{LiI-Li}_2\text{S-B}_2\text{S}_3$) that have Li^+ conductivities matching the best crystalline electrolytes ($\sigma = 10^{-3} \text{ S-cm}^{-1}$ at 25°C) and stability ranges appropriate for their use in lithium anode batteries (1-5, 10, 15).

In the course of the development of highly conductive vitreous electrolytes, it has been found that the size and polarizability of the anions to which the mobile cations are coordinated are two major factors that govern high ionic mobility. Thus, replacement of oxygen by sulfur in the glass network former and modifier will result in a

higher mobility of the alkali ions, as will doping the glass with LiI as opposed to, say, LiBr. We therefore decided to investigate the glass forming range of the $\text{LiI-Li}_2\text{S-As}_2\text{S}_3$ system. Furthermore, in light of the relatively high Ag^+ conductivities reported for the $\text{AgI-Ag}_2\text{S-As}_2\text{S}_3$ glass system (13), it was anticipated that the lithium analog might exhibit high Li^+ conductivities.

The structures and mechanisms for conduction in glass electrolytes have been studied less often and consequently not understood as well as their crystalline counterparts. We have previously applied the techniques of both solid-state NMR and ac impedance to study the highly conductive $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ glasses (16) and now report their use in the study of $\text{LiI-Li}_2\text{S-As}_2\text{S}_3$ glasses.

^7Li NMR has been used effectively to study the diffusion of Li^+ in Li_3N , Li^+ movement in the conductive lithium borate glasses (17-19), $\text{Li}_2\text{S-GeS}_2$ glasses (20), and Li^+ movement in the $\text{LiI-Li}_2\text{S-P}_2\text{S}_5$ glasses (16). A predomi-

* Electrochemical Society Active Member.

nant cause of NMR line broadening in solids is the magnetic dipole-dipole interaction between nuclei. Thermal activation of ions with increasing temperature tends to remove the dipole-dipole interaction between nuclei of activated ions, and the corresponding NMR line narrows. This phenomenon is called motional narrowing. From the NMR linewidth *vs.* temperature data, the Hendrickson-Bray (HB) equation can be used to calculate the activation energy for Li⁺ motion in the solid (18, 19).

In the ⁷Li NMR investigation of the LiI-Li₂S-P₂S₅ glass system, it was found (16) that the activation energies for ⁷Li motion (high activation energy process) correlated well with the activation energies determined from ionic conductivity measurements made on the same glass samples. In order to further explore the nature of the ionic conductivity in glasses, we have applied the same NMR techniques to a new vitreous lithium electrolyte system, LiI-Li₂S-As₂S₃.

Experimental

Starting materials were anhydrous LiI, Li₂S, and As₂S₃, and all manipulations were performed inside a helium dry box equipped with a purification train to keep residual H₂O and O₂ to less than 1 ppm. The Li₂S-As₂S₃ and LiI-Li₂S-As₂S₃ glasses were prepared by mixing and grinding the reagents in the appropriate proportions, sealing them into thick-walled quartz tubes, and heating the tubes inside an Inconel alloy pipe explosion shield to approximately 900°C for 1 h. The melts were then cooled to 700°C and quenched into a water bath at room temperature. The quenched glass was ground to a fine powder, and, for the NMR study, a portion of the glass sample was sealed under vacuum into 5 mm NMR tubes. Some of the remaining powder was then uniaxially pressed into 1/4 in. diam rods with TiS₂ electrodes on both faces. The vitreous electrolyte rod was finally isostatically pressed at approximately 40,000 psi prior to ionic conductivity measurements.

The ionic conductivity of the glasses was determined using a Solartron 1174 Frequency Response Analyzer interfaced to a Hewlett-Packard 9845B desktop computer and a General Radio 1435 programmable decade resistance box. A correction program was incorporated to compensate for inductive effects arising from electrode leads observed at high frequency (10⁵-10⁶ Hz). The signal across the sample was 350 mV. Complex impedance measurements were recorded from 10⁻² to 10⁻⁶ Hz over the temperature range of 25° to (T_g - 20)°C.

⁷Li NMR spectra were obtained on a Nicolet NT-300 Spectrometer. A broad-band probe was tuned to 116.6157 MHz on a solution sample of LiCl, and the magnetic field homogeneity was optimized for this sample at room temperature. The lithium glass sample was then placed in the magnet and cooled gradually to -100°C. The sample was not spun, and no further attempt was made to improve field homogeneity. Thermal equilibration time varied from 15 to 60 min, depending on the selected temperature. A 90° pulse was applied, and data from 1000 transients were Fourier transformed to yield one broad resonance and fit to a Lorentzian curve.

Results and Discussion

X-ray diffraction.—The Li₂S-2As₂S₃ support glass was doped with lithium iodide over the range of 0-50 mole percent (m/o) LiI. Owing to the hygroscopic nature of the vitreous electrolytes in this study, the glass samples were ground to a fine powder and sealed in plastic bags in the dry box prior to x-ray analysis. X-ray diffraction patterns showed the extent of glass formation to lie between 0 and 45 m/o LiI; (LiI)_x-(0.33Li₂S-0.67As₂S₃)_{1-x} (0 < x < 0.45). At 45 m/o LiI, x-ray diffraction patterns detected traces of LiI microcrystals dispersed in the glass matrix. At higher LiI concentrations, the amount of crystallized LiI detected in the glass increased sharply.

Thermal analysis.—Powdered glass samples were hermetically sealed in aluminum containers in the dry box and analyzed by differential scanning calorimetry. The

powders were examined over the temperature range of 25°-300°C at a scan rate of 20°C/min. All samples in the range of 0-45 m/o LiI exhibited the characteristic glass transition temperature (T_g). T_g showed a gradual decrease from about 170° to 140°C as the LiI content increased to 40 m/o.

Complex impedance and ionic conductivity.—The complex impedance plots of the LiI-Li₂S-As₂S₃ glasses conformed to a straight line intersecting the real axis at approximately a 45° angle and a semicircle (Fig. 1). The real axis intercept of the straight line portion of the complex impedance plots was taken to represent the total resistance of the glass sample. In some cases, as shown in Fig. 1, there was some evidence of a small semicircle that could indicate an interface effect, most likely at the electrodes since grain boundary effects would not be expected in glasses. If the high frequency intercept were used as the measure of bulk conductivity, the values reported here would be increased by several percent, but the more conservative approach was adopted in this investigation. For all glass compositions, the ionic conductivity was found to follow the Arrhenius law: $\sigma = \sigma^0 \exp(-E_a/kT)$, as shown in Fig. 2. The activation energies determined from the Arrhenius plots were found to decrease linearly with increasing LiI content (Fig. 3). Similarly, the total ionic conductivity was observed to increase with increasing LiI; a plot of log σ *vs.* m/o LiI yielded a straight line (Fig. 4). Accordingly, the glass sample with the highest measured ionic conductivity and lowest activation energy (Table I) was the glass with the highest attainable LiI concentration, that is, 0.45LiI-0.18Li₂S-0.37As₂S₃.

The ionic conductivities observed for the LiI-Li₂S-As₂S₃ glasses are lower than those reported (4) and observed in this laboratory for the LiI-Li₂S-P₂S₅ glasses. For example, the reported ionic conductivity for the 0.45LiI-0.37Li₂S-0.18P₂S₅ glass was about 10⁻³ S-cm⁻¹ at 25°C (4), while the 0.45LiI-0.18Li₂S-0.37As₂S₃ glass electrolyte was about 3 ×

Fig. 2. Arrhenius plot for 0.45LiI-0.18Li₂S-0.37As₂S₃ using TiS₂ electrodes. Activation energy = 7.09 kcal/mol.

Fig. 3. Activation energy as a function of LiI content in LiI-Li₂S-As₂S₃ glasses.

Fig. 4. Conductivity at 25°C as a function of LiI content in LiI-Li₂S-As₂S₃ glasses.

10^{-5} S-cm⁻¹ at 25°C. Both of these glass compositions correspond to the saturation limit of LiI in their respective support glasses 2Li₂S-P₂S₅ and Li₂S-As₂S₃. The smaller glass forming range of the Li₂S-As₂S₃ system limits the Li₂S content of the support glass to Li₂S-2As₂S₃. The conductivity of the 2Li₂S-P₂S₅ base glass is reported to be approximately 10^{-4} S-cm⁻¹ (1), whereas the ionic conductivity of the Li₂S-2As₂S₃ base glass is about 3×10^{-9} S-cm⁻¹. Although the ionic conductivities of the (LiI)_r(0.33Li₂S-0.66As₂S₃)_{1-r} glasses increase quite rapidly with increasing Li concentration (Fig. 4), the maximum conductivity is, unfortunately, not as high as other similar glass systems. This may be due to the lower total lithium content at the LiI saturation limit for the LiI-Li₂S-As₂S₃ system as compared to other glass electrolytes such as LiI-Li₂S-P₂S₅ (4) or LiI-Li₂S-B₂S₃ (10).

⁷Li NMR.—The ⁷Li NMR spectra for the lithium glasses investigated exhibited a single ⁷Li resonance over the

temperature range of -100° to 20°C that could be fit to a Lorentzian curve as shown in Fig. 5. Hendrickson and Bray (19), have developed the theory for a case where the solid contains a collection of nonexcited ions on their lattice sites with a very short T_2 relaxation time and a collection of excited ions with a long T_2 . One NMR line will be observed with its width given by a weighted average of the two T_2 's involved

$$T_2 = f_A T_{2A} + f_B T_{2B} = 1/W$$

This very simple concept leads to the Hendrickson-Bray equation (HB) for motional narrowing in solids as

$$\ln(1/W - 1/A) = -(E_a/kT) + \ln(1/B - 1/A)$$

where W is the observed NMR linewidth, A is the experimentally determined rigid-lattice linewidth, and B is the high temperature linewidth. The rigid-lattice linewidth A is determined by lowering the sample temperature until the NMR linewidth no longer broadens. A plot of $\ln(1/W - 1/A)$ vs. $1/T$ should produce a straight line with a slope of $-E_a/k$ and y intercept of $\ln(1/B - 1/A)$, as shown in Fig. 6 and 7 for 20% LiI doping. Here is where confusion begins for so many NMR studies of solid electrolytes. The activation energy for 20% LiI-doped glass from NMR was only 4.5 kcal/mol, while it was 12.9 kcal/mol from conductivity measurements as given in Table I.

A possible explanation presents itself when we look at higher LiI concentrations. For 0.30LiI-0.23Li₂S-0.47As₂S₃ glass (30% LiI), the fit to the HB equation is excellent

Fig. 6. NMR linewidth as a function of temperature for 0.20LiI-0.27Li₂S-0.53As₂S₃ glass. Line is fit using activation energy obtained from Fig. 7.

Fig. 7. NMR linewidth data fit to Hendrickson-Bray equation for 0.20LiI-0.27Li₂S-0.53As₂S₃ glass.

(Fig. 8, 9), but the two low temperature points have moved to a new line with a higher activation energy (10.4 kcal/mol). This agrees reasonably well (based on only two points) with the activation energy obtained from conductivity measurements (8.3 kcal/mol).

The picture becomes clearer yet when the NMR data are analyzed for the 40% LiI glass shown in Fig. 10 and 11. The high activation energy line in Fig. 11 gives a value of

Fig. 10. NMR linewidth as a function of temperature for 0.40LiI-0.20Li₂S-0.40As₂S₃ glass. Line is fit using both activation energies obtained from Fig. 11.

7.1 kcal/mol, which corresponds well with the activation energy of 7.3 kcal/mol determined from conductivity.

Thus, it appears that NMR line narrowing can occur by a low activation energy process involving local motion (rattling in a cage) that does not lead to the long-range motion required for conductivity. At lower temperatures, however, NMR line narrowing is controlled by a high activation energy process involving long-range motion that does correspond to the same process producing ionic conductivity. The values for the parameter *B* in the Hendrickson-Bray equation corroborate this observation. Long-range motion, as in ionic conduction or diffusion, would eliminate the dipole-dipole interaction, whereas a local restricted motion would be far less effective in removing the interaction. Therefore, one would expect the value of *B* corresponding to long-range motion to be considerably smaller than that for short-range motion. From Table II we see, for 40% LiI, that the *B* value for the low temperature region is five orders of magnitude smaller than the high temperature region.

It should be noted that the Hendrickson and Bray approach is only one way to interpret NMR line narrowing. It appears to work satisfactorily, but the experimental fit to theory could be fortuitous. A recent ⁷Li NMR study on conductive glasses, in fact, claims that the activation energy for ⁷Li movement in the glass (which correlates with ionic conductivity) is best obtained from the variation of *T*₁ with temperature (20). Thus, it appears that there is still some confusion as to the interpretation of NMR data, and it will be necessary to follow the evolution of line shape, *T*₂, and *T*₁ with temperature in order to discern

^a First listed value is for low temperature; the second value is for high temperature.

which of the various models best describe the observed phenomena. Unfortunately, such an investigation requires instrumentation not readily available, but we plan to undertake this study in the future.

Conclusion

A new vitreous lithium electrolyte system, LiI-Li₂S-As₂S₃, has been synthesized and investigated by both complex plane impedance and ${}^7\text{Li}$ NMR linewidth techniques.

The observed ionic conductivities of the LiI-Li₂S-As₂S₃ glasses increased dramatically with increasing LiI content, and the corresponding activation energies for ionic conductivity decreased linearly with increasing LiI content. The highest measured conductivity in this system was observed for the LiI-saturated 0.45LiI-0.18Li₂S-0.37As₂S₃ glass, which exhibited an ionic conductivity of 3×10^{-5} S-cm⁻¹ at 25°C.

Fitting the NMR data to the Hendrickson-Bray equation showed that, with 10-20% LiI, one line was obtained with activation energies considerably smaller than the activation energies deduced from conductivity measurements. However, with 30-40% LiI, two lines were obtained with the low temperature lines giving activation energies consistent with conductivity activation energies. The higher temperature NMR activation energies are attributed to a local motion that decreases dipole-dipole interaction, while the low temperature NMR activation energies are attributed to a long-range motion that also

reflects ionic conductivity. The fact that long-range motion was not seen from ${}^7\text{Li}$ NMR measurements of 10-20% LiI provides additional evidence that these glass compositions are poor ionic conductors.

High Sensitivity H₂S Gas Sensors

Shinji Kanefusa, Masayoshi Nitta, and Miyoshi Haradome

Physical Science Laboratories, College of Industrial Technology, Nihon University, Narashino-shi, Chiba-ken 275, Japan

ABSTRACT

H₂S gas sensors have been fabricated by the admixture of SnO₂-based powders and alcohol, hydrophobic silica, or trimethylchlorosilane. Their responses to H₂S gas have been investigated. It is found that the resistivity of the sensor whose surface is covered by trimethyl-silyl groups strongly depends on the H₂S gas concentration. A 10 ppm H₂S gas concentration changes its resistivity to a value 1000 times lower than that in air, in spite of there being small changes in the sensor resistivity in other reducing gases. By covering the sensor surface with organic materials, development of sensitivity and selectivity for H₂S gas has been achieved. Also, the mechanism of reaction between the organic materials on the surfaces of sensors and H₂S gas is discussed.

Many methods for detecting harmful gases have been proposed in order to prevent a dangerous environment (1-5). Among these methods, sensors made of semiconductors have been most interesting because of the following attractive features. They are portable, less expensive, and also detect low gas concentration sensitively and reproducibly. Active development of gas sensors using metal oxide semiconductors has been made in this dec-

ade (6-11). It is known that the addition of metal catalysts such as Pd, Pt, and other transition metals to semiconductors increases the detection sensitivity (4, 5, 9, 12) and selectivity (13). Furthermore, the selectivity could be improved by the appropriate choice of sensor operating temperatures (14). By utilizing the above characteristics, sensors made of SnO₂ for C₃H₈, CH₄, CO, or H₂S gases, and of ZnO for petroleum gases, have been reported (4, 8, 9, 15,

16). Because of its harmful nature, H₂S is one of the gases most desired to be detected easily (17). Nevertheless, there are few reports about H₂S gas detection, and the mechanism of reaction between H₂S gas and the surface of semiconductors is not well understood. In general, H₂S gas frequently occurs with reducing gases such as H₂, CO, and CH₄. Therefore, selectivity for H₂S gas against these reducing gases must be high. H₂S gas concentration to be detected for practical use is 10 ppm, corresponding to the tolerable gas concentration. On the other hand, the comparable CO, H₂, and CH₄ gas concentration limits are 50 ppm, 0.4%, and 0.5%, respectively.¹ It is desired that H₂S gas sensors exhibit low sensitivity to CO, H₂, and CH₄ gases in the above gas concentration to prevent the false detection of H₂S gas.

Recently, we discovered a new method for improving the selectivity of CO gas sensors by covering their surface with organic materials (16). With this method, we try here to develop a H₂S gas sensor based on SnO₂. We have achieved a highly sensitive and selective sensor for H₂S gas by using SnO₂ whose surface is covered with trimethyl-silyl groups.

Experimental

SnO₂ was made from SnSO₄ by firing at 600°C for 1h in air. Sensors have been prepared in the following way. SnO₂ powder or SnO₂ powder mixed with PdCl₂ which were previously sintered at 800°C for 1h in air were, respectively, dispersed in alcohol, hydrophobic silica (HP), or trimethylchlorosilane (TM) uniformly to make a paste and were painted between the Au electrodes (distance: 0.1 mm) on a 96% alumina substrate (area: 3.0 × 1.5 mm²). Then the painted samples were fired at 400°C for 1h in air after drying at 80°C for 24h to prevent cracks on the surface of the sensors. On the other side of the substrate, an RuO₂ resistor had been previously printed by use of thick film technology and fired at 780°C for 10 min. It is used as a heater to keep the sensor at an adequate temperature. Hydrophobic silica was made by the reaction between hydrophilic silica and trimethylchlorosilane. It is known that the surface of the sensor mixed with hydrophobic silica is covered with trimethyl-silyl groups (16).

The experimental system and circuit are as already reported (9). A pickup resistor (5-300 kΩ) was connected in series to the sensor, and a dc voltage (10.0V) was applied across the circuit. The resistivity change was calculated from the changes in the detection voltage across the pickup resistor. For practical use, the resistivity changes were measured in gas concentration of 10 ppm, 50 ppm, 0.4%, and 0.5% for H₂S, CO, H₂, and CH₄ gases, respectively. The purity of test gases was higher than 99.9%. The sensor temperatures were measured by an IR thermometer and controlled by the change in the applied voltage to the heater.

Results

In Fig. 1 are shown the dependences of sensitivity to various gases on the concentration of Pd in SnO₂ sensors held at 120°C. The vertical scale is the sensitivity and is expressed by the relative resistivity change. R₀ is the resistivity of the sensor in air and R is that in air containing the test gas. The symbols on the figure are the average values of several measurements, for the response differed slightly between sensors even though they were prepared similarly. The sensitivities for CH₄ and CO gases are very low, though they increase slightly with increasing Pd concentration in SnO₂. On the other hand, SnO₂-based sensors exhibit high sensitivities both to H₂S and H₂ gases. Sensitivities to both gases increase with increase of the concentration of Pd in SnO₂, and the sensors with more than 1 weight percent (w/o) Pd exhibit the same sensitivity to these gases. Thus, selective detection of H₂S gas in an environment containing H₂ gas cannot be done by use

¹The gas concentrations correspond to standard levels decided by the Society of Safety of High Pressure Gas Engineering: 1/10 of the lower explosion limits for combustible gases such as H₂ and CH₄ gases, and tolerable gas concentrations for 8h work days for toxic gases such as H₂S and CO.

Fig. 1. Relations between the sensitivity and the concentration of Pd in SnO₂ sensors at 120°C.

of these sensors. Therefore, the experiments were done by using sensors having a concentration of less than 1 w/o Pd in SnO₂.

A typical result of sensors having less than 1 w/o Pd at 100°C of sensor temperature is shown in Fig. 2. The result of the sensor mixed with hydrophobic silica (5 w/o) is also shown in the figure. Dotted and solid lines indicate the characteristics of sensors with and without hydrophobic silica, respectively. Triangles and circles denote the characteristics for H₂S gas (10 ppm) and H₂ gas (0.4%), respectively. It is clear that additions of Pd enhance the sensitivity to both H₂S and H₂ gases. Considering selective detection, we find it undesirable for the sensors to have Pd added. On the other hand, Pd-doped SnO₂ with hydrophobic silica exhibits high sensitivities to H₂S gas and shows a remarkable decrease of the sensitivity to H₂ gas. The selectivity is enhanced by the mixture of hydrophobic silica and Pd with the sensors. Furthermore, the most selective sensor for H₂S gas is obtained by SnO₂ with hydrophobic silica.

As shown in Fig. 1 and 2, the sensitivity indicated by $(R_0 - R)/R_0$ is useful for comparing the characteristics of sensors for practical use. However, the value of $(R_0 - R)/R_0$ converges to 1 with increase of the sensitivity. Therefore, the sensitivity is, hereafter, represented by R/R_0 .

Next, the dependences of the sensitivity of SnO₂ containing hydrophobic silica and SnO₂ sensors on the sen-

Fig. 2. Relations between the sensitivity and the concentration of Pd in SnO₂ sensors at 100°C.

Fig. 3. Relations between the sensitivity and the sensor temperature. H_2S gas concentration is 10 ppm.

sensor temperature were investigated. The results are shown in Fig. 3. The ordinate R/R_0 corresponds to the sensitivity to H_2S gas. In this figure, the lower the numerical value of the R/R_0 , the higher the sensitivity. The sensitivity for each sensor reaches a maximum at 45°C , and it is clear that the hydrophobic silica enhances the sensitivity about 100-fold. The sensitivity of the sensor whose surface is hydrophobic monotonically decreases with increase of sensor temperature above 45°C . On the other hand, the sensitivity of the sensor whose surface is not hydrophobic increases with increase of sensor temperature above 100°C .

Figure 4 shows the response time of sensors as a function of temperature. The response time defines the time taken for the sensitivity to reach 80% of the saturation

Fig. 4. Relations between the 80% response time and the sensor temperature. H_2S gas concentration is 10 ppm.

values after the contact of the test gas and the surface of the sensors. The response of SnO_2 sensors becomes rapid uniformly with increasing sensor temperature. The curve for SnO_2 with hydrophobic silica has a structure and exhibits a maximum around 120°C . It is, however, clear that the response to gas detection improves by adding the hydrophobic silica to sensors in these temperature regions. Characteristics of recovery time of sensors after the removal of the test gas from the environment surrounding the sensors were also examined. It was found that the higher the sensor temperature, the better the recovery characteristic, for all sensors.

Figure 5 shows the resistivity changes of various sensors as a function of the elapsed time after the injection of H_2S gas (10 ppm) into the chamber at 100°C of sensor temperature. The circles in the figure indicate the response time which was defined above and in Fig. 4. As shown in Fig. 5, the response time of the " $\text{SnO}_2 + \text{TM}$ " sensor is the shortest among these four sensors, and the sensitivities of " $\text{SnO}_2 + \text{TM}$ " and " $\text{SnO}_2 + \text{Pd}$ " are the highest. The " $\text{SnO}_2 + \text{Pd}$ " sensor is, however, poor in selectivity, as shown in Fig. 1 and 2. Therefore, it is clear that the sensitivity and responsiveness of a H_2S gas sensor made of SnO_2 are improved by the mixture of trimethylchlorosilane. From the comparison of the characteristics between the sensors with hydrophobic silica and with trimethylchlorosilane, it is presumed that the silica has no effect on the development of sensitivity and response time in sensors without Pd.

The temperature dependence of the resistivities for those four sensors is shown in Fig. 6. The heating rate of the sensor temperature was $4.4^\circ\text{C}/\text{min}$. The difference of the resistivity in the atmosphere between air and air containing H_2S gas will correspond to the sensitivity to H_2S gas. From Fig. 6, it is small around 400°C and becomes remarkably higher as the sensor temperature decreases. Therefore, it is considered that the response of the sensors to H_2S gas will increase with decrease of sensor temperature.

Discussion

H_2S gas has high reduction activity at room temperature in air containing moisture (19). However, it is known that H_2S gas decomposes to H_2 and S above 400°C (19). Therefore, the sensitivity to H_2S gas will decrease above 400°C of sensor temperature. This explains why the difference of the resistivity in the atmosphere between air and air containing H_2S gas becomes small around 400°C of sensor temperature as shown in Fig. 6. It is expected that

Fig. 5. Decay curves of the resistivity with the elapsed time after the exposure to H_2S gas (10 ppm) at 100°C of the sensor temperature.

Fig. 6. Temperature dependence of the resistivity in air and in air containing H₂S gas (10 ppm).

the surface of sensors will contain adsorbed oxygen and OH radicals in air. Furthermore, it is well known that the resistivity decreases and increases with the removal of adsorbed oxygen and OH radicals from the surface of SnO₂-based sensors, respectively (20). Therefore, the resistivity of the sensor in air depends on the amount of the adsorbed oxygen and OH radicals. It is presumed that the adsorbed oxygen will desorb from the surface when the H₂S gas reacts with the surface of SnO₂, and the resistivity of sensor thence decreases. H₂S gas will attack the adsorbed OH radicals simultaneously. The changes in the resistivity of sensors will be due to the reaction of H₂S gas with the adsorbed oxygen and with OH radicals. Therefore, the resistivity of sensors whose surface has no OH radicals will decrease noticeably when the sensor is exposed to H₂S gas. In taking account of the results that the trimethyl-silyl groups do not desorb from the surface below 500°C of sensor temperature (18, 21), it is considered that the surface of the sensor mixed with hydrophobic silica or the sensor mixed with trimethylchlorosilane will be hydrophobic in the region of examined temperatures and that there will be few adsorbed OH radicals on the surface of the sensor. This is why their sensitivity to H₂S gas is high. These considerations suggest the results described as follows. As shown in Fig. 3, the sensitivity for H₂S gas of the sensor whose surface is hydrophobic decreases with increase of sensor temperature. On the other hand, the sensitivity of SnO₂ whose surface is not hydrophobic increases with increase of sensor temperature above 100°C, since the amount of OH radicals on the surface of SnO₂ decreases above 100°C of sensor temperature; then the minimum of sensitivity would be observed at 100°C. It is, however, not clear why the highest sensitivity of every

sensor to H₂S gas is obtained around 45°C of sensor temperature. That would be due to other unknown factors. Further experiments about the phenomenon will be carried out in the near future. From the results obtained in this paper, it becomes clear that the condition of the sensor surface would have a large influence on the sensitivity and the selectivity.

Conclusion

The sensitivity of SnO₂ sensors to H₂S gas was enhanced, and that to H₂ gas decreased, by covering the sensor surface with trimethyl-silyl groups. The highest sensitivity and selectivity of the sensors were obtained at 45°C sensor temperature. Taking account of the amount of OH radicals adsorbed on the surface of sensors, we find that almost all of the results in this paper are thereby well explained, except for why the sensitivity of sensors has maximum at 45°C.

The Role of Oxygen in the Redox Chemistry of Lutetium Diphthalocyanine

M. M. Nicholson and T. P. Weismuller
(pp. 2311-2313, Vol. 131, no. 10)

Maurice L'Her:¹ From their observations of the evolution of the UV-visible spectra, the authors conclude that oxygen reversibly binds to lutetium diphthalocyanine dissolved in dimethylformamide (DMF). After dissolution of the lutetium complex, the spectrum is typical of the blue reduced form (maxima at 614 and 693 nm), the compound being reduced by impurities of the solvent, presumably aliphatic amines. When acidified, the solution turns green, the spectrum being the one well-accepted by many authors for the green molecular lutetium diphthalocyanine.^{2,3} If oxygen is removed, the solution slowly goes back to blue, but with a spectrum different from the one observed in unacidified DMF.

These facts are not clear evidences of oxygen addition to the lanthanide diphthalocyanine as stated by the authors. In our opinion, the blue-to-green color change is due to the oxidation of the reduced blue form to the green redox state, oxygen becoming a more powerful oxidizer in the acidified solvent. We observed a very similar behavior in methylene chloride where the blue diphthalocyanine, prepared by electrolysis, is unaffected by air unless an acid is added. Simultaneously, one records the characteristic voltammogram of the green form at a rotating disk electrode instead of the two oxidation waves of the blue complex.⁴ The reverse color change from green to blue in DMF after oxygen removal could be explained by the degradation of the solvent giving back dimethylamine, a known decomposition reaction pro-

moted by acids and bases.⁵ The green-to-blue color change by oxygen removal did not occur in dimethylsulfoxide, nor in acetone. When we prepared solutions of the lutetium diphthalocyanine in various solvents under rigorous exclusion of oxygen, after heating the compound under vacuum, these solutions always exhibited the characteristic spectrum of the green complex, the same as curve a in Fig. 4. Furthermore, the molecular structure obtained from x-ray diffraction analysis of the neodymium diphthalocyanine did not show any evidence of oxygen inclusion in the crystal.⁶ These facts are in favor of a chemical oxidation in acidified DMF instead of a reversible oxygen addition to the lutetium diphthalocyanine.

M. M. Nicholson⁷ and T. P. Weismuller:⁸ We proposed that oxygen adds reversibly to the blue reduction product LuHPC₂, which is present after acidification of the dye solution prepared in DMF that has not been specially purified. Such an addition, forming LuHPC₂⁺O₂⁻, is a chemical oxidation of the blue species to a green one.

The species LuPC₂ and its protonated version LuHPC₂⁺ represent the same oxidation state of the organic complex. Their absorption spectra in solution may be similar, and neither of these forms would be expected to add dioxygen in a pure solvent that contains no reducing agent.

Our paper also pointed out that several apparent anomalies in the chemistry of rare-earth diphthalocyanines may be explained by the existence of an oxygen adduct with a formula analogous to that of the known complex MnPc⁺O₂⁻. Finally, it should be noted that the crystallographic study by Kasuga *et al.*⁶ was made with a dichloromethane solvate of neodymium diphthalocyanine. This is not strictly comparable to the systems discussed here. Further research on the question of oxygen addition is, of course, desirable.

Electrodeposition of Ruthenium from a LiCl-KCl Melt

A. Bettelheim, F. Broitman, U. Mor, and R. Harth

Nuclear Research Center-Negev, Beer-Sheva 84190, Israel

Electroplating from molten salts seems a promising way of surface finishing, both with respect to protection against corrosion, high temperature oxidation and to the possibility of obtaining very hard surfaces with special mechanical properties (1). The platinum group metals: Pt, Pd, Rh, Ir, Ru and Os can be deposited in aqueous electrolytes (2) only in limited thickness ($<5 \mu\text{m}$). Apparently, it is difficult to eliminate stress cracking from these electrolytes. Better deposits are obtained from fused salt electrolytes, particularly because the deposits show better ductility and a freedom from porosity compared with those obtained in aqueous solutions.

It has been reported that LiCl-KCl eutectic melts at 450°C give deposits which are always dendritic and non adherent (3) while greater success is obtained in molten cyanide systems operated between 450 and 600°C . In the present study, we show that thick, adherent and compact electrodeposits of ruthenium (and other platinum metals, such as Ir, as it will be described in a future publication) are obtained from a LiCl-KCl (45-55 w/o) melt at temperatures as low as 400°C , provided that the melt is saturated with HCl.

An alumina crucible was used to contain the electrolyte. The reference electrode was a nickel wire immersed in a melt containing 10^{-2}M NiCl_2 and separated from the bulk using a thin walled pyrex tube. The cathode and anode were graphite rods, 6 mm in diameter and their pretreatment, before immersion in the melt, was according to procedures described in the

literature (4). Using cyclic voltammetry, the roughness factor was estimated to be between 20 to 30.

Figure 1 shows a voltammetric curve for the reduction of RuCl_3 in an HCl saturated LiCl-KCl melt (curve (a)). The half-wave potential is 0.39 V and the limiting current increases linearly with the Ru(III) ion concentration in the melt. Moreover, a stripping peak with $E_p=0.85$ V, observed when the potential is scanned anodically, indicates that the electrodic process with $E_{1/2}=0.39$ V yields metallic ruthenium. The voltammetric curve (b) is obtained when argon is introduced in the melt to remove all dissolved HCl. From comparison of the limiting currents, it can be concluded that the Ru(III) solubility in the acidic melt is twice higher than found in an argon saturated melt. Moreover, when precautions are not taken to avoid introduction of moisture to the melt, the voltammetric wave is not well shaped and the limiting current decreases as much as fifth as that found in the HCl saturated melt.

Electrodeposition of ruthenium was achieved galvanostatically and the potential of the cathode vs. the reference electrode was followed during the electrolysis. The amount of ruthenium deposited on the surface was estimated by chronopotentiometric stripping curves. On application of a constant anodic current, the electrode potential was nearly constant (0.9 V) until no metallic ruthenium was present on the surface; then it jumped instantly to 1.15 V, which corresponds to that of Cl_2 evolution (5). The electrochemical conditions for electrodeposition and the corresponding calculated thickness of the various coatings are listed in table I. Coatings up to $4.4 \mu\text{m}$ thick with a cathodic current efficiency of 77% were produced in a bath containing a Ru ion

concentration of 0.26 w/o and applying a current density of 5.4 mA cm^{-2} . Increasing twofold this concentration, the current density could be raised to 6.8 mA cm^{-2} and adhesive coatings of $14 \mu\text{m}$ could be obtained with a current efficiency of 70%. Thin but bright deposits were obtained at current densities lower than 2 mA cm^{-2} (fig. 2 (a)). When the current density was increased to higher values, ruthenium electrodeposits were dark but appeared to be tightly adherent to the substrates, with no cracks or large imperfections (fig. 2 (b)). If HCl was continuously supplied to the melt, the deterioration of ruthenium chloride, as verified by voltammetry, was less than 25% after a period of 350 hours.

The different behavior of Ru(III) ions in acidic and basic melts seems to indicate a hydrolysis reaction similar to that suggested for Cr(III) in molten LiCl-KCl (6):

This reaction is expected to be promoted by the presence of water or products of the hydrolytic decomposition of molten LiCl-KCl, i.e. hydroxide and oxide ions, and suppressed by gaseous HCl. This can also account for the successful electrodeposition of Ru in HCl saturated LiCl-KCl melts. The high stability of the baths for large periods of time is probably due to the low melting point of the chloride melt (about 200°C lower than the cyanide melts), allowing operation at temperatures where thermal decomposition of the ruthenium salt is probably slow.

The electrodeposition on metallic substrates was not successful in the acidic LiCl-KCl melt. However, preliminary experiments showed that several metals (as Mo and stainless steel) could be coated with Ru in this melt after applying protective precoatings of Pt or Rh from aqueous solutions.

Table I: Electrodeposition of ruthenium on graphite from a LiCl-KCl melt at 400°C :

A Mechanism of Electric Potential Generated on the Dissolution and Precipitation of Electrolytes

S. A. Khan, B. N. Tripathi, and T. N. Mishra¹

Department of Chemistry, St. Andrew's College, Gorakhpur 273 001, India

ABSTRACT

A mechanism of electric potential generated on the dissolution and precipitation of electrolytes has been developed. Dissolution potential is found to be equal in magnitude but opposite in sign of precipitation potential. Theoretical values of true dissolution and true precipitation potentials have been calculated and compared with the experimental data. It has been demonstrated that the true dissolution potential does not depend on the concentration of the medium and that true precipitation potential does not depend on undercooling.

The development of electric potential on the dissolution and precipitation of electrolytes has been fairly well established (1-13). Comprehensive studies on these potentials have been reported by Rastogi and co-workers (2-5). These workers have given the operational and conceptual definitions of various types of potentials associated with the crystallization and dissolution processes (5). It has been suggested by these workers (4, 5) that the sign and magnitude of precipitation and dissolution potentials depend on the unequal mobilities of cations and anions. They have postulated that the precipitation potential develops due to a difference in the rate of attachment of cations and anions during crystallization and dissolution potential develops due to a difference in the rate of detachment of cations and anions during dissolution.

Girdhar and co-workers (6-8) have reported their studies on the precipitation and dissolution potentials of electrolytes in aqueous and nonaqueous mediums. Their results are in general agreement with those of Rastogi and co-workers. Ibl and co-workers (9, 10) have also reported careful experiments on crystallization and dissolution potentials using single crystals. They have used "corrosion" model based on the difference in the kinetics of dissolution of cations and anions to explain their results. Vishnu and Khan (11) have also reported their studies on dissolution potential of alkali halides in nonaqueous medium such as D.M.F. Their results are also in general agreement with those of Rastogi *et al.*

These experimental studies show that the precipitation and dissolution potentials depend on (i) nature of the electrolyte, (ii) concentration of the medium, (iii) temperature, (iv) time, and (v) mobilities of cations and anions.

Quite recently, Rastogi and Khan (12, 13) have developed theories of dissolution and precipitation potentials. Although Rastogi and Khan's theory of dissolution potential (12) could explain qualitatively most of the experimental data on the measurement of dissolution potential, they could not make use of this theory for a quantitative calculation of dissolution potential. However, they have given only a semiquantitative treatment of the theory of precipitation potential (13) which is based on an inequality but the results are far from satisfactory. Further studies are necessary in order to have a clear understanding about the mechanism of the development of these potentials.

¹ Present address: Department of Chemistry, Gorakhpur University, Gorakhpur 273 001, India.

In the present communication, an attempt has been made to have a more comprehensive view of the processes responsible for the development of dissolution and precipitation potentials. The potential recorded by the dissolution cell may be split into (i) true dissolution potential, (ii) phase potential, (iii) diffusion potential, (iv) potential due to the establishment of a concentration cell with transference during the course of dissolution, (v) Nernst potential, and (vi) thermodiffusion potential. However, all are not simultaneously applicable. Similar splitting of observed precipitation potential has also been made. Experimental results on the measurement of these potentials are reported in the present communication. An attempt has also been made to get a quantitative check of Rastogi and Khan's thermodynamic theories of dissolution (12) and precipitation (13) potentials. An improvement of the theory of precipitation potential has also been made. True precipitation potential is found to be just the opposite of true dissolution potential.

Theory of Dissolution Potential

The physics of the development of dissolution potential can be understood from the schematic diagram given in Fig. 1. When a platinum electrode loaded with the crystals of an electrolyte (α phase) is introduced in the solvent, dissolution starts immediately, ions detach from the surface of the crystal, and a narrow zone of solute-enriched crystal/solution interface is set up in the vicinity of crystal surface. We may call it the β zone for convenience. From the kinetics of dissolution, it has been found that the process of dissolution is diffusion controlled and the crystal maintains a state of near saturation in the narrow zone adjacent to it (14). The crystal side of this zone maintains a state of supersaturation where the ions are unhydrated or only partially hydrated. The solution side of this zone maintains a state of near saturation. The ions diffuse away from β phase and go into the bulk of the solvent, where a concentration gradient is set up. We will call it a δ phase for convenience.

The process of dissolution of an electrolyte may be visualized to be made up of the following main steps: (i) detachment of unhydrated cations and anions from kink sites and their diffusion toward dissolving crystal surface in α phase; (ii) diffusion of partially solvated cations and anions from a locally solute enriched crystal/solution interface into a zone of near-saturation on the other side of β phase; (iii) complete solvation of cations and anions on

Fig. 1. Schematic diagram for the development of dissolution potential. α = solid phase; β = crystal/solution interface; and δ = solution phase. E_1 and E_2 are the platinum electrodes.

the solution side of β phase, where a state of saturation is maintained throughout the course of the dissolution process; (iv) diffusion of completely solvated ions from saturated zone (solution side of β phase) into the bulk of the solution (δ phase); and (v) adsorption of heat of solvation, which may occur stepwise after each of the solvation steps.

Conditions at a dissolving crystal surface are not completely understood, but it would not be expected that the tendencies (as measured by exchange current density) of the cation and the anion to pass from crystal into solution would be exactly equal because of intrinsic energy barriers. The rates of detachment of cations and anions from the surface of the crystal, step (i), will be different. However, electrostatic coupling in β phase forces the fluxes J_+ and J_- of cations and anions to be equal. Or in other words, electrostatically generated potential $(\Delta\phi)_{\text{diss}}$ hinders the faster process and accelerates the slower process, so that J_+ and J_- tend to be equal. The unequal rates will be directly proportional to the mobilities of respective ions in the β phase. Since the crystal side of β phase is solute enriched, the ions in this phase will be mostly unsolvated or only partially solvated. Therefore, it may be noted that the mobilities of cations and anions in β phase will be quite different from conventional mobilities. Rastogi and Khan (12) have also pointed out such a difference in the two types of mobilities in their thermodynamic theory of dissolution potential.

It is obvious that the true dissolution potential—a term coined by Rastogi *et al.* (4, 5) in 1970—would be generated between the steps (i) and (ii). Because of step (iv), a diffusion potential would also be generated. Since the α phase remains in equilibrium with the β phase till the end of dissolution process, the equilibrium phase potential would also be present at the dissolving crystal/solution interface. Moreover, since the electrodes E_1 and E_2 remain situated in the regions of different concentrations till the completion of dissolution process, and the transfer of ions keeps on taking place from the region around the electrode E_1 towards the region around the electrode E_2 , a potential difference would also be developed on account of the establishment of a concentration cell with transference. The potential difference between the electrodes E_1 and E_2 would also include the Nernst potential and thermodiffusion potential. The latter will be developed on account of enthalpy changes involved in various solvation steps. However, their values are negligible in comparison to other potentials.

The observed dissolution potential would thus be given by the equation

$$(\Delta\phi)_{\text{obs(diss)}} = (\Delta\phi)_{\text{diss}} + (\Delta\phi)_{\text{phase}} + (\Delta\phi)_{\text{diff}} + (\Delta\phi)_{\text{cc}} \quad [1]$$

where the first, second, third, and fourth term on the rhs of the above equation are true dissolution potential, phase potential, diffusion potential, and potential of the concentration cell with transference, respectively.

Thus, in order to evaluate the experimental value of true dissolution potential, we can make use of the following equation

$$(\Delta\phi)_{\text{diss}} = (\Delta\phi)_{\text{obs(diss)}} - [(\Delta\phi)_{\text{phase}} + (\Delta\phi)_{\text{diff}} + (\Delta\phi)_{\text{cc}}] \quad [2]$$

It is, therefore, obvious that the experimental values of all the terms on rhs of Eq. [2] should be known before one can evaluate the experimental value of $(\Delta\phi)_{\text{diss}}$.

Now let us consider each of the four potentials given on the rhs of Eq. [1].

The phase potential (5) is the potential difference arising from an electrical double layer and dipole orientation developed at crystal/liquid interface as a result of the dynamic equilibrium of ion migration from the liquid phase to the crystal phase and vice versa. The algebraic sign of the phase potential is the same as the electrostatic polarity (+ or -) of the end of the dipolar double layer on the crystal side of the interface.

According to Rastogi and Khan's (12) thermodynamic theory of dissolution potential, the values of dissolution and phase potentials are given by the equations

$$(\Delta\phi)_{\text{diss}} = \frac{RT}{F} (t_+^0 - t_-^0) \ln \frac{\alpha^\beta}{\alpha^{\text{sat'd}}} \quad [3]$$

$$(\Delta\phi)_{\text{phase}} = \pm \frac{1}{F} [\mu_{\pm}^{\alpha} - \mu_{\pm}^{\delta} - RT \ln \alpha^{\text{sat'd}}] \quad [4]$$

where t_+^0 and t_-^0 are the transference numbers of unhydrated cations and anions, respectively, and α^β and $\alpha^{\text{sat'd}}$ are the activities of the electrolyte in the α/β interface and saturated solution, respectively. μ_{\pm}^{α} and μ_{\pm}^{δ} are the standard chemical potential of cations (+) and anions (-) in α and δ phases, respectively. R , T , and F are gas constant, temperature, and the Faraday constant, respectively.

Because of the existence of a concentration cell with transference in the experimental setup of dissolution cell, $(\Delta\phi)_{\text{diff}}$ and $(\Delta\phi)_{\text{cc}}$ could also be developed. The total EMF of such a concentration cell can be easily calculated (15) with the help of the equation

$$(\Delta\phi)_t = 2t_- \frac{RT}{F} \ln (\alpha^{\text{sat'd}}/\alpha^\beta) \quad [5]$$

which may also be written as

$$(\Delta\phi)_t = 2 \frac{RT}{F} \ln (\alpha^{\text{sat'd}}/\alpha^\beta) - 2(1 - t_-) \ln (\alpha^{\text{sat'd}}/\alpha^\beta) \quad [6]$$

where the first term gives the contribution of the two electrodes in contact with the solutions of two different mean activities $\alpha^{\text{sat'd}}$ and α^β , and the second term gives liquid junction or diffusion potential. Thus $(\Delta\phi)_{\text{cc}}$ and $(\Delta\phi)_{\text{diff}}$ of Eq. [1] are given as

$$(\Delta\phi)_{\text{cc}} = 2(RT/F) \ln (\alpha^{\text{sat'd}}/\alpha^\beta) \quad [7]$$

and

$$(\Delta\phi)_{\text{diff}} = 2(1 - t_-) (RT/F) \ln (\alpha^{\text{sat'd}}/\alpha^\beta) \quad [8]$$

where t_+ and t_- are the conventional transference numbers of cations and anions, respectively.

An idea about the functional dependence of dissolution potential can easily be obtained from Eq. [3]. It is obvious from this equation that $(\Delta\phi)_{\text{diss}}$ would depend on (i) temperature T , (ii) transport numbers t_+^0 and t_-^0 of unhydrated or partially hydrated cations and anions, and (iii) activities α^β and $\alpha^{\text{sat'd}}$ of the electrolyte in β phase and saturated solution, respectively.

In order to have a quantitative check of Eq. [3], we have to find out appropriate values of t_+^0 , t_-^0 , α^β , and $\alpha^{\text{sat'd}}$. Since the ions are mostly unhydrated or only partially solvated in the β phase, the transport numbers t_+^0 and t_-^0 associated with the migration of cations and anions from crystal lattice to the crystal/solution interface should be different from conventional transport numbers. The region between crystal lattice and β phase is filled up mostly by unsolvated or only partially solvated ions. This is a solute-enriched zone which may be supposed to behave like a sheet of ionic melt. Hence, t_+^0 and t_-^0 will be closer to the transport number of bare ions (12, 13) in comparison to the conventional transport numbers. An idea about the transport number of the bare ions of an electrolyte can easily be obtained from the masses (16) or

the radii (17) of cations and anions from the following equations

$$t^{\circ} = \frac{M^{-}}{M^{-} + M^{+}}$$

or

$$t^{\circ} = \frac{r^{-}}{r^{-} + r^{+}} \tag{9}$$

where M^{-} and M^{+} are the masses of anions and cations, respectively, in atomic mass units, and r^{-} and r^{+} are the radii of respective ions. Theoretical values of the transport numbers of bare ions calculated from the above equations are found to be in reasonable agreement with the experimental values (18). Thus we can make use of these equations for calculating the values of t° , and t°_{-} .

On the basis of arguments presented in the preceding paragraph it is also evident that the mean activity a^{β} of the electrolyte on the crystal side of the crystal/solution β interface would be approaching unity. Since the mole fraction of the solute is very close to unity in this region, it may be supposed to be present in its standard state. Therefore, a^{β} will be equal to unity. This conclusion can also be made obvious in another way. Let us consider the concentration profile depicted in Fig. 2 about the variation of mole fraction of the solute during the course of dissolution. The curve AB of this diagram represents the change of mole fraction during the detachment of ions from crystal lattice and the establishment of a saturated zone in the crystal/solution interface. As already pointed out by Rastogi and Shukla (4), the true dissolution potential would be generated along the curve AB on account of a difference in the rate of detachment of cations and anions during the course of dissolution. The mole fraction of the solute thus changes from X^{α} to X^{β} and the corresponding mean activity changes from a^{α} to a^{β} during the development of dissolution potential. Since

we shall get

$$a^{\alpha} = a^{\beta} \rightarrow 1 \text{ and } a^{\beta} \rightarrow a^{\text{sat'd}} \tag{10}$$

Thus from Eq. [3] and [10] we shall get

$$(\Delta\phi)_{\text{diss}} = -\frac{RT}{F} (t^{\circ} - t^{\circ}_{-}) \ln a^{\text{sat'd}} \tag{11}$$

since

$$a^{\text{sat'd}} = \gamma_{\pm}^{\text{sat'd}} m^{\text{sat'd}} \tag{12}$$

where $\gamma_{\pm}^{\text{sat'd}}$ is the activity coefficient of the electrolyte in its saturated solution and $m^{\text{sat'd}}$ is its corresponding molality, Eq. [11] may also be written as

Fig. 2. Concentration profile depicting the variation of mole fraction of the solute during the dissolution of electrolyte.

$$(\Delta\phi)_{\text{diss}} = -\frac{2.303RT}{F} (t^{\circ} - t^{\circ}_{-}) (\log \gamma_{\pm}^{\text{sat'd}} + \log m^{\text{sat'd}}) \tag{13}$$

Equation [13] may now be used for calculating theoretical values of $(\Delta\phi)_{\text{diss}}$. Theoretically calculated values of $(\Delta\phi)_{\text{diss}}$ of some binary alkali-metal salts for which $\gamma_{\pm}^{\text{sat'd}}$ and $m^{\text{sat'd}}$ values were available (19, 20) are presented in Table I. These values were obtained by making use of Eq. [9] and [13].

We may now examine the data presented in Table I. It is evident from the data presented in columns 4 and 5 of this table that the magnitude of $(\Delta\phi)_{\text{diss}}$ is directly proportional to the magnitude of $(t^{\circ} - t^{\circ}_{-})$. This is in accordance with the hypothesis of Rastogi and Shukla (4). On the basis of their experimental observations, they had postulated that the magnitude of true dissolution potential should be directly proportional to the magnitude of $(t_{+} - t_{-})$ where t_{+} and t_{-} are the conventional transport numbers of cations and anions, respectively. However, Rastogi *et al.* (4, 5) could not explain the negative sign of dissolution potential of alkali halides in water on the basis of these transport numbers. Now we can easily explain the negative sign of dissolution potential of alkali halides in water on the basis of present theory. Since the mobility of unsolvated or only partially solvated cations is greater than that of similar anions, the former would detach at a greater speed, leaving behind the latter. Therefore, the electrode on which dissolution occurs would be negative. This is in accordance with the experimental observations of various workers.

In order to get an idea about the functional dependence of $(\Delta\phi)_{\text{diss}}$ on other factors, let us consider Eq. [13] once again. It can easily be predicted from this equation that $(\Delta\phi)_{\text{diss}}$ would be directly proportional to the absolute temperature and it should be independent of concentration of the medium. Since $(\Delta\phi)_{\text{diff}}$ and $(\Delta\phi)_{\text{cc}}$ depend on concentration and these are part of $(\Delta\phi)_{\text{obs(diss)}}$, the latter would also depend on concentration. However, $(\Delta\phi)_{\text{diss}}$ would not depend on concentration since it is a function of $a^{\text{sat'd}}$ only.

In order to verify the predictions made on the basis of Eq. [13], further experimental studies were made. These are reported in the proceeding sections.

Theory of Precipitation Potential

The physics of the development of precipitation potential from a supersaturated solution can be understood from the schematic diagram given in Fig. 3.

The experimental setup for the measurement of precipitation potential is such that the crystallization takes place at only one electrode. The other electrode remains free from crystal during the development of precipitation potential. Various methods have been employed in order to do so. Some of them are given below.

1. One of the electrodes is kept inside the supersaturated solution and the other is kept a little above its surface. The solution is cooled in a controlled manner, and when a tiny crystal appears on the surface of the first

electrode, the other electrode is also inserted into the solution and the development of precipitation potential is recorded potentiometrically (4, 5).

2. Crystal seeds are introduced in the surface of one of the two platinum electrodes and the other is kept bright. Both the electrodes are kept a little above the surface of the supersaturated solution which is gradually cooled. When a desired undercooling is obtained, both the electrodes are simultaneously inserted into the solution. Crystallization takes place at the seeded electrode and the development of precipitation potential is recorded electrostatically (13).

3. Both the electrodes are kept inserted in the saturated solution of the electrolyte. The solution around one electrode is cooled and the crystallization potential is recorded at the desired undercoolings (9).

In all these methods, crystallization takes place at only one electrode and the other remains free from it.

During the course of the crystallization from a supersaturated solution, the ions move from a zone of supersaturation into a zone of saturation, and therefore, a diffusion potential would be developed on account of a difference in the mobilities of cations and anions during this transition. Since the mean activity of the electrolyte changes from $a^{(ss)}$ to $a^{(sat'd)}$ during this diffusion the corresponding potential would be given by the equation

$$(\Delta\phi)_{diff} = \frac{RT}{F} (t_+ - t_-) \ln \frac{a^{(sat'd)}}{a^{(ss)}} \quad [14]$$

where $(\Delta\phi)_{diff}$ is the diffusion potential generated during crystallization from supersaturated solution and t_+ and t_- are the conventional transport numbers of cations and anions, respectively.

The situation at the growing crystal/solution interface is exactly similar to the situation at a dissolving crystal/solution interface. In both the cases, the solution side of the interface is populated by saturated ions and the crystal side of the interface is populated by the bare ions (unsolvated or only partially solvated in the case of dissolution and desolvated in the case of precipitation). Thus, following an argument similar to that presented in the case of true dissolution potential, it can easily be shown that the true precipitation potential would be given by the relation

$$(\Delta\phi)_{pption} = \frac{2.303RT}{F} (t_+ - t_-) \log \frac{a^{(sat'd)}}{a^{(\beta/\alpha)}} \quad [15]$$

where $a^{(sat'd)}$ is the activity of the electrolyte in the saturated δ/β interface, and $a^{(\beta/\alpha)}$ is the activity of the electrolyte in the desolvated β/α interface.

It may be pointed out here that an equation exactly similar to Eq. [15] has been derived by Rastogi and Khan (13) in their thermodynamic theory of precipitation potential. In this theory, they have converted the equation

$$(\Delta\phi)_{pption} = \frac{RT}{F} (t_+ - t_-) \ln \frac{a_1}{a_2} \quad [16]$$

into an inequality

$$(\Delta\phi)_{pption} < - \frac{1}{F} \frac{(\Delta H)(\Delta T)}{T_s} \quad [17]$$

by making use of Clausius-Clapeyron equation

$$\ln \frac{a_1}{a_2} = \frac{(\Delta H)}{R} \left(\frac{T_1 - T_2}{T_1 T_2} \right) \quad [18]$$

and putting

$$(t_+ - t_-) < 1 \quad [19]$$

It has been suggested by Rastogi and Khan (13) that ΔH in Eq. [17] is equivalent to the lattice energy. In fact, ΔH in the Clausius-Clapeyron equation (18), is simply the heat of fusion. It may be called the heat of precipitation in the present case, but there is no thermodynamic justification for substituting lattice energy in place of heat of fusion. As a matter of fact, the values of precipitation potential calculated on the basis of lattice energy are found to be much greater in comparison to the experimental values [Ref. (13), Table II]. On the other hand, the values of precipitation potential calculated on the basis of ordinary heat of precipitation are found to be extremely low. Thus, use of the Clausius-Clapeyron equation is not justified in the present case.

It is a well-known fact that during crystallization the lattice energy is used up in the desolvation of ions. Lattice formation and desolvation are interdependent, and crystallization process will be hampered if lattice energy is used for any other purpose. It is quite possible that the thermal energy of the system may be used in the development of precipitation potential and, consequently, a cooling may be produced around the electrode on which crystallization takes place, as reported by Rastogi and Khan (13). However, the separation of lattice energy from desolvation of ions does not seem plausible.

Now let us consider Eq. [15]. Since the β/α interface is populated mostly by desolvated ions, we shall have

$$a^{\beta/\alpha} = \text{unity} \quad [20]$$

Thus, making use of Eq. [12], [15], and [20], we get

$$(\Delta\phi)_{pption} = \frac{2.303RT}{F} (t_+ - t_-) (\log \gamma_{\pm}^{sat'd} + \log m^{sat'd}) \quad [21]$$

Now, comparing Eq. [13] and [21], we can say that the phenomenon of true precipitation potential is exactly opposite to the phenomenon of true dissolution potential. Their values are equal in magnitude but opposite in sign.

Since the α phase remains in equilibrium with the β phase until the end of crystallization process, equilibrium phase potential given by Eq. [4] would also be present along with the precipitation and diffusion potentials. Ignoring the contribution made by other very small potentials such as Nernst potential, etc., the observed precipitation potential would be given by the equation

$$(\Delta\phi)_{obs(pption)} = (\Delta\phi)_{diff} + (\Delta\phi)_{pption} + (\Delta\phi)_{phase} \quad [22]$$

It follows, therefore, that the experimental values of observed precipitation potential, diffusion potential, and phase potential should be known before one can evaluate the experimental value of $(\Delta\phi)_{pption}$. Its theoretical value would be equal in magnitude but opposite in sign to that of dissolution potential. It is also evident from Eq. [21] that true precipitation potential would be directly proportional to the saturation temperature, but it should remain independent of undercooling. Overall observed precipitation potential would depend on ΔT , owing to the dependence of thermodiffusion potential on it, but true $(\Delta\phi)_{pption}$ would remain constant. Experimental studies have been reported in the following sections in order to corroborate these points.

Fig. 4. Schematic diagram of the cell used for the measurement of $(\Delta\phi)_1$.

Experimental

Experimental techniques for the measurement of dissolution, precipitation, phase and thermodiffusion potentials were the same as already reported by Rastogi *et al.* (4, 5). While determining the precipitation potential, crystallization was invoked on only one electrode by adopting the process (ii) described earlier.

The cell used for the measurement of $(\Delta\phi)_1$, the potential associated with the establishment of a concentration cell with transference in the dissolution cell, is shown in Fig. 4. A is a Pyrex glass vessel containing conductivity water. B is another Pyrex glass vessel containing saturated solution of the electrolyte. B has a side tube T which has a stopper S. Conductivity water in vessel A and saturated solution in vessel B are adjusted at the same level. The platinum electrodes E_1 and E_2 are placed in the conductivity water and saturated solution, respectively. Solid electrolyte is kept in equilibrium with the saturated solution by putting a small amount of solid electrolyte at the bottom of vessel B in order to create a situation exactly similar to that present in the dissolution cell. Care is taken that the electrode E_2 does not come in contact with the solid electrolyte. Both the electrodes are connected with the electrometer amplifier. When the stopper S is opened, diffusion starts immediately. The buildup and decay of potential is recorded as a function of time.

A high impedance ($R > 10^{14}$) electrometer (Annadigi, Hyderabad) was used for the measurement of all these potentials. All the measurements were made in air, since it has been reported that observed potential remains almost unaffected even when the measurements are made in nitrogen atmosphere. Platinum electrodes fused in Pyrex glass tubes were welded to copper wire in order to avoid electrical contacts through mercury which might form unsuspected secondary cells. Coaxial cables were used in order to avoid the effect of stray external fields. The platinum electrodes were thoroughly cleaned by boiling in nitric acid and then by heating in a flame before each experiment. Asymmetry potential was minimized as far as possible, and it was always taken into account while evaluating the experimental values.

Results and Discussion

The dissolution, precipitation, phase potentials, and potential associated with the concentration cell with transference were recorded for KCl, KClO_3 , KBrO_3 , LiNO_3 , and LiClO_4 . The values of true dissolution potential and true precipitation potential evaluated on the basis of Eq. [2] and [22], respectively, and their theoretical values calculated from Eq. [13] and [21] are presented in Tables II, III, and IV.

The dependence of observed dissolution potential, true dissolution potential, and $(\Delta\phi)_1$ of LiNO_3 on concentration of the medium were also studied. The results are presented in Table V. The plot of $(\Delta\phi)_{\text{obs(diss)}}$ vs. $\log C$ of the medium and $(\Delta\phi)_1$ vs. $\log C$ of the medium are given in Fig. 5. Experimental studies on the effect of temperature and undercooling on $(\Delta\phi)_{\text{pptn}}$ of KClO_3 , KBrO_3 , and LiNO_3 are presented in Table VI and VII and Fig. 6.

A perusal of Tables II and III makes it quite clear that the theoretical values of true dissolution and true precipitation potentials calculated on the basis of Eq. [13] and [21], respectively, are in a good agreement with the experimental data. It is also evident from the data presented in Table IV that the precipitation potential is a phenomenon exactly opposite dissolution potential. Their experimental values are approximately equal in magnitude but opposite in sign. These observations are in accordance with the present mechanism of electric potential generated on the dissolution and precipitation of electrolytes. Theoretically

Table VI. Effect of undercooling on $(\Delta\phi)_{\text{Pption}}$ of KClO_3 , KBrO_3 , and LiNO_3 . Saturation temperature of 25°C

Electrolyte	$(\Delta\phi)_{\text{phase}}$	$\Delta T = 10^\circ\text{C}$			$\Delta T = 15^\circ\text{C}$			$\Delta T = 20^\circ\text{C}$		
		$(\Delta\phi)_{\text{obs}}$	$(\Delta\phi)_{\text{TID}}$	$(\Delta\phi)_{\text{Pption}}$	$(\Delta\phi)_{\text{obs}}$	$(\Delta\phi)_{\text{TID}}$	$(\Delta\phi)_{\text{Pption}}$	$(\Delta\phi)_{\text{obs}}$	$(\Delta\phi)_{\text{TID}}$	$(\Delta\phi)_{\text{Pption}}$
KClO_3	-20	+2	+2	+20	+3	+3	+20	+5	+4	+21
KBrO_3	-23	+7	+3	+27	+9	+4	+28	+9	+5	+27
LiNO_3	-32	+14	+4	+42	+15	+5	+42	+16	+6	+43

The data presented in this table are the nearest integer of the average of several observations. Since the magnitude of various potentials were very low and the sensitivity of the instrument was only 1 mV, several observations had to be made in order to ascertain the reliability of an experiment.

cally calculated values of $(\Delta\phi)_{\text{diss}}$ and $(\Delta\phi)_{\text{Pption}}$ and their subsequent experimental verifications are found to be in accordance with the observation made by Ibl *et al.* (9) in their work. Girdhar and co-workers have also reported similar observations in case of ammonium salts (6-8).

Results reported in Table V and plotted in Fig. 5 support the view that the true $(\Delta\phi)_{\text{diss}}$ does not depend on concentration of the medium. Since the plots of $(\Delta\phi)_{\text{obs(diss)}}$ vs. $\log C$ and $(\Delta\phi)_t$ vs. $\log C$ are parallel to each other and since $(\Delta\phi)_{\text{obs(diss)}}$ and $(\Delta\phi)_t$ are related by the equation

$$(\Delta\phi)_{\text{obs(diss)}} = \frac{[(\Delta\phi)_t]}{I} + \frac{[(\Delta\phi)_{\text{diss}} + (\Delta\phi)_{\text{phase}}]}{II} \quad [23]$$

Fig. 5. Dependence of observed dissolution potential and $(\Delta\phi)_t$ on $\log C$ of LiNO_3 .

Fig. 6. Effect of temperature on true dissolution and precipitation potentials of KClO_3 , KBrO_3 , and LiNO_3 .

Table VII. Effect of temperature on true dissolution potential and true precipitation potentials of KClO_3 , KBrO_3 , and LiNO_3 . Precipitation potential data are based on $\Delta T = 15^\circ\text{C}$. Equations [2] and [22] were used for the evaluation of respective potentials

Electrolyte	True dissolution potential			True precipitation potential		
	25°C (mV)	35°C (mV)	45°C (mV)	25°C (mV)	30°C (mV)	35°C (mV)
KClO_3	-24	-27	-31	+20	+24	+28
KBrO_3	-30	-33	-36	+28	+30	+33
LiNO_3	-41	-45	-50	+42	+47	+51

it is quite evident that the second term in the rhs of Eq. [23] should be independent of $\log C$. It therefore follows that $(\Delta\phi)_{\text{diss}}$ does not depend on the concentration of the medium.

Experimental observations on the dependence of $(\Delta\phi)_{\text{Pption}}$ on undercooling (columns 5, 8, and 11, Table VI) support our theoretical view that the true precipitation potential does not depend on ΔT . These observations are in accordance with the experimental studies reported by Workmann and Reynolds (21), Parreira and Eydtt (22), Heinmeles (23), Gross (24), and many others about the independence of freezing potential on undercooling. They have reported that ΔT has no particular effect on freezing potential. On the basis of these arguments, it can also be predicted that the phenomenon of true precipitation potential is somewhat similar to the phenomenon of freezing potential. The effects of temperature on dissolution and precipitation potential of KClO_3 , KBrO_3 , and LiNO_3 were also studied. The data are presented in Table VI and VII and plotted in Fig. 6. The true dissolution and precipitation potentials are found to be directly proportional to the temperature. These observations are also in accordance with the theory. The data presented in Table VII once again support the view that the dissolution and precipitation potentials are equal in magnitude but opposite in sign.

Effects of Curing and Other Variables on Deep-Discharge Cycling of Pb-Ca Positive Plates

T. G. Chang* and E. M. Valeriote*

Cominco Ltd., Product Research Centre, Mississauga, Ontario, Canada L5K 1B4

ABSTRACT

Effects of curing temperature and humidity, paste density, plate thickness, soaking time before formation, and electrode support on deep cycling performance of Pb-Ca positive plates were studied. It was found that although improvements could be obtained by adjusting these variables, the capacity retention was still inferior to that of Pb-Sb plates. Examination of the plates revealed that preferential discharge of the corrosion product and the formation of a PbSO₄ barrier around Pb-Ca grid wires might cause the loss of capacity. Means of extending the cycle life of nonantimonial lead positive plates are discussed.

Although lead-calcium (Pb-Ca) alloy grids were introduced for lead-acid storage batteries early in the 1930's by Bell Laboratories (1), before 1970 they were used almost exclusively for float-service applications. In recent years, they have been employed ever increasingly in starting-lighting-ignition batteries. They are also used, although not widely, in batteries for deep-discharge applications. However, it has been known that Pb-Ca batteries do not usually retain their capacities as well as lead-antimony (Pb-Sb) batteries in deep cycling, for reasons which are not clear in spite of considerable research (2-8). Means have been suggested to improve the deep cycling performance of Pb-Ca batteries (2, 5). In this work, effects of curing and other variables on deep cycling of Pb-Ca positive plates were studied. The cycled plates were also examined to determine the causes of failure.

Experimental

The Pb-Ca grids used in the experiments were expanded from Pb-0.09% Ca-0.3% Sn cast strip and measured 102 mm (H) × 52 mm (W). Pastes were prepared from a commercial leady oxide, Grenox, which contained about 25% metallic lead. The variables studied were (i) paste density (wet) of 4.0 and 4.3 g/cm³, (ii) curing temperatures of 85°, 40°, and 22°C, (iii) curing humidity of 100 and 50% RH, (iv) plate thickness of 3.5 and 2.2 mm (the grids were 1.9 and 1.4 mm thick, respectively), (v) soaking time before formation of 1 and 3h, and (vi) plate retention: without any support and with stack pressure on the electrode assembly.

For each set of experimental parameters, three to five replicates were subjected to deep-discharge cycle life testing.

The pastes were prepared by mixing leady oxide, sulfuric acid (1.350 sp gr), and water. The PbO/SO₃ ratio was 6 for pastes of 4.0 g/cm³ density, and 8 for those of 4.3 g/cm³ density. Cured plates, 2.2 and 3.5 mm thick, were formed in 1.10 sp gr H₂SO₄ at 40°C and cycled in an amount of 1.25 sp gr H₂SO₄ well in excess of the stoichiometric requirement. The potential of the positive test plate was

measured against a Hg/Hg₂SO₄ reference electrode (in 1.25 sp gr H₂SO₄) during cycling. When a plate was tested without any support, it was placed in a 600 ml beaker with a negative plate on each side and no separator, but with a wide gap between the plates. When a plate was tested with retainers, it was wrapped in a glass-fiber mat and placed in a Plexiglas cell, 26 (W) × 102 (L) × 165 (H) mm, with a Daramic® (microporous polyethylene) enveloped negative plate on each side. A stack pressure was imposed by inserting polyethylene sheets between the electrode assembly and the cell walls. The test plates were discharged at about the 5h rate to a potential of 900 mV (*i. e.*, 100% depth of discharge). After a rest time of 5 min, they were recharged at a constant potential of 1300 mV with a maximum current of 2A. When the charging current decreased to 250 mA for the 3.5 mm plates, or 185 mA for the 2.2 mm plates, the test plates were recharged at the same respective constant current till 115% (Ah) of the previous discharge was returned. Again, there was a 5 min rest before the next discharge. Cycled plates were washed, dried, and examined by optical and scanning electron microscopy. For comparison, positive plates prepared from Pb-3% Sb book-mold grids (47 × 75 × 1.9 mm) and 4.26 g/cm³ paste were also cycled and examined. These plates were pasted to a thickness of 3.3 mm when dried. They were cured at 40°C and formed and cycled without support, under the same cycling conditions already described for Pb-Ca plates.

To investigate the activity of the active material in failed Pb-Ca plates, a set of Pb-Ca book-mold grids (0.1% Ca, 0.35% Sn) was pasted and cycled in excess amount of 1.25 sp gr H₂SO₄ without support at 30°C. After the plates failed in cycling, the acid concentration was lowered to 1.10 sp gr, and the discharge capacities in the new cycling acid were recorded.

Results and Discussion

Curing temperature (at 100% RH).—X-ray diffractometry indicated that all sulfate in the plates cured at 85°C was in the form of 4PbO · PbSO₄ and that in those cured at 40° and 22°C was in the form of 3PbO · PbSO₄ · H₂O.

*Electrochemical Society Active Member.

Fig. 1. Deep-discharge performances of unsupported positive plates. All plates were prepared from a paste of 4.3 g/cm^3 density, cured in 100% RH, and cycled in $1.25 \text{ sp gr H}_2\text{SO}_4$ at 30°C .

The mechanical integrity of the cured plates appeared to increase with increased curing temperature. Figure 1 presents capacity-cycle curves for 3.5 mm plates cycled without retainers. Obviously, plates prepared from Pb-Ca grids did not retain deep-discharge capacity as well as those with Pb-Sb grids, and no improvement had been achieved by raising the curing temperature to 85°C . Figure 2 shows how Pb-Ca plates cured at different temperatures performed with retainers under the deep cycling conditions. The 85°C cured plates did not really perform better than the 40°C cured plates. Their cycle life was longer (Fig. 2), but their initial discharge capacity was very low compared with those cured at lower temperatures. It took 10-15 deep cycles for the 85°C cured plates to reach maximum capacity (Fig. 1 and 2), which was lower than that of the 40°C cured plates. Figure 2A also shows that although plates cured at 22°C had poorer integrity, when they were adequately supported and not disturbed in cycling their performance was comparable to that of plates cured at higher temperatures.

Curing humidity.—When plates were subjected to a low humidity (50% RH) environment at the beginning of the curing process, they developed numerous hairline cracks and retained a high metallic lead content in the paste. The resulting plates gave very poor performance. No $4\text{PbO} \cdot \text{PbSO}_4$ was produced in plates cured at low humidity even when the curing temperature was raised over 80°C . When the humidity was held at 50% RH, the higher the curing temperature, the greater was the damage to the plate integrity because of the higher evaporation rate at higher temperatures.

Plate thickness and paste density.—The experimental data, as shown in Fig. 2, demonstrate the well-known fact

Fig. 2. Deep-discharge performances of Pb-Ca positive plates cured at 85°C , 40°C , and 22°C , and 100% RH, and cycled with retainers in $1.25 \text{ sp gr H}_2\text{SO}_4$ at 30°C .

that when the paste density or plate thickness is reduced the discharge capacity increases and the cycle life decreases (9, 10).

Soaking time.—In general, a soaking time before forming of longer than 1h, in a cell with excess electrolyte, resulted in plates of shorter cycle life. However, plates with poor integrities, e.g., plates subjected to a low humidity environment in the incipient period of the curing process, performed better when they were soaked for 3h before commencement of formation than those soaked for 1h. Perhaps heavier and deeper sulfation due to the long soaking improved the plate integrity.

Retainer.—By comparison of Fig. 1 with Fig. 2, it is apparent that, when the plates were supported, their cycle life was substantially extended with some sacrifice in discharge capacity.

All the results clearly showed that even under the most favorable of the above-mentioned experimental conditions, the deep cycling performance of the Pb-Ca positives did not equal that of Pb-Sb.

Microscopical study.—The test plates were examined by both optical and scanning electron microscopy. Sulfur contents in the plates were measured by EDX microprobe.

Examination of the prematurely failed Pb-Ca plates revealed that the active material close to the plate surface was different from that in the center of the plate. The active material lying closer to the plate surface had either formed or was in the process of consolidating to form a coralloid structure (11-13) depending on the number of cycles the plate had undergone. Figure 3 shows the active material lying close to the surface of plates which failed after fewer than 30 cycles. The coralloid structure can be clearly seen. The center part (which was about one-third of the total plate thickness) of the failed Pb-Ca plates did not contain any coralloid structure. Figure 4a shows active material at the center of a 85°C cured plate (2.2 mm thick) which failed before the twenty-ninth cycle. The large bar-like particles retained the shape of the original $4\text{PbO} \cdot \text{PbSO}_4$ crystals, and their interior remained dense

Fig. 3. Active material close to surface of failed Pb-Ca plates which were cured at 40°C and deep cycled in $1.25 \text{ sp gr H}_2\text{SO}_4$ at 30°C . a: 30 cycles, charged. b: 31 cycles, discharged.

Fig. 4. Active material in the center of Pb-Ca plates which failed in deep cycling in $1.25 \text{ sp gr H}_2\text{SO}_4$ at 30°C . a: Cured at 85°C , 29 cycles, discharged. b: Cured at 40°C , 41 cycles, discharged.

and quite pore-free. This indicates that most of the material had never taken part in the charge-discharge process. The active material shown in Fig. 4b was in the center of a 3.5 mm plate which was cured at 40°C and had undergone 41 cycles. The structure is distinctively cellular and normally occurs when the active material has undergone only a single discharge-charge cycle after formation (13, 14). This structure in fact is optimal for high utilization (13). Microprobe analysis and visual inspection (Fig. 4) indicated that less than 5% of the active material in the center part of a failed Pb-Ca plate was converted to PbSO₄ at the end of discharge.

The book-mold Pb-Ca plates which were cycled to failure in 1.25 sp gr H₂SO₄ were placed in 1.10 sp gr H₂SO₄. It was found that the capacities of the plates increased substantially, ranging from 25 to 55%. This is in agreement with the results obtained by Nakayama *et al.* (6). The evidence suggests that the discharge of the active material was obstructed by sulfation in some parts of the plate, rather than by either reduced electrochemical activity of the active material or poor interparticle contact.

The active material close to the surface of the failed plates was carefully examined for a possible pore-free PbSO₄ layer which could have obstructed the diffusion of sulfuric acid to the interior of the plate. It was not found. On the contrary, in general, the active material close to the plate surface was much more porous than that in the plate center. When a plate was discharged, part of the microporous lead dioxide, as shown in Fig. 3a, was converted to regular nonporous PbSO₄ crystals with a dimension of about 5 μm. As shown in Fig. 3b, although there should be a volume increase of almost 90% in the conversion from PbO₂ to PbSO₄, by elimination of micropores the structure actually appeared to become much more open. It is quite reasonable to assume that, as a consequence, the diffusion of sulfuric acid would not be impeded.

The active material on the Pb-Sb plates which had undergone various lengths of cycling was also inspected. It was found that active material on either Pb-Ca plates or Pb-Sb plates, which were subjected to the same number of cycles with comparable active material utilization, appeared essentially the same, morphologically. Since the active material in the center part of a failed Pb-Ca plate appeared to be healthy and had participated in previous cycling, and since the accessibility of acid was unlikely to be limiting the capacity, the reason for the low dischargeability must be sought elsewhere.

Careful examination was, therefore, made of the grid/active material interfacial region. The corrosion product on the grid usually had two layers, regardless of whether the grid was Pb-Ca or Pb-Sb. One was dense and dark, and was adjacent to the grid; the other was porous and lighter in color. The thickness of the inner layer was about 20 μm, and that of the outer layer varied. When a plate was fully charged, no sulfate was found in either of these layers. No irreversible formation of a PbSO₄ barrier layer surrounding the Pb-Ca grids, as reported by Tudor *et al.* (2) and Perkins (15), has been observed in our laboratory. Indeed, hardly any PbSO₄ was found in a fully charged plate. When a plate was fully discharged (100% DOD), the inner corrosion layer remained unchanged and the microprobe detected no sulfur in it. The state of the outer layer depended, however, on the depth of discharge, its relative location in the plate, and the nearness of the plate to failure. When a plate was being discharged, regardless of whether it was healthy or failed, the part of the outer corrosion layer which was close to the plate surface, *i.e.*, near the bulk electrolyte, was always sulfated at the end of a deep discharge. The sulfation process started from the outside surface of the outer layer and then spread inward. Figure 5a shows that the outside surface of the outer corrosion layer in a discharged plate was covered by PbSO₄ crystals. From the outer surface inward, the sulfur content, as determined by microprobe, decreased to zero at the inner surface, where it met the dense corrosion layer. In a plate which had not yet failed,

Fig. 5. Corrosion layers on grid in discharged failed Pb-Ca plate at various locations. a: Close to plate surface. b: At the center of the plate.

or which was only shallowly discharged, the part of the corrosion layer farther from the plate surface, *e.g.*, at the center of the plate, was either not at all or only slightly sulfated. But when a failed plate was fully discharged, usually all the outer surface of the corrosion layer, regardless of its position in the plate, was completely covered by PbSO₄ crystals. Figure 5b shows part of the corrosion layers in the center of a failed plate which had undergone 22 deep cycles. The grid metal can be seen in the upper left corner of this photomicrograph. The porous substance on the right-hand side is the active material. As shown in the photomicrograph, the outer surface of the corrosion layer is completely masked by tightly packed PbSO₄ crystals. It is noteworthy that, as shown in Fig. 5, the active material next to the sulfated corrosion layer was almost completely free of sulfur. This phenomenon was found to be quite common in failed Pb-Ca plates. Figure 6 shows a microtomed failed Pb-Ca plate without any mounting material. Thus, looking down into the small interstices between corrosion products and active material, one can see that the outer surface of the corrosion layer, as shown in Fig. 6b, is completely masked by PbSO₄ crystals.

Nakayama *et al.* (6) also observed sulfation of the corrosion product around the Pb-Ca grid. However, in their model, the sulfation process is initiated on the inner surface of the dense corrosion layer contacting the grid, and then proceeds outward until all the corrosion product is sulfated to form a PbSO₄ barrier. The model also implies that the sulfation develops uniformly in every part of the corrosion product around the grid, regardless of the relative position of the part of the corrosion product with respect to the plate surface. As previously described, this model is not in agreement with our findings.

A comparison microscopical study of Pb-Sb plates was also carried out. Failure appeared to follow the same general course. The corrosion product around the grid usually also had a two-layered structure; the layer adjacent to the grid was dense and dark, and the outer layer was porous and lighter in color. As in Pb-Ca plates, no sulfur was found in the inner layer either in the charged or dis-

Fig. 6. Interfacial region between grid and active material in a failed Pb-Ca plate which was cured at 40°C and 100% RH, and had undergone 22 deep-discharge cycles. The specimen was microtomed without mounting material. b is an enlargement of the location indicated by an arrow in a.

charged state. After 24 cycles, when the discharge capacity was at about the maximum (see Fig. 1), the outer corrosion layer, at locations close to the plate surface and bulk electrolyte, was already well developed and was heavily sulfated at the end of a deep discharge. In contrast, at locations farther from the plate surface, *e.g.*, at the center of the plate, the second layer was either nonexistent or not well developed. Thus, at the end of discharge the dense corrosion layer at these locations was not completely covered by PbSO_4 crystals, if they were at all present. As cycling proceeded further, the structure of the active material close to the plate surface became more open, because of coralloid structure formation, and the active material farther inside the plate participated increasingly in charge-discharge cycling. However, opening up of the structure also promoted discharge of the corrosion product. Thus the porous outer corrosion layer progressed to locations farther inside the plate; at the end of the discharge period, a larger portion of the grid became enveloped in a layer of sulfate. At the end of cycle life, the coralloid structure dominated in the plate; large pores of greater than $100\ \mu\text{m}$ diam formed even in the center of the plate, as we described previously (13). By this time, at the end of a discharge the grid was completely surrounded by a thick PbSO_4 layer having a dendritic structure, as shown in Fig. 7.

It becomes apparent that it was the formation of a continuous PbSO_4 layer around the grid that effectively prevented the discharging of the active material, thus ending the cycle life of the plate. This occurs for both antimonial and nonantimonial plates. The difference between these two kinds of plates is that it occurs in Pb-Ca plates at a much earlier stage, before the coralloid structure has formed throughout the plate. In contrast, in a Pb-Sb plate, the grid surface deep in the center of the plate is not covered by PbSO_4 until the active material in the same location has been utilized in cycling and transformed to a very open structure, *i.e.*, a well-developed coralloid structure.

Once a plate enters the last stage of its cycle life, if it is subjected to a deep discharge, the outer corrosion layer is discharged in preference to the active material in the interior of the plate. As Fig. 5 and 7 show, the active material in contact with the almost completely discharged outer corrosion layer can be completely undischarged. In other words, the physical change in cycling becomes increasingly concentrated in the corrosion layer. The adhesion of the active material to the corrosion layer (and, thereby, to the grid) is therefore weakened. This could explain partly why apparently healthy active material spalled in big chunks from Pb-Ca plates.

It was also noted that the development of the corrosion layer in Pb-Ca plates was different from that in Pb-Sb plates. Although concentric cracks, which developed parallel to the grid surface, formed in both Pb-Ca and Pb-Sb grids, they started to form earlier and were much more numerous in Pb-Ca plates than those in Pb-Sb plates. The cracks formed in the dense layer adjacent to the grid. In Pb-Ca plates, almost immediately after the cracks were

formed, sulfate crystals started to grow in them, and, consequently, enlarged them. In contrast, cracks in Pb-Sb plates could experience many cycles without any sulfate being formed in them. Thus, the corrosion layer in a Pb-Ca plate, which has been subjected to more than 50 deep cycles, usually had a multilayered structure. Furthermore, if that plate was failing, it was often found that at the end of a discharge, layers closer to the grid were sulfated, but the outer layers were not.

All the evidence suggests that the premature failure of Pb-Ca positive plates is caused by preferential discharge of the corrosion product surrounding the grid. Therefore, design features or additives which limit access of acid to the grid or reduce its activity, or which retard discharge of corrosion product, might extend cycle life. This can be achieved in many ways, for example, by increasing the paste density or the plate thickness (2), or by reducing the quantity of acid (as in "starved" electrolyte batteries) or the concentration of acid (5). According to this model, the tubular form would be preferable for Pb-Ca positive plates, since this configuration eliminates the short cuts for acid to reach the grid surface which exist in a flat plate. The application of pressure on the plates has been shown to beneficially affect cycle life (25, 26). Pressure might function by slowing down the development of macropores as a result of structural changes which occur in the active material during cycling (13). These macropores increase access of acid to the plate interior; thus, prevention of their formation would be expected to result in an increase in cycle life.

Some additives may achieve extended cycle life by retarding the discharge of the corrosion product. Antimony and phosphoric acid have been proven to extend cycle life (2, 4, 16), and both of them have also been shown to inhibit the discharge of PbO_2 (2, 16-21). There is also evidence that antimony and phosphoric acid promote the formation of $\alpha\text{-PbO}_2$ over that of $\beta\text{-PbO}_2$ (18-24). It is usually agreed that $\alpha\text{-PbO}_2$ is more difficult to discharge than $\beta\text{-PbO}_2$. This may be why the presence of antimony and phosphoric acid prevents a PbSO_4 barrier from forming in the corrosion layer.

Conclusions

Retention of the deep-discharge capacity of Pb-Ca plates could not be improved appreciably by modification of curing and forming conditions within the range of those considered to constitute normal practice. A low humidity environment in the initial stage of curing should be avoided; otherwise, substantial loss in capacity and cycle life results.

The premature loss of discharge capacity of Pb-Ca plates was caused by preferential discharge of the corrosion product and the formation of a PbSO_4 barrier around the grid. It followed that the cycle life of the plate might be extended by reduction of access of acid to the corrosion layer on the grid and by additives which retard discharge of the corrosion product around the grid.

Acknowledgments

The plate preparation and cycling were carried out by Mr. M. J. Dewar. Specimen preparation and part of the microscopic study were done by Mr. W. W. Gregory; Mr. K. Cowan also assisted with specimen preparation.

Characterization of the Li/MnO₂ Multistep Discharge

John C. Nardi

Union Carbide Corporation, Battery Products Division, Westlake, Ohio 44145

ABSTRACT

The electrochemical discharge, differential capacity, open-circuit voltage-temperature dependence, and open-circuit relaxation techniques were combined to investigate the cathodic reduction mechanism of the Li/MnO₂ nonaqueous couple. These techniques indicate three different stages of MnO₂ reduction by insertion of lithium ions into the lattice of the cathode. The initial stage of the reduction of the MnO₂ occurs within approximately the first 10% of discharge. It involves the insertion of lithium ions into the lattice of the MnO₂ forming Li_xMnO₂ (0 ≤ x ≤ 0.1). It is typical of a homogeneous reaction. The next step in the discharge involves a heterogeneous or two-phase reaction. It is distinguished by the flat portion of the Li/MnO₂ discharge curve (0.1 ≤ x ≤ 0.4). The final discharge regime is again a homogeneous reaction. This reaction involves insertion of lithium ions into the new structural form of Li_xMnO₂ (x > 0.4) and accounts for the final sloping section of the discharge curve.

Considerable work has been focused on the development of nonaqueous lithium batteries. A promising class of nonaqueous cathode materials appears to be the transition metal oxides, with one of the most studied being MnO₂ (1-4). Still, little is known about the mechanistic aspects of lithium ion incorporation into the MnO₂ structure. This study reports results of investigations into the cathodic reduction process of MnO₂. Electrochemical discharge, differential capacity, and open-circuit relaxation techniques at selected temperatures were used.

Experimental

Two types of electrochemical cell configurations were used in this series of experiments. A flooded experimental cell consisted of an electrically insulated, sealed, stainless steel container that provided good internal electrode contact by means of a stainless steel spring. Such cells were cathode limited in capacity. The other cell configuration was of the anode-limited CR 2016 "coin" type.

The flooded electrochemical cells were assembled in a dry box by placing in the cell holder a MnO₂ cathode pellet, a highly porous separator material, lithium disk, a stainless steel contact plate and spring. The cells were then filled with electrolyte and closed. The electrolyte was 1M LiCF₃SO₃ dissolved in a 50/50 volume percent propylene carbonate (PC)-dimethoxyethane (DME) solution. The PC and DME organic solvents were obtained from the Burdick and Jackson Laboratories, Incorporated, and the Grant Chemical Corporation, respectively. The salt was purchased from the 3M Corporation. Scrupulous drying of the solvents and solute resulted in an electrolyte with a water content below 25 ppm. The organic solvents were stored over 4Å molecular sieves in order to remove any traces of residual water while electrolyte solutes were dried under vacuum. Water analyses were accomplished using a Photovolt Aquatest IV. The

cathode consisted of a pressed powder pellet containing nonheat-treated (NHT) or heat-treated (HT) electrolytic manganese dioxide (EMD), a carbon conductive additive, and a Teflon® binder (5). Heat-treatment consisted of heating the EMD at 350°C for 8h. Before heat-treatment, the adsorbed or 120°C water is typically 3-4% of the MnO₂. After heat-treatment, this was reduced to approximately 0.2%. The x-ray diffraction patterns of these MnO₂'s are comparable to x-ray data already reported in the literature (1). All cathode pellets were dried at 150°C under vacuum for 16h prior to incorporation in the complete cell.

The CR-2016's are similar to commercially available cells and represent state-of-the-art design and manufacture. These cells also contained the 1M LiCF₃SO₃-PC/DME electrolyte (6).

Discharge and open-circuit potentials were continuously monitored using an automatic data acquisition system consisting of an Esterline-Angus PD-2064 datalogger and Hewlett-Packard HP-9835A desktop computer. This system was also used to store, tabulate, correlate, and graph the electrochemical data from all cells tested. A Thermotron S1.2 environmental chamber capable of maintaining a preset temperature within ± 0.5°C was used when evaluating cells at temperatures other than ambient.

Results and Discussion

Differential capacity analysis.—Figure 1 shows discharge curves at 35°C for the flooded experimental cells containing the NHT and HT MnO₂. The cells were discharged to a 2.0V cutoff across a constant resistive load of 30,000Ω. This represents a current density of approximately 0.05 mA/cm² at 3.0V. The NHT MnO₂ has a higher initial discharge plateau than does the heat-treated MnO₂. However, the overall corrected cathode efficiencies for freshly discharged NHT and HT MnO₂ are quite close. To better assess the shape of the Li/MnO₂ discharge profile,

Fig. 1. Discharge curves at 35°C for Li/MnO₂ experimental cell under 30 kΩ background load. Cathodes utilize HT MnO₂ (solid line) or NHT MnO₂ (broken line).

a differential capacity analysis (DCC) was performed on these data (7-9). The sensitivity of the DCC method prevents its use on cells not discharged in strictly controlled temperature environments. The DCC analysis uses the slope of the discharge curve to interpret the data. It involves calculating the change in charge divided by a change in voltage over a specified time interval and plotting such against the average potential for this time increment. If, during the discharge, a very stable potential plateau exists, the DCC curve will indicate it by a sharp peak at the plateau's voltage. The sharpness of the peak also gives an indication of the relative flatness of the discharge plateau it represents. Any slope or voltage step in the discharge curve will be seen as a sharp decrease in the DCC curve. The DCC analysis of the two curves of Fig. 1 are shown in Fig. 2. The NHT MnO₂ has a very sharp peak at 3.2V, while the same relatively sharp peak occurs at 3.0V for the HT MnO₂. An initial, very sloping discharge region is denoted by the flat DCC region prior to the main peak. After the sharp peak, the NHT curve displays a sharp decrease followed by a second, more washed-out peak. This peak is centered at about 2.9V. Note that the HT material has the same washed-out peak at 2.9V. It suggests that the latter halves of the two discharge curves are almost identical and in all likelihood represent the same reaction. Heat-treatment has not affected this part of the MnO₂'s discharge curve. The main effect of the heat-treatment has been to shift the high voltage plateau to a lower average potential. This technique clearly shows the differences and similarities in the discharge of the two types of MnO₂'s. The flatness of the Li/MnO₂ discharge between approximately 10 and 40% depth of discharge (DOD) indicates a reaction that is not entirely homogeneous in nature, contrary to previously published descriptions (3, 4).

Figures 3 and 4 show the discharge and DCC analysis curves of NHT MnO₂ under 15, 7.5, and 4 kΩ loads at 35°C. The discharge of HT MnO₂ under 15, 7.5, and 4 kΩ loads at 35°C with their corresponding DCC curves are shown

Fig. 2. Differential capacity curves for Li/MnO₂ experimental cells at 35°C under 30 kΩ background load. Cathodes utilize HT MnO₂ (curve A) or NHT MnO₂ (curve B).

Fig. 3. Discharge curves for Li/MnO₂ (NHT) experimental cells at 35°C under 15 kΩ (solid line), 7.5 kΩ (broken line), or 4.0 kΩ (dotted line) background loads.

in Fig. 5 and 6, respectively. The DCC analyses (Fig. 4 and 6) show that, as the current density is increased, the sharp peak representing the flat discharge plateau for HT MnO₂ moves to lower and lower potentials, but the second, more washed-out peak remains stationary. The reaction responsible for the voltage plateau is easily polarized as the current density is increased, but still remains very flat, as evidenced by the sharpness of the peaks. The second reaction, while more sloping, can tolerate the increased current density with little or no increased polarization. The same general trend is seen in the DCC analysis of the NHT MnO₂ and is consistent with potential pulse experiments and open-circuit voltage recovery rates.

Another important characteristic of the Li/MnO₂ discharge is the length of the voltage plateau. It appears that the heat-treatment process controls both the discharge potential and length of the voltage plateau. Table I shows the percent capacity delivered to the second inflection point in the discharge curve as calculated from the DCC curves. The percent capacity delivered by the NHT MnO₂ remains relatively constant at 25% until high current den-

sities are imposed on the cell. For HT MnO₂, the inflection point at end of flat portion of discharge curve is extended to 40% DOD despite the lower discharge voltage.

Open-circuit voltage.—An important aspect in attempting to establish a discharge mechanism is the equilibrium open-circuit voltage corresponding to various depths of discharge along the discharge curve. In the Li/MnO₂ system, these values cannot be easily obtained by simply removing the load and measuring the open-circuit potentials, since a steady state is attained only after an appreciable length of time. Depending upon the depth of discharge and cell temperature, weeks or even months are required to achieve this steady state. This work represents the first thoroughly equilibrated open-circuit recovery curves for Li/MnO₂ cells at various depths of discharge. Similar work (10, 11) has been done, but it used cells that still had rising OCV's (10 mV/24h), and the EMD was heat-treated for 24h at 350°C. This would produce an MnO₂ with decidedly more beta character. Such differences could have an effect on the discharge and subsequent open-circuit recovery profiles. At selected depths of discharge, CR-2016's discharged at 60°C were taken off load and allowed to reach a steady-state potential. Each open-circuit recovery curve represents an individual cell. Reproducibility between cells discharged to nominally the same DOD was ± 5 mV. Figure 7 shows the first 2000h of open-circuit recovery at room temperature for selected cells. Within the first 200h of open-circuit recovery, all the curves are similar in that they display two different time constants. However, the OCV recovery curves do have different shapes, indicating a different recovery mechanism or structure present during this equilibration period. Even after a period of 2000h, the potentials of the equilibrating CR-2016's are still increasing except for cells discharged past 60% DOD. This is graphically shown in Fig. 8. The open-circuit voltages are plotted at various times in their recovery phase. The most rapid increase in

Fig. 7. Long-term, room temperature open-circuit recovery curves for selectively discharged CR2016's: 0.8% (*), 10.1% (+), 25.5% (o), 43.0% (x), and 65.7% (-).

Fig. 8. Comparison of room temperature OCV recovery curves as a function of time on open circuit: 3 weeks (*), 3 months (o), 4 months (x), 5 months (-), 7 months (v), and 8 months (z).

the open-circuit voltages was seen after three months. However, it must be noted that the OCV remained essentially constant after three weeks off load for cells discharged past 70% DOD. Initially, the open-circuit recovery curve was S shaped. However, after approximately eight months, the recovery curve appeared to stabilize. Three distinct regions of recovery became apparent. The first region occurs between 0 and 10% DOD. This sloping recovery profile is indicative of a homogeneous reaction and is most likely the insertion of lithium into the hexagonal close-packed oxygen lattice of the MnO₂ (Eq. [1])

It may also partially reflect contributions of carbon, Teflon, and impurities to the open-circuit voltage. However, a lithium cell with a cathode made solely from the carbon and Teflon used in the MnO₂ cathodes delivered only a negligible capacity at a low current density. The second portion of the MnO₂ discharge occurs between 10 and 40% DOD. This is characterized by the flat open-circuit recovery profile and is representative of a heterogeneous reaction (Eq. [2]).

This indicates the possible occurrence of a two-phase reaction occurring. This can be explained if the MnO₂ is undergoing a slow solid-state transformation as shown by the slow open-circuit recovery. The final discharge region occurs at depths of discharge greater than 40% and might involve the homogeneous insertion of lithium ions into a new structure (Eq. [3])

This new structure and new grain boundaries formed during the solid-state transformation, reaction [2], now al-

lows for the more rapid movement of lithium ions and thus a faster open-circuit recovery is realized for cells discharged past approximately 60% DOD. It was found that the partially discharged MnO₂'s were air and water sensitive. This led to poor and somewhat confusing x-ray diffraction patterns.

A series of CR-2016's were also discharged at 60°C. At various points in the discharge, the cells were taken off load and their recovery closely monitored and recorded. Figure 9 compares the OCV recovery curves for equally discharged cells at 25° and 60°C. The two sets of recovery curves display the same general shape, but the 60°C curves have shorter time constants. Comparisons of the recovery voltages at three weeks for both temperature regimes and seven months at 25°C are made in Fig. 10. Cells discharged past approximately 50% DOD have very similar open-circuit voltages, while cells discharged to less than 50% DOD have very different recovery potentials. The latter part of the Li/MnO₂ discharge appears to be temperature insensitive during open-circuit recovery, while recovery in the early part of the discharge is quite temperature dependent. The differences in recovery voltages at the two different temperatures most likely reflect kinetic rather than temperature effects since the recovery voltages at a selected depth of discharge (Table II) do not significantly differ as a function of temperature. A similar phenomenon was seen in the DCC analysis. The peak centered at 2.9V did not change after heat-treatment of the MnO₂. This again suggests two or more different recovery processes or structures present. Figure 10 shows that three weeks' recovery at 60°C is comparable to seven months' recovery at 25°C. It has revealed that recovery at 60°C can provide a rapid way to equilibrate Li/MnO₂ cells for further study.

Another method to determine if there has been a change in the reaction mechanism during the discharge of the Li/MnO₂ couple is to monitor the change in the system's entropy as a function of depth of discharge. CR-2016's that had been previously discharged to varying degrees and been on open circuit at 60°C for a minimum of two months were cycled in temperature from 60° to -10°C and back. The new open-circuit voltage was recorded for every 10°C change in temperature (Table II). From the slope of the curves generated from these data and the open-circuit voltages, a series of thermodynamic values were calculated (Table III) and plotted as a function of depth of discharge (Fig. 11). The calculated entropies compare favorably with similar data ranging from -28.9 to -13.3 J/mol-K generated for another insertion-type compound, Li_xV₆O₁₃ (11). The abrupt change in the calculated entropies from an average -26.9 to -1.6 J/mol-K after 7.4% DOD suggests that a process change has occurred in the system, which would not be expected for a single-insertion-type mechanism.

Consideration has also been given (4) to the possibility that EMD would be suitable for use in nonaqueous secondary batteries owing to its insertion-type mechanism. However, the solid-state transformation apparent in this work may preclude EMD's use in such a cell system.

Table III. CR-2016 thermodynamic data

MnO ₂ efficiency (%)	ΔG (kcal)	ΔS (e.u.)	ΔH (kcal)

73.8	-67.5	-0.3	-67.6

Other investigators (13, 14) report that discharged Li/MnO₂ exhibits poor cycling for DOD's as low as 25%.

Conclusions

From the results of long-term open-circuit recovery data, differential capacity analysis, and electrochemical discharge, the cathodic reduction process in Li/MnO₂ nonaqueous cells is dependent on the structure and composition of the MnO₂. These two factors establish three distinct stages in the discharge profile. The overall process apparently involves a change in the MnO₂'s structure during discharge. The initial stage of the MnO₂'s reduction occurs within approximately the first 10% of discharge. Insertion of lithium ions into the lattice of MnO₂ forming Li_xMnO₂ (0 ≤ x ≤ 0.1) is proposed for this stage. It is a homogeneous reaction, as evidenced by the sloping nature of the discharge and recovery curves. The next stage in the discharge is consistent with a heterogeneous or two-phase reaction. This occurs between approximately 10 and 40% depth of discharge. It is distinguished by the flat portion of the open-circuit and discharge curves. This may involve a slow, solid-state transforma-

tion or structural change in the MnO₂ from its initial hexagonal close-packed configuration to a cubic close-packed structure characteristic of the LiMnO₂ reaction product. This slow structural change would be responsible for the slow open-circuit recovery curves typical of

Li/MnO₂ cells discharged in this region. The final discharge regime is again characteristic of a homogeneous reaction and may involve insertion of lithium ions into the new structural form of Li_xMnO₂ ($x > 0.4$).

Microscopic Ellipsometric Observation of the Change in Passive Film on 18Cr-8Ni Stainless Steel with the Initiation and Growth of Pit

Katsuhisa Sugimoto,* Shiro Matsuda, Yoshiaki Ogiwara, and Koza Kitamura

Department of Metallurgy, Faculty of Engineering, Tohoku University, Sendai 980, Japan

ABSTRACT

Changes in passive films on 18Cr-8Ni stainless steel with the initiation and growth of pit have been measured in 1 kmol · m⁻³ NaCl using a microscopic ellipsometer which provides a maximum magnification of ca. 600 times. The spatial distribution of film thickness within each grain was observed on the steel before pit initiation. The first pit initiated at a site where there was a small difference of 0.2-0.5 nm in the film thickness. With the growth of the first pit, film thinning first occurred around the pit, and then film thickening started beneath the pit. The second pit broke out on the boundary between the film thinned area and the original film thickness preserved area.

Ellipsometry is one of the promising methods for examining *in situ* the change in films on passivated metals and alloys with the introduction of Cl⁻ ions, which leads to the initiation of pitting. For example, using this method, McBee and Kruger (1, 2) have demonstrated that significant changes occur in the optical properties of the passive film on iron upon introduction of chloride.

* Electrochemical Society Active Member.

Matsuda *et al.* (3) also have reported the changes in the thickness and optical constant of the passive film on commercial 18Cr-8Ni stainless steel as a function of potential in NaCl solution and of the lapse of time after the introduction of Cl⁻ ions into Na₂SO₄ solution. It is impossible, however, to observe a microscopically localized change in the film by conventional ellipsometry which measures an area of more than tens of square millimeters on a specimen.

In order to overcome this limitation of ellipsometry, Sugimoto and Matsuda (4) have developed a microscopic ellipsometer which provides the determination of the thickness and optical constant of a thin film on an area of ca. 10 μm diam. This ellipsometer was first applied to the measurement of passive films on α and γ grains of 22Cr-10Ni austeno-ferritic stainless steel. The results showed that significant differences in film thickness exist between α and γ grains and the film thickness varies even among grains of the same phase (4).

The purpose of the present investigation is to examine the distribution of thickness of the passive film on a microstructure of solution-treated 18Cr-8Ni stainless steel, to reveal the change in this distribution with the initiation and growth of a pit, and to observe the effect of this change on the inducement of a successive pit. To accomplish these objectives, the spatial distributions of film thickness on the steel have been measured by the microscopic ellipsometer before and after pit initiation in NaCl solution.

Experimental

Microscopic ellipsometry.—The same microscopic ellipsometer as that reported in our previous paper (4) was used in the present study. The characteristic of this ellipsometer is that it is equipped with two groups of lenses behind the analyzer for magnifying the polarized reflection image of specimen, in addition to a common polarizer-compensator-sample-analyzer configuration. This combination of lenses can provide a maximum magnification of ca. 600 times and makes it possible to measure a region of ca. 10 μm diam on the specimen surface.

Monochromatic light of wavelength 546.1 nm was used for all measurements. The angle of incidence of the monochromatic light was 59.65°, except for measurements using the technique of multiple-angle-of-incidence ellipsometry. The compensator was fixed at an angle of -45°. Two optical parameters, the relative phase retardation Δ and the relative amplitude reduction Ψ , were obtained from the extinction angles of the polarizer P and the analyzer A for a desired position in the microstructure of specimen. An area of ca. 25 \times 50 μm was subjected to a single determination of Δ and Ψ in the present experiment. The determination of Δ and Ψ was performed every 50 μm in a horizontal direction and also every 25 μm in a vertical direction using a point-by-point scanning technique.

Cell.—A Pyrex glass cell with two optical windows was used. It was also equipped for electrochemical measurements.

Specimen.—A cold-rolled sheet 2 mm thick of high purity 18Cr-8Ni stainless steel with chemical composition given in Table I was used. Coupons 12 \times 28 mm were cut from the sheet, heated at 1050°C under vacuum for 1h, and then water quenched. The surfaces of all the specimens were ground with emery paper up to no. 1500, finished with diamond paste, and degreased in ultrasonic baths of acetone and ethyl alcohol. The degreased specimen was electrochemically etched in 10 weight percent (w/o) oxalic acid to reveal crystallographic microstructure. The area for the measurement of the spatial distribution of film thickness, ca. 500 \times 700 μm , were marked by a Micro-Vickers hardness tester. Then, the etch structure on the surface was erased by polishing slightly with diamond paste. After degreasing again in ultrasonic baths, the specimen was covered by a clear vinyl chloride coating except for the marked area.

Solutions.—In most electrochemical experiments, 1 kmol \cdot m⁻³ NaCl adjusted to pH 6.0 was used. Deaeration was achieved by bubbling purified N₂ through the solution for 4h. All experiments were

carried out in a N₂ atmosphere at 20° \pm 0.5°C under stationary condition.

Electrochemical polarization.—The passivation and pitting of the specimens were accomplished under potentiostatic control. Electrode surfaces of the specimens were set vertically. After keeping a specimen at a given potential for a given time, ellipsometric parameters of the specimen surface were measured. A saturated calomel electrode was used as the reference electrode, and the potentials reported here are referred to this base.

Processing of ellipsometric data.—Drude's exact optical equations were used in the calculation of theoretical Δ vs. Ψ curves for the growth of passive films with given optical constants and also in the determination of thicknesses and optical constants of passive films with multiple-angle-of-incidence ellipsometry. In these calculations, 1.342 for the refractive index of 1 kmol \cdot m⁻³ NaCl and 2.67 - 4.03i for the complex refractive index of the matrix of 18Cr-8Ni stainless steel (5) were used.

Easy method for the determination of film thickness.—In the case of the measurement of a specimen surface before the initiation of pitting, an easy method was employed in order to reduce the time required for the measurement. That is, the change in the angle of P at an extinction condition was only followed at a fixed angle of A.

Figure 1 shows calculated P vs. A, or Δ vs. Ψ , plots for the growth of passive films with varying optical constants of N₂ = n₂ - k₂i, where 2.4 \leq n₂ \leq 2.6 and 0.4 \leq k₂ \leq 0.6, on 18Cr-8Ni stainless steel in 1 kmol \cdot m⁻³ NaCl. The value N₂ = 2.5 - 0.5i has been reported as the optical constant for a passive film on 18Cr-8Ni stainless steel in 1 kmol \cdot m⁻³ Na₂SO₄ (5). As will be mentioned in "Change in film thickness with pit growth" section, almost the same value has been obtained for the passive film before pit initiation in 1 kmol \cdot m⁻³ NaCl in the present study. It can be seen from the figure that the change in A, or Ψ , at a given optical constant N₂ with a unit change in film thickness d is much smaller than that in P, or Δ . The change in P, or Δ , at a given film thickness with changes in n₂ and k₂ is also small. This substantiates the propriety of making use of the easy method.

Relations between d and P for films with three different optical constants around N₂ = 2.5 - 0.5i are derived from Fig. 1 and given in Fig. 2. Linear relations can be seen at least for the films having thicknesses of less than 5.0 nm. Errors in the determination of film thickness due to deviations in n₂ and k₂ such as N₂ = (2.5 \pm 0.1) - (0.5 \pm 0.1)i can be estimated, for example, as \pm 2.5% at d = 2.0 nm, \pm 3.3% at d = 3.0 nm, and \pm 3.6% at d = 5.0 nm.

Multiple-angle-of-incidence ellipsometry.—In the measurement of specimen surface after the initiation of

Fig. 1. Calculated P vs. A, or Δ vs. Ψ , plots for the growth of passive films having optical constants N₂ = n₂ - k₂i in the ranges 2.4 \leq n₂ \leq 2.6 and 0.4 \leq k₂ \leq 0.6.

Table I. Composition of 18Cr-8Ni stainless steel (w/o)

Cr	Ni	Mn	C	Si	Mo	Cu	S	Fe
18.8	8.92	0.0017	0.0014	0.026	0.0018	0.0017	0.0083	Balance

Fig. 2. Relations between d and P for films having three different optical constants.

pitting, multiple-angle-of-incidence ellipsometry (6, 7) was used together with the easy method. First, the optical change in a given area was measured by the easy method and an approximate spatial distribution map of film thickness over the area was immediately made. Then, in order to determine one consistent value of the optical constant in association with compatible value of film thickness, measurements by multiple-angle-of-incidence ellipsometry were performed at several points within each area where a characteristic change in the film thickness was recognized in the map. Three incident angles 50.00° , 55.00° , and 59.65° were used. In the estimation of the most reasonable values of optical constants and thicknesses of films, a computer program, similar to the one used by Johnson and Bashara (7), in which the sum of squares of the residuals was minimized, was employed.

Results and Discussion

Spatial distribution of film thickness before pit initiation.—Figures 3a, 3b, and 3c show the microstructure of an 18Cr-8Ni stainless steel specimen, the spatial distribution of film thickness on the microstructure, and the detailed distribution of film thickness around the site at which the first pit initiated, respectively. The specimen was passivated in $1 \text{ kmol} \cdot \text{m}^{-3}$ NaCl at 0.3V for 5h. No pitting occurred at this potential. After the passivation, $4.44 \text{ kmol} \cdot \text{m}^{-3}$ NaCl was added to the solution in order to start pitting. The site at which the first pit occurred is indicated by a dotted circle in the figures.

As shown in Fig. 3b, the film thickness varies from place to place in the small area of $500 \times 500 \mu\text{m}$ on the specimen. By overlapping Fig. 3a and 3b, the distribution of film thickness within each grain can be seen. Furthermore, we notice that the configuration of the electrode affects the distribution of film thickness; namely, the film on the lower part of electrode, which corresponds to the lower part of Fig. 3b, is slightly thicker than that on the upper part. Concerning the relationship between the distribution of film thickness and the preferable site for pit initiation, as seen from Fig. 3c, it has been frequently experienced that the place where there was a small difference of 0.2-0.5 nm in film thickness tended to offer the site for pit initiation.

Change in film thickness with pit growth.—Pitting was performed in $1 \text{ kmol} \cdot \text{m}^{-3}$ NaCl at 0.8V for a given period after preliminary passivation at 0.3V for 3h. In this solution, the pitting potential obtained with the scanning rate

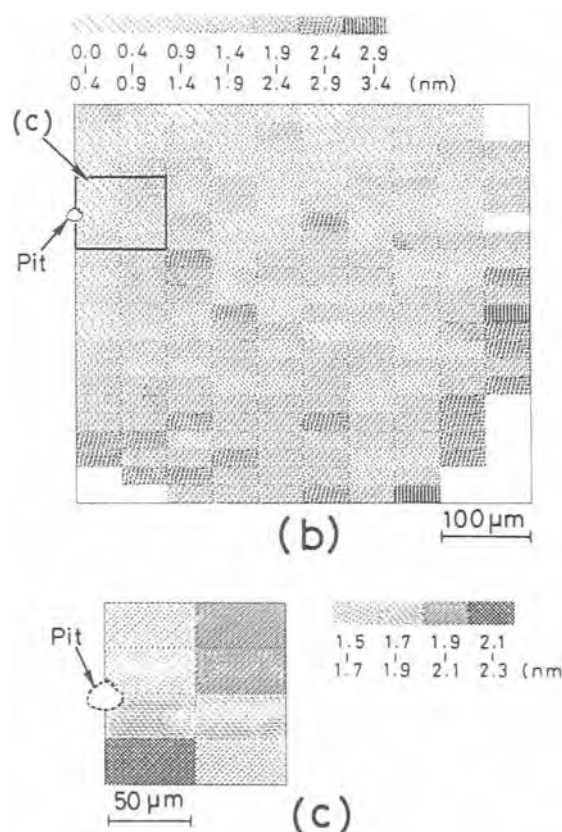

Fig. 3. Microstructure (a), the spatial distribution of film thickness on the microstructure (b), and the detail of the distribution around the initiation site of the first pit (c) on 18Cr-8Ni stainless steel passivated in $1 \text{ kmol} \cdot \text{m}^{-3}$ NaCl at 0.3V for 5h.

of $22 \text{ mV} \cdot \text{min}^{-1}$ was 0.55V . In most cases, pitting started after an average induction time of 230s at 0.8V. Figure 4 shows the increase in film thickness with lapse of time at 0.8V; a film *ca.* 2.6 nm thick is formed before the start of pitting.

After growing the first single pit for given periods the polarization current was stopped and the distribution of film thickness was measured at the corrosion potential of *ca.* -0.01V . The ellipsometric measurement by the easy method at the angle of incidence of 59.65° was first performed over the area of *ca.* $400 \times \text{ca. } 400 \mu\text{m}$ around the pit. On the basis of the result of this measurement, a map showing the approximate spatial distribution of film thickness was made assuming the optical constant of films over the area as $N_2 = 2.5 - 0.5i$. Three characteristic areas—that is, a film thickened area, a film thinned area, and an original film thickness preserved area—were rec-

Fig. 4. Relation between d and t for 18Cr-8Ni stainless steel in $1 \text{ kmol} \cdot \text{m}^{-3} \text{ NaCl}$ at 0.8V .

ognized on the map. Then, in order to determine precisely the optical constants and thicknesses of films, the multiple-angles-of-incidence ellipsometry was applied on these areas. From this analysis, it was found that each area has its own optical constant: $N_2 = 2.53 - 0.48i$ for the original film preserved area, $N_2 = 2.32 - 0.27i$ for the film thinned area, and $N_2 = 1.65 - 0.00i$ for the film thickened area. Figure 5 shows d vs. P (or Δ) relations calculated using these optical constants. These relations were used to get the exact spatial distributions of film thickness on the areas.

Figures 6a, 6b, and 6c show the spatial distributions of film thickness around pits grown for 3, 6, and 12s, respectively. The figures on the left-hand side are maps and those on the right-hand side are the bird's-eye views of the distributions.

In the early stage of the growth of a pit, film thinning occurred around a pit (Fig. 6a). Then, after several seconds, film thickening started below the pit in a downward direction, accompanying the area of film thinning (Fig. 6b). With further growth of pit, both the areas of film thinning and film thickening expanded and the distribution of film thickness with high hills and deep valleys was accomplished around the pit (Fig. 6c).

It is thought that the film thinning is due to etching by a low pH solution which is discharged from the inside of

Fig. 5. Relations between d and P , or Δ , for films on three characteristic areas formed around the first pit.

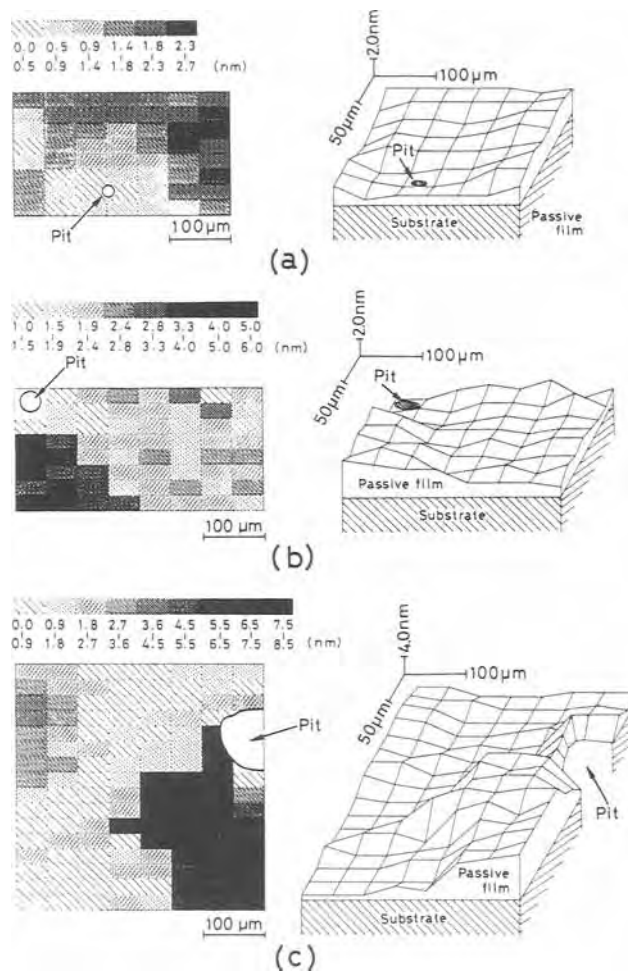

Fig. 6. Spatial distributions (left) and their bird's-eye views (right) of film thickness around pits grown for 3 (a), 6 (b), and 12s (c), respectively, on 18Cr-8Ni stainless steel in $1 \text{ kmol} \cdot \text{m}^{-3} \text{ NaCl}$ at 0.8V .

a growing pit. Suzuki *et al.* (8) have reported that the pH of solutions within active pits of Type 304L is lowered to 0.60-0.80. The film thickening below the pit should be mainly due to the deposition of iron hydroxide by the hydrolysis of Fe^{2+} ions contained in the solution from the inside of pit. The low refractive index value of 1.65 and the value of zero of extinction coefficient of the optical constant for the film on the film thickened area suggest the existence of hydroxide (5). An increase in film thickness around a pit has been reported by Kodama (9, 10) in the case of pitting of iron in a borate-buffer solution containing SO_4^{2-} ions.

Effect of changes in passive film caused by first pit on initiation of second pit.—Figures 7a, 7b, and 7c show the optical micrograph of the first and the second pits, the spatial distribution of film thickness around the first pit and the initiation site of the second pit, and the bird's-eye view of the distribution, respectively. The first pit was grown in $1 \text{ kmol} \cdot \text{m}^{-3} \text{ NaCl}$ at 0.8V for 25s, and then polarization current was stopped. After the measurement of the distribution of film thickness around the first pit, the potential was again set at 0.8V and the second pit was introduced and grown for 3s.

In Fig. 7b, the area of film thinning can be seen above the level of the lower edge of the first pit and the area in the shape of an inverted triangle of film thickening below the level. On both the sides of the inverted triangle area are areas in which the original film thickness is preserved without the effect of the first pit. The second pit occurred on the boundary between the area of film thinning and the area of original film thickness. The difference of ca. 0.5 nm in the film thickness was on this boundary. This result again shows the tendency of pit ini-

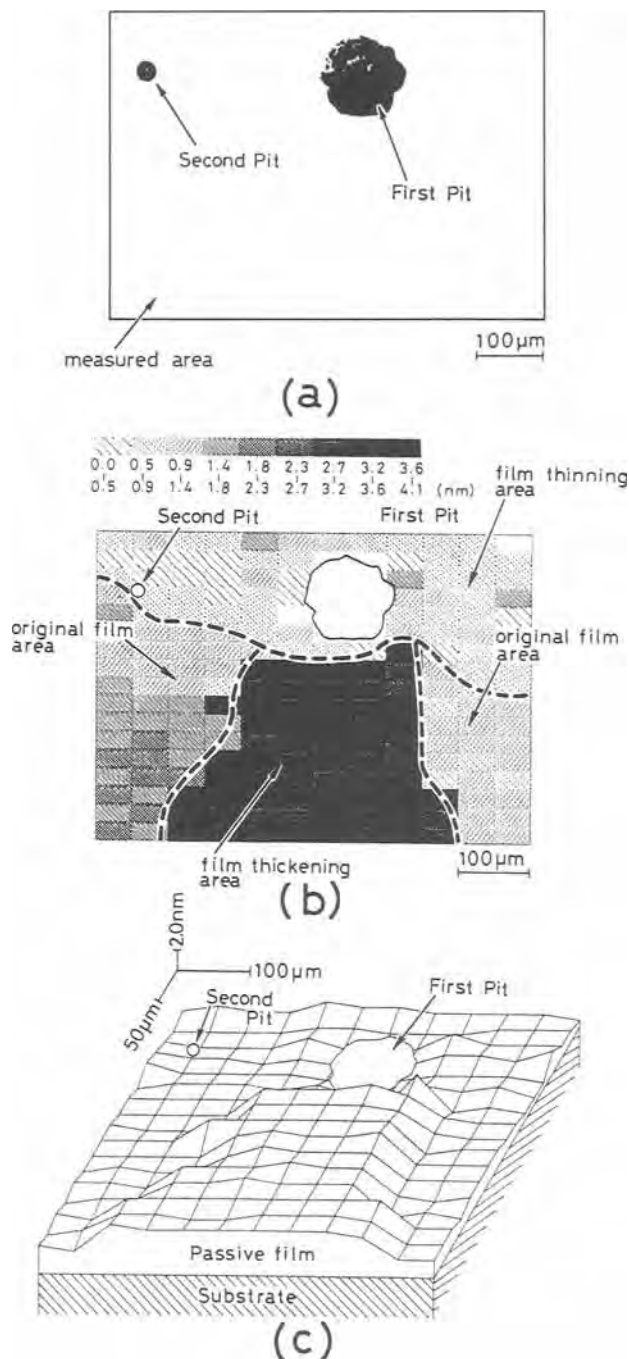

Fig. 7. Optical micrograph of the first and the second pits (a), the spatial distribution of film thickness around the first pit (b), and the bird's-eye view of the distribution (c) on 18Cr-8Ni stainless steel pitted in $1 \text{ kmol} \cdot \text{m}^{-3} \text{ NaCl}$ at 0.8V .

tiation at the place where there is a slight difference in the film thickness.

Although the reason why the second pit initiates preferentially on such a boundary is not clear at present, it is possible to assume that microcracks leading to the nucleation of pits arise on the boundary. That is, stress caused by differences in the volume, chemical composition, hydration, electrostriction pressure, and interfacial tension of films could act concentrically on the boundary and cause the mechanical breakdown of films there. The adsorption of Cl^- ions on the films is reported by Sato (11) to decrease the critical breakdown stress. This should be accelerated by higher chloride concentration caused by discharge from the first pit (8). This atmosphere should accelerate the initiation of pit nuclei at the microcracks thus formed on the boundary in question.

Conclusion

1. There is a spatial distribution of film thickness within each grain of 18Cr-8Ni stainless steel.
2. The first pit tends to occur at the place where there is a small difference of 0.2-0.5 nm in film thickness.
3. With the growth of the first pit, an area of film thinning is first formed around the pit and then an area of film thickening below the pit.
4. The second pit tends to occur on the boundary between the film thinned area and the original film thickness preserved area.

Stochastic Models of Pitting Corrosion of Stainless Steels

I. Modeling of the Initiation and Growth of Pits at Constant Potential

D. E. Williams,* C. Westcott, and M. Fleischmann*

AERE Harwell, Materials Development Division, Oxon, England OX11 0RA

ABSTRACT

A stochastic model for pit initiation is developed, involving as parameters an initiation frequency for pit nuclei, a death probability for unstable pits, and a critical age which defines the transition between a stable and an unstable pit. Emphasis is placed on validating methods for data analysis to recover the parameters of the model from observed current-time series. Such methods are developed and tested using data generated by computer simulation of the process. The expected induction time for stable pit initiation is derived. Results for the statistics of ensembles of current-time transients are given. Methods of analysis of the spectral power density of the current, taking into account the nonstationary process of stable pit propagation, are considered.

Localized corrosion processes of metals such as stainless steels in aqueous environments (1) are interesting and unusual because most of the material is in fact not corroding; it is passive and stable. In general, localized corrosion processes — pitting corrosion, crevice corrosion, stress corrosion cracking, corrosion fatigue, intergranular corrosion — are unpredictable as regards the time of initiation and often also as regards the place of attack. Indeed, localized corrosion is properly considered as a rare event, and a statistical treatment is appropriate for its description (2). Such a treatment is presented in this and the following papers (3, 4). Although the work is concerned with the pitting corrosion of stainless steels in dilute aqueous solutions of sodium chloride, it is believed that the stochastic model developed from the results is of general application. Preliminary reports of the work have appeared elsewhere (5, 6).

Several different mechanisms for the initiation of pitting corrosion have been proposed. These have been reviewed recently (7-9). It is agreed that corrosion pits propagate as a result of the development and maintenance of an elevated local acidity. As far as the nucleation of pits is concerned, authors have variously emphasized, among other phenomena, inhomogeneity in the metal, cracking and slow healing of the passive film (8, 9), development of critical acidity levels in microscopic flaws (7), defect transport in passive films (10), and chloride adsorption or incorporation into localized areas of passive film (11, 12), including the idea of adsorption of a number of halide ions into a "transitional complex" (12) or of local thinning of the oxide under chloride "islands" (13). Local acidification (14) has been related to local adsorption of chloride (15).

Recent literature has been concerned with the definition of critical potentials for pit initiation and repassivation. Simple cyclic polarization experiments to measure these parameters can be determined by the formation of only one pit on the surface of the test specimen, so it is not surprising that the resulting data can be extremely variable. Despite this, relationships have been given for the chloride-concentration dependence of pitting potentials obtained in such an experiment (7-9).

A further feature of pitting corrosion of stainless steels is the observation of an induction time, τ , before pit initiation (12, 15), either following potential change from the inert into the pitting range in a halide solution, or upon the addition of halide into an inert solution. Hoar and Jacob (12), using the second approach, in which the specimen was prepassivated in a slowly flowing solution, with subsequent addition of halide ions, showed that the induction time for initiation of stable pitting on 18Cr 8Ni stainless steel varied as $[X^-]^n$ with $2.5 < n < 4.5$ for $X = Cl^-$ and $4 < n < 4.5$ for $X = Br^-$; the exponent n was different at different electrode potentials E , but did not show an obvious systematic variation with E . It was also shown that the induction time has a very strong temperature de-

pendence and an electrode potential dependence of 250-450 mV/decade for chloride solutions and 30-70 mV/decade for bromide solution.

It has been noted above, however, that localized corrosion is properly considered as a rare event, so that statistical treatments are appropriate for its description (2). A consequence of these rare events is the generation of current fluctuations at constant potential (3, 5, 6, 15, 17), and these fluctuations during the induction period make a definite induction time difficult to define experimentally. Shibata and Takeyama (18, 19) determined τ as the time for the current to exceed an arbitrarily determined (and rather high) value. The induction time thus defined is a statistical variable; the survival probability for steel specimens determined as a function of time showed a Poisson distribution with a potential-dependent nucleation rate. It is evident that the values of the derived parameters must depend on the current level chosen.

More generally, pitting corrosion must be described by potential-dependent and chloride-concentration-dependent pitting probabilities and the values of parameters such as the "critical potential" depend on the threshold values of the probability chosen for the description (20) (as well as on other probabilities such as that of repassivation). One objective of our work is to take some steps towards a more rigorous definition of the parameters of a stochastic model so that the potential and concentration dependences can be modeled. Another objective is to define and validate methods of data analysis for obtaining such parameters from experimental data with some degree of confidence. We shall show that this is not straightforward. The application and limitation of each method needs to be carefully considered, particularly when experimental data are being treated and one wishes to make a distinction between the inadequacies of the model being tested and the inadequacies of the data processing methods.

The general modeling is based on nucleation-type theory in conjunction with the statistical methods used to describe rare-event processes; the evolution of the current at a site following nucleation is assumed to follow a definite rule determined, perhaps, by the shape of the evolving defect. The theory describing the statistics of current-time transients resulting from random nucleation processes followed by a deterministic evolution of the current to the resulting growth centers has already been developed in some detail for electrocrystallization (21-28), and one objective of this present work is to explore to what extent this theory can be applied to pitting corrosion. The experimental approach (3, 5, 6) dictated by this modeling is the determination of ensembles of transients of the corrosion current and the analysis of the changes in the ensemble statistics brought about by changing the alloy, solution conditions, stirring, electrode potential, or other variables. We also show (4) that a new technique, an interrupted potentiodynamic sweep, can be used to evaluate rapidly the potential dependence of pitting probability.

*Electrochemical Society Active Member.

The phenomenological model is developed in this paper and analyzed by simulation and algebraic methods. Methods for data processing are developed and tested using simulated data. In the following paper (3), parameters derived from a comparison with experimental data are related to appropriate microscopic models of pitting corrosion.

Model

We model the pitting process as a series of events which are randomly distributed in time and space over the metal surface. Each event results in a local current which evolves with time according to rules which are the same for every event, and the total current is obtained as the sum of the local currents. This type of model is easily explored by computer-based simulation procedures. Agreement with experiment (3-6) is obtained with a model having the following features: (i) events are nucleated with a frequency λ ($s^{-1} \cdot cm^{-2}$); (ii) events have a probability, μ (s^{-1}), of dying; (iii) events which survive beyond a critical age, τ_c (s), do not die; and (iv) each event has an induction time, τ_1 (s), during which the local current does not increase but during which the event may die.

According to this model, pits are unstable when they are first nucleated. A pit then becomes stable only after it has survived past the critical age.

Simulation Technique

The electrode surface was considered as an array of equal areas, each of which was allowed to support at most one pit. In each cycle of the program, the time increment of the experiment, each area was examined and a random-number generator used to decide whether or not to nucleate a pit there, according to a predetermined probability of birth; each existing pit was examined and eliminated or not according to a predetermined probability of death; the current to each pit was incremented according to a predetermined rule, the same for each pit, and the total current at the end of the time increment obtained by summation of the pit currents. A "pit area" of 1/50 of the total area was normally assumed.

Linear and quadratic rules for the current increase to each pit, the effect of changing probabilities of birth and death, and the effect of circumstances in which pits which had survived beyond some predetermined critical age continued to grow indefinitely were explored. The model is represented schematically in Fig. 1.

The effect of defining a precursor state is also interesting. This was allowed for in the simulation by defining a fixed time period after each nucleation event during which the current remained zero, but in which the event could die [assumption (iv) above]. The effect of the precursor state appeared as an apparent reduction in nuclea-

tion rate, with the apparent nucleation rate being a function of the death probability chosen. This apparent nucleation rate was very sensitive to the values chosen for the precursor time and death probability.

Algebraic Formulation

Statistics of pit formation.—It will be shown that by selecting a first or last passage time of a given current level as defining the formation of a stable pit the statistics of stable pit formation can be defined. Modeling of the birth of stable pits is developed in this section; the modeling of the ensemble statistics of current-time transients is discussed in the following section.

We denote the specimen area by a (cm^2). Then the expected number of events in time t is λat , and the probability of survival of a single event for time τ_c is $\exp(-\mu\tau_c)$. Thus, the rate of birth of stable pits Λ (s^{-1}) is given by

$$\Lambda = a\lambda \exp(-\mu\tau_c) \quad [1]$$

and the probabilities $P(n,t)$ of generating stable pits are governed by the set of simple differential equations (see Appendix A)

$$\frac{dP(n)}{dt} = \Lambda P(n-1) - \Lambda P(n) \quad [2]$$

By defining a probability generating function, the set of equations can be solved. The following results are obtained (see Appendix A for details).

The expected number of stable pits at any time, $t > \tau_c$, is

$$\langle n \rangle = \lambda a(t - \tau_c) \exp(-\mu\tau_c) \quad [3]$$

Evidently, if $t < \tau_c$, $\langle n \rangle = 0$. This is one of the assumptions of the model.

The probability that no stable pit is formed within a time, $t > \tau_c$ is $P(0)$, is given by

$$\ln [P(0)] = -\lambda a(t - \tau_c) \exp(-\mu\tau_c) \quad [4]$$

Again, an assumption of the model is that $P(0) = 1$ if $t < \tau_c$.

Equation [4] gives the probability of a specimen remaining unpitted as a function of the exposure time and of the parameters of the model, λ , μ , and τ_c . An expected value for the induction time before the onset of stable pitting, $\langle \tau \rangle$, can be obtained by substituting $\langle n \rangle = 1$ in Eq. [3]

$$\langle \tau \rangle = \left(\frac{1}{a\lambda} \right) \exp(\mu\tau_c) + \tau_c \quad [5]$$

and Eq. [4] can then be conveniently rewritten

$$\ln [P(0)] = -(t - \tau_c) / (\langle \tau \rangle - \tau_c) \quad [6]$$

Current-time transients: theory of ensemble statistics.—The theory outlined in the previous section refers to the observation of the probability of the formation of a defined number of pits or, more specifically, to the probability of the survival of an unpitted specimen. While these probabilities can be derived under favorable circumstances, the directly measured variable is the current and the processes are therefore more correctly modeled using this as the stochastic variable (21-23). Alternatively, a variable directly related to the current such as the surface area or volume of the pits should be used. Modeling at this level is closely related to the modeling of fluctuations in electrocrystallization processes (21-28), except that we are here considering the birth, growth, and, under certain circumstances, death of two- or three-dimensional holes rather than that of two- or three-dimensional growth centers.

An ensemble of experiments is a set of experiments all starting from the same initial condition, and the ensemble mean value and standard deviation of the current are defined as the mean and standard deviation of the values of current observed in all of the experiments at a given time.

Fig. 1. State diagram illustrating the behavior of an element of surface in the simulation procedure.

It has been shown that it is particularly convenient to interpret the time dependence of the ratio of the ensemble standard deviation, $\sigma(I)$, to the ensemble mean, $\langle I \rangle$ (21-26). Additional information can be obtained from an analysis of the spectral power density of the current, $G_i(\omega)$, and this is discussed in the Spectral power density of the current section below.

The model outlined above can be divided into two time ranges. In the stable pitting limit, at long times ($t > \tau_c$ and $\Lambda t > 1$), the behavior of the system is dominated by the nucleation and growth of stable pits, since the current due to these is assumed to increase without limit.

In the unstable pitting limit, at short times ($t < \tau_c$ or $\Lambda t < 1$), only the nucleation, growth, and death of unstable pits are observed. The theory for these two limits of the model is largely available, and we will confirm its applicability using simulated data in the Discussion section. We also use the simulated data to explore the circumstances under which the behavior of the unstable pits can be distinguished from that of the stable pits and to develop methods of analysis of the data to recover the parameters of the model.

Stable pitting limit.—For the nucleation (rate Λ , Eq. [1]) and unrestricted growth of pits, we obtain, at sufficiently long times (21-23)

$$\sigma(I)/\langle I \rangle = (\Lambda/\Lambda t)^{1/2} \quad [7]$$

irrespective of whether the growth takes place in two (islands) or three (holes) dimensions.

The model described above postulates the nucleation of stable pits subject to a delay time, τ_c (the critical age parameter). This is not a simple delayed-nucleation problem, however, since there is a current due to any given pit before it reaches the critical age.

If the current to a stable pit increases with its age, ν , according to some general rule $i = f(\nu)$, then the ensemble mean current at time t is

$$\langle I \rangle = \int_0^t \Lambda f(\nu) d\nu \quad [8]$$

Given a constant rate parameter, Λ , then the function $f(\nu)$ can be recovered from experimental data by differentiation of $\langle I \rangle$ with respect to t .

For the special case of a linear growth law for pits, the current to a pit of age ν at time t being

$$i = C\nu \quad [9]$$

the effect on the ensemble mean of the introduction of a critical age parameter, τ_c , can be obtained by writing the current as

$$i = C(\nu_1 + \tau_c) \quad [10]$$

The ensemble mean current at time $t > \tau_c$ is, then

$$\langle I \rangle_s = \int_0^{t-\tau_c} \Lambda C(\nu_1 + \tau_c) d\nu_1 = \frac{\Lambda C}{2} (t^2 - \tau_c^2) \quad [11]$$

where the subscript s denotes stable pits.

Unstable pitting limit.—The ensemble mean current in the unstable pitting limit can be obtained by calculating the contribution to the average from each pit, weighted by the probability of observing that pit. If $P(\nu_1)$ denotes the probability of observing a pit dying at age ν_1 , and $Q(\nu_1)$ the charge contributed by that pit, then

$$\langle I \rangle = \frac{1}{t} \int_0^t Q(\nu_1) P(\nu_1) d\nu_1 \quad [12]$$

With the assumption of the Model section of a uniform probability, μ , of death of pits

$$\begin{aligned} P(\nu_1) &= \{\text{probability of observing the birth of a pit} \\ &\quad \text{in the interval } (0, (t - \nu_1))\} \\ &\times \{\text{probability of survival of the pit to age } \nu_1\} \\ &\times \{\text{probability of death of the pits}\} \\ &= \alpha\lambda (t - \nu_1) [\exp(-\mu\nu_1)] \mu \end{aligned} \quad [13]$$

With the special assumption of a linear growth law for pits (Eq. [9]), the charge, $Q(\nu_1)$, contributed by a pit dying at age ν_1 is $C\nu_1^2/2$. Hence, the ensemble mean current is, from Eq. [12] and [13]

$$\begin{aligned} \langle I \rangle_{un} &= \frac{1}{t} \int_0^t (C\nu_1^2/2) \cdot P(\nu_1) d\nu_1 \\ &= \frac{1}{t} \int_0^t \frac{C\nu_1^2}{2} \cdot \mu e^{-\mu\nu_1} \cdot \alpha\lambda (t - \nu_1) d\nu_1 \\ &= \frac{\alpha\lambda C\mu}{2} \left[\frac{te^{-\mu t}}{\mu^2} + \frac{2}{\mu^3} (1 + 2e^{-\mu t}) - \frac{6}{\mu^4 t} \right. \\ &\quad \left. (1 - e^{-\mu t}) \right] \end{aligned} \quad [14]$$

where the subscript, un , denotes unstable pits. In the limit at long enough time

$$\langle I \rangle_{un,z} = \alpha\lambda C/\mu^2 \quad [15]$$

If the birth of stable pits is sufficiently rare in comparison with the birth of unstable pits, then the ensemble mean current for the complete model can be obtained as the sum of Eq. [11] and [14].

The behavior of the variance of the current can be obtained in the limit of short and long times. At short times, the system is dominated by the birth of unstable pits, so (23)

$$\sigma(I)/\langle I \rangle = (1/\alpha\lambda t)^{1/2} \quad [16]$$

while at long times the system reaches an equilibrium distribution of the number and age of unstable pits, and

$$\sigma(I)/\langle I \rangle \sim (\mu/\alpha\lambda)^{1/2} \quad [17]$$

The transition from Eq. [16] to [17] occurs around $t \sim 1/\mu$. Derivations, and some additional results, for the mean and variance of the number and age of pits, are given in Appendix B.

Effects of overlap of pits.—In the limit where one has overlap of two- or three-dimensional holes, pitting corrosion becomes active dissolution or anodic brightening. In these cases, different forms for $\sigma(I)/\langle I \rangle$ are expected, depending on the details of the process (21-26). Pits may also interact over greater distances than their physical diameter by virtue of their associated concentration and potential gradients. Such effects would appear in diagrams of $\sigma(I)/\langle I \rangle$ as effects due to overlap.

Spectral power density of the current.—In the case of a system whose behavior is dominated by the nucleation, growth, and death of unstable pits, analysis of the spectral power density of the resulting current leads directly to the nucleation rate and average lifetime of the pits. Some information about the form of the elementary current-time transient for an individual pit can also be obtained. The process is a "stationary" one,¹ and data processing to yield the estimate of spectral power density from a set of experimental records is straightforward.

A system whose behavior is dominated by the nucleation and growth of stable pits, is "nonstationary": the estimate of spectral power density obtained from a set of experimental records depends both on the observation time and on the details of the method used to process the data. One particular problem is that, in the application of a discrete Fourier transform to a record of limited length, the record is assumed to be cyclic, repeating with period equal to the record length.

In this section, we consider some methods for obtaining spectral power density estimates for systems having both stable and unstable pits. We give some theoretical results, and, in the Discussion section, we compare these results with calculations on simulated data. Our objective is to define and test the methods of data analysis which we will be applying to experimental data.

¹That is, one for which the statistical properties are independent of time.

The theory of the spectral power density of the current resulting from the pitting model outlined above can be developed in a simple fashion with the assumption that each pit, whether stable or unstable, is an independent noise source. The total power can therefore be obtained by summation of the power due to each of the individual sources.

The spectral power density cannot formally be defined for a nonstationary process, such as the unlimited current increase assumed here for stable pits. However, the imposition of a restricted observation time produces a signal for which a discrete Fourier transform, and hence a spectral power density, can be calculated. The difficulty arises in producing an analytical description of the result of such a procedure, given knowledge of the process which gave rise to the nonstationary signal.

Unstable pitting limit.—It is difficult to calculate the spectral power density of the current for the model assumed here of uniform probability of death of an unstable pit. However, the spectral power density has been previously derived for the related case of random nucleation at rate $\alpha\lambda$, of centers of a defined lifetime, ν_1 (23), i.e.

$$i = C(t - u) \quad u < t < \nu_1 + u \quad [18]$$

$$= 0 \quad \text{otherwise} \quad [19]$$

where u is the time of birth of the center. The spectral power density of the current for the process thus defined is

$$G_I(\omega) = \alpha\lambda C^2 \left[\frac{2}{\omega^4} + \frac{\nu_1^2}{\omega^2} - \frac{2\nu_1 \sin(\omega\nu_1)}{\omega^3} - \frac{2 \cos(\omega\nu_1)}{\omega^4} \right] \quad [20]$$

The noise is white at low frequencies

$$G_I(\omega) \sim \alpha\lambda C^2 \nu_1^4 / 4 \quad [21]$$

The level of $G_I(\omega)$ begins to fall at $\omega \sim 1/\nu_1$, and the high frequency asymptote is

$$G_I(\omega) = \alpha\lambda \frac{C^2 \nu_1^2}{\omega^2} \quad [22]$$

The linear current-time relationship (Eq. [18]) has been assumed for simplicity of calculation. Different forms for Eq. [18] change the shape of the high frequency asymptote of $G_I(\omega)$. This is a stationary process, so, given a set of experimental records, each with a limited observation time, T_0 , the best estimate of $G_I(\omega)$ is obtained by stringing the data files end to end and calculating using the resulting extended record (Fig. 2a).

Stable pitting limit.—Consider a stable pit formed at time, u . Again, the linear current-time relationship, Eq. [9], is assumed.

If only stable pits are considered, then an individual experimental record will comprise the sum of a number of current ramps according to Eq. [9], randomly initiated after the start of the experiment, with frequency $\Lambda = \alpha\lambda e^{-\mu\tau}c$, and terminated at $t = T_0$, the observation time. The Fourier transform of the signal can now be defined, as a consequence of the imposition of the artificial constraint $i = 0$ if $t > T_0$. The signal is the same as a set of randomly initiated sawtooth waveforms, constrained such that they all terminate at $t = T_0$.

Two different theoretical results (derivations given in Appendix C) can be given, depending on the value of Λ .

The first result comes about when $\Lambda T_0 < 1$. If $\Lambda T_0 < 1$, then at most one stable pit is expected in each observation interval, and it is likely that many of the intervals will show no stable pit. Stable pits nucleated within the observation interval grow until they reach an age, ν_1 , determined by the observation time, T_0 : $0 \leq \nu_1 \leq T_0$. If the condition $\Lambda T_0 \leq 1$ holds, then the extended record obtained by concatenating the data files from each observation interval (Fig. 2b) can be approximated as a series of randomly initiated triangles, with a uniform distribution of age, ν_1 , in the range $0 \leq \nu_1 \leq T_0$.

(a) Stationary process

(b) Non-stationary process

(I) $\Lambda T_0 < 1$

(II) $\Lambda T_0 \gg 1$

Fig. 2. Processing experimental records to obtain spectral density estimates.

The spectral power density of such a current trace is

$$G_I(\omega) = \frac{\Lambda C^2}{T_0} \left[\frac{2T_0}{\omega^4} + \frac{T_0^3}{3\omega^2} + \frac{2T_0 \cos(\omega T_0)}{\omega^4} - \frac{4 \sin(\omega T_0)}{\omega^5} \right] \quad [23]$$

The noise does not become white at low frequency. The high frequency asymptote is

$$G_I(\omega) \cong \frac{\Lambda C^2 T_0^2}{3\omega^2} \left(\omega > \frac{1}{T_0} \right) \quad [24]$$

and there may be a possibility of determining Λ from the value of the power at $\omega = 1/T_0$

$$G_I\left(\frac{1}{T_0}\right) = 0.048\Lambda C^2 T_0^4 \quad [25]$$

The second result obtains when $\Lambda T_0 \gg 1$. If the density of stable pits is sufficiently high, then the current in each observation period can be approximated as the ensemble mean current, Eq. [11]. Thus, in the concatenated data set, in the r th interval

$$I \cong \frac{1}{2} \Lambda C(t - rT_0)^2 \quad [26]$$

In this case (see Appendix for details)

$$G_I(\omega) = \frac{\Lambda^2 C^2}{4T_0} \left[\frac{T_0^4}{\omega^2} + \frac{4T_0^2}{\omega^4} \cos(\omega T_0) - \frac{8T_0 \sin(\omega T_0)}{\omega^5} - \frac{8}{\omega^6} \cos(\omega T_0) + \frac{8}{\omega^6} \right] \quad [27]$$

and the high frequency asymptote is

$$G_I(\omega) = \Lambda^2 C^2 T_0^3 / 4\omega^2 \quad [28]$$

The power given by Eq. [28] is a factor of $(3/4)\Lambda T_0$ greater than that given by Eq. [24]. Since ΛT_0 is the expected

Fig. 3. Survival probability derived from passage times. $\sigma = 5$. $\lambda = 0.05$. $\mu = 0.05$. $\tau_c = 100$. $C = 0.1$. The critical age corresponds to pit current = 10. Passage time assumptions are as follows. 1: First passage through $i = 40$. 2: Last passage through $i = 15$. 3: First passage through $i = 15$.

number of stable pits, $\langle n \rangle$, Eq. [24] and [28] may be rewritten

$$G_1(\omega) = C^2 T_0 \langle n \rangle / 3\omega^2 \quad (\langle n \rangle \leq 1) \quad [29]$$

and

$$G_1(\omega) = C^2 T_0 \langle n \rangle^2 / 4\omega^2 \quad (\langle n \rangle \gg 1) \quad [30]$$

emphasizing how the power level obtained using this method of concatenation of data files increases with the expected number of stable pits formed in each observation interval.

Discussion

The probability of survival of an unpitted specimen.—We have shown above that this probability is given by Eq. [4], but we have noted that there is an ambiguity in the definition of induction time as a time of first passage through some arbitrary current level. The results will be dependent on the choice of level. A better definition is the time of last passage through some lower level of current. This hypothesis has been tested using the ensemble of simulated current-time transients, and Fig. 3 both confirms the validity of Eq. [4] and shows that, with the definition of last passage time, the critical age parameter can be recovered accurately.

Shibata and Takeyama (18, 19) interpreted their data on the induction time distribution for pitting of 18Cr 8Ni stainless steel in terms of three different nucleation frequencies, each applicable to a different time range of the data. Given the uncertainties in the definition of the induction time, Eq. [4] accounts for two of these time ranges, one for $t < \tau_c$ and the other for $t \geq \tau_c$. The data of Shibata and Takeyama and our own data (3) show a deviation at long times from the behavior predicted by Eq. [4]. Specimens which survived for longer than some time seemed less likely to nucleate propagating pits. Shibata and Takeyama postulated the occurrence of a death process, repassivation of active pits, to explain this behavior (29). There are, indeed, a number of possible adaptations of the general model which will account for a deviation like this from the expected behavior. For example, the initiation frequency, λ , could be time dependent or could have a distribution of possible values over the surface, or the critical age, τ_c , could have a distribution of possible values. Another possible phenomenon is the occurrence of a "renewal process," in which nucleation is more likely to occur on the site of a previous unstable pit than elsewhere. It will be a matter of further work to consider the applicability of such adaptations of the model.

Determination of nucleation rate by peak counting.—Since most of the pits nucleated according to the model outlined above are unstable, the rate of death of pits closely matches the rate of nucleation. Since each death results in a sharp reduction in the current, the number of deaths can be obtained simply by counting current peaks. We confirmed, using simulated data, that peak counting gave an accurate determination of the nucleation rate, λ . We shall see subsequently (3), however, that it is not straightforward to apply this technique to real data. Problems arise in the definition of what constitutes a real event and what is merely noise introduced by the measuring instruments.

The statistics of ensembles of current-time transients.—The simulated data, Fig. 4, clearly show the effects described in the Current-time transients section. At short times, Eq. [16] is followed. For only unstable pitting, Eq. [17] is followed at longer time with the transition between the two regimes occurring at $t \sim 1/\mu$. With both stable and unstable pitting, following the transition from Eq. [16] to [17] at $t \sim 1/\mu$, there is a sharp rise in $\sigma(I)/\langle I \rangle$ starting at $t \sim \tau_c$ caused by the delayed nucleation of stable pits; a pronounced maximum is observed in the plot, and Eq. [7] is followed at longer time, when the behavior of the system is dominated by the nucleation of stable pits.

Figure 4c shows that the presence of a small background current changes the time variation of $\sigma(I)/\langle I \rangle$ profoundly at short times, such that information about the nucleation, growth, and death of unstable pits is lost. This is an important consideration in the analysis of experimental data.

Spectral power density analysis.—Figure 5a shows the spectral power density derived from a set of records having only unstable pits. The individual records were concatenated, as illustrated in Fig. 2a.

The simulations assume a uniform probability for the death of centers rather than a defined age as in Eq. [20]–[22]. We have observed empirically that the power level at a frequency

$$\omega = 2\pi\mu \quad [f = \mu \text{ (Hz)}] \quad [31]$$

is 20 dB below the white noise level. The high frequency asymptote of $G(\omega)$ varies as $1/\omega^2$, as in Eq. [22] and as expected from the assumption of a linear current-time relationship for the pits during their lifetime. A comparison of the white noise level observed (Fig. 5a) with that expected theoretically can be made in a semi-empirical fashion. Thus, if the defined lifetime ν_1 in Eq. [21] is replaced by the most probable lifetime, $1/\mu$, the resulting calculated limiting spectral density is close to 40 times less than the observed value, *i.e.*

$$G_1(0) \sim 10\alpha\lambda C^2/\mu^4 \quad [32]$$

We further note that, with the ensemble mean current given by Eq. [15], Eq. [32] gives for the white noise level

$$G_1(0) \sim 10(\langle I \rangle_{un,x})^2/\alpha\lambda \quad [33]$$

Thus, in the case of unstable pits, the spectral density affords a convenient method for determination of both λ and μ . A constant background current shifts the curves parallel to the $G_1(\omega)$ axis. A time varying background would be more difficult to deal with, although if it were small it would not greatly affect the results. Certainly, the spectral density was not as sensitive to small background currents as the ratio $\sigma(I)/\langle I \rangle$ turned out to be (see previous section).

When both stable and unstable pits are present, the power contributed by the stable pits swamps that due to the unstable pits at high values of Λ ; at low enough values of Λ , a separation between the two processes can still be made (Fig. 5b). The stable pits dominate the power at low frequencies. Figure 5c shows how the power changes from that given by Eq. [24] to that given by Eq. [28] as Λ increases.

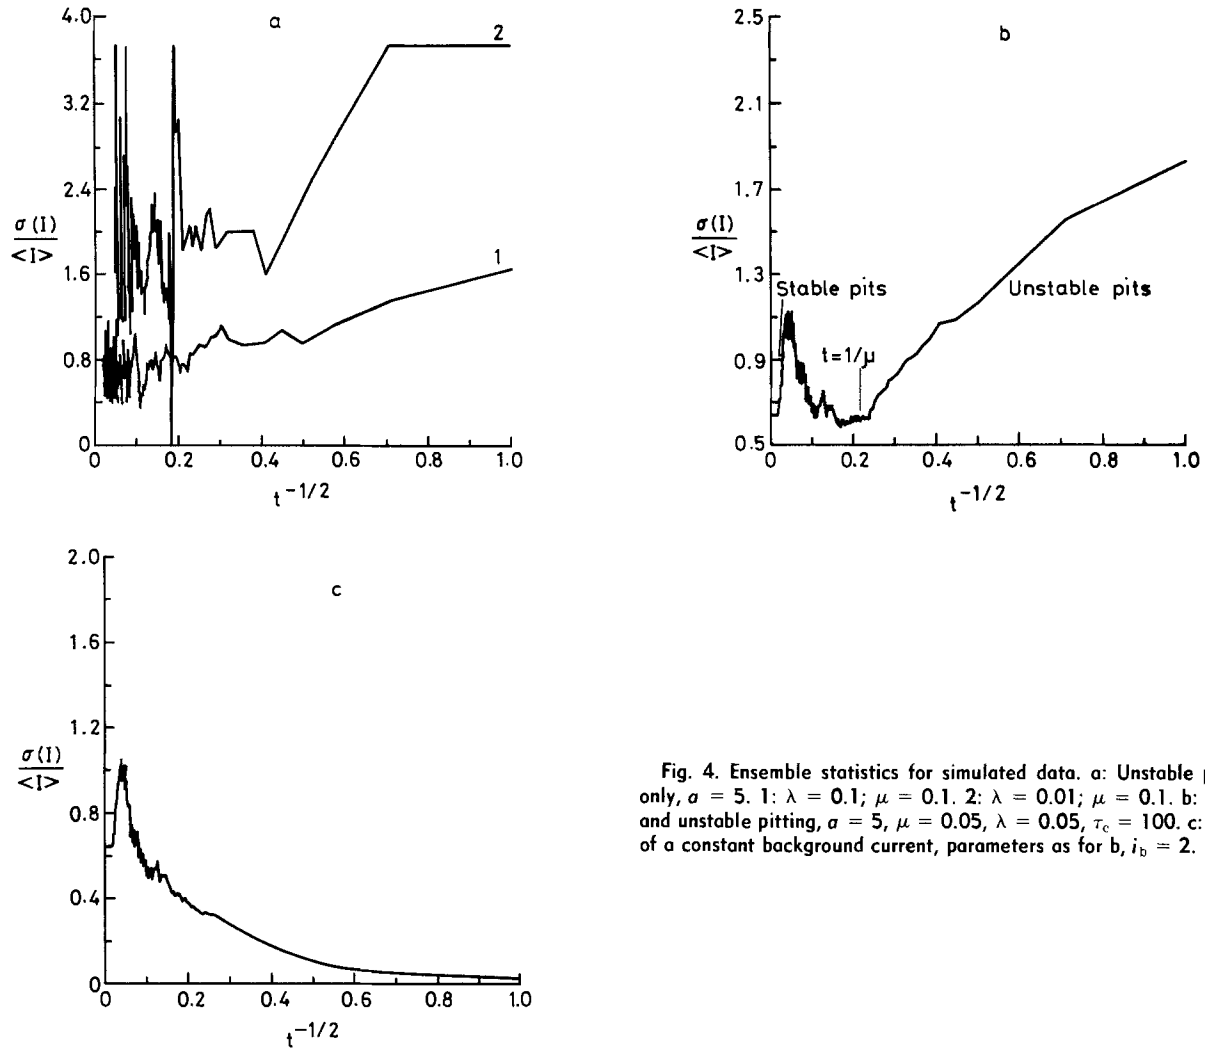

Fig. 4. Ensemble statistics for simulated data. a: Unstable pitting only, $\sigma = 5$. 1: $\lambda = 0.1$; $\mu = 0.1$. 2: $\lambda = 0.01$; $\mu = 0.1$. b: Stable and unstable pitting, $\sigma = 5$, $\mu = 0.05$, $\lambda = 0.05$, $\tau_c = 100$. c: Effect of a constant background current, parameters as for b, $i_b = 2$.

If the power contributed by the unstable pits is not completely swamped by that contributed by the stable pits, then the power due to the stable pits can be estimated and subtracted from the total to give the unstable pit contribution. An induction time is defined as a time of last passage of the current through some level, as in the Probability of survival section. The data for times longer than the induction time are then fitted to a regression polynomial and the data for times shorter than the induction time are set to zero or to some appropriate background level. The resulting set of current-time transients is then assumed to represent the behavior of the stable pits only. Figure 6a shows how the spectral density obtained from a concatenated set of data files processed in this way matches the behavior of the simulation data at low frequency. The differences between the two traces, attributable to the unstable pits, is clearly seen. The parameters, λ and μ , for the unstable pits are recovered.

Even when the power due to stable pits appears to completely swamp that due to the unstable pits, there is still a possibility of recovering information about the unstable pits by using only those sections of data at times earlier than the induction time, or by "detrending" the data. For the first method, the sections of data before the induction time are taken to represent only unstable pitting. These sections are removed and concatenated and the spectral density is calculated. Figure 6b illustrates that λ and μ can be recovered in this way. The assumption that is implicitly made in this procedure is that the sections of data from the different files, where only unstable pits are present, represent different samples of the same stationary, random process. If this assumption is valid, then the data files may be chained and treated as a single record of the process. While this assumption may hold for simulated data, there is no means of being sure of its validity

for experimental data. The success of the method also clearly depends on the use of a reasonable criterion for determining the induction time.

In a process where the resultant current is the sum of the currents from independent events, if the current from any one event can be estimated, it may be subtracted from the record. "Detrending" the data comprises estimating the current due to the stable pits and subtracting it. Clearly, the result can be very dependent on the method used, and the method is only likely to be successful if the fluctuations are not too small in comparison with the trend. Figure 6b illustrates the use of a regression polynomial to detrend data; again, the parameters of the unstable pitting process can be recovered.

Conclusion

The parameters of a general statistical model of pitting corrosion can be recovered by appropriate data analysis. The model includes the phenomena of nucleation, growth, and death of unstable pits and the continued propagation of pits which survive beyond a critical age. Appropriate limiting cases have been derived theoretically and the results confirmed by analysis of simulated data.

Peak counting yields the nucleation rate directly, but the definition of what constitutes a "real" peak as opposed to instrument noise may be difficult in practice. Analysis of passage time distribution yields the critical age and a composite parameter, the nucleation rate of stable pits, but suffers from the difficulty of unambiguous definition of appropriate current levels. Analysis of ensemble statistics yields all the parameters of the model, but is very sensitive to the effects of background currents. Analysis of spectral power density is, in principle, a most useful method, even in the presence of the nonsta-

APPENDIX A Probability of Generation of Stable Pits

We observe that

$$P(n,t) = \left\{ \begin{array}{l} \text{probability that there were } (n-1) \text{ stable pits at} \\ \text{ } (t-\delta t) \text{ and that one pit reached the critical age} \\ \text{ } \text{in the interval } t-\delta t \text{ to } t \\ + \text{ probability that there were } n \text{ stable pits at } t-\delta t \\ \text{ } \text{and that no additional pit reached the critical} \\ \text{ } \text{age in the interval } t-\delta t \text{ to } t \end{array} \right. \quad [\text{A-1}]$$

Then

$$P[n,t] = P[(n-1), (t-\delta t)] \Lambda \delta t + P[n, (t-\delta t)] [1 - \Lambda \delta t] \quad [\text{A-2}]$$

Therefore

$$\left[\frac{P[n,t] - P[n, (t-\delta t)]}{\delta t} \right]_{\delta t \rightarrow 0} = \frac{dP(n)}{dt} = \Lambda P(n-1) - \Lambda P(n) \quad [\text{A-3}]$$

Multiplying the set of equations by s^n where s is a dummy variable and summing

$$\frac{dH(s)}{dt} = \Lambda(s-1) \cdot H(s) \quad [\text{A-4}]$$

where the probability generating function is defined by

$$H(s) = \sum_{n=0}^{\infty} s^n P(n) \quad [\text{A-5}]$$

In practice, the series will be truncated at a finite value of n , but this does not affect the argument.

Since there are no pits at $t \leq \tau_c$, that is $P(n) = 0$ for all nonzero values of n , Eq. [A-5] gives the initial condition

$$H = 1 \text{ at } t = \tau_c \quad [\text{A-6}]$$

Hence

$$H = \exp[\Lambda(s-1)(t-\tau_c)] \quad [\text{A-7}]$$

The mean value of the number of stable pits $\langle n \rangle$ is then

$$\langle n \rangle = \left. \frac{dH}{ds} \right|_{s=1} = \Lambda(t - \tau_c) \quad [\text{A-8}]$$

Fig. 6. Recovery of parameters of unstable pitting in the presence of stable pitting. a: Estimation of spectral power density due to stable pitting by use of a regression polynomial. $\lambda = \mu = 0.1$; $\tau_c = 100$; $\sigma = 5$; $C = 0.1$. 1: Unprocessed data. 2: Stable pits only. b: Estimation of spectral power density due to unstable pitting, in the presence of stable pitting. $\lambda = \mu = 0.05$; $\tau_c = 100$; $\sigma = 5$; $C = 0.1$. 1: Spectral density of sections of dots lying within the induction period. 2: Result of detrending using a regression polynomial.

so that

$$\langle n \rangle = \lambda a(t - \tau_c) \exp(-\mu\tau_c) \text{ for } t \geq \tau_c \quad [A-9]$$

Furthermore

$$\sigma^2(n) = H''(1) + H'(1) - [H'(1)]^2 = \Lambda(t - \tau_c) = \langle n \rangle \quad [A-10]$$

we also obtain from Eq. [A-7]

$$P(0) = H|_{s=0} = \exp(-\Lambda(t - \tau_c)) \quad [A-11]$$

and

$$\ln P(0) = -\Lambda(t - \tau_c) \exp(-\mu\tau_c) \quad [A-12]$$

APPENDIX B
Statistics of Unstable Pitting

For the case where unstable pits are nucleated at a rate $a\lambda$, with a probability μ of death, the probability generating function for the number of pits can be written (30)

$$H(s,t) = \exp\left\{\frac{a\lambda}{\mu}(s-1)(1-e^{-\mu t})\right\} \quad [B-1]$$

The mean and variance of the number of unstable pits can then be obtained, as above

$$\langle n \rangle = \sigma^2(n) = \frac{a\lambda}{\mu}(1-e^{-\mu t}) \quad [B-2]$$

The mean, $\langle \nu \rangle$, and variance, $\sigma^2(\nu)$, of the age of unstable pits can be computed

$$\begin{aligned} \langle \nu \rangle &= \frac{1}{a\lambda t} \int_0^t \nu a\lambda t \mu e^{-\mu \nu} d\nu \\ &= \frac{1}{\mu} \{1 - e^{-\mu t} \cdot (\mu t + 1)\} \quad [B-3] \\ &\rightarrow 1/\mu \text{ as } t \text{ increases} \end{aligned}$$

and

$$\begin{aligned} \sigma^2(\nu) &= \frac{1}{a\lambda t} \int_0^t \nu^2 \cdot a\lambda t \mu e^{-\mu \nu} d\nu \\ &= \frac{1}{\mu^2} \{2 - e^{-\mu t} \cdot (t^2 \mu^2 + 2)\} \quad [B-4] \\ &\rightarrow 2/\mu^2 \text{ as } t \text{ increases} \end{aligned}$$

The variance of the current at longer time can be obtained

$$\begin{aligned} \sigma^2(I) &\sim \left(\frac{\partial I}{\partial \langle n \rangle}\right)^2 \cdot \sigma^2(n) \text{ (} t \rightarrow \infty \text{)} \\ &\sim (C \langle \nu \rangle)^2 \cdot \sigma^2(n) = \frac{C^2 a \lambda}{\mu^3} (t \rightarrow \infty) \quad [B-5] \end{aligned}$$

which, together with Eq. [15], gives Eq. [17] in the main text.

APPENDIX C
Spectral Density Estimates for the Stable Pitting Process,
Constrained by a Limited Observation Time

In the following, the linear-growth rule for stable pits, Eq. [9], is assumed.

Random nucleation of stable pits (limiting case, for $\Lambda T_0 < 1$).—We have a uniform probability in time and space of forming pits of any given age, θ , provided $\theta < T_0$. If the age of a pit is ν then

$$F(\omega) = \int_0^\theta f(\nu) \exp(j\omega\nu) d\nu = \int_0^\theta C\nu \exp(j\omega\nu) d\nu \quad [C-1]$$

$$|F(\omega)|^2 = C^2 \left[\frac{2}{\omega^4} + \frac{\theta^2}{\omega^2} - \frac{2\theta \sin \omega\theta}{\omega^3} - \frac{2 \cos \omega\theta}{\omega^4} \right] \quad [C-2]$$

The effective rate of nucleation of pits of age θ is the fraction nucleated in the interval $d\theta$

$$\Lambda' = \frac{\Lambda d\theta}{T_0} \quad [C-3]$$

The contribution of the nucleation of pits of age θ to the total noise is

$$\begin{aligned} dG_1(\omega) &= \Lambda' |F(\omega)|^2 = \frac{\Lambda |F(\omega)|^2}{T_0} d\theta \quad [C-4] \\ G_1(\omega) &= \frac{C^2 \Lambda}{T} \int_0^{T_0} \left[\frac{2}{\omega^4} + \frac{\theta^2}{\omega^2} - \frac{2\theta \sin \omega\theta}{\omega^3} - \frac{2 \cos \omega\theta}{\omega^4} \right] d\theta \\ &= \frac{\Lambda C^2}{T_0} \left[\frac{2T_0}{\omega^4} + \frac{T_0^3}{3\omega^2} + \frac{2T_0 \cos(\omega T_0)}{\omega^4} \right. \\ &\quad \left. - \frac{4 \sin(\omega T_0)}{\omega^5} \right] \quad [C-5] \end{aligned}$$

Ensemble mean current transient in each observation period (limiting case for $\Lambda T_0 \gg 1$).—If ΛT_0 is sufficiently large, the current due to stable pitting in each observation window can be approximated as the ensemble mean current (stable pitting case, $i = C\nu$ for each pit of age ν)

$$i = ACt^{1/2} \quad [C-6]$$

Here

$$F(\omega) = \int_0^{T_0} \frac{AC}{2} t^2 \exp(j\omega t) dt \quad [C-7]$$

and, since the pulse rate in the chain analyzed is $1/T_0$ (one pulse for each observation window)

$$G(\omega) = \frac{|F(\omega)|^2}{T_0} \quad [C-8]$$

$$= \frac{A^2 C^2}{4T_0} \left[\frac{T_0^4}{\omega^2} + \frac{4T_0^2}{\omega^4} \cos(\omega T_0) - \frac{8T_0}{\omega^5} \sin(\omega T_0) - \frac{8}{\omega^6} \cos(\omega T_0) + \frac{8}{\omega^6} \right] \quad [C-9]$$

Stochastic Models of Pitting Corrosion of Stainless Steels

II. Measurement and Interpretation of Data at Constant Potential

ABSTRACT

The experimental evaluation of the parameters of a general stochastic model for the initiation of pitting corrosion on stainless steels is described. The variation of these parameters with experimental conditions is used in the development of a microscopic model. A microscopic model which accords with the observed behavior attributes the initiation of pitting corrosion to the production and persistence of gradients of acidity and electrode potential on the scale of the surface roughness of the metal. The observed fluctuations are related to fluctuations in the hydrodynamic boundary layer thickness. A pit becomes stable when it exceeds a critical depth related to the surface roughness.

It has been pointed out in a preceding paper (1) that, in common with other localized corrosion processes, pitting corrosion is a rare event so that a statistical treatment is necessary for an adequate description [cf. Ref. (2-4)]. An appropriate level of modeling of the processes is suggested by the analogy to electrocrystallization (5, 6) with formation of pits replacing the growth of crystallites: namely, the triggering (nucleation) of events by a suitably filtered Poisson process coupled to growth of pits by an essentially deterministic mechanism. A special model has been examined (1) which has the features that (i) events are nucleated with frequency λ ($s^{-1} cm^{-2}$), (ii) events have a probability μ (s^{-1}) of dying, and (iii) events which survive beyond a critical age, τ_c (s), do not die.

For certain aspects of the modeling, we also assume that all pits evolve according to the deterministic law

$$i = Cu \quad [1]$$

where u (s) is the age of the pit. The model assumes formation of stable pits [step (iii)] following a "prepitting" stage [steps (i), (ii)]. The microscopic model given recently by Okada (7) falls into this general class. The objective of our work is to derive the parameters of the general model from the experimental data, so that their variation with experimental conditions can be examined. A rigorous assessment of microscopic models of this general class can then follow. Two types of predictions have been based on this model. The first is the probability of survival of unpitted specimens (*i.e.*, specimens in the prepitting stage). The second is the ensemble statistics of potentiostatic current-time transients. We have also shown how to analyze the spectral power density of the current. In this paper, we show how the probability distribution function of the slope of the experimental transients can be ob-

* Electrochemical Society Active Member.

tained and used to reduce the time series of the current to time series of the number of pits; statistical analysis of these time series is simpler than analysis of the current. Predictions have been made both by computer simulations and by algebraic methods, and the two approaches have been compared. It has been shown that the last passage time of the current through a chosen low level is especially useful in defining survival probabilities, and a new method for the rapid determination of quantities related to this probability has been described (8). The present paper is concerned with the determination and evaluation of the statistics of ensembles of potentiostatic current-time transients. The derived data are shown, in general, to accord with the predictions of the phenomenological theory (1), with values of the parameters given by the various methods of data analysis being self-consistent. Measurements of the chloride-ion concentration and the potential dependence of the phenomena as well as of the influence of other solution variables (stirring, support electrolyte concentration, buffer capacity) lead to the definition of a microscopic model of pit initiation. The behaviors of a number of stainless steels are compared.

Experimental

Stainless steels used in this investigation were 18Cr 13Ni 1Nb, ANSI 304L, ANSI 316L, and 25Cr 20Ni. Analyses are given in Table I. Disk specimens 5 cm² in area were stamped out from single sheets of each of the steels, set in a cold setting epoxy mounting resin ("Araldite" HY and EY), polished to a 240 grit finish and rinsed with acetone. The electrochemical cell was formed simply by clamping the specimen mount onto a 25 mm diam glass flange joint set vertically. Gas feed, Luggin capillary, Pt secondary electrode, and glass stirring paddle were introduced from the top. The solution contained in the assembly was purged with purified argon for 30 min before each experiment, and a slow flow of argon was maintained during each experiment. Current was measured as a voltage across a 100Ω resistor in the secondary electrode lead, and was logged from a number of cells simultaneously using a reed relay multiplexer and autoranging digital voltmeter (Datron, 1 μV resolution) controlled via the IEEE 488 interface bus by a microcomputer (CBM, PET 4032). The cells were independently controlled by H. B. Thompson "Microstats"; application of the control potential and potential ramp (H.B. Thompson Digital Ramp Generator) were also under the control of the microcomputer. Data were transferred to a minicomputer for analysis. Potentials were measured with respect to a saturated calomel electrode, and solutions were prepared with analytical reagent-grade chemicals and distilled water. The buffer was tris (hydroxymethyl) amino methane, ("tris") adjusted to pH 7.0 with 1M HClO₄ solution.

The potentials at which pitting would start at a given probability were determined from measurements with the interrupted potentiodynamic sweep technique (IPS technique) described elsewhere (8). The potential of the specimens was changed from the rest potential to potentials predetermined in this way, either stepwise or using a ramp of 10 mV·s⁻¹. The current was monitored for 2400s with a resolution of 0.01 μA, truncated subsequently to 0.1 μA, at a sampling frequency of 1 Hz; a typical ensemble comprised 20-30 experiments. We have previously reported (4) that the initial current pulse associated with a step initiation was sufficient to start crevice corrosion at

the joint between the specimen and mounting material in a significant number of experiments. This effect was avoided with the ramp initiation and, unless otherwise stated, this was employed for the work reported here.

Results

The shape of potentiostatic current-time transients.—Figure 1 shows typical current-time transients and illustrates, first, the general form of the fluctuations and, second, the large variation in results from one experiment to another, performed under nominally identical conditions. The transients comprised fluctuations superimposed on a rising background; the fluctuations had a characteristic form of a slow rise and a sharp fall. The charge passed during a fluctuation was typically 10-500 μC, equivalent to the dissolution of 10⁻¹⁰-10⁻⁸ cm³ of metal, a cube of typical linear dimension of ~10 μm. The form of the fluctuations was opposite to the form of current fluctuation observed by Bertocci (9), namely, sharp rise and slow fall, for steels of lower chromium content (Fe9Cr, below the limit of "stainlessness").

In the following sections, we present, first, the analysis of ensemble statistics; second, the determination of the initiation frequency for the events which cause the current fluctuations; third, the analysis of the slope of the current-time transients and the conversion of these into time series of the number of pits; fourth, the determination of the rate of formation of stable pits; and, last, the determination of the average lifetime of the events from the spectral power density of the current. The development and validation of the methods of analysis have been given in the previous paper (1). Effects of stirring, buffering, supporting electrolyte concentration, chloride concentration, alloy type, and electrode potential are shown.

Ensemble statistics: effects of environment and comparison of alloys.—Figure 2 shows ensemble mean transients and the ratio of ensemble standard deviation to ensemble mean, $\sigma_I/\langle I \rangle$. The potentials were chosen from the cumulative distribution of breakdown potentials measured in IPS experiments (8). The lowest potential for each alloy was the 50% point on this distribution. The general form of the ensemble mean current was concave upward; a tendency for the current to start leveling off at high currents was noted. For each alloy, the time evolution of the ratio $\sigma_I/\langle I \rangle$ changed from being virtually flat (at $\sigma_I/\langle I \rangle = 1$) over the time span of the experiment at the lower potential to a sharply peaked form at the higher potential. The behavior of the 25Cr 20Ni alloy was different from that of the others; for this alloy, the current transients fell into one of two classes, of either very low currents with only isolated small fluctuations, or of a sudden, and early, current increase to high values which oscillated violently about a given level. The ensemble mean current transient for 25Cr 20Ni reflected the behavior of the latter class.

25/20	25.4	19.6	0.27	< 0.01	0.79	0.07	< 0.01

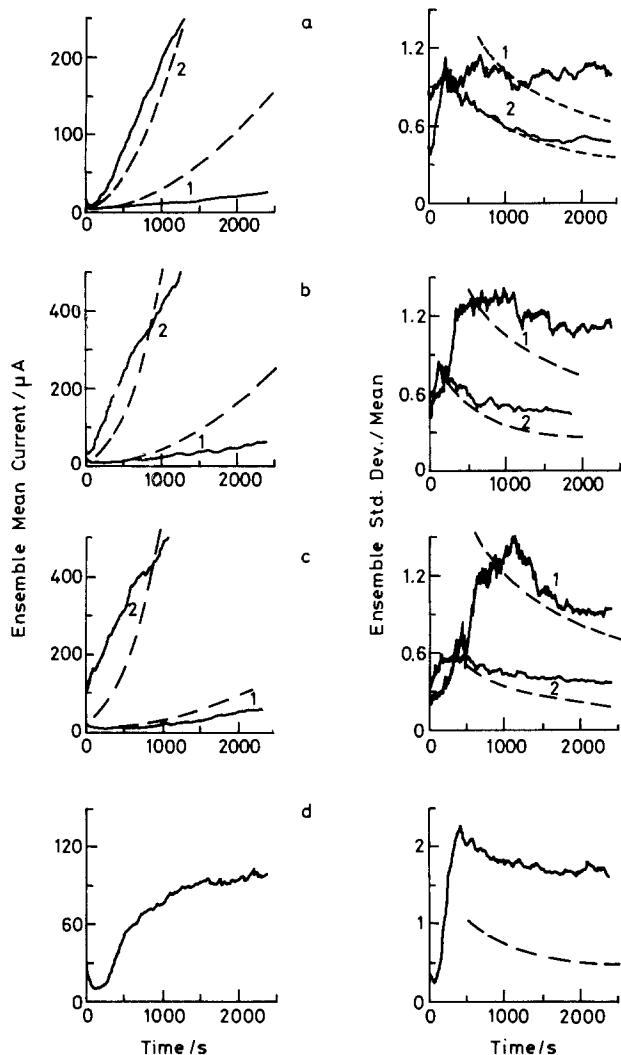

Fig. 2. Ensemble mean current and standard deviation/mean in 0.028M NaCl, unstirred. a: 18Cr 13Ni 1Nb; curve 1 is +50, curve 2 is +200 mV SCE. b: 304L, curve 1 is +200, curve 2 is +300 mV SCE. c: 316L, curve 1 is +300, curve 2 is +400 mV SCE. d: 25Cr 20 Ni, +400 mV SCE. Dashed lines are theoretical results calculated using nucleation rates for stable pitting derived from passage time and slope analysis.

As well as the expected effects of chloride concentration and electrode potential, marked effects of the solution buffer capacity, supporting electrolyte, and stirring were also observed. Figure 3 shows the effects of buffer capacity and supporting electrolyte on ensemble mean transients for the 18Cr 13Ni 1Nb steel. Increasing the buffer capacity decreased the likelihood of pitting corrosion. Adding a sufficient concentration of supporting electrolyte rendered the alloy immune to pitting corrosion. The effect of the presence of 1M NaClO₄ supporting electrolyte persisted up to high potentials (at least +500 mV SCE) in chloride solutions of up to 0.3M for times in excess of 2 days. Addition of the supporting electrolyte into the dilute chloride solution during the propagation of pitting corrosion had the effect of stopping the pits: the current fell immediately to zero (Fig. 5a). Addition of a sufficient concentration of buffer had the same effect (Fig. 5b), although the current fall in this case was in two steps. In both cases, not only was the current reduced but also the fluctuations were eliminated. It is assumed that there would be some depth of pit above which these effects would not be observed.

Vigorous stirring of the solution with a small paddle prevented the initiation of pitting corrosion in dilute chloride solution, and inhibited initiation in more concentrated solutions (Fig. 4). These experiments were designed to illustrate the effects of the hydrodynamics and were not well controlled. We will report separately the results

Fig. 3. Effect of buffer capacity, and electrolyte conductivity on ensemble mean current. 18Cr 13Ni 1Nb + 50 mV, potential step initiation, unstirred. 1: 0.028M NaCl. 2: 0.028M NaCl + 0.005M "tris" (pH 7.0). 3: 0.028M NaCl + 0.05M "tris" (pH 7.0). 4: 0.028M NaCl + 1M NaClO₄.

of experiments in which the Reynolds number is systematically varied under conditions of controlled hydrodynamic flow (10).

Initiation frequency of events.—In principle, the initiation frequency of the events which give rise to the current fluctuations can be obtained simply by counting the number of peaks in the current transient. In fact, this gives the number of "deaths" of events, and it is assumed that most events "die" so that the number of "births" is indeed close to the number of deaths. This approach also assumes that the current due to each event increases monotonically with time.

Fig. 4. Effect of stirring on ensemble mean transients. 18Cr 13Ni 1Nb, +50 mV (SCE), 0.28M (a) and 0.028M (b) NaCl.

Fig. 5. Effect of addition, in the course of pitting corrosion, of buffer, and supporting electrolyte. a: NaClO_4 added (1M). b: "tris" added (0.05M). Time of addition marked by arrows. 18Cr 13Ni 1Nb, + 50 mV SCE, 0.028M NaCl, unstirred.

The use of any peak counting technique involves some judgment as to what is a significant peak and what is due to mere adventitious noise in the measurement system. In the peak counting procedure that was finally adopted, the experimental data were first smoothed slightly using a short section length (four points) running mean. A second running mean, with a long section length (100 points), was used to smooth out most of the fluctuations, and the difference between the four- and 100-point means calculated to give a trace which oscillated about

Fig. 6. Initiation frequency, determined by peak counting, as a function of time. Counting on 100s intervals. 0.028M NaCl unstirred. Triangles: 18Cr 13Ni 1Nb, + 50 mV SCE. \times : 18Cr 13Ni 1Nb, + 200 mV SCE. Plus signs: 304L, + 200 mV SCE. Squares: 304L, + 300 mV SCE.

zero. All peaks and troughs outside a noise band ($\pm 0.5 \mu\text{A}$) on the difference trace were counted; division by two yielded the estimate of the initiation rate. The value for the noise band was obtained from measurements made in 1M NaClO_4 , and from measurements made on a dummy cell. Figure 6 illustrates an important result, namely, that the event frequency, or nucleation rate, was effectively constant throughout the current transient. In Table II, nucleation rates for the different steels and environmental conditions are compared. A second important result was obtained, namely, that the nucleation rate was not significantly dependent on the nature of the steel or on the electrode potential. However, at low enough electrode potentials (different for each steel) (8, 10), or in the presence of a sufficient buffer concentration or of a supporting electrolyte, or in the absence of chloride, the nucleation rate was zero.

Slope analysis.—Inspection of the experimental transients (Fig. 1) implied that the current for each event rose linearly with time. If this was the case, then positive values of the slope of the $i-t$ record at any time should be the product of the number of active pits and the slope of the elementary transient, given the assumption that the time evolution of every event is the same. Figure 7 shows the probability density function (PDF) for positive values of the slope obtained over an ensemble of current transients. A running four-point regression, stepping along

the transient one point at a time, was used to obtain the values of the slope. The PDF shows regularly spaced maxima at values which are multiples of an elementary slope; this result shows that the representation of the current as a sum of identical elementary linear ramps is quite adequate. Values of the elementary slope, C (Eq. [1]), are collected in Table II.

The time series of the current was converted into a time series of the number of pits by dividing the slope at any time by the elementary slope obtained from the PDF and rounding to an integral value. The ensemble mean number and the standard deviation of the number both rose rapidly to constant values (Fig. 8). The values are collected in Table II. The expected values are, for the unstable pits

$$\langle n_u \rangle = \sigma_{nu}^2 = a\lambda/\mu \quad (t \rightarrow \infty) \quad [2]$$

and for the stable pits

$$\langle n_s \rangle = \sigma_{ns}^2 = a\Lambda(t - \tau_c) \quad [3]$$

with the mean and variance for the total number being the sum of the quantities for the stable and unstable pits. It is assumed that, since the experimental records give constant values for $\langle n \rangle$ and σ_n , the unstable pits outnumber

Fig. 8. Ensemble mean, and standard deviation of number of pits, derived from the experimental $i-t$ traces, and the elementary slope, C . 304L, + 200 mV SCE, 0.028M NaCl, unstirred.

ber the stable ones. Hence, given λ from peak counting, μ was calculated from $\langle n \rangle$ using Eq. [2], and values are collected in Table II. The observed σ_n (not σ_n^2 as predicted by Eq. [2] and [3]) were approximately equal to $\langle n \rangle$.

Passage time analysis.—In a previous paper (1), we related the probability of survival of an unpitted specimen to the initiation rate for stable pitting, Λ

$$\ln [P(0)] = -a\Lambda(t - \tau_c) = a(t - \tau_c) \lambda e^{-\mu\tau_c} \quad [4]$$

and showed that the time of onset of stable pitting was best defined as a time of last passage through some predetermined current level. The experimental data were complicated by a time varying charging current induced by the initial transition of the potential (Fig. 1); this introduced an arbitrary element into the definition of the passage current level, which was taken to be just above the minimum value of the ensemble mean current. Figure 9 shows typical plots according to Eq. [4]; values of Λ and τ_c are collected in Table II.

Spectral power density of the current.—Figure 10 illustrates the spectral power density of the current calculated from a chained set of current-time records and from a “detrended” set of records (1). Both traces show a high frequency decay as ω^{-2} , as expected for a linear elementary transient. Comparison of the power levels obtained for the chained set with the simulation and theoretical results given before (1) yielded a value for Λ . Values for μ were obtained from the power spectrum of the detrended records. A check on the consistency of the values for λ , μ , and C (the elementary slope) was obtained by comparing theoretical (1) and observed values for the low frequency white noise (detrended records).

Discussion

The discussion is in two parts. First, we discuss the adequacy of the general model and the self-consistency of the derived parameters, and point out where the general model fails. Second, we discuss the behavior of the derived parameters in terms of microscopic models for the corrosion process.

General model.—For the most part, the general model is adequate for describing the general behavior of the ensemble statistics, the slope distribution, the survival probability, and the power spectrum of the fluctuations. Experimental data and simulated data show the same general form. The values of the parameters C , Λ , λ , and μ derived by the different methods of analysis are self-consistent (Table II). There are, however, a number of deviations of behavior from that predicted by the general model. First, the values of τ_c related to Λ , λ , and μ by the

Fig. 9. Survival probability from passage time analysis, of 18Cr 13Ni 1Nb steel specimens, 0.028M NaCl, unstirred. Upper line +50 mV SCE. Lower line: +200 mV SCE.

postulates of the model

$$\tau_c = -(1/\mu) \ln (\Lambda/\lambda) \quad [5]$$

are consistently much larger than the value given by passage time analysis. Second (Figure 2), the ensemble statistics show some deviations from the expected behavior for stable pitting (1), calculated using values of Λ (passage time) and C (slope analysis). The agreement between observed and expected behavior is, in general, quite striking, given that the parameters used have come from quite different methods of analysis of the data. However, at longer times, the mean $\langle I \rangle$ falls below, while the standard deviation, σ_I , falls above the value expected: the variability, especially at the lower potential, is greater than predicted. Third, in agreement with the results of Shibata and Takeyama (3), the survival probability at longer times was greater than that predicted by Eq. [4]. It seems that specimens which survive for longer than some given time are less likely to form stable pits than the rest of the ensemble of specimens. This effect is reflected by the values of Λ derived from spectral density analysis being consistently lower than those derived from passage time analysis: the ensemble power spectrum gives an average value of Λ for all specimens.

It would appear (11) that these difficulties with the general model can be resolved by allowing both λ and τ_c to take a distribution of values. Additionally, for both stable and unstable pits, in a development of an earlier idea (12), one could postulate propagation by a succession of growth, death, and renucleation events.

The main conclusions which follow from the application of the general model are as follows.

First, the nucleation frequency of unstable pits, λ , varies from zero to about $0.01 \text{ s}^{-1}\text{-cm}^{-2}$ over a rather narrow range of potential different for each alloy. The limiting value of nucleation rate, λ , does not depend on the nature of the alloy, the chloride concentration, or the electrode potential. This potential dependence is the classical form for a nucleation phenomenon.

Second, the death probability of unstable pits, μ , is also not sensibly dependent on electrode potential, nature of alloy, or chloride concentration.

Third, the critical age for transition of an unstable to a stable pit, τ_c , and elementary slope of the current-time transient, C , depend on the electrode potential.

Additions of buffer, and of supporting electrolyte, reduce the nucleation rate, λ , markedly. Stirring may affect both the nucleation rate and the death probability. We note that the potential at which the nucleation frequency drops to zero provides a rigorous definition of a pitting breakdown potential (8, 10).

These results may be interpreted in terms of a simple microscopic model of local acidification for the initiation of pitting corrosion.

Microscopic model.—We propose that the initiation of pitting corrosion requires the production and persistence of gradients of acidity and electrode potential on the scale of the surface roughness of the specimen. Fluctuations in these gradients, leading to the birth and death of events, could arise because of fluctuations in the boundary layer in the liquid at the metal surface; a pit becomes stable when its depth significantly exceeds the thickness of the solution boundary layer. The solution boundary layer is in two parts, one part defined by the roughness of the surface, the other part being the hydrodynamic boundary layer (Fig. 11). Local acidification would arise as a result of the hydrolysis of metal ions in the solution, formed as a result of the slow dissolution of the passive metal

$$i_p = k_1 f([\text{Cl}^-]_s, [\text{H}^+]_s) \exp\left(\frac{\beta \Delta \phi_{fs} F}{RT}\right) \quad [6]$$

where i_p denotes the passive current density, $\Delta \phi_{fs}$ the potential difference across the film-solution interface, β the transfer coefficient and $[\]_s$ denotes concentrations at the metal surface. In the most general case, the rate constant, k_1 , could be considered to be variable over the surface, for example, because of the presence of inhomogeneities in the alloy composition or of inclusions. The passive dissolution current is, of course, a material-dependent parameter which can, in principle, be measured independently. Its variation with solution composition is susceptible to detailed mechanistic description. One such description, a mechanism for rationalizing the acceleration of oxide dissolution by chloride, is at the heart of the discussion of pitting corrosion given recently by McDonald and co-workers (13).

In their discussion of the initiation of crevice corrosion, Oldfield and Sutton (14) introduced the idea of a critical crevice solution: a solution composition at which the metal could not remain passive, so that, should it be attained, rapid corrosion would commence. We postulate that a critical local solution composition can similarly be defined for the initiation of pitting corrosion. For example (4), if the passive current density has a dependence on $[\text{H}^+]$ of the form

$$i_p = k_2(1 + [\text{H}^+]_s/K_2) \quad [7]$$

then a critical local solution would have $[\text{H}^+]_s \approx K_2$. We derive additional support for this view from the fact that the current pulse associated with potential step initiation of the experiment was sufficient to initiate crevice corrosion around the specimen mount in a significant number of cases (4). This effect was suppressed by buffering the solution and was assumed to be triggered by a momentary local acidification at the edge of the specimen caused by the faradaic component of the charging current.

The parameters of the general model, λ , μ , and τ_c , can now be reconciled with this microscopic model.

Nucleation rate.—The nucleation rate is determined by the time required to establish the critical local pH. Some order-of-magnitude calculations can be given. Thus if δ_r denotes the roughness and δ_h the thickness of the hydrodynamic boundary layer, then the surface acidity attained as a result of the passive dissolution would be at most

Fig. 11. Representation of boundary layers and critical penetration.

$$[H^+]_s \sim i_p(\delta_r + \delta_h)/FD_H \quad [8]$$

With our specimens, $\delta_r \sim 10^{-2}$ cm, and in an unstirred solution, one expects $\delta_h \sim 10^{-2} \cdot 10^{-1}$ cm, so if $i_p \sim 10^{-7}$ A-cm $^{-2}$, $pH_s \sim 5-6$.

Any change in local potential would result in a local value of i_p which might be substantially larger. In our work (Fig. 1), the ramp of potential at the start of the experiment gave current densities initially in the range 1 to 10 μ A-cm $^{-2}$, while a step change of potential gave local currents momentarily of greater than 100 μ A-cm $^{-2}$; Eq. [8] then implies $pH_s < 2$ if such currents last long enough. Such conditions, if maintained locally for a sufficient time, could certainly lead to a local breakdown.

One consequence of these ideas is that the nucleation rate for unstable pitting should depend upon the passive current density. Since the passive current density decreases steadily with time at constant potential, the probability of observing a pitting breakdown should decrease with time and the survival probability for the specimen should increase. In this respect, these ideas give a natural explanation why the survival probability at longer time was greater than that predicted by Eq. [4] (see Fig. 9, and the General model section above). These ideas also predict that the probability of pitting breakdown in experiments in which the specimen is prepassivated, then chloride introduced, at constant potential, should be less than that observed in experiments in which the potential is changed, provided that the introduction of chloride in the former experiment does not cause a current pulse.

The minimum local pH indicated by Eq. [8] for a passive current density of 10^{-7} A-cm $^{-2}$ ($pH_s \sim 5-6$) is clearly too high to promote a local breakdown, yet pitting events are observed when the current is as low as this. We can achieve some resolution of this difficulty by recognizing that the conditions required to trigger an event might be different from the conditions required to maintain one. Here, we explore qualitatively two ideas concerning the triggering of pitting events; later we discuss the maintenance of the events.

The first idea concerning the triggering of pitting events focuses attention on the transient behavior of the passive current. Any fluctuation of local potential and of local pH would give a local transient in i_p . The transient in i_p would feed back on the local potential and pH. Hence, depending on the coupling between transients in i_p , local potential, and pH, any small local disturbance would either damp out or self-amplify.

The second idea for the triggering of pitting events concerns the nature of the observed passive current density, i_p . It might be argued that the passive current is in reality a stream of rapid current pulses, as could arise from passive film breakage events, filtered by the specimen capacitance to appear as a steady current. As far as the local environment of the surface is concerned, one such pulse could be treated as an instantaneous deposition into the environment of a certain quantity of charge. If the volume of an occluded zone of the solution defined by the surface roughness is taken as 10^{-9} cm 3 , then a local pH 0 could be obtained by a charge pulse of 10^{-7} C—a local current pulse of, say, 100 mA for 1 μ s. Following such a pulse, locally, the resulting pH gradient would begin to disperse by diffusion, and, during a time scale defined by the rate of diffusion, there would be the possibility of a pit initiating in this local environment. If fast current pulses, like the ones which we have just postulated, were to occur all over the surface, then they would be filtered by the specimen capacitance and would only be separately observable if the capacitance was sufficiently low, that is if the area of the specimen was sufficiently small. The interfacial capacitance of the stainless steel in aqueous solution is of the order of 10 μ F-cm $^{-2}$; given this, it might be necessary to use electrodes as small as 10 μ m diam in order to observe noise events on the microsecond time scale.

In the presence of a sufficient concentration of buffer, a critical local pH could not be attained: this would explain why additions of buffer inhibit the nucleation pro-

cess. If i_p were too low, a critical local pH could not be obtained since unreasonably large values of δ_h would be required: a small potential dependence of i_p , different for the different alloys, could thus be the explanation for the fall of the nucleation rate to zero at low enough potential. Low enough chloride concentration at the surface would have the same effect. The effect of stirring would be to inhibit nucleation by reducing δ_h . Specimen orientation would be expected to affect the nucleation rate because of the effects of convection and density gradients in the solution; one might expect pit nucleation to occur more easily on horizontal specimens facing upward, as in our experiments, than on specimens facing downward or mounted vertically.

The effect of a supporting electrolyte is a crucial piece of evidence. In the absence of the supporting electrolyte, electromigration would increase the surface concentrations of chloride. The absence of a supporting electrolyte also increases the solution resistance. Both of these effects mean that, if the local current density was high enough, significant further concentration of chloride, and significant potential gradients on the scale of the surface roughness, could be obtained. However, for these effects to manifest themselves, the local current density would have to be far higher than the passive current density. Of course, once a pit has started, the local current density is much higher: a current of 1 μ A into an area of, say, $10 \times 10 \mu$ m is 1 A-cm $^{-2}$, so that once the critical conditions are established transport by electromigration and local potential gradients become extremely important phenomena (15, 16). Thus, the resistivity of 0.03M NaCl is about 100 Ω -cm, so that, on the scale of the surface roughness, 100 μ m with a local current density of 1 A-cm $^{-2}$ the local potential drop is 100 mV. It is therefore quite conceivable that the pit nucleus could find itself displaced from the passive into the active potential range. However, in the presence of 1M NaClO $_4$, resistivity about 10 Ω -cm, the local potential drop would only be 10 mV, so that the local zone could not get into the active range. One can therefore rationalize the phenomena by saying that a supporting electrolyte would not prevent the attainment of a critical pH, but that even if this was attained in the presence of a supporting electrolyte no pit would develop from it.

This is a more subtle view than the apparently straightforward kinetic idea of a critical pH embodied in Eq. [6]. In the modified view, attainment of the critical pH triggers off a local instability which is maintained by a local potential gradient. The solution resistance and chloride transport are important factors in maintaining this instability. The elementary slope, C , should depend upon the rate of change of the local conditions, upon the alloy composition, and, upon the local potential gradient, determined by the solution resistance. The possibility of the formation of salt films, which then limit the current, has been discussed (16).

Death probability.—Death of an event is supposed to occur as a consequence of a reduction in δ_h , so that the large local concentration excursions, caused by the large local current density, cannot be maintained. The observed event lifetimes, 50-100s in an unstirred solution, are indeed of the magnitude one might expect from fluctuations in a hydrodynamic boundary layer in such an unstirred solution, subject to natural convection. This idea predicts that the lifetime would not depend on anything other than the stirring of the solution, the roughness of the surface, and perhaps the orientation of the specimen.

Critical age.—The critical age can be defined as the ratio critical depth/velocity of propagation. The critical depth is determined by the boundary layers and would be smaller for a rougher specimen. The velocity of propagation is expected to vary strongly with the electrode potential, the chloride concentration, and the nature of the alloy. According to this view, the critical age and elementary slope are related. The elementary slope is a func-

tion of the electrode kinetics and solution resistivity in the local environment. If a simplified view is taken that the pit nuclei propagate at constant area, then the rate of penetration is proportional to the current: $v = \zeta i$. Writing δ_c for the critical penetration, and introducing Eq. [1] and the boundary layer thicknesses δ_r and δ_h , gives

$$\tau_c = [2(\delta_c - \delta_r - \delta_h)/\zeta C]^{1/2} \quad [9]$$

We note that the idea of a critical penetration contains the idea of a critical defect size for pit initiation. A defect could be a crack, for instance, or a microscopic crevice around the edge of an inclusion.

Recently, Okada (7) has given a model for pitting corrosion which postulates the formation of an unstable chloride nucleus as the precursor state. This model falls into the class defined by our general stochastic theory and affords an alternative microscopic interpretation of the values of the parameters. The ideas given (7) imply that the nucleation frequency and death probability should be functions of electrode potential and chloride concentration; effects of buffer capacity and electrolyte conductivity are not predicted. In these respects, Okada's model does not accord with our experimental results.

Conclusion

The application of a stochastic approach to the study of the initiation of pitting corrosion on stainless steels and the development of methods of analysis of data, based on a general phenomenological model, has led to a clarification of which aspects of the process are dependent upon the composition of the steel and which are not. Rigorous definitions of a pitting breakdown potential and of survival probability can be made. Strong effects of buffer capacity, solution conductivity, and stirring at constant chloride concentration have been shown. The results have been interpreted in terms of a simple microscopic model of local acidification for the initiation of pitting corrosion. Production, on the scale of the surface roughness of the specimen, of a gradient of acidity, as a consequence of the small passive dissolution current of the metal, triggers off a local instability, which is maintained by a local potential gradient. Fluctuations in these gradients, leading to the birth and death of events, arise because of fluctuations in the thickness of the solution boundary layer at the metal surface. The concept of a critical penetration or critical defect size for the onset of stable pitting forms a part of this view. It is notable that in emphasizing the importance of boundary layers, roughness, and local transport conditions these ideas eliminate

the need for special postulates to explain why pitting corrosion is localized. It is notable also that, in breaking down a complex phenomenon into much simpler component parts, the stochastic approach and the general model have rendered much more tractable the problem of constructing and testing suitable microscopic models. The use of the stochastic approach has led to the possibility of testing microscopic models much more rigorously than has been possible hitherto.

Cooling Kinetics: Evidence for a Hydrogen Countercell in 304L Stainless Steel Crevices at High Temperatures

D. F. Taylor* and C. A. Caramihas-Foust

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Cell current reversals deep within tubular 304L stainless steel crevices containing 0.2M NaCl electrolyte at 290°C demonstrated H(I) reduction at previously anodic sites. Analysis of transient currents during cooling showed an increase in anodic activity adjacent to the crevice mouth as oxygen reduction at the mouth decreased, a direct indication that molecular hydrogen was diffusing outward and oxidizing in the active/passive transition region. Calculations confirmed that a similar hydrogen counter cell was operating in crevices containing 0.1M Na₂SO₄.

Previous papers in this series on the high temperature aqueous crevice corrosion of Fe-Ni-Cr alloys concluded that the reduction of H₃O⁺ ions or water molecules to molecular hydrogen makes an important contribution to the solution composition and electrode potential in the occluded region (1-3). These experiments examined corro-

* Electrochemical Society Active Member.

sion behavior under conditions where the presence of dissolved oxygen outside a tubular crevice established potential gradients within the system. Since no artificial imposition of potential or current was present to establish a steady state, some rather sudden and dramatic changes in crevice chemistry occurred. In alloys with sufficient nickel content, there was a tendency for the internal crev-

ice electrode potential to attain or exceed the electrode potential of the external surface during acidification (2, 3). Rapid neutralization always followed. In other systems, iron oxidation controlled the anodic corrosion reaction, and the crevice interiors remained acidic until the temperature started to decrease, but those solutions always had attained neutral pH by the time they reached 25°C. Thermodynamic calculations implicated H(I) reduction, but the nature of the neutralization reaction, especially the sink for H⁺, and the extent to which such a cathodic reaction might have been occurring at temperature, prior to the neutralization, were unclear. This paper describes current measurements on active crevices both at 290°C and during cooling that indicate strong opposition to the acid-generating oxygen/metal macrocell by a hydrogen counter-cell.

Experimental

Commercial 304L stainless steel tubing (18.2Cr, 10.9Ni, 0.02C) (3) with an inside diameter of 1 mm was cut into 46 cm lengths, and each of these pieces was subdivided into two parts, either 3, 9, or 15 cm from one end. All components were degreased with trichloroethylene and rinsed first with acetone, then with distilled, deionized water. One end of each longer segment was arc welded closed in an argon atmosphere, and both segments of each pair were attached to autoclave feedthroughs of the same material. The segment pairs were reassembled by inserting electrically insulating 5 mm tubular zirconia spacers with the same inner and outer diameters as the metal tubing and heat shrinking sufficient Teflon® PTFE tubing over the junctions to extend several centimeters on either side. For most experiments, stainless steel tubing unions were modified to fit closely over the Teflon PTFE sleeves. These insulated jackets strengthened the divided crevice fixtures and prevented detrimental amounts of oxygen from reaching the junction.

The tubes were bent into a U shape, filled with deaerated 0.1M Na₂SO₄ or 0.2M NaCl by evacuation, mounted in a 1 liter titanium alloy autoclave, and exposed at 290°C, 10.3 MPa for five days to water which was air saturated at room temperature and pressure (8.5 ppm dissolved O₂) and flowed through the autoclave at 10 cm³ min⁻¹. A PAR Model 173 potentiostat electrically isolated from the autoclave served as a zero resistance ammeter and measured current flow from one section to the other while maintaining both parts of the crevice fixture at the same electrical potential. After cooling, the tubes which had contained Na₂SO₄ solution were immersed in liquid nitrogen, cut into 3 cm segments, and warmed to room temperature for pH measurements on their contents.

Results

Figure 1 illustrates the effect on divided tubular crevices of a protective stainless steel jacket and an electrical connection between open and closed ends. In the absence of an effective barrier, abundant molecular oxygen diffused through the Teflon PTFE coating and established a cathodic region at the open end of the inner segment. Unable to diffuse away easily, excess reaction-product hydroxyl ions accumulated at the junction, and the pH profile at room temperature shows how little mixing occurred during cooling and contraction of the crevice electrolyte. With a protective jacket, but no electrical connection between segments, oxygen eventually passivated the outer portion of the crevice and established a cathodic region at the open end of the inner segment. A comparison of pH profiles shows that this deactivation of the outer segment shifted the acidic region an equivalent distance into the crevice and perhaps slightly reduced the amount of crevice activity, and hence acidity, by restricting oxygen transport.

Figure 2 reproduces the current-time profiles for a set of three divided crevices which contained 0.2M NaCl. The current reversals in the crevices divided at 9 and 15 cm from the mouth show directly the slow development of a net cathodic reaction deep within the crevice. Measure-

Fig. 1. Room temperature pH profiles in 304L stainless steel crevices after exposure with 0.1M Na₂SO₄ electrolyte to aerated water at 290°C for 5 days. Abscissa units are the number of 3 cm lengths, starting at the open end. "Connected" signifies electronic continuity from one side of the division to the other.

Fig. 2. Cell current in 304L stainless steel crevices during exposure with 0.2M NaCl electrolyte to aerated water at 290°C. Open end cathodic, interior anodic for positive values.

ments on identical crevices containing 0.1M Na₂SO₄ showed no such reversals, but the currents were similar in magnitude.

After the current reversed in chloride containing crevices, cooling the systems increased cathodic current flow within the inner segment. If the location of the dividing insulator was such that no current reversal occurred during exposure at 290°C, cooling induced the anodic to cathodic transition in chloride systems. The dotted curve in Fig. 3 illustrates this latter type of behavior for a sulfate crevice with the junction at 9 cm from the open end. Division of sulfate containing crevices at 3 or 15 cm produced complex cooling-current transients with multiple reversals like those of the dashed curve.

Discussion

Room temperature pH measurements after cooling reveal little about the high temperature behavior of stainless steel crevices containing chloride electrolytes, but Na₂SO₄ solutions produce interesting post-exposure results. Figure 1 shows the characteristic room temperature distribution of acidity in an electrically reconnected divided fixture which macrocell crevice corrosion with Na₂SO₄ always has produced in 46 cm crevice tubes during

Fig. 3. Cell current in 304L stainless steel crevices during cooling after exposure with 0.1m Na₂SO₄ electrolyte to aerated water at 290°C. Polarity as in Fig. 2.

exposure to aerated water at 290°C (1, 3). The reproducibility of this behavior and the absence of any measurable effect from division provided justification for combining the results from different experiments with the same electrolyte. Positioning the insulators at either 3, 9, or 15 cm limited resolution of the current profiles to the net current between adjacent insulator locations. Thus at any time after the start of an experiment the difference between the current which was flowing into a 9 cm section and that flowing into a 3 cm section should have had its source or sink at the alloy/electrolyte interface between 3 and 9 cm from the crevice mouth. For the 1 mm crevice diameter, an average current of 1×10^{-6} A-cm⁻¹ (linear current density) was equivalent to 3.2×10^{-6} A-cm⁻². Figure 4 shows selected results from this type of reconstructive calculation for crevices containing each electrolyte. Although the cathodic reaction deep in the sulfate crevices never became strong enough at 290°C to reverse the current, it was sufficient to create a locally cathodic region and current profiles quite similar to those in the chloride system.

Oxygen/alloy macrocell corrosion and metal hydrolysis generate hydrogen ions. Thermodynamics dictates that electrochemical reduction of these hydrogen ions must counteract their generation as the pH decreases (4). There is little doubt that the internal cathodic reaction evident between 9 and 15 cm from the crevice mouth was

Fig. 4. Calculated average linear current density in 304L stainless steel crevices after 2×10^2 , and 2×10^3 (sulfate), or 7×10^3 min (chloride), at 290°C. Positive values are cathodic.

in both systems, but the isothermal data contained no evidence for a balancing anodic reaction other than metal oxidation. Upon cooling, however, the crevice electrolyte contracted and relatively pure autoclave water entered the crevice mouth. Figure 3 shows how rapidly the separation of conductive electrolyte from the supply of dissolved oxygen external to the crevice allowed an oxidation to take over and dominate the reactions near the opening. Evidently, this anodic reaction was occurring before the temperature started to drop. Figure 5 shows that as the temperature decreased, the current between 0 and 9 cm from the mouth became more anodic, while H⁺ ion reduction increased significantly between 9 and 15 cm. Although some metal may have been oxidizing, the dominating anodic reaction, therefore, must have been the reoxidation of molecular hydrogen, which was diffusing from its source toward the crevice mouth.

The operation of such a hydrogen counter-cell helps to explain the rapid neutralizations, the negligible internal potential drop, and the remarkable uniformity of electrolyte chemistry which are characteristic of these crevice systems (1-3). Once oxygen/alloy macrocell corrosion has lowered the internal pH sufficiently to cause local redox corrosion and establish a flux of molecular hydrogen toward the crevice mouth, reoxidation of that hydrogen reduces the dependency on an internal potential gradient for continued cell operation. Figure 6 summarizes these relationships in a schematic diagram. Thus, in the steady-state limit of a perfect balance with complete hydrolysis,

Fig. 5. Calculated average linear current density in 304L stainless steel crevices just before cooling, and at 260°C (electrolyte/water interface at 3 cm). Positive values are cathodic.

Fig. 6. Schematic representation of crevice corrosion with a balancing hydrogen counter-cell.

diffusion of water and H_2 would replace the transport of charged species between the transition and interior regions, including the movement of electrons in the metal, and corrosion would continue with a constant acidic interior pH. Potential/pH measurements at 290°C on 304L stainless steel crevices containing chloride electrolytes indicated behavior approaching this type of balance (3).

The hydrogen shuttle can reduce, eliminate, or reverse intermediate potential gradients within the crevice, but continuing corrosion still depends on the driving force of an oxygen/alloy macrocell EMF between the crevice mouth and its interior. When this driving force disappears, there are two mechanisms available for crevice neutralization. First, the hydrogen countercell can continue to operate in the absence of oxygen reduction and metal oxidation. This requires an outward flow of negative ionic charge in the crevice electrolyte from the interior to the site of H_2 oxidation, a direction opposite to that required for macrocell acidification, and the cooling-current kinetic curves clearly demonstrated that current reversal. Second, local redox corrosion in the interior could electrochemically reduce excess H^+ ions to H_2 . These experiments showed that hydrogen could diffuse away from the reaction site, but this mechanism also requires that a significant fraction of the metal corrosion products not hydrolyze, *i.e.*, remain as positively charged species or as complexes with anions other than OH^- . The hydrogen countercell offers an attractively simple explanation, but whether one or both mechanisms are opera-

tive, these experiments have revealed directly a substantial and important contribution from the diffusion of molecular hydrogen to the electrochemical conditions in active crevices at high temperatures.

A New (W,Mo)C Electrocatalyst Synthesized by a Carbonyl Process

Activity Enhancement Resulting from Water Vapor Treatment in the Synthesizing Process

T. Kudo, A. Ishikawa, G. Kawamura, and H. Okamoto

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

It has been revealed that electrocatalytic activity of tungsten and molybdenum mixed carbides formed on a carbon fiber substrate using a process in which metallic film formed by CVD at 450°C from $W(CO)_6$ and $Mo(CO)_6$ is carburized with CO at 820°C is enhanced by exposure to water vapor (~20 torr) at its synthesizing stage before the carburization. Activity tests in relation to electro-oxidation of H_2 and CH_3OH conducted in 1M H_2SO_4 at 50°C show that the potentiostatic current generated by reactants per real surface area of the catalyst thus obtained is 0.27 $A\cdot m^{-2}$ (at 0.2V vs. RHE) and 0.0037 $A\cdot m^{-2}$ (at 0.5V), respectively. The activity enhancement resulting from water vapor treatment is discussed in the light of surface analyses using Auger electron spectroscopy.

Tungsten carbide, often considered to have platinum-like catalytic properties (1), is one of the most promising alternative catalysts for replacing costly platinum for hydrogen electrodes in fuel cells using acidic electrolytes. Ross *et al.* have conducted extensive studies of WC electrocatalyst, especially on the relation between activity and surface compositions, and have demonstrated that only a catalyst having carbon deficient surface composition exhibits high activity (2-4). The most active catalyst reported by them (4) can generate a hydrogen oxidation current as high as 1.05 $A\cdot m^{-2}$ (real or BET surface area of the catalyst) at 177°C, though this value is three or four orders of magnitude lower than that for platinum (5).

In a previous paper (6), the authors disclosed a novel preparation technique whereby WC and (W, Mo)C electrocatalysts are formed on a carbon fiber substrate, in which metallic film formed by CVD at 450°C using $W(CO)_6$ and/or $Mo(CO)_6$ is then carburized with CO at 820°C.

The (W, Mo)C catalyst thus obtained has a hexagonal WC structure (a_0 :2.89Å; c_0 :2.85Å), and there is little contamination by carbon in elemental forms, on its surface, according to observations by Auger electron spectroscopy (AES). Activity tests in relation to electro-oxidation of H_2 , HCHO, and CH_3OH conducted in 1M H_2SO_4 revealed that the potentiostatic current produced by each

reactant per real surface area of the catalyst is 0.12 $A\cdot m^{-2}$ (at 0.2V vs. RHE), 0.04 $A\cdot m^{-2}$ (at 0.3V), and 0.00082 $A\cdot m^{-2}$ (at 0.5V), at 50°C.

Particularly for the oxidation of methanol, Mo is indispensable, as the oxidation current generated by a Mo-free catalyst quickly decays resulting in almost a null current at a steady state. Molybdenum seems, therefore, to act as a center to remove poisonous intermediates from the methanol electro-oxidation, or to lead the reaction to another path in which poisons are not formed.

The (W, Mo)C electrocatalyst obtained by the CVD process is, therefore, expected to provide an economical negative electrode for acid electrolyte-type methanol fuel cells, which would be a most hopeful electrochemical energy conversion device because methanol is a high energy density liquid fuel capable of being easily handled and widespread usage is expected in the near future.

In this report, we show that the activity of (W, Mo)C catalyst is notably improved by a water vapor treatment during its synthesizing process, and this effect is examined by characterizing the catalyst's surface using AES.

Experimental

Catalyst preparation.—A schematic drawing of the apparatus used for catalyst preparation is shown in Fig. 1,

Fig. 1. Schematic drawing of the apparatus to synthesize the catalysts. 1 and 2: CVD sources [$W(CO)_6$ and $Mo(CO)_6$, respectively]. 3: Quartz reaction tube. 4: Image furnace. 5: Water vapor source. 6: Pressure gauges. 7: Liquid N_2 trap. 8: Diffusion pump. 9: Rotary pump. 10: Cald baths.

this being the same in principle as that used in the previous work except that (i) two source vessels for $W(CO)_6$ and $Mo(CO)_6$ are equipped to separately control the evaporations and that (ii) CVD pressure is reduced using a diffusion pump. The CVD rates were controlled by monitoring CO pressure generated by the decomposition of hexacarbonyls. The total pressure employed in this experiment was 1×10^{-3} torr, in which partial pressure from $Mo(CO)_6$ decomposition was 2×10^{-4} torr. The pressure observed when the sources ceased evaporating was 1×10^{-6} torr. In order to induce carbonyls to decompose completely, a porous glassy carbon rod was placed in the downstream side of the reaction tube. However, a considerable part of carbonyls was probably allowed to pass through without decomposition.

The synthesizing procedure and conditions are summarized in Fig. 2. As a substrate, the same carbon paper (E-715, Kureha Chemical Company) was used as in the previous work. The size of the substrate piece was 1.2×3 cm, and its surface area was estimated to be about 50 cm^2 . The sample was stored in 1M sulfuric acid to prevent its coming into direct contact with air.

Electrochemical measurements.—The electrocatalytic activity was investigated by a conventional technique using a potentiogalvanostat (Princeton Applied Research, Model 173), and a three-compartment glass cell, in which the working electrode was connected to the outer circuit through a Au lead wire, as Au proved to be almost inert to the reactants, i.e., H_2 and CH_3OH . The details were reported in the previous paper (6).

The real surface area of the electrode was estimated from its capacitance associated with the double layer and the adsorption-desorption of hydrogen on the electrode. Details about this technique, involving linear sweep voltammetry, are also given in the previous paper.

Surface analyses.—The surface composition in relation to W, Mo, C, and O was determined by AES using an instrument equipped with a thermal field emission-type cathode consisting of titanium-coated tungsten, with a probe diameter of $0.03 \sim 0.5 \mu\text{m}$. This instrument was recently developed at Central Research Laboratory of Hitachi Limited. The details of measuring conditions are given in the caption of Fig. 3.

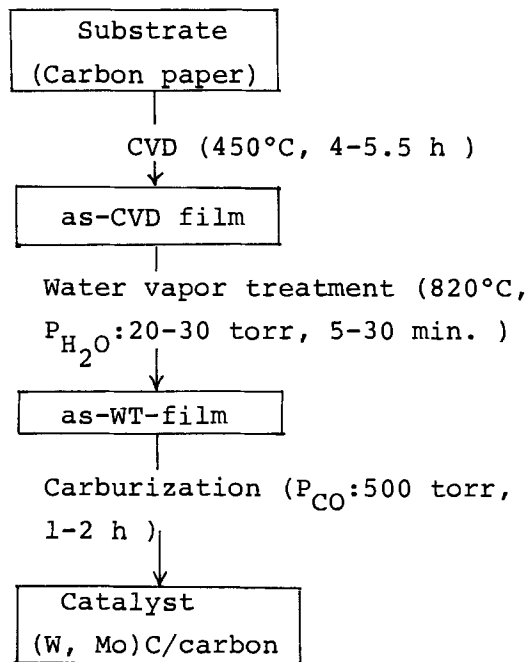

Fig. 2. Catalyst synthesizing procedure

A $5 \times 5 \text{ mm}$ piece of carbon paper coated with catalyst, etc., was used as a specimen for AES analysis. Spots to be analyzed were selected through SEM observations to provide an average. In order to examine distributions of each element as a function of depth from the original surface, sputter etching using Ar ion (5 keV , 5×10^{-5} torr) was conducted. Etching rate was about $10 \text{ \AA} \cdot \text{min}^{-1}$.

A typical Auger spectrum given by (W, Mo)C catalyst with the assignment of each peak is shown in Fig. 3. The concentration of each element was calculated from the peak-to-peak heights of a specific transition on the basis of the following equation

$$C_k = \frac{H_k/S_k}{\sum_i H_i/S_i}$$

where C_k , H_k , and S_k represent atomic concentration, peak-to-peak height, and sensitivity factor, respectively. The values of sensitivity factor (7) corresponding to the transition in the relevant elements used for the analysis with the electron energy at which the peak appears are

Fig. 3. Auger electron spectrum obtained with (W, Mo)C catalyst (sample C). Peaks a, b, c, and d, assigned to the transitions in W NNN, Mo MNN, C KLL, and O KLL, respectively, are used for quantitative surface analyses. $E_p = 10 \text{ keV}$. $E_m = 4 \text{ eV}$ peak-to-peak. $\tau = 300 \text{ ms}$.

Table I. Peaks of AES and their sensitivity factors used for quantitative surface analyses

Elements	Transition	Energy (eV)	Sensitivity factors
W	N ₅ N ₆ N ₆	180	0.13
Mo	M ₂ N _{4,5} N _{4,5}	221	0.26
C (graphite)	KLL	273	0.11
C (carbide)	KLL	273	0.23
O	KLL	503	0.67

shown in Table I. Although the peak at 188 eV is usually used in a quantitative analysis of Mo, the one at 221 eV was employed in the present study because the former overlaps with the W NNN transition at 180 eV. The factor of this transition is estimated to be 0.26, as compared to peak heights of pure Mo at 188 and 221 eV.

Results

SEM observation and x-ray diffraction.—Scanning electron micrographs of carbon paper substrate, as-CVD film, and catalyst carbide film are shown in Fig. 4a, 4b, and 4c, respectively. The as-CVD film has a smooth surface and shows good coverage. Conversely, there are many fine ripples on the surface of the catalyst film, which may have arisen from a volume increase which accompanied the carburization of the CVD film.

X-ray diffraction showed that the as-CVD film is substantially amorphous, though a weak and broad peak assigned to metallic W or Mo was seen. It was found that all catalysts investigated in the present paper take the hexagonal WC structure with a_0 : 2.84Å and c_0 : 2.90Å, regardless of the differing surface composition in each sample, as shown in a later section.

Enhancement of electrocatalytic activity resulting from water vapor treatment.—Rather accidentally, we have found that the electrocatalytic activity of (W, Mo)C formed on carbon fiber substrate using the CVD process is notably promoted by exposure to water vapor at its synthesizing stage just preceding carburization.

In Table II, electrocatalytic activities, represented by oxidation currents produced by H₂(i_{H_2}) and CH₃OH(i_{CH_3OH}), are shown for several catalysts synthesized under various conditions. The oxidation currents were measured at 50°C in 1M H₂SO₄ containing saturated H₂ or 5M CH₃OH. Data for sample A are taken from the previous report (6).

Activity difference between sample A and B may be attributed to difference of carbonyl pressures at the CVD stage, which has a substantial influence on the amount of carbon inclusion in CVD film, as shown in a later section in this text. The carbon monoxide pressure generated by decomposition of carbonyl compounds in the CVD process was about 1×10^{-3} torr for the apparatus in the present paper, whereas it was around 10^{-2} or more in the previous work.

Sample C, synthesized under essentially the same conditions as for sample B except for having been subjected to the water vapor treatment, shows activity two times

Fig. 4. Scanning electron micrographs of carbon paper substrate (a, top), as-CVD film (b, middle), and catalyst (carbide) film (c, bottom) in the final form. As-CVD film and catalyst are identical to sample D-as-CVD and D in Table III, respectively.

Table II. Activity of catalysts prepared under various conditions

Sample	Pressure at CVD (torr)	H ₂ O treatment	Carburization	Anodic current at 50°C (mA·m ⁻² real surface area)	
				H ₂ ^a	CH ₃ OH ^b
A ^c	10 ⁻²	None	1h, 500 torr	115	0.82
B	1 × 10 ⁻³	None	1h, 500 torr	100	1.5
C	1 × 10 ⁻³	5 min, 20 torr	1h, 500 torr	240	2.9
D	1 × 10 ⁻³	5 min, 20 torr	2h, 500 torr	270	3.7
E	1 × 10 ⁻³	30 min, 30 torr	1h, 500 torr	155	3.0

higher than untreated sample B. Sample D, which underwent 2h carburization with CO after water vapor treatment, exhibits still higher activity, in contrast to the fact that, for catalysts without water vapor treatment, prolonged carburization caused deterioration in activity. Sample E, subjected to a water vapor treatment heavier than that for sample C, showed almost the same activity.

The results of potentiostatic current measurements at various potentials conducted at 50°C in 1M H₂SO₄ with H₂ bubbling or 5M CH₃OH are shown in Fig. 5, in which the current is normalized by the real surface area of the electrode. The plot of H₂ oxidation current is nonlinear due to the influence of diffusion control. However, the exchange current for sample D can be estimated to be about 2×10^{-2} A·m⁻² by extrapolation of the quasi-linear part of

Fig. 5. Potentiostatic currents generated by the oxidation of H_2 and CH_3OH on various catalyst electrodes at $50^\circ C$ in $1M H_2SO_4$. Current densities are based on the real surface area of the electrodes. Concentrations of H_2 and CH_3OH are saturated H_2 and 5 mole/liter. Open circles: Sample A. Solid circles: Sample B. Closed squares: Sample D.

the plot, of which the slope is approximately 65 mV/decade, suggesting the two-electron processes for the relevant H_2 oxidation. The current associated with methanol oxidation, presumably generated by the reaction

is $0.0037 A \cdot m^{-2}$ at $0.5V$ vs. RHE and $50^\circ C$, which is almost the same order of magnitude as the value reported for pure Pt (5).

Surface analyses using AES.—In order to elucidate the promotion of catalytic activities through water vapor treatment, the following analyses were conducted focusing on catalyst surface characterizations.

The surface compositions determined by AES are shown in Table III for the catalysts as well as the films at the intermediate stages of the preparation with three different Ar ion sputtering times before spectra measurements. Sputtering time of 1 min is approximately identical to a depth of 10\AA from the original surface. Samples represented by D-as-CVD and D-as-WT are as-CVD and as-water vapor-treated film, respectively, were taken from the intermediate stage of sample D synthesis for analytical purposes. Samples D, B, and C are identical to those in Table II.

To understand the distributions of component elements in the surface layer and their change according to the synthesizing stage, the ratios of each element's atoms to total metal atoms, i.e., $X/(W + Mo)$, are shown in Fig. 6a-6d as a function of sputtering time, 1 min of which being equal to 10\AA of depth from the original surface.

These results show that as-CVD film includes a significant amount of carbon and that it is distributed

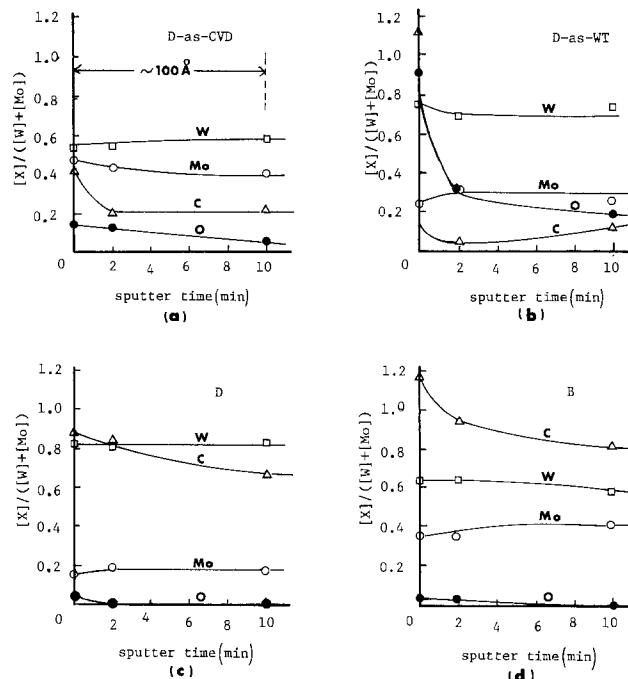

Fig. 6. Variations of the atomic ratio of each element (X) to total metals (W + Mo) in the surface layer with sputtering times for (a) D-as-CVD, (b) D-as-WT, (c) D, and (d) B, each of which is identical to the sample in Table II or III. Sputtering time of 1 min corresponds to a depth of 10\AA .

not solely on the surface but also in the deeper part of the film. A part of surface carbon might be driven into the bulk during Ar ion sputtering, but the amount of carbon thus introduced is so little that it does not affect the bulk concentration. Figures 7a and 7b show patterns of the C KLL transition given by nonsputtered and 2 min sputtered surface of D-as-CVD, respectively. The shapes of Fig. 7b indicate that carbon in the sputtered surface is in a binding state with metal, i.e., W and/or Mo, since the main peak is followed by two smaller but clear subpeaks characteristic of such a binding state.

On the other hand, the spectrum shape in Fig. 7a given by the nonsputtered surface indicates that there are carbons in different states as in graphite or carbonate which may be the contaminants introduced from the storage or handling atmospheres. A much higher carbon concentration at the original surface in Fig. 6a is due to such contaminations. It is, therefore, reasonable to consider that the binding state carbon, probably introduced in the CVD process, is distributed uniformly through the surface layer with its atomic ratio per total metals being about 0.2. A very likely origin of this carbon is carbonyl CVD sources.

The ratio of $Mo/(W + Mo)$ in sample D-as-CVD was determined to be about 0.44 for both sputtered and nonsputtered surfaces, while the CVD process had been controlled so as to give a value of 0.2. This suggests that a significant amount of $W(CO)_6$ passed through the reaction tube without being decomposed, probably because its decomposition rate is considerably slower than $Mo(CO)_6$. X-ray diffraction revealed that the film is almost amorphous, though a very broad peak indicating the onset of metal crystallization was detectable.

Results obtained with sample D-as-WT (Fig. 6b) show that the water vapor treatment at $820^\circ C$ brings about a notable increase in oxygen, which extends more than 100\AA from the original surface, though it decreases as depth increases. Extremely high concentration of C and O at the original surface may be attributed to adsorption species such as CO_2 for the same reason as is given for the as-CVD film. It is interesting to note that the average O/metals ratio between 20 and 100\AA is about 0.3, which coincides with that in compound W_3O_8 or $(W, Mo)_3O_8$, known as β -W, though x-ray diffraction only revealed a pattern

Table III. Surface composition of (W,Mo)C catalysts and films at the intermediate stages in the preparation

Sample	Sputtering time (min)	Composition (atomic percent)			O
		W	Mo	C	
D-as-CVD	0	34	30	27	9
	2	42	33	15	10
	10	46	32	17	5
D-as-WT	0	25	8	37	30

identical to W in the bulk of the film. Neugebauer *et al.* (8) stated that β -W can be prepared with less than 0.01 atoms of O per atom of W. It is conceivable, therefore, that the surface layer of water vapor-treated film is a β -W like compound of alloy.

Parallel with the introduction of oxygen, the water vapor treatment gives rise to an elimination of carbon from the surface layer as shown in Fig. 6b. Possibly, carbon escapes from the surface as CO. If this is true, the diffusion of carbon in the surface suboxide layer is considered to be significantly fast.

Another important effect of the water vapor treatment is a significant decrease of Mo in the surface layer. The value of Mo/(W + Mo) in the sputtered surface was found to be reduced from 0.43 in as-CVD film to 0.28. Since MoO₃ has a vapor pressure of 1300 Pa (9) at 820°C, it is likely that Mo evaporated from the surface in this form.

Sample D, given by carburization of as-WT film, is a final form of the catalyst. Figure 6c shows that its surface with a carbon deficient composition provided the stoichiometry of metal to C to be 1:1, and that the ratio of C/(W + Mo) decreases from 0.88 to 0.67 as the depth increases from 0 to 100Å. However, it is not reasonable to assume a monotonic decrease in carbon content in the deeper part of the film, because x-ray diffraction revealed that the film as a whole is in a single phase with a hexagonal WC structure. It was found by the shape of AES spectrum that carbon is in a binding state with metals, not only in the sputtered surface, but also at the original one, suggesting that the original surface of the carbide catalyst is not contaminated with free carbon from the disproportionation of CO or the adsorption of CO₂.

The ratio of Mo/(W + Mo) in the surface layer is about 0.2, suggesting that a Mo loss has occurred during the heating process in vacuum just before the carburization or during the carburization process itself. Although the mechanism is not clear, the former is more likely.

It is worthwhile for these results to be compared with those for sample B, which was prepared in the same way,

except that the water vapor treatment was omitted. As shown in Fig. 6d, the carbon content in sample B is greater than in sample D throughout the surface layer, and, especially in the former's original surface, carbon is excessive for metals. This fact indicates that the non-sputtered surface of sample B is, to some extent, covered with free carbon produced by the disproportionation of CO during the carburization. As a matter of fact, the shape of the C KLL transition showed that a small part of this surface carbon is in elemental forms. In addition, it is observed that the Mo level in sample B is roughly two times greater than that in sample D, confirming that one of the effects of water vapor treatment is to reduce Mo content in the catalyst surface.

Sample C, prepared in the same manner as sample D except that the carburization time was shorter (1h), contains residual oxygen in its surface layer, as shown in Table III. This catalyst exhibits much higher activity than sample B (no water vapor treatment), but less than sample D, in which no oxygen was detected at its sputtered surface. Thus, it seems that oxygen in the surface layer does not play an essential or positive role during electrocatalysis, though there have been many discussions (10, 11) concerning the relation between surface oxygen and activity of WC catalysts for H₂ electro-oxidation.

Discussion

Miles (12) reported that molybdenum-treated WC, synthesized by a carburization of a mixture of ammonium paratungstate and molybdate with CO at 700°C, exhibited catalytic activity for the electro-oxidation of methanol in an acidic solution. However, the oxidation current generated by his catalyst was estimated to be in the order of as little as 10⁻⁷ A·m⁻² (based on real surface area), and a not negligible corrosion current of the catalyst itself was observed even at a potential as low as 0.4V (*vs.* RHE). It was not, therefore, clearly concluded that Mo played an essential role in the electro-oxidation of methanol.

In the previous report (6) the present authors have shown that the oxidation current produced by the pure WC catalyst (Mo free) decays rapidly though it is detectable initially just after methanol is introduced into the electrolyte. We concluded that Mo acts as a cocatalyst to remove poisonous intermediates, or to lead the electrochemical reaction to another path in which poisons are not produced.

Since Mo in the catalyst of the present study plays a role of cocatalyst, there should be an optimum value of x in W_{1-x}Mo_xC, at which the activity is maximized. However, a clear result has not yet been obtained although the present authors have conducted extensive studies to find the optimum composition using not only the CVD technique described above, but also conventional synthesizing methods. It is reasonable to conclude that the results were unsuccessful because the catalytic activity depends more on the microscopic distribution of Mo in the surface layer than it does on the bulk composition.

A typical example showing the importance of a homogeneous distribution of cocatalyst in surface is Pt/Sn electrocatalyst, in which Sn introduced onto Pt surface as adatom is believed to protect it from too strong adsorption of species like CHO, an intermediate of methanol oxidation, by virtue of the microscopic surface geometry consisting of Pt and Sn. For that reason, Pt/Sn has higher activity than pure Pt (13).

As far as the results of x-ray diffraction are concerned, (W, Mo)C catalysts obtained in the present study are in a single-phase and homogeneous substance. This does not always, however, assure that each component element is distributed homogeneously through the film. For example, if Mo is too excessive to form a single-phase compound, the phase separation into WC and Mo₂C might occur in a level so microscopic that it could not be observed by x-ray diffraction. In the present catalyst, however, the likely cause of its possible nonhomogeneity might lie in the CVD process according to the following considerations.

The AES results show that the as-CVD (at 450°C) film contains carbon in a binding state with metal, and its concentration in terms of C/(W + Mo) is about 0.2 for the sputtered surface. It is reasonable to consider that carbon has been introduced into the CVD film according to the following reactions

where M is W and/or Mo. Carbon content in the film may thus be determined by the relation between the rate of reaction [1] and [2]. For example, the higher the CO pressure, the faster reaction [2], and carbon content would increase. Such a tendency has, in fact, been found in the carbonyl pyrolysis process for Mo (14) coating, as the Vickers hardness increases with an increase in CO pressure because of carbon inclusion. Miyake (15) also reported that Mo CVD film prepared under a CO pressure of less than 10^{-4} torr at 400°C exhibits hardness about four times larger than pure Mo, suggesting that an appreciable carbon inclusion occurs at such a low pressure.

At temperatures as low as 450°C, the rate of reaction [2] may depend on the catalytic activity of film itself. Since it has been reported (14) that Mo CVD film from its carbonyl contains much more carbon than W film does, Mo or its carbide is considered to catalyze the reaction better than W. If this stands true for the CVD film of the present study, carbon would be deposited selectively on Mo sites and a fluctuated distribution of carbon would be formed in the film. Suppose reaction [2] proceeds via reaction of two CO's adsorbed on adjacent two Mo's. Then, Mo₂C would readily be formed, and the film would assume a structure in which its clusters are included in metallic W. The fact that the ratio of Mo:C in the as-CVD film is 2:1 suggests such a situation though it is not a direct evidence. In addition, it is worthwhile to note the fact that, according to x-ray diffraction, only the Mo₂C type phase was clearly detected for the film given by annealing the as-CVD film at 820°C for 10 min, though distinguishing between W₂C and Mo₂C was impossible.

Carburizing such a film as it is, the resulting carbide film would have a nonhomogeneous distribution of Mo because diffusion of metals in carbides is very slow at 820°C. Water vapor treatment before the carburization would, conversely, turn the surface into a more homogeneous distribution in the following way. When the as-CVD film is exposed to water vapor, carbide cluster in its surface is decomposed and the surface changes into a suboxide, presumably, such as defective (W, Mo)₃O. Accompanying with this change, the surface Mo distribution would become more homogeneous, because a rather open structure of suboxide would allow Mo to diffuse in the surface layer. Molybdenum would be uniformly distributed also in the carbide film surface obtained from such a suboxide film. It is, therefore, reasonable to conclude that the difference of activity between sample D and B is due to that of the microscopic homogeneity in the surface Mo distribution.

It should be added that the inclusion of Mo₂C gives rise to the degradation of catalytic activity not only through the above manner but also through the surface contamination with free carbon, because Mo₂C catalyzes carbon deposition in the carburization process. The surface of sample B seems to be contaminated with free carbon.

There is no clear answer as to how the Mo loss from the catalyst surface in its synthesizing process influences the

activity. It is, however, presumable that, if Mo in the as-CVD film was too much to form (W, Mo)C in a single hexagonal WC-type phase, a reduction of Mo content would have a positive effect because the catalyst surface would then be prevented from undergoing phase separation, for example, into WC, Mo₂C, and C.

Conclusion

Tungsten and molybdenum mixed carbide [(W, Mo)C] electrocatalysts, synthesized on a carbon substrate using a technique involving CVD from hexacarbonyl compounds, have been investigated. It has been found that the activity is enhanced by exposing the CVD films to water vapor at 820°C just before it is carburized with CO. The catalyst thus obtained generated H₂-oxidation current density of 0.27 A·m⁻² (based on real surface area) in a 1M H₂SO₄ at 0.2V (vs. RHE) and 50°C. An oxidation current of CH₃OH as large as 0.0037 A·m⁻² was also observed with the same catalyst at 0.5V (vs. RHE) at the same temperature.

Surface analyses using Auger electron spectroscopy (AES) revealed that the as-CVD film formed at 450°C contains about 15 atomic percent carbon of which AES spectrum shape is characteristic of one in binding state with metals. This carbon seems to form Mo₂C clusters included in metallic W. Its surface is turned into suboxide like (W, Mo)₃O with water vapor treatment, and carbon content in it is notably reduced, suggesting the decomposition of such clusters. The enhancement of catalytic activity is probably due to the homogenized surface Mo distribution in catalyst carbide brought about during the above process.

Performance Predictions for Solar-Chemical Convertors by Computer Simulation

J. D. Luttmer*

Texas Instruments, Incorporated, Dallas, Texas 75265

Isaac Trachtenberg*

Department of Chemical Engineering, University of Texas, Austin, Texas 78712

ABSTRACT

A computer model which simulates the operation of Texas Instruments solar-chemical convertor (SCC) was developed. The model allows optimization of SCC processes, material, and configuration by facilitating decisions on trade-offs among ease of manufacturing, power conversion efficiency, and cost effectiveness. The model includes various algorithms which define the electrical, electrochemical, and resistance parameters and which describe the operation of the discrete components of the SCC. Results of the model which depict the effect of material and geometric changes on various parameters are presented. The computer-calculated operation is compared with experimentally observed hydrobromic acid electrolysis rates.

The Texas Instruments Solar Energy System (1-14) converts solar energy into chemical energy, stores the chemicals, and on demand converts the chemical energy into electrical energy. The system consists of four major subsystems: solar-chemical convertor (SCC); hydrogen storage; fuel cell/inverter; and heat recovery. This discussion will be limited to the solar-chemical convertor (SCC). The SCC converts solar energy into chemical energy via the electrolysis of hydrobromic acid (HBr) to hydrogen (H_2) and bromine (Br_2). The performance of the SCC is influenced by the electrical characteristics of the spherical solar cells, the electrochemical parameters of the front metal electrodes, the membrane, and the physical arrangement of cells. In operation, the SCC experiences a wide range of operating conditions which include variable electrolyte composition, temperature, and solar insolation.

A computer model was developed which simulates the operation of the SCC and allows characterization and optimization of SCC processes. The model facilitates decisions involving materials selection and design of the SCC to achieve optimum performance and maximum cost effectiveness. By employing the model, the number of actual laboratory experiments needed to begin the design and optimization study was greatly reduced. The computer-modeled SCC processes and comparisons of the calculated and observed SCC performance are outlined below.

Computer Simulation Model

The processes which occur in the SCC are illustrated in Fig. 1. Photons from the sun are absorbed by the spherical n⁺/p and p⁺/n silicon solar cells either directly or by reflection and scattering from the SCC matrix glass. Some photons are lost owing to reflection or absorption by the electrolyte, cover glass, or membrane separator. Photons that are absorbed in the silicon generate electron-hole pairs. The minority carriers diffuse to the junctions. The majority carriers flow to the electrode-electrolyte interfaces. At the electrodes on the n⁺/p cells (cathodes), hydrogen ions are reduced to H_2 . At the electrodes on the p⁺/n cells (anodes), bromide ions are oxidized to bromine. Electroneutrality is maintained by a flow of ions across the separator. The separator functions to minimize backreaction losses by restricting bromine transport to the cathode (n⁺/p) cells.

The computer model incorporates electrical, electrochemical, and resistance parameters which are functions of the SCC panel composition (9, 14). For example, the electrical characteristics of the solar cells are functions of the light incident on the cells, which in turn is dependent

on the incident panel insolation and the optical properties of the panel and electrolyte. The effects of the optical and resistive components of the panel on the electrical characteristics of the solar cells were determined empirically as functions of panel design, electrolyte composition, and insolation. The interdependent relationships among these parameters and functions are outlined in Fig. 2. Algorithms which describe these relationships are included in the computer model.

The model initially assumes a given panel geometry and bulk electrolyte concentration. Various panel designs can be considered in order to maximize the light incident on the solar cells while minimizing the resistance and electrochemical losses. Electrical, electrochemical, and resistance terms are calculated upon selection of insolation, operating temperature, and electrode material. Finally, the algorithms are used with iterative numerical techniques to solve for the electrolysis rate.

The electrical characteristics of the solar cells used in the model are obtained with a semiautomatic probe system. The solar cells of the panel are randomly probed at simulated air-mass 1 insolation using ELH type tungsten-halogen lamps to obtain representative values for the open-circuit voltage (V_{oc}), the short-circuit current (I_{sc}), and the fill factor (FF). When the density of spheres is known, the average maximum power output per sphere can be calculated. Array positioning, lamp power supply switching, and photocurrent-voltage data acquisition are fully automated. A fine tungsten wire probe is positioned manually on each solar cell sphere. Typically, four solar

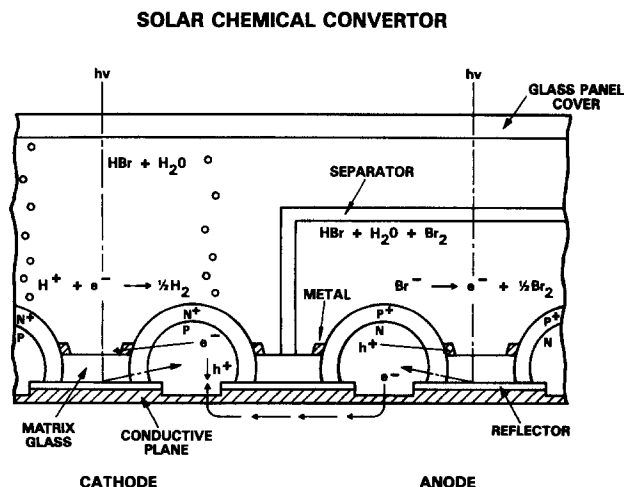

Fig. 1. Cross section of solar-chemical convertor (SCC)

* Electrochemical Society Active Member.

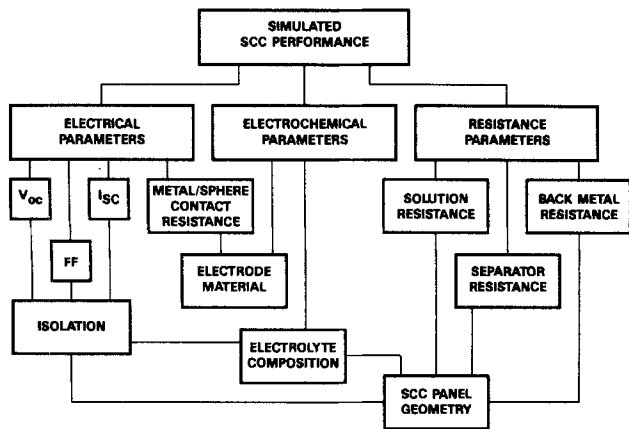

Fig. 2. SCC modeling parameters

cells are probed for each square centimeter of array area for both cell types. The cells sampled correspond to 0.5-0.7% of the total cell population. For the standard size arrays tested, this required probing 160 cells: 80 anodes and 80 cathodes.

The rates for the photoinduced electrochemical oxidation and reduction of hydrobromic acid in the SCC are determined by both the electrical (photovoltaic) characteristics (15) of the individual solar cells and the electrochemical characteristics (16) associated with the front metal electrodes in the HBr electrolyte. During operation, the electrochemical (faradaic) and solar cell currents are equivalent and can be approximated by

$$I_{op} = I_{sc} - I_0[\exp(qV_s/NkT)] = A_e[\exp(\alpha n + \beta)] \quad [1]$$

I_{sc} , I_0 , q , and N are the short-circuit current, reverse bias dark current, absolute value of electronic charge, and quality factor associated with the solar cells, respectively. A_e , α , and β are the electrode area, Tafel slope, and intercept associated with the electrochemistry, respectively. Different values are appropriately used for anode and cathode cells. The solar cell photovoltage V_s and the electrochemical overvoltage are related by

$$\eta = V_s - \sum i_j R_j - V_{ref} \quad [2]$$

where $\sum i_j R_j$ includes all resistance losses associated with the back-side conductor, membrane separator, and electrolyte. The resistance terms can be calculated with simple models of the array geometry using numerical iteration techniques. V_{ref} defines the potential difference between the back-side conductor and the H^+/H_2 and the Br_2/Br^- redox couples. The equations given above define the operation of the anode cells (p^+/n) or the cathode cells (n^+/p). Equations which govern the behavior of anode cells differ from those which govern the behavior of cathode cells only in the sign and magnitude of their coefficients. The values of the electrochemical coefficients are determined experimentally from the electrochemical behavior of thin film electrode materials on n^+ and p^+ silicon substrates in hydrobromic acid-bromine mixtures.

The flow chart for the model is outlined in Fig. 3. The model initially assumes that the operating current of each solar cell is equal to half its short-circuit current and that the potential of the back-side conductor is midway between the two redox couples. The resistance terms are then obtained with a knowledge of the solar cell spacing and SCC panel geometry. iR losses associated with each cell are then calculated from the panel resistance terms and the assumed current flow. The operating currents of the cells are then calculated from Eq. [1] and [2]. On each iteration, the sum of the anode cell currents or cathode cell currents is tested for convergence after the iR loss terms and individual cell operating currents are recalculated. Finally, the back-side conductor potential is varied systematically until the sum of the calculated anode cell currents is equal to the sum of calculated cathode cell currents.

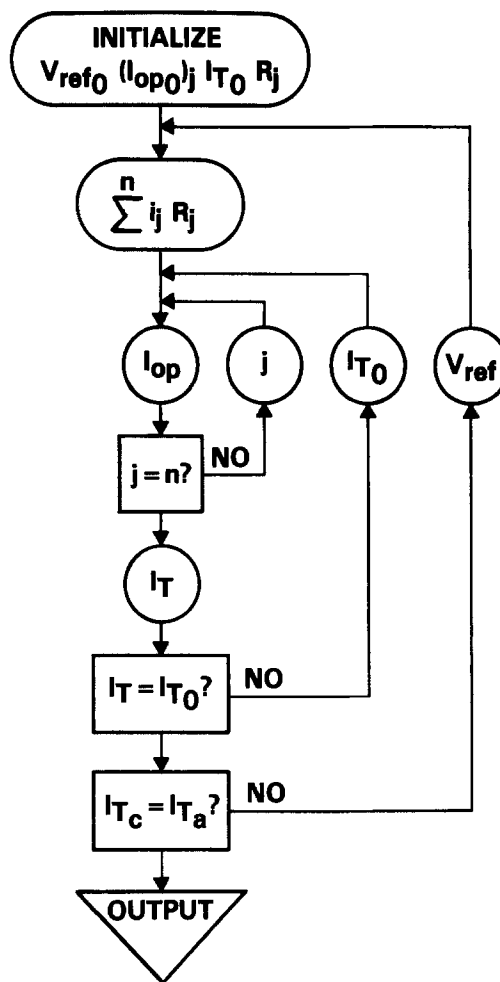

Fig. 3. Computer model flow chart

Figure 4 illustrates the typical interaction between various anode solar cells and a HBr/bromine redox couple. The dashed line represents the electrochemical load imposed on three different solar cells. The operating point for a given solar cell is defined as the point at which solar cell I-V curve intersects the electrochemical load line. The best solar cell anodes produce bromine at a rate approaching the short-circuit current of the solar cell, while the poorest solar cells can consume bromine at the mass-transport-limited rate. Under the conditions given in Fig. 4, two shorted anode cells consume all the bromine produced by three good anode cells. At higher operating bromine concentrations, shorted anode cells have a more detrimental effect. In the cathode compartment, the slight solubility of hydrogen (approximately 0.5 mM) (17) results in negligible losses on the shorted cathode cells.

Fig. 4. Simulated electrical and electrochemical behavior of anode section. Dry efficiency of solar cells is 13% (A), 9.33% (B), and 2.44% (C). Operation at 23°C, air-mass 1 insolation, 0.3M bromine + 8.3M hydrobromic acid electrolyte, Pt/Ir electrodes.

Computed SCC Design Performance

Decisions on SCC panel design aided by computer modeling include choice of electrode material, electrode area, solution compartment depth, anode and cathode compartment width, membrane separator, and optimum operating electrolyte concentration. Results of various simulations and optimum SCC operating conditions are listed below.

Calculated solar-chemical conversion efficiencies as a function of anolyte bromine concentration for an ideal SCC panel and for nonideal panels incorporating different electrode materials are depicted in Fig. 5. The efficiency is defined as the product of the operating current density and the difference in the electrochemical potential of the bulk anolyte and the bulk catholyte divided by the incident light power. The simulations assume air-mass 1 insolation, 23°C operation, dry solar cell efficiency of 13%, and fixed anolyte and catholyte bromine-bromide concentrations of 8.9 eq/liter. Simulations in which optical and resistance losses are neglected are given in Fig. 5 (curve A). As the anolyte bromine concentration increases, the solar-chemical efficiency increases from 10% to about 12% before tailing off at the highest concentrations evaluated. The idealized panel simulation includes overvoltage losses associated with the electrochemistry and the mismatch between the electrochemical load and the solar cell electrical output. At low anolyte bromine concentrations, the performance of the panel is limited by the short-circuit current of the solar cells. At high anolyte bromine concentrations, the performance becomes limited by the open-circuit voltage of the solar cells. Coupling the optical and resistance losses into the simulations for typical panels produces results such as those given in Fig. 5, curves B and C. Optical losses are primarily responsible for the decreased solar-chemical conversion efficiency in these examples, especially at high anolyte bromine concentrations. Additional simulations detailing the effect the optical losses have on the SCC performance are outlined below.

The use of less electrochemically active electrode materials results in additional degradation in the solar-chemical conversion efficiency, as illustrated in Fig. 5, curve C. Electrochemical overvoltage losses are minimized by assuming Pt/Ir alloy electrodes in Fig. 5, curves A and B. Iridium electrodes, which are more corrosion resistant but less active electrochemically, were assumed in the simulations depicted in Fig. 5, curve C. Overvoltage losses can be reduced by maximizing the electrode area on the solar cell spheres. This results in attenuation of photons, producing electron-hole pairs in the silicon.

Optical losses caused by light absorption by bromine strongly degrade the solar-chemical conversion efficiency. Figure 6 illustrates the increased optical losses encountered when the anolyte compartment depth is increased. The losses are significant at anolyte depths as

Fig. 5. Simulated SCC array performance Pt/Ir electrodes (A), excluding optical and resistance losses, Pt/Ir electrodes (B), including optical and resistance losses, and Ir electrodes (C), including losses. Dry solar cell efficiency = 13%; 0.32 cm anolyte depth; depth/width ratio = 0.28, temperature = 23°C.

Fig. 6. Effect of anolyte depth on simulated SCC performance. Nafion 115 membrane; dry solar cell efficiency = 13%; depth/width ratio = 0.28; temperature = 23°C; Pt/Ir electrodes. Anolyte depth: 0.15 (A), 0.32 (B), 0.48 (C), 0.64 cm (D).

small as 1.5 mm at high bromine concentrations ($\geq 1.0M$). At low bromine concentrations ($\leq 0.75M$), the major optical losses are caused by the membrane separator over the anolyte compartment and the panel cover glass. Together, these losses reduce the light reaching the solar cells by about 10% and result in lower output.

Characteristics of the membrane separator which affect the operation of the SCC include optical transmittance, resistivity, and bromine diffusivity. The effects of the resistivity and bromine diffusivity parameters on SCC performance are illustrated in Fig. 7. An ideal separator which is transparent and infinitely conductive and which totally restricts bromine transport yields the results depicted in Fig. 7, curve A. The other separators outlined illustrate the trade-offs that can exist between the separator resistance and separator bromine diffusivity. Separators with high resistance and low bromine diffusivity result in low solar-chemical efficiency at low as well as high anolyte bromine concentrations. Separators with low resistance and high bromine diffusivity result in low solar-chemical efficiency only at high anolyte bromine concentrations. These results suggest a requirement for a transparent separator with less than $2 \Omega\text{-cm}^2$ resistance and bromine diffusivity less than $4 \times 10^{-9} \text{ cm}^2/\text{s}$.

SCC panel performance is also influenced by the electrolyte resistance, which is governed almost entirely by the depth/width ratio of the anode and cathode compartments. Figure 8 illustrates the effect that varying the total electrolyte depth has on the SCC panel performance. As the depth increases, the resistance losses associated with the electrolyte become negligible. A modest electrolyte depth/width ratio of ca. 0.2 is suitable for optimal performance in this typical example. Larger resistance values (smaller electrolyte depth/width ratios) are acceptable when the SCC operates at lower rates.

Fig. 7. Effect of membrane separator on simulated SCC performance. Dry solar cell efficiency = 13%; depth/width ratio = 0.28; anolyte depth = 0.32 cm; temperature = 23°C; Pt/Ir electrodes.

Fig. 8. Effect of solution depth on simulated SCC performance. Dry solar cell efficiency = 13%; anolyte depth = 0.32 cm; temperature = 23°C; Nafion 115 membrane; anode-cathode width = 3.4 cm, Pt/Ir electrodes. Depth: 1.27 (A), 0.95 (B), 0.63 (C), and 0.48 cm (D).

Changes in the operating temperature of the SCC panel most significantly affect the electrical characteristics of the solar cells and the redox potentials required for electrolysis of the acid. Figure 9 depicts the effect of temperature on the performance of a SCC panel. The two temperature effects tend to counteract each other. The required electrolysis voltage decreases by 0.9 mV/°C. The open-circuit voltages of the solar cells decrease by approximately 2 mV/°C. Larger decreases in V_{oc} are obtained at elevated temperature with poor quality solar cells.

Additional electrical energy is obtained from the system if the electrolyte is cooled prior to use in the hydrogen-bromine fuel cell. Cooling the electrolyte increases the potential difference between the anolyte and the catholyte and results in direct thermal-to-electric energy conversion.

Comparison with Experiment

The accuracy of the computer model was determined by comparing the computer-calculated SCC performance with the experimentally observed hydrobromic acid electrolysis rates of various anode-cathode combinations. Hydrobromic acid electrolysis rates of anode-cathode combinations were determined by measuring the hydrogen generation rates of 40 cm² SCC arrays in 48% hydrobromic acid. The SCC sections and arrays were illuminated with multiple tungsten-halogen lamps (ELH) at 1000 W/m².

Excellent agreement is observed between the calculated electrolysis rates and the observed rates for SCC arrays over a wide range of operating conditions. Figure 10 compares the calculated and observed performance of a series of SCC arrays, where the calculated average current efficiency is plotted against the observed average

Fig. 9. Effect of operating temperature on simulated SCC performance. Dry solar cell efficiency = 13%; depth/width ratio = 0.28; anolyte depth = 0.32 cm; Nafion 115 membrane; Pt/Ir electrodes. Temperature: 23° (A), 40° (B), and 60°C (C).

Fig. 10. Comparison of observed and simulated average current efficiency for SCC anode-cathode combinations. Temperature = 23°C; electrolyte = 48% hydrobromic acid.

current efficiency. The average current efficiency is defined as the ratio of the sum of the operating solar cell currents to the sum of the solar cell short-circuit currents

$$\eta_c = \frac{\sum I_{op}}{\sum I_{sc}} \quad [3]$$

Arrays which had low average V_{oc} and FF values were chosen for the series as a more challenging comparison. These arrays consequently operate at rates well below their short-circuit current limitation. Excellent agreement is observed between the calculated rates and the observed rates for SCC arrays constructed of solar cells of widely varying electrical characteristics.

Conclusions

Computer simulation is an accurate technique for predicting the performance and efficiency of a given solar-chemical convertor. Excellent agreement is obtained between the computer-calculated hydrobromic acid electrolysis rates and observed electrolysis rates for a variety of arrays.

Characterization and optimization of SCC processes are readily achieved by computer simulation. The computer model facilitates decisions on trade-offs among ease of manufacturing, power conversion efficiency, design, materials selection, and cost effectiveness. The SCC computer model suggests that solar-chemical efficiencies approaching 10% should be achievable with optimally designed, relatively large area panels.

Photoelectrochemistry of CuIn_5S_8 and HgIn_2S_4

Ralph S. Becker,* Tan Zheng, and John Elton

Department of Chemistry, University of Houston-University Park, Houston, Texas 77004

ABSTRACT

CuIn_5S_8 was prepared by gradient freeze techniques. Doping was done, and annealing was carried out under various sulfur atmosphere vapor pressures and vacuum. HgIn_2S_4 was prepared by chemical vapor phase transport and was annealed under various sulfur vapor pressures. Both materials showed increased photocurrent density with photoetching at short circuit, which was particularly dramatic for HgIn_2S_4 . Purely n-type response was seen for HgIn_2S_4 samples as well as for CuIn_5S_8 , except where phosphorus plus sulfur dopants were used (both n- and p-type responses). Quantum efficiencies of carrier collection were 10-15% at short circuit for CuIn_5S_8 (maximum of 77%) and ~22% for HgIn_2S_4 (maximum of 83%) in a polysulfide couple. Considerable increase in the short-circuit current density and open-circuit photovoltage could be obtained for CuIn_5S_8 in a $\text{Ce}^{4+}/\text{Ce}^{3+}$ couple, but this was offset by substantial photocorrosion. Power efficiencies up to ~0.4% and ~0.2% were obtained for CuIn_5S_8 and HgIn_2S_4 , respectively. Stability in a polysulfide couple was up to ~97% for CuIn_5S_8 and >99% for HgIn_2S_4 .

CuIn_5S_8 appears to be one of two chemical compounds in the $\text{Cu}_2\text{S}-\text{In}_2\text{S}_3$ system (1) (CuIn_2S_4 is the other). CuIn_5S_8 is a cubic spinel with indium found principally on octahedral sites rather than on tetrahedral sites as found in most chalcopyrite structures (2). This material shows an indirect gap near 1.3 eV and a direct gap near 1.5 eV (3).

HgIn_2S_4 appears to have a normal spinel structure (4) and a bandgap of 2.0 eV (4, 5). Its Cd analog, CdIn_2S_4 , also has the spinel structure but with partial inverse character (6), and a bandgap of 2.4 eV (7). Very little information is available for HgIn_2S_4 , although photocurrent-wavelength data indicate a maximum near 615 nm for nonpolished crystals (5). Synthesis employing chemical vapor transport has been reported [see Ref. (4) and (5), for examples]. Only recently have some PEC data been reported in a note for HgIn_2S_4 (8), and more fully for the CdIn_2S_4 analog (7). Also, only very recently has PEC data been reported for CuIn_5S_8 (9).

Experimental

CuIn_5S_8 (1, 3) and HgIn_2S_4 (4, 5, 10) have been previously prepared.

CuIn_5S_8 was prepared by us using gradient freeze techniques employing 99.999% pure elements and dopants. The following technique was developed prior to the appearance of Ref. (3). Table I shows the various samples prepared, conditions of growth, and dopants used.

In particular, the CuIn_5S_8 -2 samples utilized polycrystalline CuIn_5S_8 and In_2S_3 (Sn) ($\sim 1 \times 10^{19}$ at.-cm⁻³ Sn), both of which had been previously prepared and characterized by x-ray diffraction. The In_2S_3 was added to give a dopant level of Sn of $\sim 1 \times 10^{17}$ at.-cm⁻³. The CuIn_5S_8 -3 and CuIn_5S_8 -4 samples were synthesized using polycrystalline CuIn_2S_4 previously prepared by us and In_2S_3 (Cerac, Incorporated). In both cases, 1 atomic percent (a/o) excess S was added in an attempt to obtain p-type material. In addition, for the CuIn_5S_8 -4 sample, phosphorus was added to give a dopant level of $\sim 1 \times 10^{20}$ cm⁻³ of P in an attempt to obtain p-type material.

The starting charges were sealed in 9 mm id quartz tubing which had previously gone through a thorough clean-

ing procedure involving both HF etches and vacuum annealing for ~12h at ~1000°C. Such thorough cleaning is necessary in order to prevent strong adherence of the samples to the quartz walls after synthesis. The ampuls had tapered ends in order to facilitate single-crystal nucleation and growth. Samples were sealed in the quartz tubes at a vacuum of $\sim 10^{-5}$ torr. Those inner ampuls were then placed into an outer protection tube of 13 mm id which had also undergone a cleaning procedure but did not include the vacuum-anneal step. Quartz wool was used to hold the inner ampul rigidly within the outer ampul. The outer quartz tube was then sealed in vacuum at 10^{-5} torr.

The quartz ampul system was next placed into a three-zone Lindberg furnace with independently controlled zones. For the CuIn_5S_8 -2, a mechanical controlling unit was used which could vary the rate of temperature increase or decrease over a range of 0.6°-120°C/h. For the CuIn_5S_8 -3 and CuIn_5S_8 -4 samples, a computerized

^a This is the temperature where the sulfur was located, except for sample 2f (where vacuum annealing was done).

controlling unit was used which had, in principle, no limits to possible rates. The three-zone furnace was positioned in a 45° tilted position with the tapered ends of the inner ampuls at the lowest point. All three samples were taken to above the melting point of CuIn₅S₈ (1085°C) and then slowly cooled at a rate of ~1.25°C/h. Gradients at the melting point were approximately 5°C/cm for the CuIn₅S₈-2, 14°C/cm for CuIn₅S₈-3, and 14°C/cm for CuIn₅S₈-4. The CuIn₅S₈-2 was cooled at the above rate until its temperature was ~800°C and then subsequently cooled to room temperature at a rate of ~10°C/h. The CuIn₅S₈-3 and CuIn₅S₈-4 samples were cooled at the above rate until their temperatures were both ~850°C. At this point, the furnace was turned off and allowed to cool naturally to room temperature. Chromel-Alumel thermocouples were used to monitor temperatures of samples and determine gradients.

Powder x-ray diffraction after synthesis showed single-phase CuIn₅S₈ material in all the cases. The appearance of the samples after synthesis and after polishing of the materials indicated single-crystal material, although this has not been verified by single-crystal x-ray diffraction techniques.

Several different dopants were used and various methods of annealing were carried out, as shown in Table I. Generally, the samples were n-type, except in the case of CuIn₅S₈-4, which was a melt growth with 1% except sulfur and doped with ~10²⁰ cm⁻³ phosphorus which showed both n- and p-type responses.

Samples were polished with diamond paste to a 1 μm finish. All samples were etched in 6-8M HCl for approximately 3 min and then immersed in 0.2M S-1M NaS-1M NaOH solution at 50°C in a sonicator for 1-3 min to remove any surface sulfur. An In-Ga eutectic (25:75) was used to form an ohmic contact. The samples were mounted for study as described previously (7).

The HgIn₂S₄ was prepared using chemical vapor phase transport techniques employing 99.999% pure starting materials (including dopants). The method used represents a notable modification of that given earlier (5, 10). A sample of HgIn₂S₄ was prepared by chemical vapor transport using HgS and In₂S₃ with I₂ as the transport agent as described below. Previously prepared Sn-doped In₂S₃ was also added to give a dopant level of ~1 × 10¹⁹ at.-cm⁻³ Sn in the source material. Iodine was present at a concentration of ~5 mg/cm after ampul sealing. The above starting charge was placed into a 2.2 cm id tube and then placed under a vacuum of ~10⁻⁵ torr. Subsequent sealing of the tube under this vacuum gave a final ampul length of 19 cm.

Since binary compounds (HgS and In₂S₃, and Sn-doped In₂S₃) were used as starting materials, four stages in the synthesis were employed. First, the tube was raised to a temperature of 980°C over a period of 7h and then maintained at this temperature for 16h with a slight reverse gradient to prevent any transport to the other end of the tube. This step was taken in an attempt to presynthesize HgIn₂S₄ before transport. Next, a relatively large reverse gradient of ~10°C/cm was employed for 12h in order to clean the walls at the growth end of the ampul of any material prior to transport. This large reverse gradient was then slowly reduced over a period of 2 days to condition in which no gradient existed, and then a forward gradient was also slowly established over a period of 3 days to give a final forward gradient for transport of 1.5°C/cm. The source and growth ends of the ampul at this point were at ~730° and 700°C, respectively. This condition was maintained for 7 days, and then the ampul was cooled in such a way that the I₂ would condense at the source end of the ampul. The above slow gradient reversal was done because it has been found that this often gives larger crystals than if the final growth conditions are imposed quickly (11).

The crystals so obtained were of moderate size (~3 × 2 × 2 mm) and showed well-developed natural faces. Powder x-ray diffraction of these crystals revealed only single-phase HgIn₂S₄. The appearance of the crystals suggested

their single-crystal nature, but no single-crystal x-ray diffraction methods were performed to verify this.

Polished HgIn₂S₄ samples were subjected to various annealing procedures as shown in Table II. Also, all samples were chemically etched in 6 or 8M HCl for approximately 3 min (sometimes repeated 2-3 times) and finally placed in a polysulfide solution (0.2M S-1.0M Na₂S-1.0M NaOH) at 50°C in a sonicator for 1-3 min to remove any sulfur deposits.

Electrolytes were prepared from analytical-grade materials in deionized water. The polysulfide couple was 0.2M S-1M Na₂S-1M NaOH, the cerium couple was 0.1M Ce(IV) and Ce(III) with 1M H₂SO₄, and the "cyanide" couple was 0.1M [Fe(CN)₆]⁴⁻ and [Fe(CN)₆]³⁻ with 1M Na₂SO₄. All solutions were deaerated with nitrogen or argon prior to PEC experiments.

Electrochemical measurements were carried out as described previously (7). Polychromatic light experiments employed a 150W Xe source with a light intensity of ~100 mW/cm at the plane of the electrode as determined utilizing a calibrated thermopile (Eppley). Monochromatic light was provided as described previously (7) employing a 450W tungsten halogen lamp. Corrections were applied to the photocurrent-wavelength plots for the variation of lamp intensities and monochromator efficiency with wavelength, as determined by a thermopile, to obtain the quantum yield of carrier collection (see Results).

Atomic absorption (AA) analyses were carried out using a Hitachi AA instrument. One standard was a solution of 984 μg In/ml (from InCl₃) in deionized water containing 1.3 volume percent (v/o) HCl (Alfa Products). Analysis of known concentrations of this reference showed a maximum deviation of <0.5% as measured. However, when known concentrations of In were prepared in the polysulfide solution, AA analyses showed the concentration of In to be significantly less than the actual value. The deviation was 50% (too low) at 2 ppm In in polysulfide, and up to 58% (too low) at 100 ppm In in polysulfide. Thus, the reference standard for calculations of In concentration in polysulfide that could result from photocorrosion of CuIn₅S₈ or HgIn₂S₄ (with a polysulfide couple) was that determined in polysulfide. We believe this to be an important observation, and, if it is not recognized, incorrect electrode stability evaluation (too high) could be obtained.

Results

All potentials here and in the discussion are with reference to SCE.

CuIn₅S₈.—With reference to Table I, the resistance of the -2a-type sample was in the 0.25-1 kΩ range; for the -2b sample in the 50-200Ω range, for the -2c, 2e, and -2g samples in the 2 (-2g) to 14 kΩ (-2d) range, for the -3 and -3a samples in the 3-4 kΩ range, and for the CuIn₅S₈-4 sample in the 1 kΩ range.

For the discussion below, reference will be made to a 2a sample unless otherwise noted. Initially, there is considerable dark anodic current positive of -0.2V reaching ~6

Table II. Preparation conditions for HgIn₂S₄ (and annealed) samples

Sample	Sample temp. (°C)	Sulfur			Dopant
		Low temp. (°C) ^a	Pressure (atm)	Time (h) ^b	
HgIn ₂ S ₄ -1	(Initial growth)	—	—	—	Sn
HgIn ₂ S ₄ -1a	690	315	0.1	24	Sn
HgIn ₂ S ₄ -1b	690	400	0.15	24	Sn
HgIn ₂ S ₄ -1c	690	220	0.006	0	Sn
HgIn ₂ S ₄ -1d	690	330	0.1	0	Sn

^a This is the temperature where the sulfur was located.

^b Sample 1a was annealed for 24h with controlled 120°C/h temperature increase to and decrease from 690°C. Sample 1b was annealed as 1a. Sample 1c was annealed by controlled 120°C/h temperature increase to and decrease from 690°C with no time at 690°C. Sample 1d was annealed as 1c.

mA/cm² at +0.2V. Upon multiple dark current scans from -0.8 to +0.8V, this dark current decreases significantly to 0.4 mA/cm² at +0.2V (and 0.8 mA/cm² at +1.0V). A rapid onset of dark cathodic current occurs at -1.5 to -1.6V in initial dark scans. The photocurrent can show up to approximately 150% increase near short circuit with multiple light scans but progressively less with forward bias. A typical current-voltage plot (I-V) in polysulfide after multiple light scans is shown in Fig. 1 for a sample having a resistance of 260Ω using polychromatic light (light chopping not shown). Short-circuit current densities of 4.5 mA/cm² were obtained and up to ~22 mA/cm² at +0.1V.

The onset of photocurrent occurs near -1.08V, and a Mott-Schottky plot of 1/C² (where C is capacitance) vs. applied potential gave an intercept value of -1.14V. This indicates an open-circuit photovoltage of 0.3V.

A typical photocurrent vs. wavelength plot is shown in Fig. 2 at -0.4V. Quantum yields of carrier collection (ϕ_c) were calculated at several applied potentials at 600 nm, which is at slightly shorter wavelength than the maximum attainable (625 nm). For the sample of concern here, ϕ_c at 600 nm is 12% at short circuit (-0.8V), 24% at -0.4V, and 77% at +0.8V after light cycling in polysulfide.

Extrapolation of the long wavelength linear region (840-940 nm) of the wavelength vs. photocurrent plot, Fig. 2, leads to a bandgap of 1.25-1.30 eV. We also analyzed the data using I_{ph}^x vs. $h\nu$ plots, where x is equal to 0.5 or 2 for indirect and direct allowed transitions [see, for example, Ref. (12, 13)]. Using data in the 900-980 nm region, we obtained a linear plot with an extrapolated value of 1.16 eV when $x = 0.5$, indicating an indirect transition. Using data over the 780-860 nm region as well as that over the 820-910 nm region, we obtained separate linear plots extrapolating to 1.36 and 1.31 eV, respectively, when $x = 2$, indicating a direct transition. Appropriate plots of $\log(h\nu I_{ph})$ vs. $\log(h\nu - E_d)$ or $\log(h\nu - E_{ind})$ gave slopes of 0.55 for the direct cases and 2.0 for the indirect case, presumably verifying the assigned nature of the transitions. These data are not in agreement with those of others (3, 9), where an indirect transition was found at 1.3-1.35 eV (vs. direct in our case). Also, no indirect transition was assigned in the 1.16 eV energy region.

The calculated power efficiency, ϕ_p , with 100 mW/cm² white light was calculated to be 0.3% (the fill factor was ~0.22). No corrections were made for light reflection (for ϕ_c or ϕ_p).

A photocurrent vs. time experiment was carried out. At an initial applied potential of -0.8V, the photocurrent first increased ~20% over the first hour and slowly decreased over the next 6h (by ~6%). The potential was then changed to +0.2V, after which there was a gradual increase (~14%) up to 11h. A total photocharge of ~390C/cm² was passed. Following this, atomic absorption analysis of the solution for In was accomplished. Assuming a photocorrosion reaction

Fig. 1. Photocurrent-potential (vs. SCE) response of CuIn_5S_8 in the polysulfide couple. Dotted line: dark. Solid line: white light.

Fig. 2. Photocurrent vs. wavelength response of CuIn_5S_8 in the polysulfide couple. Short wavelength cutoff is due to absorption by the redox couple.

the In analysis showed an approximate 97+% stability of the cell (using In in polysulfide at the standard; see the discussion in the Experimental section concerning the correct standard that should be used).

In addition to the polysulfide couple, a $[\text{Fe}(\text{CN})_6]^{3-}/[\text{Fe}(\text{CN})_6]^{4-}$ couple ($E_{\text{redox}} = +0.25\text{V}$ at pH = 9) and a Ce(IV)/Ce(III) couple ($E_{\text{redox}} = +1.15\text{V}$ at pH = 0) were employed. These were chosen in an attempt to increase the photovoltage. In the cyanide couple, a substantial shift of the photocurrent onset occurred to approximately -0.1V (relative to polysulfide at -1.15V). Also, there was a notable decrease in current at short circuit compared to polysulfide. In the Ce(IV)/Ce(III) couple, the photocurrent onset of 0.0 V was nearly the same as for the cyanide couple. At short circuit, the current density was ~18 mA/cm² (compared to ~4 mA/cm² in polysulfide), and the open-circuit photovoltage was 1V (compared to 0.3V in polysulfide). However, a photocurrent vs. time plot showed a rapid decay of photocurrent at short circuit. After the passage of 20°C/cm² photocharge, the current had decayed by ~95% and yellow sulfur deposits appeared on the surface of the electrode.

Other samples of the CuIn_5S_8 -2 type, such as 2b-2e and 2g, showed lower short-circuit photocurrents in polysulfide; recall that all 2b-2e and 2g samples have resistances higher than that of 2a. In the case of a sample of type 4, where sulfur and phosphorus were used as dopants in the melt growth, both n- and p-type responses were clearly seen. The transition potential (V_{tr}) between n- and p-type response was near -0.9V. The p-type response was weaker than the n-type at the same applied potential by a factor of approximately two.

One sample of the 2 type, 2f, was treated differently than the others in that annealing was done in vacuum instead of a sulfur atmosphere. This sample showed the highest current density at short circuit, approximately 6 mA/cm². It also showed an onset the most negative of any type 2 sample, -1.2V, giving an open-circuit potential of 0.4V. However, the fill factor was only ~0.16 (vs. 0.22 for the 2a sample described above). Nonetheless, the power efficiency was ~0.4%, which was 60% greater than for the 2a sample discussed above. We also found that during photoetching in the polysulfide couple (done by multiple white light scans), the photocurrent of the 2f sample decreased by ~50% in 3h.

n-HgIn₂S₄ (Sn-doped).—Samples 1a and 1b had high resistances of ~110 and 150 kΩ, respectively, 1c of 0.3 kΩ, and 1d of 3 kΩ after etching with HCl followed by sonication in a polysulfide solution.

Both with and without annealing, only n-type material resulted.

The initial unannealed material (HgIn_2S_4 -1) showed poor photoresponse and essentially no photocurrent at

short circuit (in polysulfide). The 1a sample initially showed only 0.15-0.2 mA/cm² photocurrent at short circuit, as did the 1b and 1c samples. The 1d sample was the best and is discussed below.

A typical voltage-current plot for the 1d sample is shown in Fig. 3. Note that, initially, the dark current was essentially absent over the range -1.2 to 1.0V. The photocurrent showed a marked increase with photoetching in the polysulfide couple as shown in Fig. 1, and the fill factor also increased significantly. At short circuit, a current density of ~2.7 mA/cm² was obtained after photoetching, which rapidly increased to a near-maximum value of 6.5 mA/cm² at -0.4V (maximum current density was 7.4 mA/cm²). Accompanying this photocurrent increase was a dark current increase, but only in the -0.8 to -1.1V region. The onset of photocurrent occurred near -1.06V. The calculated fill factor was ~0.22.

Figure 4 shows a wavelength vs. photocurrent plot at -0.2V applied bias. From this and other parallel plots, a bandgap of approximately 1.95 eV was calculated (by extrapolation of the linear rising portion at long wavelength). Analyses of the data for indirect and direct transitions were carried out as previously described for CuIn₅S₈. Data over the 560-600 nm region showed the presence of a direct transition with a value of 2.04 eV. Data over the 570-650 nm region indicated the presence of an indirect transition with a value of 1.78 eV. In addition to these, a plot of $I_{ph}^{1/2}$ vs. $h\nu$ over the 710-760 nm region was linear, extrapolating to 1.19 eV.

Quantum yields of carrier collection (ϕ_c) were calculated at 550 nm and were 22% at short circuit (-0.8V) and ~66% at 0.4V (the maximum obtained was 83%).

Stability studies were carried out in polysulfide. At short circuit, the photocurrent first increased (first 15 min) and then stayed approximately constant for ~2h. After this, the potential was increased to +0.4V, at which time the current increased again over a 3h period (by approximately twofold), followed by a 5% decrease in current over the next hour, and then became constant for the next 6h, at which time the experiment was stopped. A few yellow spots were observed on the crystal after the experiment. Atomic absorption analysis for In showed a >99.5% stability of the electrode.

The power efficiency with 100 mW/cm² white light was calculated to be 0.2%. No corrections were made for light reflections (for either ϕ_c or ϕ_p).

Discussion

CuIn₅S₈.—Sulfur annealing can improve the overall PEC performance of this material. However, this improvement clearly depends on the sulfur vapor pressure and temperature, since the 2a type was definitely the best of the sulfur-annealed samples. It is also clear that dark current cycling in the polysulfide is necessary to

Fig. 3. Photocurrent-potential (vs. SCE) response of HgIn₂S₄ in the polysulfide couple. Dashed line: initial response. Solid line: response after photoetching. Dotted-dashed line: dark current.

Fig. 4. Photocurrent vs. wavelength response of HgIn₂S₄ in the polysulfide couple. Short wavelength cutoff is due to absorption by the redox couple.

first condition the surface and that photoetching in the couple definitely improves the fill factor. Others have also found that chemical and photoetching improve the PEC performance of this kind of material (9).

Quantum efficiencies of carrier collection using a polysulfide couple were relatively small at short circuit (10%), but they did improve significantly upon photoetching of the electrode. However, significant bias is required to attain >50% efficiency. This indicates substantial (h^+e^-) recombination must be occurring in the vicinity of the depletion layer at short circuit. Nonetheless, the attainment of 77% quantum efficiency for carrier collection indicates that improvement of the crystal quality in general, and particularly near the surface, could result in significant improvement in the PEC results. Also, there is a question of whether the tin dopant is properly distributed as a true dopant, since, if it is not, it could act as a recombination center, at least in part.

Our photocurrent onset of -1.08V and Mott-Schottky plot intercept value of -1.14V are very similar to what was referred to as the flatband values by others (-1.1 and -1.15V respectively, by the two preceding methods). However, in our case, we are not certain if these represent flatband values and have not called them such. If we consider the potential -1.5 to 1.6V, at which cathodic dark current becomes rapidly increasing (nearly exponential) as a measure of the conduction bandedge and if the Fermi level is within 0.1-0.2 eV of this edge because of the doping, then the flatband would really be located near -1.4V. In such a case, the situation would be worse than described above in that even at the photocurrent onset there is already some 0.25-0.35V forward bias and even greater recombination is occurring than indicated in the discussion above. In one of our cases where vacuum annealing was done instead of sulfur annealing, we found the photocurrent onset (-1.2V) to be 0.1-0.15V more negative than the representative 2a sample (sulfur annealed). It is also interesting to note that others found the "flatband" potential moved 0.3V more negative than -1.1V for a freshly etched electrode (9). These latter two results are consistent with our earlier analysis, indicating the possibility that the photocurrent onset and the Mott-Schottky data may not provide true flatband potentials for this material, or that the flatband potential is varying because of variable different composition at the surface.

The foregoing, plus the relatively small fill factor of 0.22, resulted in a poor power efficiency of ~0.25%. However, 0.4% was obtained for a vacuum-annealed sample. Others (9) have reported values of short-circuit current, open-circuit photovoltage, and power efficiencies (~0.5%) similar to ours, although in isolated cases larger values of the first two were found (also, they found quantum efficiencies significantly higher than ours in at least one instance). In one of our cases where sulfur annealing was not done but vacuum annealing was done instead,

larger short-circuit current, open-circuit voltage, and power efficiency were obtained compared to the representative sulfur annealed 2a type. This material did show a reduced fill factor and less stability than the 2a type. It appears as if both the sulfur annealing and vacuum treatment improve the surface quality. This may be due in part to a temperature annealing effect.

The stability results for the 2a (sulfur annealed) type in polysulfide (0.2M S-1M Na₂S-1M NaOH) do not indicate total stability, but indicate a respectably high value (97+%). Others (9) have also reported an initial increase and then a decrease in photocurrent at short circuit, but did not test for the increase again at positive applied potential. Pitting of the surface was noted, but stability was not determined (9) (in a polysulfide couple of twice our concentrations). The greater apparent instability of the vacuum-annealed material may result from removal of sulfur on the surface, although it did not at all affect the open-circuit voltage, short-circuit current, or power efficiency (but did lower the fill factor). There is probably a critical balance required regarding the amount of sulfur present in terms of crystal quality, lattice vacancies, and interstitial sites, all of which affect the PEC results.

The results in the Ce(IV)/Ce(III) couple are interesting from the point of view of the dramatic improvement in PEC results. However, the great instability negates the improvement. The results in the cyanide couple were not as good at short circuit as for polysulfide. Others (9) have noted increased performance in the cyanide couple, and Fe(III)/Fe(II), but the electrodes were also unstable in these couples.

Our data for direct and indirect transition values differ from others. Our absorption over the 900-980 nm region may be the result of states in the gap which happens to plot correctly for an indirect transition. However, it is not apparent why our data in the ~780-910 nm region indicate a direct transition (1.33 ± 0.02 eV) vs. an indirect one for others. A direct comparison may be difficult since the wavelength region over which one group (9) determined their results may not have been the same as ours and the methodology used in the other case (3) was different.

It is clear that substantial improvement in the quality of the crystal matrix (and possibly dopant distribution) needs to be achieved to improve the performance of this kind of material before it approaches that of the ternary CuInS₂ (14, 15). Nonetheless, there seems to be potential for this.

HgIn₂S₄.—In contrast to CuIn₂S₈, dark current cycling was not necessary for the 1d sample to reduce dark currents, since they were already very small (<25 μA/cm). However, there was a significant increase in photocurrent upon photoetching (12-fold at short circuit). This obviously indicates a conditioning of the surface by photoetching was important in improving PEC (ϕ_c) performance. Nonetheless, based on the stability studies, this conditioning did not involve any significant corrosion of bulk HgIn₂S₄; also, very little visual change in the surfaces occurred over a 2h photoetch generally required to obtain maximum PEC performance. Thus, it would appear that excess sulfur (from the annealing procedure) was removed, plus perhaps some surface modification, which provided a surface considerably more free of recombination sites than without photoetching.

Quantum efficiencies for carrier collection are higher at short circuit and with applied bias than for CuIn₂S₈, but the fill factor is almost identical. Nonetheless, the power efficiency is smaller than for CuIn₂S₈ principally because of smaller short-circuit current. Obviously, the considerably higher bandgap contributes to the poorer results compared to CuIn₂S₈.

The open-circuit photovoltage is almost identical to that of CuIn₂S₈. This low value (0.25V) also contributes to a poor power efficiency. Also, as in the case of CuIn₂S₈, a dark photocathodic current becomes rapidly large near -1.6V. Again, if this is considered to be the conduction bandedge and if the Fermi level is within 0.2 eV positive

of this edge, then the flatband potential should be near -1.4V. Therefore, considerable recombination must again be occurring as for CuIn₂S₈, although it is not quite so severe, since ϕ_c at short circuit is about twice that of CuIn₂S₈ (22% vs. 10% for CuIn₂S₈). Nonetheless, it is clear that the quality of the crystal near the surface and/or dopant distribution must be providing significant recombination sites. Despite the foregoing results, it is clear that sulfur annealing produces much better results than those found for the initial material (unannealed).

The stability results indicate very little corrosion (<0.5%) of the electrode in the polysulfide couple.

Our data indicate the presence of a direct transition at 2.04 eV. Others (4, 5) indicate a bandgap of 2.0 eV, but whether it was direct or indirect was not indicated. Also, over the 570-650 nm region, we found indication of an indirect transition with a value of 1.78 eV. Again, whether the latter represents a true indirect transition or is the result of states in the gap depends upon one's estimation of the reliability of the methodology.

Based on the results of others (8) for polycrystalline HgIn₂S₄, our photocurrent onset appears to be more negative (by ~0.2V) where our couple was 0.2M S-1M Na₂S-1M NaOH, while that of the others was 1M Na₂S-1M NaOH. Our photocurrent onset appears not to be significantly different than that of others (8) (~850-900 nm), but our data showed a noticeable tail before a rapid increase in photocurrent began at shorter wavelengths. Also, our photocurrent maximum is at ~550 nm, whereas that of others (8) is near ~725 nm. Although it is not possible to be exact, it would appear that a bandgap calculated from extrapolation of the approximately linear long wavelength edge of the photocurrent vs. wavelength plot of others (8) would give a bandgap value considerably lower (up to 0.5 eV) than that we determined by the same method (1.94 eV); moreover, the latter value is close to that determined from our I_{ph}^2 vs. $h\nu$ plots for a direct transition, 2.04 eV and to the value in other literature (4, 5), 2.0 eV.

Comparison with CdIn₂S₄ results indicate that HgIn₂S₄ has a somewhat smaller photopotential (0.3 vs. 0.4V), a larger short-circuit current density (2.7 vs. 0.5 mA/cm²), and a somewhat higher power efficiency (0.2 vs. 0.1%). The photocurrent onset of CdIn₂S₄ is ~0.15V more negative than with HgIn₂S₄.

ABSTRACT

The photoelectrochemical properties of the ternary semiconductor CdIn₂Se₄ is further investigated. Photoelectrochemical etching increases the photocurrent of this material by an order of magnitude in various electrolytes. Cyclic voltammetry, Auger analyses, and thermodynamic calculations suggest that oxide is unlikely to be produced during photoetching. Degradation of the photocurrent with time in polysulfide electrolyte due to photocorrosion is studied with x-ray photoelectron spectroscopy (XPS). Thermodynamic and solid-state data are used for the construction of the band diagram of CdIn₂Se₄/polysulfide system. It is shown that the time behavior of this system resembles that of CdSe/polysulfide photoelectrochemical cell.

Ternary semiconductor compounds have many interesting physical and chemical properties and also show great potential for use in electro-optical devices and solar cells in particular. Much of the research is focused on the CuInX₂ (X = Se, S) group (1-5), but other families of compounds have been investigated as well (6-11).

The mixing of Cu 4d and Se 4p atomic orbitals which leads to a decrease in the optical gap of CuInSe₂ as compared to its binary analog (CdSe) (5), and to the remarkable stability of this material against photocorrosion is of much interest. For CdIn₂X₄ compounds, there is a change in the structure between, say, CdIn₂Se₄ to CdIn₂S₄ with concomitant changes in the optical gaps (6).

CdIn₂Se₄ is material with a "defect" structure material (the space group D_{2d}¹). Each fourth cation site is unoccupied. The energies of the optical bandgaps are 1.73 eV for the direct transition and 1.55 eV for the indirect transition (6, 8). It was recently observed (8) that a short photoelectrochemical etching (photoetching) of this material leads to at least tenfold increase in the short-circuit photocurrent of the CdIn₂Se₄/polysulfide photoelectrochemical cell. Subbandgap photocurrent, which was attributed to a surface state located some 0.3 eV below the conduction band, disappeared after short photoetching. Electrolyte electroreflectance measurements (11) lent further support to this hypothesis. Fermi energy pinning substantially increased after photoetching (11). This result was attributed to yet another type of surface state, the density of which increased while photoetching. Their chemical nature was not fully resolved, although indications that they consist of chemisorbed sulfide ions were found.

The present study is a continuation of our effort to understand the chemical and electrochemical processes

which occur at the CdIn₂Se₄ surface while operating in a photoelectrochemical cell. One important aspect of that chemistry is the Se/S exchange. According to a recent study (12), CuInSe₂ is stable in polysulfide solution, and no evidence for Se/S exchange was found after ~20,000C of charge passed under illumination. Contrarily, CdSe undergoes under most solar conditions slow photodecomposition in polysulfide solution and Se/S exchange (13). Long-term stability tests of CdIn₂Se₄ electrode in polysulfide electrolyte revealed that, although the photoelectrode is stable for appreciable time, slow photocorrosion takes place. Its extent depends on the quality of the electrode material and its surface in a manner similar to Cd-chalcogenide electrodes (14).

Here, we use cyclic voltammetry and Auger spectroscopy for the analysis of the electrochemical processes which occur during photoelectrochemical etching of CdIn₂Se₄, and x-ray photoelectron spectroscopy (XPS) in conjunction with output stability runs were employed for the analysis of the Se/S exchange during the slow photocorrosion which takes place in polysulfide electrolyte.

On the basis of the proposed mechanism for the Se/S exchange and using rough estimates for the free energy of formation of CdIn₂Se₄, we have established the decomposition potential toward oxidation of this material. Taking into account the estimated flatband potential of CdIn₂Se₄, the full band diagram for the CdIn₂Se₄/polysulfide interface has been established. It is concluded that this system is expected to have similar stability as the CdSe/polysulfide photoelectrochemical cell.

Finally, experiments are described in which we have tried to evaluate the role of an In₂O₃ overlayer on the performance and output stability of the above cell. It appears

that, in contrast with CuInX_2 ($X = \text{S}, \text{Se}$) (12), thin over-layers of In_2O_3 have no positive effect on this surface. Other surface treatments are briefly discussed as well.

Experimental

CdIn_2Se_4 crystals (n-type) were grown by one of us (W.G.). Their resistivity was $<5 \Omega\text{-cm}$. Crystallographic faces were not used. The surfaces of the semiconductors were polished down to $0.3 \mu\text{m}$, etched in aqua regia (1:4 v/v HNO_3 : HCl mixture) and immersed in KCN (10% w/w) for a few minutes. Ohmic contact was established by rubbing an In-Ga alloy on the back surface of the crystals. The crystals were then attached to a Ti plate by means of a silver epoxy (Transene 50) and were finally encapsulated with the help of an insulating epoxy, apart from the front surface which was exposed to the electrolyte. Etching procedures included aqua regia etching; Br_2 (2% v/v)-methanol etch and dichromate (4g $\text{K}_2\text{Cr}_2\text{O}_7$, 10 ml HNO_3 ; 20 ml H_2O) etch; the former procedure led to the best results. Photoetching in either five times diluted aqua regia or 4M HClO_4 solution led to at least tenfold increase in the photocurrent (8). Solutions for photoelectrochemical measurements included (2;2;2) polysulfide (S; Na_2S ; KOH , 2M for each component); 1M sulfite (Na_2SO_3), and a solution of potassium ferri/ferrocyanide. A conventional three electrode setup was used for the electrochemical measurements with standard calomel electrode (SCE) as a reference electrode. A home-made programmer (linear scan generator) was used for the cyclic voltammetry measurements together with a Wenking MP 81 potentiostat and Graphtec Model WX 4422 X-Y recorder. A Philips 505 scanning electron microscope (SEM) was used to determine the morphology of the CdIn_2Se_4 surface prior to and after photoetching. A Physical Electronics Model 590A scanning Auger microprobe (SAM) was used for Auger analysis prior to and after photoetching. Se/S exchange was followed by x-ray photoelectron spectroscopy (XPS) on a AEI ES 200B spectrometer, using Mg $K\alpha$ (1253.6 eV) radiation.

Results

Figure 1 shows the I-V curve of CdIn_2Se_4 in three different solutions prior to and after photoetching (the photocurrent of the electrode exhibited in Fig. 1a is not larger than $0.5 \text{ mA}\cdot\text{cm}^{-2}$ before photoetching). In all three solutions, a remarkable increase in the photocurrent was observed after photoetching and dip in KCN solution. No effect of the KCN solution alone was observed. These results show that the improved performance of CdIn_2Se_4 after short photoetching is not limited to a specific solution. Rather, it is a manifestation of the improved state of the semiconductor surface.

The micrographs of Fig. 2 allow one to compare the surface morphology of aqua-regia etched (a), and photoetched (b), CdIn_2Se_4 . The corrugation of the surface after photoetching is obvious. The distribution of etch pits is not nearly the same as in Cd-chalcogenide and Zn-chalcogenide semiconductors (15, 16) although in certain regions of the semiconductor surface they are quite dense and uniformly distributed. This was essentially our first indication for the spatial nonuniformity of the semiconductor, a conclusion that was reinforced by the Auger analysis.

Cyclic voltammetry is a useful tool for the study of decomposition mechanisms of semiconductors. In the case of n-type semiconductors, one can photo-oxidize the semiconductor in the anodic half-cycle and dissolve the oxidation products or reduce the outdiffusing metal ions in the cathodic half-cycle (17).

Figure 3 exhibits such cyclic voltammogram for CdIn_2Se_4 in 0.5M KCl solution. The first cycle is run in the dark. A small reduction peak is observed at -1050 mV vs. SCE. Going back to zero bias, the light source is opened and a second (half) cycle is carried out in the anodic direction which is followed by a third (half) cycle (in the dark) in the cathodic direction. A series of reduction peaks is observed which cannot be easily deconvoluted. A fourth cycle (in the dark) exhibits two reduction peaks only. Referring to previous work with CdSe (17),

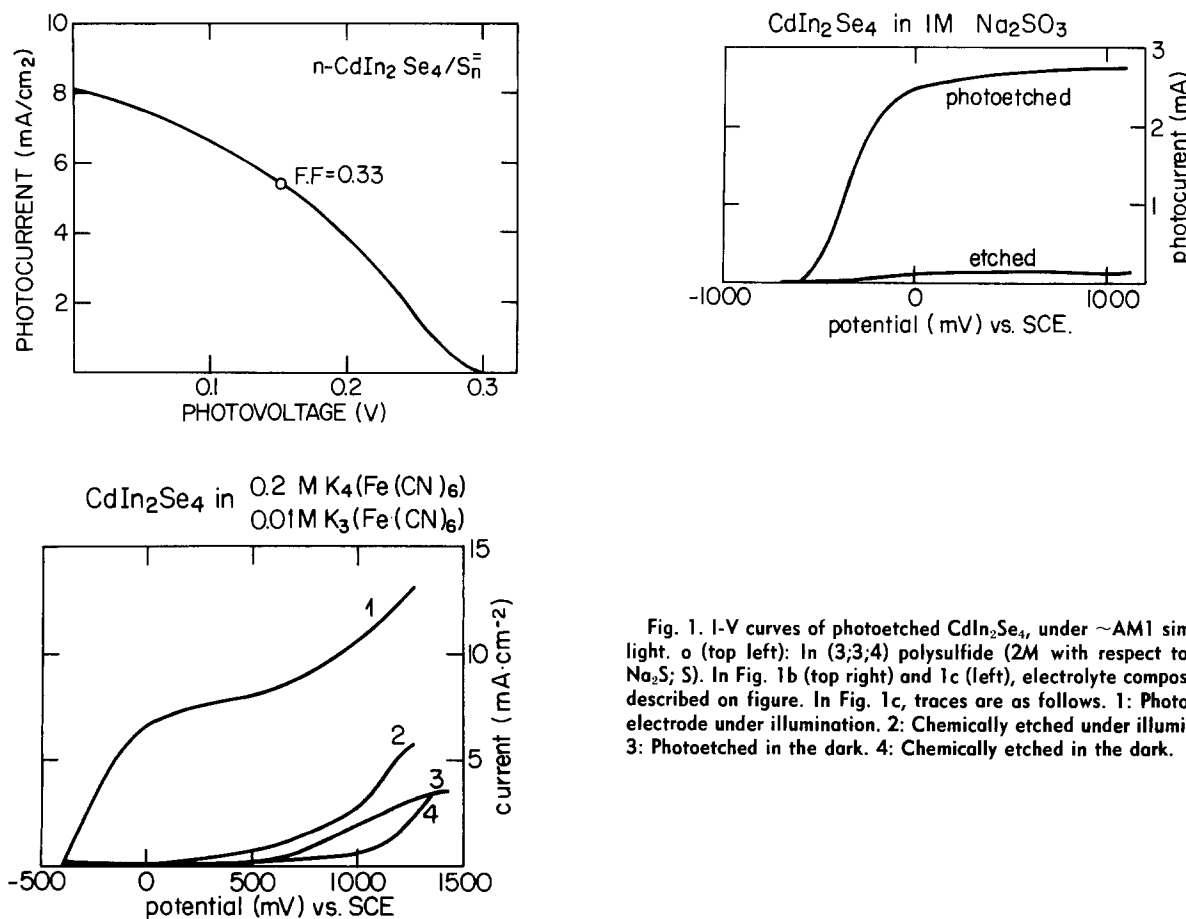

Fig. 1. I-V curves of photoetched CdIn_2Se_4 , under $\sim\text{AM1}$ simulated light. (a) (top left): In (3;3;4) polysulfide (2M with respect to KOH ; Na_2S ; S). In Fig. 1b (top right) and 1c (left), electrolyte composition is described on figure. In Fig. 1c, traces are as follows. 1: Photoetched electrode under illumination. 2: Chemically etched under illumination. 3: Photoetched in the dark. 4: Chemically etched in the dark.

Fig. 2. Scanning electron micrographs for etched (a, left) and photoetched (b, right) CdIn_2Se_4 .

these two peaks can be attributed to reduction of elemental selenium which was produced during the second cycle (photoetching). The third cycle included, in addition to the reduction peaks of selenium, reduction peak(s) of the metal ion(s) which out-diffuse from the semiconductor surface following the anodic half-cycle under illumination. This is further visualized in Fig. 4. Here two experiments were carried out. In the first one (1 + 2), the cathodic part in the dark (2) followed the anodic half-cycle under illumination (1) immediately. Thus, in addition to the Se reduction peaks, some reduction peak of the outdiffusing metal ions(s) is observed at -500 mV vs. SCE. In the second experiment (1 + 3), the cathodic half-cycle (3) is carried out only 1 min after the completion of the photoetching (1). Thus, all metal ions have diffused from the semiconductor surface already and the Se reduction peak is observed under cathodic scan only. The separation between metal ion(s) reduction peak(s) and selenium reduction becomes even more evident when the photoetching (anodic part) is done at higher light intensities. However, the separation between the reduction peaks of indium (3+) and cadmium (2+) ions is not nearly as simple since on a platinum electrode they are only 60 mV apart. In the Discussion section, we propose a mechanism for the light-induced decomposition of CdIn_2Se_4 which is consistent with the results of cyclic voltammetry.

Additional information on the surface chemistry which is involved in the photoetching was obtained from Auger spectroscopy. The results of the Auger analysis are summarized in Table I.

Fig. 3. Cyclic voltammograms of CdIn_2Se_4 ($200 \text{ mV}\cdot\text{s}^{-1}$), in the dark and under illumination. Curve 1 (short dashes) In the dark prior to illumination. Curve 2 (solid line): Anodic half-cycle under illumination (photoetching). Curve 3 (dotted line): In the dark immediately after photoetching. Curve 4 (long dashes): After few cycles (in the dark). Light intensity ca. $5 \times \text{AM1}$.

The sample showed a large heterogeneity on each of the two analyzed surfaces, but it was especially large on the etched surface, which contained appreciable amounts of oxygen in either adsorbed form or more likely as an oxide of indium. Thus, Fig. 5 presents a wide scan of the Auger

Fig. 4. Cyclic voltammogram of CdIn_2Se_4 ($200 \text{ mV}\cdot\text{s}^{-1}$). Solid line: Under illumination (photoetching). Dashed line: Immediately after photoetching. Metal reduction is seen. Dotted line: Starts 60s after photoetching. Most metal ions outdiffused already. Light intensity ca. $5 \times \text{AM1}$.

Fig. 5. Wide Auger scan of CdIn_2Se_4 prior to and after photoetching.

Fig. 6. Narrow Auger scan of cadmium (374, 381 eV) and indium (400, 407 eV) peaks of the sample presented in Fig. 5.

spectrum prior to and after photoetching. Some carbon contamination is obvious, but, nevertheless, the abundance of oxygen on the chromate etched surface is clearly exhibited. The oxygen signal almost disappears after photoetching. Furthermore, comparison of the narrow scans (Fig. 6) indicates that indium oxide is the most likely oxygen containing species. This is indicated from the ratio R between the height of the 407 eV peak of In to the height of the 400 eV peak of In. Thus, R is larger than one for the etched electrode (Fig. 6a). After photoetching (Fig. 6b), this ratio (R) becomes smaller than 1 (18).

Also observed is the relative depletion of cadmium after photoetching. The larger amount of sulfur and selenium after photoetching can be attributed to (i) release of elemental selenium during photoetching (see Eq. [1]-[3]) and to (ii) the post-treatment of the electrode, after photoetching, in polysulfide solution. Although a thorough rinse and immersion in hot KCN solution follows the immersion in polysulfide (which should dissolve all the free selenium generated during photoetching), the high degree of porosity of the photoetched surface inhibits the completion of these two processes and thus both sulfur and selenium are more abundant after photoetching. Generation of some selenium oxide during photoetching cannot be ruled out conclusively, but both thermodynamic calculations (see Table II) and surface analyses of photoetched CdSe (17a) suggest that this reaction is not favorable here.

After sputtering a layer of 285 Å, the oxygen concentration went down appreciably and the composition of the etched part became almost stoichiometric (CdIn_2Se_4). Contrarily, the photoetched surface had much less oxide on it, but cadmium depletion, which increased with the depth, is evident here.

Figures 7 and 8 exhibit a wide and a narrow scan, respectively, of CdIn_2Se_4 after sputtering of a layer of a few hundred angstroms. Figure 7 exhibits much less oxygen

Fig. 7. Wide Auger scan of CdIn_2Se_4 prior to and after photoetching and after ion sputtering of $\sim 300\text{Å}$.

on the etched surface after Ar sputtering. This is further shown in the narrow scan, where the ratio R for the In peaks is smaller than 1 now. Hence the amount of indium oxide went down drastically, on the chromate etched surface, following argon sputtering. Cadmium depletion increases, on the photoetched surface, after sputtering.

The Auger analyses suggest that the oxide layer on the etched surface (probably indium oxide) has an adverse effect on the performance of CdIn_2Se_4 in photoelectrochemical cells in contrast with CuInSe_2 (12, 13). Thermodynamic calculations (see Discussion section) show that the oxide layer is unstable during photoetching.

A second phase of the present study concerns the long-term stability of CdIn_2Se_4 in polysulfide solution under illumination and the Se/S exchange. It was shown previously (8) that CdIn_2Se_4 is remarkably stable in polysulfide electrolyte after photoetching. Figure 9 compares the output stability of photoetched CdIn_2Se_4 to that of CdSe in (2;2;2) polysulfide electrolyte. The CdIn_2Se_4 is very stable at a current density of $80\text{ mA}\cdot\text{cm}^{-2}$, and the sharp drop in the photocurrent occurs upon addition of water, which is lost due to evaporation under intense illumination. At a higher photocurrent ($\sim 100\text{ mA}\cdot\text{cm}^{-2}$), the photocurrent drops somewhat faster in the beginning,

Table I. Relative composition of CdIn_2Se_4 prior to and after photoetching as determined by scanning Auger analysis

	Chromate etched ^b	Photoetched ^b
Surface	$\text{CdIn}_4\text{Se}_{2.74}\text{O}_{3.86}\text{S}_{0.082}$	$\text{CdIn}_{2.42}\text{Se}_{3.46}\text{O}_{1.338}$
160 Å ^a	$\text{CdIn}_{2.46}\text{Se}_{3.98}\text{O}_{1.84}\text{S}_{0.12}$	$\text{CdIn}_{4.46}\text{Se}_{9.55}\text{O}_{0.2}\text{S}_{0.2}$
285 Å ^a	$\text{CdIn}_{2.12}\text{Se}_{4.52}\text{O}_{0.51}\text{S}_{0.05}$	$\text{CdIn}_{3.6}\text{Se}_{11.39}\text{O}_{0.3}\text{S}_{0.3}$

^a Calibrated according to Ta_2O_5 .

^b Immersion in polysulfide and in 10% (w/w) KCN solution for 15 min was done prior to Auger analysis. Immersion in polysulfide leads to the dissolution of elemental selenium, the final cleaning of the surface from elemental sulfur and selenium is done in KCN solution. This procedure was favored over KCN treatment alone since it permitted less frequent disposal of the KCN solution.

Fig. 8. Narrow Auger scan of cadmium and indium peaks of the sample presented in Fig. 7.

and then it falls off slowly. The output stability of CdSe is somewhat inferior to that of CdIn₂Se₄, as shown in Fig. 9. This is even more important if one takes into account that (i) the photocurrent of CdSe is two times higher than that of CdIn₂Se₄ under the same illumination intensity, so that in order to get the same photocurrent one must utilize at least twice as intense light for CdIn₂Se₄ than for CdSe and (ii) CdIn₂Se₄ is a "defect" structure material, and one would expect that migration of ions through it may facilitate the photocorrosion process.

Figure 10 presents the XPS depth profile of a photoetched CdIn₂Se₄ sample which passed 1200C of photocharge. These results show that the Se/S exchange occurs, and even after 62 min of Ar⁺ sputtering, which can be roughly estimated as 500Å (100 atomic layers), there is some sulfur present. The fact that Se/S exchange occurs to such an extent and that during that period the cell performance went down by 30% could only indicate that the surface is highly nonuniform and that surface corrugations may have a large effect on the XPS results. The Se/S exchange implies that CdIn₂Se₄ is oxidized under illumination in the photoelectrochemical cell to Cd²⁺, In³⁺, and Se, which agrees well with the cyclic voltammetry results (Fig. 3). The Cd²⁺ and In³⁺ ions recombine with excess S⁻ ions to give CdS and In₂S₃, respectively, which precipitate on the surface of the electrode. The results presented in Fig. 7 show that the CdIn₂Se₄ is more akin to the Cd-chalcogenide family than to the CuInX₂ family. The CdS and In₂S₃ become obstructive for hole tunneling if their thickness exceeds, say, 20-30Å, in which case the photocurrent goes down and the rate of photocorrosion increases (19).

It is also important to note that electrodes which were properly prepared (*i.e.*, received optimal surface treatment) show both improved I-V characteristics and better output stability. This observation is not unique to that system (20). Higher rate for the charge transfer (higher photocurrent) leaves a smaller concentration of holes at the semiconductor surface to carry out the photocorrosion reaction (better stability) (19b).

Fig. 9. Comparison of the output stability of photoetched CdIn₂Se₄ under two light intensities and compared also to photoetched CdSe. All experiments carried out in (2;2;2) polysulfide. Potential 0 vs. SCE. Temperature: 30°C.

Discussion

Based on energy of formations for the oxidation products of CdSe, it was recently shown (17a) that the most favorable oxidation product of CdSe in acidic and neutral media is Se, rather than the oxides of selenium (although SeO₂ formation is only slightly less likely). From the many decomposition reactions which may occur during photoetching, we list the following three as representative ones

In the absence of any quantitative data on the free energy of formation of CdIn₂Se₄, we take it as a rough estimate to be four times the free energy of formation of CdSe (-135.2 kcal·mol⁻¹) (14). Another estimate for the free energy of formation of CdIn₂Se₄ can be done from the sum of the free energy of formation of CdSe and In₂Se₃ (-112.88 kcal·mol⁻¹). All the calculations which rely on this latter value are given in parentheses. Table II is a list of the free energy of formation of species involved in Eq. [1]-[3] (21).

Table III summarizes the free energy of decomposition for reactions [1]-[3] and their respective decomposition potentials.

Clearly then, Eq. [1] is the most favorable decomposition reaction for CdIn₂Se₄ under oxidative conditions; the

¹Systematic overestimation of ~20% was obtained by a similar calculation for CuInX₂ compounds for which experimental figures were published recently.

Fig. 10. XPS analysis of a partially deactivated CdIn₂Se₄ which show the Se/S exchange (photocorrosion). Numbers on curves represent the time (min) for argon sputtering. Curve on the right is the photocurrent vs. time (stability) of the examined electrode (0.1 cm²).

Table III. Free energies of decomposition and decomposition potentials for reactions [1]-[3]

Reaction	[1]	[2]	[3]

PE_D° (V vs. SCE)	0.100(0.007)	0.363(0.332)	0.199(0.106)

Table IV. Free energies of formation for species involved in reactions [4] and [5]

	S_3^{2-}	SeS_3^{2-}	In_2S_3	CdS	OH^-	HS^-
ΔG° (kcal-mol ⁻¹)	17.61	16.48	-98.55	-37.39	-37.56	3.01
Ref.	(22)	(22b)	(22)	(22)	(22)	(21)

Table V. Decomposition potentials for CdSe and CdIn₂Se₄ in aqueous polysulfide solution

	CdSe	CdIn ₂ Se ₄
$P\Delta G_D^\circ$ (kcal-mol ⁻¹)	-26.8	-98.86 (-115.98)
PE_D° (V vs. SCE)	-0.83	-0.78 (-0.88)

differences are even larger than for CdSe. This estimation supports the Auger measurements which have shown little oxide on the semiconductor surface after photoetching. It may also suggest that oxides, and particularly In_2O_3 , which was found to benefit the performance of $CuInX_2$ ($X = S, Se$) electrodes are not stable in the oxidative environment which prevails at the semiconductor surface during illumination (see below for further details on the matter).

The output stability of $CdIn_2Se_4$ in polysulfide electrolyte is more akin to that of CdSe than to that of $CuInX_2$ family (3). A possible overall mechanism for the Se/S exchange in $CdIn_2Se_4$ is (14)

For CdSe, the following mechanism is consistent with the experimental observations

Table IV gives the free energy of formation of the species involved in reactions [4] and [5].

Based on these values and on the values given in Table II, the decomposition potentials for CdSe and $CdIn_2Se_4$ in aqueous polysulfide solution are summarized in Table V.

To establish the full band diagram, one has to know the flatband potential of the semiconductor in the respective electrolyte. For CdSe, this figure is available (-1.54V vs. SCE). For $CdIn_2Se_4$, this number is estimated from the maximum open-circuit potential (under strong illumination). For CdSe, the density of states in the conduction band N_c is calculated from the known (22) effective mass of the electron.

Table VI. Various data relevant for constructing the band diagram and thermodynamic stability diagrams

	N_c (cm ⁻³)	$E_{CB} - E_F$ (eV)	E_F vs. SCE (eV)	E_{CB} vs. SCE (eV)	E_g (eV)	E_{VB} vs. SCE (eV)
CdSe	1.25×10^{18}	0.125	-1.59	-1.72	1.72	0.00
$CdIn_2Se_4$	5.2×10^{18}	(0.15)	(-1.2)	(-1.35)	1.55	+0.20

N_c : density of states in the conduction band.
 E_{CB} : bottom of the conduction band.
 E_F : Fermi level.
 E_{VB} : top of the valence band.
 Numbers in parentheses are best estimates.

**Fig. 11. Band diagram and decomposition potential (shaded area) for CdSe and CdIn₂Se₄ in polysulfide.**

Figure 11 and Table VI summarize these calculations. The most prominent result here is that the band diagram and the decomposition potential for $CdIn_2Se_4$ /polysulfide interface resembles that of CdSe/polysulfide and hence the output stability of the two systems are expected to be similar if thermodynamic considerations are taken into account only. Thus, the experimental observations in Fig. 5 agree with the model calculations presented herein that similar output stability is obtained for photoetched CdSe and $CdIn_2Se_4$ in (2;2;2) polysulfide electrolyte. However, no consideration of the kinetic factors affecting the photocorrosion processes were used, although, ultimately, they may be of greater relevance to the present problem than the thermodynamic factors.

Some unsuccessful attempts were carried out to improve the performance of the $CdIn_2Se_4$ /polysulfide photoelectrochemically. It was attempted to create a thin In_2O_3 overlayer by several means. Thus, $CdIn_2Se_4$ was heated at 100°-150°C for different periods of time in air atmosphere. Such heating is beneficial for the $CuInX_2$ cells (12). Furthermore, electrochemical deposition of In which was followed by a heat-treatment was not of great help either. Immersion in $InCl_3$ solution (at different temperatures) was not successful either. Finally, $InCl_3$ was dissolved in a concentrated (2;2;2) polysulfide which led to a rapid deactivation of the electrode.

Treatments in solutions of ionic Cu (23) and Zn (24) were attempted, the latter treatment being of little help only. Addition of small quantities of Se did not lead to an improved output stability.

So far, we have not found a surface treatment which has but a marginal effect on the performance or output stability of $CdIn_2Se_4$ in polysulfide electrolyte other than photoetching. Further work is necessary in that direction and also in order to understand the basic physics of that interface.

Very recently, Fornarini *et al.* (25) presented some new observations on the $CdIn_2Se_4$ /polysulfide photoelectrochemical cells. First, the quality of their starting material was superior to the one used during this work. This is borne out by the higher photocurrents produced after photoetching (~ 20 mA-cm⁻²), and also through the lack of Fermi level pinning as observed in our crystals (11) *i.e.*, no breakdown of the Schottky barrier under reverse bias (8). They observe Se/S exchange and discuss the output stability of $CdIn_2Se_4$, which they find also more akin to the CdSe than to $CuInSe_2$.

Acknowledgment

We are indebted to Philips Company and to Dr. Van-Haas of Philips for the assistance with the electron microscopy. We are also grateful to Dr. D. Cahen for his ad-

vice in the interpretation of the surface analyses results. We are also grateful to Mr. Arend Heeres for his assistance in the XPS experiments. R. T. is grateful to Helen and Milton A. Kimmelman for support of his work.

The Properties of Electrochromic Film Electrodes of Lanthanide Diphthalocyanines in Ethylene Glycol

G. C. S. Collins

Wolfson Centre for Electrochemical Science, Department of Chemistry, The University, Southampton, Hampshire, England SO9 5NH

ABSTRACT

The electrochromic properties of film electrodes of lutetium, erbium, gadolinium, and ytterbium diphthalocyanines in contact with ethylene glycol solutions have been studied. The stability of the electrochromic film under electrochemical cycling in this medium is at least three orders of magnitude better than that in neutral aqueous solutions. The stability of the electrochromic is improved if the film is written galvanostatically from the yellow-tan to the green state. A simplified model for the galvanostatic transition is proposed, and some of the problems of this family of electrochromic materials are discussed.

The preparation of the diphthalocyanine complexes of the rare earth elements [Lan(PC)₂]¹ by reaction of their acetates with o-phthalonitrile was first achieved by Kirin *et al.* in 1967 (1). Subsequently, Moskalev and Kirin (2) showed that the absorption spectrum of Lu(PC)₂ changed reversibly with electrode potential and later proved that all the lanthanide diphthalocyanines as well as those of yttrium and scandium were electrochromic (3).

Because these compounds are stable and those of Eu through to Lu can be sublimed (4) onto an electrode surface to form a thin electrochromic film, there has been

* Electrochemical Society Active Member.

¹ Although the stoichiometry Lan(PC)₂ is used in this paper, there is still some discussion regarding the presence of an imino hydrogen in the molecule. In particular, very recent spectroscopic work by Nicholson and Weismuller (32) favors the existence of Lu H(PC)₂ · O₂⁻ as the green form. Further work is required to elucidate the discrepancy between the spectroscopic results and the isotopic mass distribution of the parent ion in the mass spectra, which appears to favor the Lu (PC)₂ stoichiometry (10).

considerable interest in their possible use as visual display units (5-8).

The structure and electrochemistry of the lanthanide diphthalocyanines have been widely studied over the last few years. This work has been recently reviewed by Nicholson (9), who concluded that there was a problem with stability under switching and that the development of practical displays would depend on the achievement of adequate cycle life (10⁶-10⁸ color transitions) and a technique for matrix addressing.

Repeated cycling of Lu(PC)₂ film electrodes in neutral aqueous electrolytes between the green and the red states results in the degradation of the color change after 10⁴ cycles. It has been proposed that this is due to attack of the nitrogen atoms in the phthalocyanine rings by water or by OH⁻ ions (10), when the dye is in its oxidized form, *i.e.*, as a diradical dication (11, 12). In common with many radical cations, the oxidized form appears to be stabilized by strong acid solutions, and Bessonnat *et al.* (13) achieved 5

$\times 10^6$ color changes for a dye electrode in sulfuric acid medium.

The purpose of the present work was to study the electrochemistry of $\text{Lu}(\text{PC})_2$ in a nonaqueous solvent having a lower ionization constant than water, thus reducing the problems of nucleophilic attack by OH^- on the oxidized form of the rare earth complexes.

Experimental

The $\text{Lu}(\text{PC})_2$ and other (Gd, Er, Yb) phthalocyanines were prepared and purified as described previously (10). The remaining chemicals used were either BDH AnalaR grade (ethylene glycol, sodium chloride, potassium chloride, ammonium fluoride) or Fluka "purum" grade (tetraethyl ammonium halides).

Most of the cycling experiments were carried out using purpose-built electrochemical modules with a single array of 28 pels per cell. The working electrodes consisted of evaporated layers of titanium (50 nm) covered with platinum (200 nm), on Rowi glass. The electrode pattern was obtained by a lift-off technique using photoresist leaving 28 square electrode pads of 1.25 mm²/side. The conductor lines to each electrode were protected by a 1.1 μm layer of cured du Pont 5057 polyimide, except at the contact points. The electrochromic film was evaporated over the working electrode surfaces as a continuous film at 10^{-4} torr in an Edwards 6E4 coating unit by resistance heating to $450^\circ \pm 50^\circ\text{C}$. Film thickness measurement was established by relating optical density at λ_{max} (Table I) to the step height of standard films as measured by a profilometer (Tencor Alphastep).

The module was built up by placing a silicone rubber gasket on the glass substrate followed by an acrylic molded spacer with an adhesive-bonded glass top. The acrylic spacer had inlets for a platinum black counterelectrode, a reference electrode, for filling the module, and also for a thermocouple. The various items fitted to the molding were glued in place with 3M 3532 structural adhesive. Silicone rubber gaskets protected the module from copper platens, which were tightened to form a liquid-tight seal. The upper platen had a square opening through which the pels could be viewed. Modules were then filled with electrolyte and the filling tubes sealed. No attempt was made to deoxygenate the electrolyte prior to use.

Solutions of the halide salts in ethylene glycol were used as electrolytes. With chloride electrolytes, an Ag/AgCl reference electrode was used, but with fluorides this was changed to Cu/CuF₂. Prior to use, each reference electrode was anodized to form the salt on the electrode surface. Ethylene glycol was used without further purification. The electrolyte used in most of this work was a saturated solution of NaCl (ca. 1M), which has a conductivity $5 \times 10^{-3} \text{ Scm}^{-1}$ at 20°C and $1 \times 10^{-2} \text{ Scm}^{-1}$ at 40°C .

The modules were driven by a purpose-built microprocessor potentiostat/galvanostat. This instrument had potentiostatic, tensiostatic, and galvanostatic units coupled together to enable writing or erasing from either one or two of the units. The range was $\pm 2\text{V}$ in 10 mV steps on the potentiostatic and tensiostatic units and $\pm 40 \text{ mA}$ in 100 μA steps on the galvanostatic unit. The current and voltage required could be set either manually or by com-

puter, but the time base was computer controlled over a wide range down to 250 μs .

The potentiostat/galvanostat incorporated a Motorola M6800 microprocessor, and was linked to an IBM 5100 computer for input. Control programs were written in a high level language based on APL and compiled to 6800 machine code, which was loaded into the 6800 from the 5100 memory, thus freeing the 5100 for other tasks. Using this system, it was possible to set up and change the write, hold, erase, and off parameters simply and at will. The current and voltage transients were fed from the potentiostat/galvanostat to a Tektronix 7633 storage oscilloscope for observation and evaluation.

Optical density changes on simple pels were measured using a spotmeter (Spectra, Model UBD, 1/4 degree). This precluded obtaining absolute absorption measurements.

In all cycling experiments a four-step cycle will be referred to containing write, off, erase, and off periods. The off periods were used for measuring decay transients and to study fade rates. Because both potential and current steps and varying time were used to write and erase in a cycle, a particular experiment will always be defined in the text.

A Hi-Tek potentiostat, transient recorder, and signal generator were used for the voltammetric measurements, and the results were plotted on a Bryans 26000 X-Y recorder. In these experiments, a tin oxide electrode was used. The film electrodes were prepared as previously described (10).

The x-ray photoelectron spectroscopy (XPS) studies were performed with a VG Scientific ESCA 3 Mark II instrument. The $\text{C}_{(1s)}$ band was used as the internal reference.

The potential limits of the 1M NaCl/ethylene glycol electrolyte on Pt were arbitrarily taken as the potential for which the current density was $10 \mu\text{A}\cdot\text{cm}^{-2}$, and were determined by cyclic voltammetry. The values obtained were +800 and -600 mV, corresponding to glycol oxidation and the hydrogen evolution reaction, respectively. It was found that ammonium fluoride attacked the glass of the module, and for this reason tetraethylammonium fluoride was used for the tests with F^- ion containing solutions. Similar potential limits were found for this electrolyte.

The polarization limits of the electrolytes for a Pt electrode were further confirmed by studying the possible formation of polymeric oxidation films by x-ray photoelectron spectroscopy (XPS). It was found that at 1.2V, a tenfold increase in the $\text{C}_{(1s)}$ and $\text{O}_{(1s)}$ signals was observed after 30 min of polarization, whereas at +0.7V, no detectable change in the XPS spectrum was obtained. Similar results were observed by cycling between the positive and negative limits established from the cyclic voltammetry results. From these results, an anodic limit of +0.7V was chosen for most of the cycling experiments, as no significant solvent decomposition or solvent degradation products were observed.

Stability problems of the base platinum were experienced when writing the electrochromic film galvanostatically to the yellow-tan (0.7V) color from the green state (0 V). The anodic excursion led eventually to Pt dissolution due to inevitable inhomogeneities in the current distribution, which resulted in some parts of the Pt surface becoming sufficiently positive to initiate its anodic dissolution in the chloride containing solutions. This problem was particularly serious when working at high current densities, of over $\sim 250 \text{ mA}\cdot\text{cm}^{-2}$, and for this reason a cycle comprising a galvanostatic write from the yellow-tan to the green state was used for long-term testing experiments. The erase to the yellow-tan state was carried out potentiostatically in order to avoid the problems of substrate instability mentioned above.

Results

Similar to aqueous electrolytes (10), the current-potential response during the first color transition in ethylene glycol differed significantly from the response of a

Table I. Absorption maxima of vacuum-deposited films of various lanthanide diphthalocyanines

Compound	λ_{max} (nm)	
	Blue form	Green form
$\text{Lu}(\text{PC})_2$	630	665
$\text{Er}(\text{PC})_2$	—	665
$\text{Gd}(\text{PC})_2$	644	—
$\text{Yb}(\text{PC})_2$	—	665

The absorbance of the $\text{Lu}(\text{PC})_2$ film was approximately of 1 unit per 100 nm of film.

cycled electrode (Fig. 1 and 2). The cyclic voltammogram of a virgin electrode showed a very irreversible behavior, with the main oxidation wave occurring at +0.8V. The charge required for the first color transition was similar to that required for the cycled electrodes, and the difference in charge between cycled and uncycled electrodes observed for aqueous solutions (10) was not apparent with the organic solvent used. The origin of this difference is not clear at present.

The difference in color stability previously observed with aqueous F^- and Cl^- containing solutions (10) was again apparent. In fluoride solutions, the yellow-tan to green color fade occurred in 2-4 min in the off condition, whereas the films cycled in chloride media retained their color for several hours on open circuit.

Figure 3 shows typical potential-time responses of $Lu(PC)_2$ film electrodes for different current densities of the galvanostatic-potentiostatic cycle. The initial potential step corresponds to the total ohmic drop in the solution and in the film. This potential drop was found to be linearly dependent on the applied current density. The slope of the galvanostatic transient was dependent on the applied current density, and for a given state of charge of the film, a linear dependence was observed, as is shown in Fig. 4.

The fast degradation of the $Lu(PC)_2$ electrochromic film on continuous switching from the green to the yellow-tan state in aqueous electrolytes is shown in Fig. 5a. There is a rapid loss in color over 10^4 cycles allied to a drop in the current flow during switching.

Figure 5b shows a similar experiment when using ethylene glycol as the solvent. There is little visual degrada-

Fig. 1. Cyclic voltammetry of a $Lu(PC)_2$ film electrode supported on conducting tin oxide glass in contact with a 0.7M NaCl/ethylene glycol electrolyte. First sweep; $T = 21^\circ C$, sweep rate = $0.02V \cdot s^{-1}$. The observed colors are indicated in the figure.

Fig. 2. As in Fig. 1 but after 516,000 red-green potentiostatic cycles (Write 0V/0.5s; Erase 0.9V/0.5s). The electrode was left at $-0.25V$ for 5 min before recording the voltammogram. The observed colors are indicated in the figure.

Fig. 3. Galvanostatic-potentiostatic cycling experiment for pel electrodes of $Lu(PC)_2$ in 1M NaCl. The cycle was: Write/10 ms; Off/100 ms; Erase +700 mV/50 ms; Off/50 ms. The writing current was $12.3 mA \cdot cm^{-2}$ for A and $49.2 mA \cdot cm^{-2}$ for B and the film was written from the yellow-tan to the green state. W = Write; O = Off; E = Erase.

tion of the film after 5×10^6 cycles. The use of a variety of electrolytes such as 1M sodium chloride, 3.5M tetra-ethyl ammonium chloride, 3.5M lithium chloride, and 2M tetra-ethyl ammonium fluoride gave similar results. More than 10^6 potentiostatic switching cycles have been obtained with the diphthalocyanines of lutetium, erbium, gadolinium, and ytterbium in the same potential range using these electrolytes in ethylene glycol.

The films did lose some electroactivity with time. The rate of decay of a $Lu(PC)_2$ film on cycling can be seen from the current-time transients measured with a digital transient recorder shown in Fig. 6. These experiments were carried out cycling the electrode into the red color region, where the dye is less stable and solvent decomposition can begin to interfere with the electrochromic behavior of the film. The total loss of charge for 516,000 cycles was $\sim 8\%$, but even under this cycling condition a useful lifetime of over 4×10^6 cycles could be estimated. Figure 7 shows the potential-time dependence in a long-term cycling experiment, using galvanostatic writing conditions from the yellow-tan to the green state. As can be

seen, aging of the cycled film results in a greater negative potential excursion during the galvanostatic charging process. For 6.4×10^5 cycles, the difference in the negative limit was of $\sim -0.1\text{V}$. From an estimation of the film capacitance in the negative limit, this amounted to a loss of electrochemical film activity of $\sim 10\%$, i.e., of the same order of magnitude as observed for the potentiostatic transients. However, further cycling did not lead to a linear loss of charge with time. Furthermore, the optical density changes observed with the spot meter were independent of cycling time (Fig. 5b), and the small decay observed is probably related to a small change of active area of the dye film. A slight degradation of the Pt substrate was observed with cycling; this reduced the pel area and hence increased the current density.

Discussion

The difference between the first redox transformation of the film and its electrical characteristics after cycling has been observed repeatedly for film and polymer elec-

trodes (10, 14-17). As can be seen in Fig. 1, the first color transition occurs in a well-defined potential range. It is likely that the extension of the potential range in which the solid-state film oxidation occurs is related to the loss in crystallinity on cycling of the vapor phase deposited dye. The x-ray diffraction pattern of a sample of $\text{Lu}(\text{PC})_2$ that had been purified by vacuum sublimation indicated a crystalline structure for the powder.² It is expected that the structure of the film will become rapidly amorphous on cycling and, hence, a wide spread of redox potentials will be observed, related to the different inductive effects of the randomly oriented phthalocyanine rings.

The difference in fade rates of the diradical cation-anion complex responsible for the color change (12) between chloride and fluoride solutions is similar to previous observations in aqueous media (10). The greater stability of the chloride complex is due to the lower solvation energy of Cl^- as compared with the F^- ion, resulting in an enhancement of the thermodynamic stability of the $\text{Lu}(\text{PC})_2^+$, Cl^- complex formed by a $1e^-$ oxida-

² X-ray spectra of vacuum-deposited films were measured by Mr. B. A. Hatt of the Fulmer Research Institute.

tion. This is probably a general feature of electrochromic film electrodes, which can be used as a selection criterion of the anions of the electrolyte to be used to give a long fade rate. It was found that the replacement of Cl^- by Br^- gave very stable compounds and, as expected, the iodide-diradical cation complex is even more stable (18). This compound is so stable that its use has been suggested for decontaminating solutions containing radioactive iodine.

The Kinetics of the Color Transition

Nicholson and Pizzarello (5) proposed a space-charge-limited (SCL) mechanism for the kinetics of the color transition. The model was based on the observation that a moving boundary of the red oxidation product of $\text{Lu}(\text{PC})_2$ was generated when a dye film deposited on an insulating substrate was immersed in an aqueous electrolyte solution, and a current was passed between the dye film and the solution (7). It was observed that the moving boundary contained the anion of the electrolyte (6). Charge neutralization must occur within the film as the net amount of free charge that can be supported by the geometrical capacitance of the film is always orders of magnitude smaller than the requirements of film oxidation or reduction. In the case of $\text{Lu}(\text{PC})_2$, anion incorporation appears to be the charge neutralization mechanism, as has been determined by XPS analysis (10). Similarly, for Fe, Co, Ni, Cu, and Zn monophthalocyanine film electrodes, changes in the redox state of the film results in the corresponding uptake or elimination of the anion of the electrolyte, as determined by Auger electron spectroscopy (19). Similar effects on thionine film electrodes have been observed by Alberty *et al.* (20, 21). Charge neutralization is also a general feature of polymer electrodes displaying redox properties (16, 22), and the understanding of the mechanism of anion incorporation is of general importance.

The SCL mechanism is of interest, as it provides a simple interpretation to the optical transition observed by Nicholson *et al.* (5). There are, however, several features that require some further discussion. Green and Faulkner (19) carried out Auger depth profiles of partially oxidized films of monophthalocyanines, and observed that the distribution of the anion was uniform throughout the film, and no boundary between the oxidized and reduced regions in films of transition metals phthalocyanines could be detected. The technique used for film etching did not result in films reorganization as it was shown in separate experiments with sandwich layers of different metal phthalocyanines (23). The absence of a clearly defined front does not exclude the SCL mechanism. The basic assumption of the SCL equations used by Nicholson *et al.* (5) is that the diffusion of the transported species is unimportant within the time scale of the experiment and the drift of the transported ions accounts entirely for the observed transients. The results of Green and Faulkner (19) perhaps indicate that the film reaches a distribution equilibrium in the time required for the extraction and analysis of the samples, due to diffusion.

The complete formulation of the SCL problem requires taking diffusion into account; in the steady state, the current for the one dimensional case is given by (25, 26)

$$I = Z_j F D_j \frac{dC_j}{dx} + Z_j F \mu_j X C_j \quad [2]$$

where F is the Faraday constant, D_j is the diffusion coefficient of the transported species j , μ_j is its mobility, Z_j is its charge, C_j its concentration, and X is the field.

The integration of Eq. [2] has been discussed several times (25-28) and the diffusional transition time, τ_D , is given by

$$\tau_D = \frac{d^2}{2D_j} \quad [3]$$

where d is the film thickness. In order to assess τ_D across the film, and therefore have an indication of the validity

of using only the second term in Eq. [2] for determining the SCL currents, a value of the diffusion coefficient of the diffusing species is required. Nicholson *et al.* (7) estimated that the mobility of the chloride ion was $4 \times 10^{-6} \text{ cm}^2 \cdot \text{V}^{-1} \cdot \text{s}^{-1}$ in the oxidized $\text{Lu}(\text{PC})_2$. Using the Einstein relationship

$$D_j = \frac{RT\mu_j}{F} \quad [4]$$

a diffusion coefficient $D_{\text{Cl}^-} = 1.1 \times 10^{-7} \text{ cm}^2 \cdot \text{s}^{-1}$ can be estimated for the chloride ion in the film. In the case of the thionine films studied by Alberty *et al.* (20), of a value of D_{Cl^-} of $6.5 \times 10^{-13} \text{ cm}^2 \cdot \text{s}^{-1}$ was estimated. The difference between the thionine and $\text{Lu}(\text{PC})_2$ films may be significant because the former are probably more compact (20) compared with the open structure of the rare earth biphthalocyanines (28). These considerations are particularly relevant to cycled films, where an amorphous structure probably prevails.

Using the value of D_{Cl^-} derived from the electrical mobility, the diffusional characteristic time calculated from Eq. [3] and for $d = 100 \text{ nm}$, is $\tau_D \approx 0.5 \text{ ms}$. This very short diffusional time is lower than the time scale of the galvanostatic transients studied by Nicholson *et al.* (5) and in the present work. This could imply that the film is always at equilibrium with respect to the transported anion and should behave as a homogeneous redox electrode of finite thickness for the time scale of the transients studied.

The observed linear dependence of the slope of the galvanostatic transient (Fig. 4) is characteristic of a capacitance. This is confirmed by the linear response of the current with sweep rate in cyclic voltammetry experiments (10). The capacitance response of the film is potential dependent, and is given by

$$\frac{dE}{dt} = \frac{I}{C(E)} \quad [5]$$

where E is the potential, $C(E)$ is the differential capacitance as a function of potential, and t is the time. The decrease in slope with charge passed, observed in the galvanostatic results (Fig. 3 and 7) is simply a consequence of the potential dependence of the film capacitance indicated also by the cyclic voltammetry results shown in Fig. 2. In fact, the differential capacitance of the film does increase with potential when the film is reduced from the yellow-tan region at $+0.7 \text{ V}$, to the green state, and passes through a maximum at $\sim 0 \text{ V}$.

The results shown in Fig. 4 are for a constant injected charge of $0.27 \text{ mC} \cdot \text{cm}^{-2}$. For a greater degree of reduction, an inflection in the potential time dependence should be observed, and Fig. 8 shows that this is indeed the case. As expected, the potential of the inflection point is very close to the pseudo-capacitance maximum observed for the corresponding cyclic voltammogram (Fig. 2).

The SCL Capacitance

It is interesting to compare the predictions of the simple SCL model used in Ref. (5) with those derived from a simple redox capacitance model. The latter predicts a linear dependence of the slope dE/dt with current density. In the SCL model used by Nicholson *et al.* (5), the potential drop across the moving front is

$$E_2 = \frac{I}{\epsilon_2 \epsilon_0 \mu_2} x_2^3 \quad [6]$$

where E_2 is the potential drop across the product layer [the red form of $\text{Lu}(\text{PC})_2$], x_2 and ϵ_2 are its thickness and dimensionless dielectric constant, respectively, and ϵ_0 is the permittivity of free space ($8.85 \times 10^{-14} \text{ F} \cdot \text{cm}^{-1}$). Since the mobility of the electron in the $\text{Lu}(\text{PC})_2$ lattice is much greater than that of an anion such as Cl^- , the total potential drop predicted by this model will occur only in the red layer. If a well-defined boundary is formed, *i.e.*, when the first term in the steady-state approximation given by

Fig. 8. Potential-time transient for a cycled Lu(PC)₂ film pel electrode in 1M NaCl in ethylene glycol. Charging current during the galvanostatic transient = 6.4 mA·cm⁻². Writing from the yellow-tan to the green state.

Eq. [2] is negligible, the boundary velocity is given by (5)

$$\frac{dx}{dt} = \frac{I}{C_j F} \quad [7]$$

From Eq. [6] and the integrated form of Eq. [7], the current-potential time relationship for the idealized SCL model discussed is obtained

$$E_2 = \left(\frac{1}{\epsilon_2 \epsilon_0 \mu_2} \right)^{1/2} \left(\frac{1}{Z_j C_j F} \right)^{3/2} I^{2/3} t^{3/2} \quad [8]$$

From Eq. [8], and for a given amount of injected charge $Q_{inj} = \text{const.}$, the slope of the galvanostatic transient is given by

$$\left(\frac{\partial E}{\partial t} \right)_{Q_{inj}} = \frac{3}{2} \left(\frac{1}{\epsilon_2 \epsilon_0 \mu_2} \right)^{1/2} \left(\frac{1}{Z_j C_j F} \right)^{3/2} I^{3/2} Q_{inj}^{1/2} \quad [9]$$

A comparison between the SCL (Eq. [9]) and a distributed capacitance model (Eq. [5]) can be made by comparing the current density dependence of the slope $(\partial E/\partial t)_{Q_{inj}}$ predicted from the two models. As shown in Fig. 4, the experimental results are in better agreement with a simple capacitance model, although a distinction between the two models is not easy to make only on the basis of this type of information.

A Reversible Redox Film Electrode Model

The voltammetry of cycled films indicates a fairly reversible redox behavior. However, the response of a reversible redox film electrode should result in a sharp peak centered at the standard potential for the film redox reaction. The peak half-width ($\Delta E_{1/2}$) of this peak is the potential difference between the two conditions in the voltammetric scan for which the current is half the maximum and has a value of 90.46 mV at 25°C (10) for a one-electron process. The voltammetric response observed for the cycled films does not correspond to this model with a single redox species. As discussed by Albery *et al.* (20), a spread in redox potentials of the electroactive species in the film is a more realistic model of a redox film electrode, and some digital simulations of the voltammetric response of film electrodes for discrete redox potentials in the film and considering interaction coefficients between the electroactive species have been carried out by Peerce and Bard (29).

It is very difficult to discriminate between different film models on the basis of voltammetric experiments only. Several parameters can be used simultaneously to match the observed cyclic voltammogram, such as the distribution of standard potentials for the different spe-

cies present in the film, the distribution in concentration of species having different standard potentials, and interaction coefficients (29).

For a discrete centers model, the equilibrium condition of each center i having a standard potential E_i° is

$$P_i = \ln \frac{q_{i(\text{ox})}}{q_{i(\text{red})}} \quad [10]$$

where

$$P_i = (E - E_i^\circ)F/RT \quad [11]$$

and $q_{i(\text{ox})}$ and $q_{i(\text{red})}$ are the equilibrium charges of oxidized and reduced i at the potential E . F is the Faraday constant. Equation [10] assumes equality of the activity coefficients of the different species in the film (20).

For an oxidation reaction, the total charge accumulated at a given potential, $Q_{(\text{ox})}$, is

$$Q_{(\text{ox})} = \sum^N q_{i(\text{ox})} \quad [12]$$

when N is the number of discrete redox centers in the film. From Eq. [10]-[12]

$$\int_0^t i dt = Q_{(\text{ox})} = Q_T \sum \frac{\tau_i G_i}{1 + G_i} \quad [13]$$

where Q_T is the total charge required to oxidize all the centers of the film, τ_i is the fraction of the total charge corresponding to the redox centers i , *i. e.*

$$\tau_i = \frac{q_i(t)}{Q_T} \quad [14]$$

$q_i(T)/F$ is the total number of moles of species having a standard potential E_i° . G_i is defined by

$$G_i = \exp(P_i) \quad [15]$$

Equation [13] can be used for determining the potential-time dependence of the galvanostatic transients. The linear sweep voltammetry response of a film electrode can be derived from Eq. [13] and [11], *i. e.*

$$i = Q_T \frac{\nu F}{RT} \sum^N \frac{\tau_i G_i}{(1 + G_i)^2} \quad [16]$$

where ν is the sweep rate.

Equations [13] and [16] can be converted to the corresponding integral forms when a continuous distribution of redox states is assumed. Albery *et al.* (20) used this approach for the thionine film electrodes and considered that the E_i° values were spread in a gaussian distribution around the average value of the standard potential of the film. The cycled lutetium biphthalocyanine electrodes studied appear to have a much wider spread of redox potentials for the different centers than that encountered in the thionine films (20, 21) or in other polymer electrodes (14-17). The physical basis of a gaussian distribution corresponds to a model where all distinct microscopic states of the assembly are equally probable and independent of each other. As we are attempting to describe a system for which the state of charge is a variable, the *a priori* use of the normal distribution does not necessarily follow. In fact, the loss in crystallinity that appears to occur on cycling will give a fixed range of inductive effects on the phthalocyanine rings and hence on the values of E_i° . Another important consideration is the possible coexistence of several oxidation states of the dye in the film due to the proximity of the values of E_i° corresponding to the different redox centers. The standard potentials of the blue-green and the green-yellow transitions in dichloromethane are -0.45 and 0.03V *vs.* the ferrocene/ferrocinium couple, respectively (30). Although the yellow-red transition was not studied, the results of Corker *et al.* (7) indicate a similar difference in redox potentials between the green and yellow-red states. In the solid state, the ex-

pected spread of redox potentials for the amorphous material will result in the overlap of the $1e^-$ and the $2e^-$ processes, leading thus to a very wide range of possible redox potentials.

For these reasons, an oversimplified cutoff approximation of the redox centers in the film will be used for analyzing the transients. In this approximation, a uniform distribution of species between the two standard potentials E_1° and E_2° is assumed, and it is considered that no sites having potentials outside the range E_1° - E_2° exist. Thus the fraction of sites within the standard potential E_1° and $E_1^\circ + dE^\circ$ is $dE/(E_2^\circ - E_1^\circ)$, and Eq. [16] can be integrated

$$i = \frac{Q_T \nu F}{(E_2^\circ - E_1^\circ) RT} \int_{E_1^\circ}^{E_2^\circ} \frac{G(E^\circ) dE^\circ}{[1 + G(E^\circ)]^2} \quad [17]$$

and

$$i = \frac{Q_T \nu}{(E_2^\circ - E_1^\circ)} \left[\frac{1}{1 + G_2} - \frac{1}{1 + G_1} \right] \quad [18]$$

The voltammetric response will depend on the spread in the range of standard potential values considered, and Fig. 9 shows the behavior expected for different values of $\Delta E^\circ = E_2^\circ - E_1^\circ$. The voltammetric response of the film occurs in a wider potential range as the values of ΔE° are increased, as might be expected. The galvanostatic transients can be analyzed using the same model; from Eq. [18].

$$i = \frac{Q}{\Delta E^\circ} \left[\frac{1}{1 + G_2} - \frac{1}{1 + G_1} \right] \frac{dE}{dt} \quad [19]$$

and the galvanostatic transient is given by

$$\frac{it}{Q_T} = \frac{RT}{\Delta E^\circ F} \ln \left\{ \frac{1 + G_1}{1 + G_2} \right\} \quad [20]$$

Figure 10 shows the expected galvanostatic transients for different values of ΔE° . From Eq. [18], the slope of the galvanostatic transient at any potential is given by

$$\frac{dE}{dt} = \frac{\Delta E^\circ i}{Q_T} \frac{(1 + G_1)(1 + G_2)}{(G_1 - G_2)} \quad [21]$$

and Eq. (20) predicts that an inflection point will occur at a potential E_{inf} given by

$$E_{inf} = \frac{1}{2} (E_1^\circ + E_2^\circ) \quad [22]$$

From Eq. [21] and [22]

$$\left(\frac{dE}{dt} \right)_{E = E_{inf}} = \frac{\Delta E^\circ i}{Q_T} \frac{1 + \cosh \left(\frac{\Delta E^\circ F}{2RT} \right)}{\sinh \left(\frac{\Delta E^\circ F}{2RT} \right)} \quad [23]$$

Fig. 9. Linear sweep dependence voltammetry for a distributed redox potential model. Equation [18] for values of ΔE° of: 0.2 (a); 0.4 (b); and 0.6V (c). $F(E) = i \Delta E^\circ / Q_T$; the potential E is referred to the middle point of the redox potential distribution, i.e., with respect to $1/2(E_2^\circ + E_1^\circ)$.

Fig. 10. Potential-fractional charge dependence for a galvanostatic transient predicted for a distributed redox potential model (Eq. [20]) for different values of ΔE° of 0.2 (a); 0.4 (b); and 0.6V (c).

The simple cutoff approximation predicts the correct shape of the galvanostatic transients and a linear dependence of the slope dE/dt with current density, in accordance with the results in Fig. 4. For values of $\Delta E^\circ > 0.20V$, Eq. (22) simplifies to

$$\left(\frac{dE}{dt} \right)_{E = E_{inf}} = \frac{\Delta E^\circ i}{Q_T} \quad [24]$$

and the apparent film capacitance at this potential is simply related to the spread in redox potentials of sites in the film. From the data shown in Fig. 8, an approximate value of $\Delta E^\circ = 0.55V$ can be estimated for the cycled films. This value is consistent with the cyclic voltammetry results, although the latter show a fine structure in the distribution of redox potentials for the electroactive centers in the film, which, as expected, is not apparent under constant current charging conditions. The reason for this is that cyclic voltammetry gives a differential measurement of the electrical properties of the film, whereas chronopotentiometry gives integral quantities.

The main difficulty in the analysis of a film model is in the many different parameters that can be, in principle, used for assigning a response to a particular model, and the purpose of the analysis given above is to show that a very simple cutoff approximation can give a reasonable qualitative description of the switching behavior.

Technological Problems

Although the rare earth biphthalocyanine film electrodes appear very attractive for colored flat display applications, there are still many unresolved problems. The underlying substrate degradation problem is related to fast switching applications, i.e., for transition times of less than ~ 20 ms, where inhomogeneities in current distribution can result in excessive potential excursions at the edges of the pels. The loss in switching charge observed in some of the long-term fast switching experiments is most likely related to problems of cell geometry. Certainly, the optical response does not appear to be degraded on cycling. For switching times greater than approximately 40 ms and using a galvanostatic write procedure to the green state, the lifetime expected is well over 10^7 cycles.

The color contrast of the $\text{Lan}(\text{PC})_2$ is, unfortunately, not very good. The color transitions must be restricted to present to the red-yellow tan-green states, since all at-

Potential

Fig. 11. Effect of temperature on the potential-time dependence for a $\text{Lu}(\text{PC})_2$ film pel electrode. The temperatures in degrees centigrade are indicated in the figure. The cycle was Write $77 \text{ mA-cm}^{-2}/10 \text{ ms}$, Off 100 ms , Erase 0.7V , Off 50 ms .

tempts to drive the film electrodes in the blue region resulted in rapid failure. Part of the problem is that the blue transition occurs at a potential range where water or ethylene glycol are electroactive and the adhesion between the film and the substrate becomes a problem. The origin of these difficulties is not clear at present, but multichromatic displays may be achievable using substituted phthalocyanines.

A general feature of film electrodes, in common with many electronic devices, is the need to have accurate control of the operating conditions as they are not self-healing and any accidental operation outside the stability range results in the irretrievable loss of electrochromic activity. One such operation variable is the temperature and the response of the film electrodes is strongly temperature dependent. The temperature dependence of a $\text{Lu}(\text{PC})_2$ film electrode is shown in Fig. 11 for a cycling condition using a galvanostatic write and a potentiostatic erase. As can be seen, a decrease in operating temperature results in two effects: (i) the ohmic drop in the cell increased substantially, and (ii) the integral capacitance of the film decreases resulting in a wider potential excursion for a given state of charge. However, this limitation reduces the color contrast, which may be a problem in display applications.

A high ohmic drop in the electrolyte is deleterious for the device, as the resulting decrease in throwing power leads to current inhomogeneities which cause rapid deterioration of the substrate and loss of adhesion of the film. The electrochemical parameters of the film are also altered, with the electrochemical reaction becoming increasingly irreversible at low temperatures; an optimum temperature of operation was around $35^\circ\text{--}40^\circ\text{C}$.

Conclusions

The rapid decay of the electrochromic characteristics of rare earth diphthalocyanines film electrodes on cycling in neutral aqueous solutions has been considerably reduced by using ethylene glycol as the solvent, and by limiting the range of colors used to yellow-tan and green. However, this is an unfortunate limitation to the potential use of $\text{Lu}(\text{PC})_2$ displays, as the contrast between these colors is not very good. Further work is necessary, possibly with other electrolytes and solvents, to extend the stable color range.

The number of color reversals possible has been increased from 10^4 to a minimum of 5×10^6 . Under these conditions, the parameters that control the stability of the film electrode are the temperature and switching speed.

The equivalent electrical circuit for the film electrode is a capacitance in series with a resistance and a distributed redox state model can account for the observed galvanostatic transients.

Acknowledgments

The authors would like to thank H. G. Youlton, who prepared the thin film metallurgy, and Dr. V. V. Patel (IBM Thomas J. Watson Research Center, Yorktown Heights, New York), who supplied the sample of $\text{Lu}(\text{PC})_2$. IBM United Kingdom Laboratories are thanked for permission to publish this work.

ABSTRACT

The isothermal permeation of oxygen through CaO-ZrO₂ was studied at 960°-1450°C and oxygen pressures P'_{O_2} of 10⁻³ to 1 atm on one side of the permeation cell and P''_{O_2} of 10⁻⁶-10⁻⁴ atm on the other. In the steady state, the permeating flux was directly proportional to $(P'_{O_2}{}^{1/n} - P''_{O_2}{}^{1/n})$, where n varied from 2.5 to 4.0. The value of n depended on the microstructure of the sample. For samples without micropores, a value of $n = 4$ was found. These samples also contained a second phase whose composition depended on the nature and extent of impurities. For samples with nonconnected micropores, n varied from 3.6 to 2.5, depending on the thickness, and the results were consistent with a mechanism in which permeation is limited partly by diffusion within the solid and partly by a surface reaction. Both the bulk and surface processes have activation energies of about 200 kJ·mol⁻¹.

The semipermeability of lime-stabilized zirconia (CSZ) to oxygen has received increasing attention in recent years due to the ever more stringent demands on the use of this material as a solid electrolyte at high temperatures. Although electronic conduction and accompanying transport of oxygen are often considered to be negligible in the ionic domain this cannot always be assumed, and drifting EMF's due to oxygen permeability are a common occurrence in unbuffered systems. In addition, oxygen permeability can influence the equilibrium between the electrode microsystem and the surrounding gas, yielding errors far larger than predicted purely on the basis of departure of the ionic transference number from unity (1).

In the present study, the isothermal permeation of oxygen through CSZ tubes was measured at 960°-1450°C and from 10⁻⁶ to 1 atm. It is well established that the permeability in this regime is due to p-type electronic conduction. Electronic defects are considered to arise by the reaction

where, using Kröger's notation, O_o^x is an oxygen ion on a normal lattice site, $V_{O^{\cdot\cdot}}$ is an anion vacancy, and h is a positive hole. The flux, J , of oxygen permeating is then given by (2, 3)

$$J = \frac{\beta}{l} (P'_{O_2}{}^{1/4} - P''_{O_2}{}^{1/4}) \quad [2]$$

where l is the thickness of the electrolyte, P'_{O_2} and P''_{O_2} are the oxygen pressures on opposite sides of the electrolyte, and β is a proportionality factor, which we shall call the bulk permeation coefficient. It should be noted that Eq. [2] is derived on the basis of the following assumptions: (i) only free or untrapped electron holes contribute to the conductivity; (ii) their concentration is directly proportional to $P_{O_2}{}^{1/4}$, as derived (4) from Eq. [1]; and (iii) the transport process is governed entirely by diffusion in the solid.

In spite of numerous studies (3, 5-14) there is no universal agreement on the general validity of Eq. [2]. The expected 1/4 power oxygen pressure dependence of the permeability was observed by Smith *et al.* (7), Fisher (9), Palguev *et al.* (11), and Iwase *et al.* (12). An exponent of 1/3 was reported by Heyne and Beekmans (3), who suggested that the observed deviation from 1/4 might be due to either a different incorporation mechanism for the electronic defects or to partial rate control by a surface reaction. An exponent of 1/2 was reported by Alcock and Chan (8) and one of 1/2-1/4 by Kitazawa and Coble (10).

In the present study, we resolve these apparent discrepancies and show that the value of the exponent depends

on the microstructure of the specimen. This, in turn, is governed by the nature and extent of impurities. For samples with an exponent greater than 1/4, the exponent depends on the thickness of the specimen. For this case, a steady-state treatment is presented which describes the kinetics in terms of combined bulk and surface control.

Experimental

Specimens.—The properties of the CSZ tubes are given in Table I. For the tubes supplied by the Zirconium Corporation of America (Zircoa) and the Nippon Chemical Ceramics Company Limited, the analyses were provided by the manufacturers. Tube G was made in our laboratories by a slip casting technique (15). For analysis, a portion of this tube was fused with anhydrous sodium carbonate and boric oxide, dissolved in water, and the solution examined by inductively coupled plasma atomic emission spectroscopy.

The densities of the specimens, also listed in Table I, were determined by weighing in kerosene and in air.

The microstructure of the specimens was examined by means of a JEOL Type JXA-35 scanning electron microscope, equipped with a Kevex 7000 energy dispersive x-ray analyzer and Quantex software. Figure 1a shows a photomicrograph typical of tubes A to D. Numerous small pores, less than 10⁻⁵m in diameter, can be seen. These pores, about 10% of the total volume, account for the lower densities of these tubes (Table I). The other tubes, exemplified by Fig. 1b, had fewer pores but had a dark second phase between the grains of CSZ. X-ray analysis showed that the second phase consisted largely of impurity elements, which were generally present to a greater extent in tubes E, F, and G.

The tubes were 30 cm long and 1.4-2.0 cm in outside diameter and were closed at one end. The wall thicknesses varied between 1.6 and 2.75 mm. A 3 cm long portion adjacent to the closed end of tube D was milled to a wall thickness of 0.5 mm.

Permeation cell.—The cell assembly used for the permeability measurements is shown in Fig. 2. The specimen tube, B, was mounted centrally within a mullite tube C by an arrangement of water-cooled brass flanges A. Vacuum-tight connections between the ceramic and metal parts were made by silvering the ceramic by chemical deposition, followed by copper electroplating and soldering. A mullite thermocouple sheath F passed through the lower flange and extended upwards to within 0.2 cm of the CSZ tube B. Platinum radiation shields D were used in some experiments.

The diffusion cell was attached to a vacuum system and an electronic manometer (Barocel pressure transducer,

Type 590 A, Datametrix, Incorporated) by means of four flexible, bellows-type metal tubes H, also shown in Fig. 2. The entire cell assembly could be raised or lowered by a scissors-type jack J within a tubular resistance furnace E, wound with platinum-rhodium wire. Stops were attached to the jack to define accurately the upper and lower limits of travel.

Experimental procedure.—The vacuum and measurement system, illustrated in Fig. 3, consisted essentially of a calibrated gas burette, 3, a two-stage mercury diffusion pump, 4, and associated stopcocks and gauges.

For the permeability measurements, a combination of the techniques described by Alcock and Chan (8) and Smith *et al.* (7) was employed. Before each experiment, both sides of the sample tube were evacuated at the temperature of measurement for 12h. An argon-oxygen mixture, dried by passage through a column of Drierite, 8, was introduced to the exterior of the CSZ tube. The oxygen which permeated through the specimen was collected and measured in the gas burette, 3.

(a)

(b)

Fig. 1. Photomicrographs of CSZ. a: Tube A. b: Tube G. The white bar just below each photograph represents a length of 10⁻⁵m.

The temperature profile along the furnace, as measured by means of a Pt/13% RhPt thermocouple, was constant to within $\pm 2^\circ\text{C}$ over a length of 3 cm. The sample tube was located so that its lower end coincided with the lower end of this zone for a series of measurements of the volume collected as a function of time. A second series of measurements was made by raising the sample tube to the upper limit of this zone and repeating. By taking the difference between the two measurements, one could obtain an isothermal permeability through a defined area of the tube. During an experiment, the temperature was controlled with respect to time to within $\pm 1^\circ\text{C}$.

Results

Analysis by mass spectrometer indicated that at least 99.5% of the collected gas was oxygen even when the outside of the tube was flushed with 99.9% argon and 0.1% oxygen.

Figure 4 shows the number of moles of oxygen, Q_t , collected as a function of time for specimen tube C in the upper and lower positions, with thermocouple G2 at 1210°C and with $P'_{\text{O}_2} = 0.21$ atm. Following an induction period, the amount of O₂ collected increased linearly with respect to time. This was also reported in Ref. (11). The difference between the two curves represents the isothermal permeation through a length of tube equal to the displacement. In the steady state, the ratio, f , of the amount collected in

the upper position to the amount collected during an equal period in the lower position varied from one tube to another, but, for each tube, this was constant and independent of temperature and oxygen pressure. The gas collection rate, R_1 or R_u , was equal to the slope of line V_1 or V_2 in Fig. 4.

For all tubes and under all conditions of this work, the pressure of O_2 in the chamber inside the CSZ tube, P''_{O_2} , as measured with the electronic manometer, varied in an approximately linear manner with the gas collection rate, as shown in Fig. 5. This observation may be explained simply by Knudsen flow through the tubing and valves between this chamber and the diffusion pump. Figure 5 could be used to estimate P''_{O_2} in cases where this was not measured directly.

Different flow rates of Ar- O_2 mixtures were used. No effect on permeation rate was observed provided the rate of supply of oxygen was kept substantially faster than the collection rates.

The flux, J ($\text{mol}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}$), was calculated from Eq. [3]

$$J = (R_1 - R_u)/A \quad [3]$$

where A is the average circumference of the specimen multiplied by the distance between the upper and lower positions.

Oxygen pressure dependence.—In general, the results did not conform to the theoretical order of $1/4$ as given by Eq. [2], but were consistent with the following equation, where the order, $1/n$, was allowed to vary

$$J = J^0(P''_{O_2})^{1/n} - P''_{O_2}^{1/n} \quad [4]$$

Here J^0 is numerically equal to the flux with 1 atm of O_2

Fig. 4. Numbers of moles of oxygen which permeated specimen tube C with thermocouple G2 at 1210°C with $P''_{O_2} = 0.21$ atm. V_1 : Tube at lower position. V_2 : Tube at upper position. ΔV : Difference between quantities at the two positions.

Fig. 5. Relation between the pressure inside the CSZ tube and the gas collection rate, R_1 or R_u . $T = 1100^\circ\text{--}1300^\circ\text{C}$; $P'_{O_2} = 0.005\text{--}1.0$ atm.

on one side and a negligible pressure on the other side. By means of a nonlinear least squares computer program, the parameter J^0 and the order $1/n$ were determined for each tube at the temperature of measurement. Values are listed in Table II. The listed uncertainties are standard deviations. It can be seen that values of n vary from 2.5 to 3.6 for samples A to D, while n is approximately equal to 4 for samples E to G. Examples of fits to Eq. [4] are shown in Fig. 6.

Effect of thickness of specimens.—Figure 7 shows plots of flux against thickness for tubes A to D, which have the same composition. At high pressures of oxygen, the flux decreases with increasing thickness, as expected from Eq. [2]. However, at low P''_{O_2} , flux is approximately independent of thickness.

Figure 8 shows a plot of the order, $1/n$, from Table II as a function of specimen thickness. One can see that the order decreases from 0.4 to 0.28 as the thickness increases from 0.05 to 0.194 cm for samples A to D, and remains constant at 0.25 as the thickness increases from 0.175 to 0.275 cm for samples E to G. The order does not appear to be affected significantly by the temperature.

Discussion

For specimens E to G, in which a second phase was present, the observed order was $1/4$. This is consistent with Eq. [2] and with the hypothesis that permeation is limited by bulk diffusion of electron holes, as is generally favored in the literature.

It is evident from Fig. 8 and from Table II that the order is variable for samples A to D. This indicates that permeation is limited by two or more processes. The relative importance of these processes depends on the experimental conditions.

The order increases with decreasing sample thickness. For thick samples, the order appears to approach $1/4$. Under these circumstances, transport within the solid ceramic is expected to be limiting and the observed order is consistent with the accepted model. For thin samples, transport in the gas phase or on the ceramic surface could participate in limiting the overall transport.

It has been shown in the previous section that the flow rate of the Ar/O₂ mixture had no influence on the overall transport. The resistance of the tubing and stopcock between the CSZ tube and the diffusion pump was such that a measurable P''_{O_2} was obtained. However, we estimate that this pressure reduced the overall rate of transport by only 17% in the worse case. This factor was taken into account by the second term in Eq. [4].

It is necessary then to suggest that a surface reaction participates in limiting the overall transfer. For thin tubes, the order appears to approach 1/2. It is possible that the surface reaction involves adsorbed O atoms, whose concentration would be expected to be proportional to $(P'_{O_2})^{1/2}$.

To incorporate a surface reaction and bulk diffusion, a possible mechanism is as follows

Here g refers to a gas phase species and w to a surface species; single and double primes refer to opposite sides of the CSZ tube. As in a previous treatment (4), we assume that $(V_{O'})$ and $(O_{O'})$ are constant.

This mechanism has been interpreted by supposing that reactions [5a] and [5f] are at equilibrium and by making the steady-state approximation for electron holes. It has not been possible to obtain an analytic expression for the permeability unless one of three additional approximations is made, as described in the next three paragraphs.

If it is assumed that reactions [5b] and [5e] are at equilibrium, an expression of the form of Eq. [2] is obtained, with $\beta = 0.25k_dK_b^{1/2}K_a^{1/4}[(V_{O'})/(O_{O'})]^{1/2}$. Here k_d is the rate coefficient for reaction [5d], and K_a and K_b are equilibrium constants for reactions [5a] and [5b].

If it is supposed that reactions [5b] and [5e] are limiting and that reaction [5d] is rapid and at equilibrium, as for a very thin sample, it is found that

$$J = \frac{1}{4} \alpha (P'_{O_2})^{1/2} - P''_{O_2})^{1/2} \quad [6]$$

Here, the surface parameter, α , equals $k_bK_a^{1/2}(V_{O'})$. The order is predicted to be 1/2 for the case of surface control.

Fig. 6. Examples of fits of flux and pressure data to Eq. [4]. Line 6 is for specimen G; others are for specimens A to D. Values are as follows for the various lines. 1: $l = 0.05$ cm, $T = 1205^\circ\text{C}$. 2: 0.165 cm, 1230°C . 3: 0.165 cm, 1450°C (right scale). 4: 0.5 cm, 1112°C . 5: 0.165 cm, 1338°C (right scale). 6: 0.275 cm, 1344°C . 7: 0.165 cm, 1115°C . 8: 0.194 cm, 1090°C . 9: 0.194 cm, 960°C .

Fig. 7. The effect of the sample thickness on oxygen flux at 1230°C . The points are experimental for specimens A to D. Solid lines are theoretical results calculated from Eq. [7] by nonlinear least squares. The quoted pressures are P'_{O_2} .

Fig. 8. The effect of sample thickness on the order. Open circles: specimens A-D. Triangles: specimens E-G. Curves 1 and 2 were generated by Eq. [8] for $L = 4.4 \times 10^{-2}$ and 0.0 cm, respectively. Curve 3 was generated by Eq. [14] with $M = 8 \times 10^{-2}$ cm.

If both reactions [5b] and [5d] are limiting, but the inside pressure, P'_{O_2} , is negligible, the following expression is obtained

$$J = \frac{\beta^2}{\alpha l^2} [(1 + \alpha^2 l^2 P'_{O_2} / \beta^2)^{1/2} - 1] \quad [7]$$

As shown earlier, P'_{O_2} makes little difference to permeation, so there is reason to expect that this equation will be a good approximation.

The order, $1/n$, may be determined by differentiating Eq. [7] as follows

$$\begin{aligned} 1/n &= d \ln J / d \ln P'_{O_2} \\ &= 1/4 [(L_2/l^2 + 1)^{1/2} - L/l]^{-1} (L_2/l^2 + 1)^{-1/2} \end{aligned} \quad [8]$$

Here L equals $\beta/[\alpha(P'_{O_2})^{1/4}]$ and is a characteristic thickness at which bulk and surface processes compete about equally.

The observed orders for specimens A to D have been fitted by least squares to Eq. [8], as shown by curve 1 in Fig. 8. The value of the parameter L was found to be $4.4 (\pm 1.4) \times 10^{-2}$ cm. The average value of $(P'_{O_2})^{1/4}$ for these experiments was $0.604 \text{ atm}^{1/4}$, so that $\beta/\alpha = 2.7 (\pm 0.8) \times 10^{-2} \text{ cm-atm}^{1/4}$. This indicates that the transition from bulk control to surface control would occur at 1 atm pressure for a sample thickness of about 2.7×10^{-2} cm.

A nonlinear least squares computer program was used to fit Eq. [7] to the experimental permeabilities at 1230°C . The calculated results at fixed pressures and varied thicknesses are represented by solid lines in Fig. 7. The bulk and surface parameters, β and α , for these fits are listed in Table III. It can be seen that the bulk coefficient is independent of pressure, with an average value of $(1.25 \pm 0.06) \times 10^{-10} \text{ mol-cm}^{-1}\text{-s}^{-1}\text{-atm}^{-1/4}$. The surface coefficient appears to increase slightly as the pressure decreases. The order of this quantity with respect to P'_{O_2}

Fig. 9. The temperature dependence of the bulk diffusion and surface reaction parameters. Points on line α : specimens A to D. Closed triangles on line β : specimens A to D. Open triangles on line β : specimens E to G.

is -0.10 ± 0.07 , which is not significantly different from the order of zero assumed in the preceding derivation.

Equation [7] was similarly fitted to permeabilities with fixed l and temperature, but with P'_{O_2} variable. The resulting parameter values are listed in Table II. For samples A to D at 1230°C , it can be seen that both β and α are independent of sample thickness, with the average values being $\beta = (9.38 \pm 1.44) \times 10^{-11} \text{ mol-cm}^{-1}\text{-s}^{-1}\text{-atm}^{-1/4}$ and $\alpha = (3.34 \pm 0.25) \times 10^{-9} \text{ mol-cm}^{-2}\text{-s}^{-1}\text{-atm}^{-1/2}$. The ratio, $\beta/\alpha = 2.7 \times 10^{-2} \text{ cm-atm}^{1/4}$, agrees with the value found from Fig. 8.

It can also be seen from Table II that both β and α increase with increasing temperature. Arrhenius plots are shown in Fig. 9. The straight lines, as determined by least squares, have the following equations

$$\begin{aligned} \ln \alpha \text{ (mol-cm}^{-2}\text{-s}^{-1}\text{-atm}^{-1/2}) \\ = -(0.690 \pm 0.437) - \frac{191 \pm 5 \text{ kJ/mol}}{RT} \end{aligned} \quad [9]$$

$$\begin{aligned} \ln \beta \text{ (mol-cm}^{-1}\text{-s}^{-1}\text{-atm}^{-1/4}) \\ = -(3.08 \pm 0.96) - \frac{206 \pm 11 \text{ kJ/mol}}{RT} \end{aligned} \quad [10]$$

Table III. The surface reaction and bulk diffusion parameters as determined by a nonlinear least squares fit of Eq. [7] or [13] to the data of Fig. 7 at fixed P'_{O_2} and variable thickness ($T = 1230^\circ\text{C}$)

P'_{O_2} (atm)	$\alpha \times 10^9$ (mol-cm ⁻² -s ⁻¹ -atm ^{-1/2})	$\beta \times 10^{10}$ (mol-cm ⁻¹ -s ⁻¹ -atm ^{-1/4})	$\gamma \times 10^9$ (mol-cm ⁻² -s ⁻¹ -atm ^{-1/2})	$\delta \times 10^{10}$ (mol-cm ⁻¹ -s ⁻¹ -atm ^{-1/4})
1.0	1.88 ± 0.19	1.33 ± 0.06	1.21 ± 0.01	1.00 ± 0.01
0.21	2.03 ± 0.04	1.21 ± 0.04	1.34 ± 0.04	0.89 ± 0.03
0.05	2.70 ± 0.05	1.26 ± 0.02	1.81 ± 0.07	0.84 ± 0.04
0.005	3.10 ± 1.33	1.17 ± 0.50	2.14 ± 0.20	0.95 ± 0.25

It is seen that the activation energies for bulk diffusion and for surface reaction are very similar. From the expression for β , the following expression may be obtained (3, 12, 13) for the electronic conductivity σ^o at 1 atm

$$\ln \sigma^o (\Omega^{-1}\text{-cm}^{-1}) = (10.9 \pm 3.4) - \frac{195 \pm 10 \text{ kJ/mol}}{RT} \quad [11]$$

The activation energy may be compared with the following values (in kilojoules per mole) from the literature: 217 (2), 183 (3), 233 (7), 232 (9), 263 (10), 155 (11), and 98 (12).

Reactions [5a]-[5f] are not the only ones which allow a competition between surface and bulk processes of differing order. Setaka and Kwan (16) have observed the species O_2^- on the surface of zirconia. This species could be an intermediate if reactions [5a] and [5b] were replaced by the following

If these reactions are interpreted as before, with reactions [12b] and [5d] limiting, Eq. [7] and [8] are replaced by the following

$$J = \frac{\delta^2}{\gamma l^2} [(1 + \gamma^4 l^4 P'_{\text{O}_2} / \delta^4)^{1/2} - 1]^{1/2} \quad [13]$$

$$1/n = 1/4(M^4/l^4 + 1)^{-1/2} [(M^4/l^4 + 1)^{1/2} - M^2/l^2]^{-1} \quad [14]$$

Here $\gamma = (k_a K_b K_d/2)^{1/2}$, $\delta = 0.25 k_a (K_a K_b)^{1/4} [K_c (V_{\text{O}^{2+}})/(O_{\text{O}^{2+}})]^{1/2}$, and $M = \delta/[\gamma(P'_{\text{O}_2})^{1/4}]$.

Equation [14] was fitted to the experimental orders, as shown by curve 3 in Fig. 8. The average value of M was $(8.0 \pm 2.3) \times 10^{-2}$ cm, so $\delta/\gamma = (4.8 \pm 1.4) \times 10^{-2}$ cm-atm $^{1/4}$. It can be seen that the change in order occurs over a smaller range of thickness for this model.

Equation [13] was fitted to the permeability data. The resulting values of the surface, γ , and bulk, δ , parameters are listed in Tables II and III. The patterns of values for these parameters are similar to those noted earlier for α and β , respectively. The temperature dependences are given by the following equations for specimens A to D

$$\begin{aligned} \ln \gamma (\text{mol}\cdot\text{cm}^{-2}\cdot\text{s}^{-1}\cdot\text{atm}^{-1/2}) \\ = -(4.39 \pm 0.58) - 196 \pm 7 \text{ kJ}\cdot\text{mol}^{-1}/RT \quad [15] \end{aligned}$$

$$\begin{aligned} \ln \delta (\text{mol}\cdot\text{cm}^{-1}\cdot\text{s}^{-1}\cdot\text{atm}^{-1/4}) \\ = -(6.54 \pm 0.78) - 207 \pm 9 \text{ kJ}\cdot\text{mol}^{-1}/RT \quad [16] \end{aligned}$$

In order to distinguish more clearly between these mechanisms, it would be desirable to extend the range of experimental conditions.

Effect of pores.—Figure 1a shows that there are significant numbers of pores in specimens A to D. Pores on the outer and inner surfaces of the specimens will increase the surface area. We estimate the true area of the surface to be 10% greater than calculated in the Results section. The surface coefficients, α and γ , should then be reduced by 10% for an ideal sample without pores.

Most of the pores are in the bulk of the specimen. If the pores served as barriers to solid-state diffusion, they would increase the path of diffusion and decrease the effective volume. The true permeability would then be larger than the measured permeability. Alternatively, diffusion could be sustained by gaseous transport across the pores. This would shortcut the solid-state diffusion, and the true diffusion distance would be shorter than the overall thickness of the tube. Electron holes would have a choice of two paths on passing from one side of a pore to the other. They could diffuse around the pore through the ceramic, traveling a distance $\pi\rho$, where ρ is the radius of the pore, or they could pass across the pore by reactions [5a], [5b], [5e], and [5f] or [12a], [12b], and [12c].

In previous sections of this article, we have considered the competition for dominance between surface and bulk processes. There the competition was between two suc-

cessive processes, and the slower of these processes was found to dominate. In particular, bulk diffusion was predicted to be slower when the diffusion distance was greater than about 4.7×10^{-2} cm at 1 atm. Now we are considering competition for dominance between two parallel processes; the faster of these will dominate. For diffusion around a pore, the average distance is about 10^{-3} cm. Therefore, diffusion should be faster and should dominate transport within the specimens.

For specimens A to D, with 10% pores by volume, the diffusion distance would be increased by 4% and the cross-sectional area of ceramic between pores reduced by 10%, in comparison with an ideal ceramic without pores. For an ideal ceramic, the bulk diffusion parameter would be expected to be 14% greater.

Effect of segregation.—As discussed previously, the surface effect was responsible for the variable order for samples A to D. The order for samples E to G was, however, approximately constant. The surface parameters, α and γ , and the bulk parameters, β and δ , are given in the lower part of Table II for these samples. The bulk parameters are similar to those for samples A to D, as seen in Fig. 9. The surface parameters were larger, indicating that surface processes were not limiting. To account for these observations, the possible effect of a surface phase must be considered.

In Fig. 1, it was seen that there was a second phase in samples E to G but not in samples A to D. The second phase consisted of a mixture of metal silicates with an approximate composition of 40% SiO_2 , 40% CaO , and 20% Al_2O_3 . This composition is similar to that of a SiO_2 - Al_2O_3 - CaO eutectic with melting point at about 1250°C . Permeation of oxygen through this liquid was studied by Sasabe *et al.* (17). The order with respect to oxygen pressure was found to be 1/4. For similar conditions, permeation was an order of magnitude faster than for CSZ. There was no indication of limitation by a surface process, indicating that surface processes on this eutectic are faster than bulk processes, and hence much faster than bulk processes in CSZ. It is possible that a very thin layer of this second phase may be present on the surface of specimens E to G in the present work. Surface processes on this phase would be very rapid, and permeation would be controlled by bulk diffusion.

It is suggested that discrepancies in the orders quoted in the literature are also due to surface effects.

General.—The conclusion that both surface and bulk effects are important in describing the kinetics of oxygen permeation through stabilized zirconia is supported by the results of other studies. It is well known, for example, that the conductivity of CSZ and other oxide electrolytes depends markedly on their microstructure and that the response of grain boundaries or a second phase to an applied electric field is not the same as that of the bulk material (18-23). Chu and Seitz (19) showed that, although the resistivities differed by several orders of magnitude, the resistance values for the bulk and grain boundaries in several CSZ specimens were comparable. Beekmans and Heyne (20) attributed high grain boundary resistivities in CSZ to the presence of a second phase.

Studies of oxygen surface exchange reactions, including electrode kinetics, have also been used to distinguish between bulk and interface effects. Fouletier *et al.* (1) showed that, for cells with Y_2O_3 - ZrO_2 electrolytes of large surface area, considerable time was required for equilibrium to be attained between the surface and the surrounding gas phase, particularly at low partial pressures of oxygen. This effect, coupled with the flux of oxygen through the ceramic, could lead to errors in the EMF even if the flux were not large enough to alter the oxygen pressure in the gas being measured (24). In their studies of electrode phenomena at the Pt/CSZ interface, Kroger *et al.* (25, 26) suggested that oxygen could be absorbed directly on the electrolyte from the gas phase and that the electrons required for the incorporation of oxygen atoms in the lattice were obtained by diffusion from the

electrode-electrolyte interface. Other mechanisms have been discussed by Subbarao and Maiti (22). In studies of polarization phenomena in cells with CSZ electrolytes, Gur *et al.* (27) showed that bulk and interface effects could be separated and analyzed individually.

Summary and Conclusions

The isothermal permeability of oxygen through CSZ tubes was found to be proportional to $(P'_{O_2}{}^{1/n} - P''_{O_2}{}^{1/n})$, where n varied from 2.5 to 4.

The experimental results of this work raised two major questions. First, why is the order variable? Second, why do samples A to D behave differently than samples E to G? To answer the first question, we have proposed mechanisms involving competition between surface processes and bulk diffusion. There are two differences between samples A to D and E to G which could be invoked to explain their differing behavior—the presence of pores in samples A to D and the presence of a second phase in samples E to G. We have shown that diffusion around the pores will dominate over transport through the pores; therefore, the pores cannot explain the variable order for samples A to D. We have also shown that surface exchange on the second phase is likely to be very rapid. This accounts for the lack of a variable order with samples E to G.

The steady-state approach was used to investigate the mechanisms. On the assumption that the bulk process was of order 1/4 and the surface process of order 1/2, rate parameters for the bulk and surface processes were calculated.

Flow Reactor Studies of the Paired Electro-Oxidation and Electroreduction of Glucose

K. Park,* P. N. Pintauro,* M. M. Baizer,* and K. Nobe*

Department of Chemical Engineering, University of California, Los Angeles, California 90024

ABSTRACT

The electrochemical oxidation of glucose to gluconic acid and reduction of glucose to sorbitol have been paired in an undivided packed-bed electrode flow reactor. A Raney Ni powder electrocatalyst significantly improved the current efficiency for sorbitol production, as compared to a high hydrogen overpotential Zn(Hg) cathode. The optimum operating conditions for the paired syntheses are activity W-2 Raney Ni powder cathode, graphite chip anode, a 1.6M glucose and 0.4M CaBr₂ initial solution composition, pH 5-7, 60°C solution temperature, an applied current of 250-500 mA per 10g of nickel powder cathode and a solution volumetric flow rate of 100 ml·min⁻¹. Under these conditions, the sorbitol current efficiencies are 80-100%, the gluconic acid efficiencies are 100%, and the product yields are very high.

The paired syntheses of sorbitol and gluconate from glucose, a biomass-derived aldehyde, in undivided flow reactors have been investigated. There are a number of comprehensive articles on the chemistry of the individual electrode reactions (1-7). The separate oxidation and reduction reactions of glucose have been and are commercial processes (8-10). The commercial production of sorbitol by electrochemical reduction of glucose on high hydrogen overpotential cathodes, such as Pb(Hg) or Zn(Hg)

has been replaced by a high temperature and high pressure catalytic hydrogenation process.

At a graphite anode, glucose can be indirectly oxidized to gluconic acid with electrogenerated HOBr. As shown in Eq. [2]-[4], the oxidation proceeds via an electroreducible δ -gluconolactone intermediate

Our initial investigation of the paired syntheses showed that at 25°C a 0.8M glucose-0.8M NaBr solution can be electrolyzed in an undivided flow reactor to produce both sorbitol and sodium gluconate (4). Optimum results for a flow-through packed-bed reactor were obtained with a Zn(Hg) shot cathode, a graphite chip anode, a constant cathode potential of -2.1V vs. SCE, a solution pH of 7, and an electrolyte flow rate of 0.8 liter/min. Although

Electrochemical Society Active Member.

the sorbitol and gluconate yields were high, current efficiencies for sorbitol and sodium gluconate were low. Current losses at the cathode were primarily due to H₂ evolution; subsequently, it was found that some of the current loss at the cathode and all of the current loss at the anode were due to a parasitic δ -gluconolactone/glucose redox couple (cf. Eq. [4]).

The results presented in this paper are based on more recent experiments to (i) examine the use of CaBr₂ instead of NaBr as the supporting electrolyte because separation of the oxidation product would be facilitated due to the low solubility of calcium gluconate, (ii) increase the gluconate current efficiency at pH 7 by minimizing the transport of δ -gluconolactone from the anode to the cathode, and (iii) increase the sorbitol current efficiency by using low hydrogen overpotential Raney Ni in place of the high hydrogen overpotential Zn(Hg) cathode.

Experimental

Preliminary electrolysis experiments on each half of the glucose oxidation-reduction "pair" were carried out in a standard glass H-cell containing a medium porosity glass frit. Electrode potentials were measured relative to a saturated calomel electrode, and mixing was provided by magnetic stirring bars.

The paired syntheses were studied using flow-through packed-bed flow reactors. One was made of Plexiglas and is shown in Fig. 1. The reactor diameter was 3.2 cm; the anode and cathode packed beds were both 1.2 cm long. The cathode consisted of reagent-grade zinc shot (0.5 cm shot diam with a surface area/volume ratio of 6.6 cm²/cm³) amalgamated with Hg; the anode consisted of cylindrical graphite chips (Poco Graphite, Incorporated) with an area/volume ratio of 8.5 cm²/cm³. External electrical contact was made by a graphite rod in the anode compartment and a zinc amalgam rod in the cathode. 5 mm diam glass beads above and below the electrodes were used to ensure a uniform flow distribution in the packed beds. The anode and cathode were separated from one another by a perforated polypropylene disk sandwiched between two nylon mesh screens. Reference electrode probes were inserted between the anode and the cathode.

A second packed-bed parallel current/electrolyte flow reactor (Fig. 2) was constructed to accommodate a Raney Ni powder cathode. The cylindrical flow reactor (6.7 cm diam) was made of glass with a fine porosity glass frit separating a 2.5 cm thick graphite chip anode from a 3 mm thick Raney Ni powder cathode. The electrolyte flow was in the downward direction to press the nickel powder against the glass frit. A spiral wound nickel sheet (3 mm high) was embedded in the Raney Ni and electrical contact to the sheet was made by a nickel-plated aluminum rod.

The flow reactors were operated in a batch recycle mode by inserting them into a circulation loop (Fig. 3) which normally consisted of a pump, flowmeter, throttle

Fig. 1. The packed-bed, undivided flow reactor with a Zn(Hg) cathode and graphite chip anode.

Fig. 2. The packed-bed flow reactor with a Raney Ni powder cathode.

valve, hydrocyclone gas disengager, and a holding tank (500-1000 ml) immersed in a constant temperature water bath. The individual elements of the reaction loop were connected by silicone tubing.

Constant cathode potential experiments were performed with either a Magna Research Model 4700M or a Wenking ST72 potentiostat. A Sorensen DCR80-60B or a Hewlett-Packard Harrison 61D/B dc power supply was used in constant-current electrolyses. Currents were measured with a Simpson ultrahigh sensitivity microammeter; potentials were measured with a Keithley 610B Electrometer and a Keithley 168 digital multimeter; and the total charge passed during an electrolysis was measured using a Model 541 Koslow Scientific Company coulometer.

All chemicals were of analytic reagent grade, and the water was deionized and doubly distilled. The zinc metal shot and flat sheet zinc electrode (for H-cell experiments) were amalgamated using the procedures described by Creighton (11).

The active Raney Ni cathode was prepared from Raney Ni alloy powder (Alfa Products, 50/50 Ni/Al content) by adding the alloy powder to a 17 weight percent NaOH solution. On addition, an exothermic reaction occurred,

Fig. 3. The batch recycle reaction loop for the paired syntheses of sorbitol and gluconic acid.

with vigorous hydrogen evolution. After the evolution of hydrogen slowed, the metal powder/caustic suspension was heated to 60°C for ca. 1h. The solution was occasionally stirred, then allowed to cool to room temperature. The alkaline solution was then decanted, and the nickel powder washed several times with distilled water until the rinse water pH was neutral. Raney Ni powder catalyst obtained in this way has an activity comparable to that of W-2 (12). Before H-cell and flow reactor electrolysis, adsorbed hydrogen atoms formed on the nickel powder during the activation process were removed by immersion of the catalyst in a 1.0M glucose solution for ca. 20h.

Current efficiencies and product yields were obtained by HPLC analyses of glucose and the reaction product. For glucose and its reduction products, a Bio-Rad Laboratories HPX-87C cation exchange resin column in its calcium ion form was used with a refractive index detector. A cation exchange column in its hydrogen form (Bio-Rad Laboratories HPX-89H) with a UV detector (216 nm wavelength) was used for oxidation product analyses. Products were identified by comparing retention times with those of known commercial samples. Calibration of peak areas with standard solutions indicated that sorbitol concentrations can be determined within $\pm 5\%$, while glucose and gluconate concentrations are within $\pm 10\%$.

Results and Discussion

The δ -gluconolactone/glucose parasitic redox couple.—The electro-oxidation of glucose to gluconic acid proceeds via a gluconolactone intermediate (13), as shown in Eq. [4]. Fedoronko (1) has reported that lactones can be reduced to the corresponding aldoses at a Hg cathode. Since the hydrolysis of δ -gluconolactone is acid-base catalyzed (14), the low gluconic acid current efficiencies and some of the current loss at the cathode for the pH 7 paired electrolysis are attributed to δ -gluconolactone exiting the anode, circulating through the external reaction loop of the experimental apparatus and re-entering the cathode compartment, where it is reduced to glucose; hence, there is no loss in product yields based on glucose consumed.

A series of divided H-cell cathodic polarization experiments were performed to determine the electroreducibility of δ -gluconolactone. Figure 4 shows the i-E curves for the reduction of a 0.15M δ -gluconolactone-0.8M NaBr solution at pH 4.5, 6, and 9 using a Zn(Hg) cathode. These

Fig. 4. The effect of pH on the electrochemical reduction of δ -gluconolactone (divided H-cell; Zn(Hg) cathode; $T = 26^\circ\text{C}$). Open circles: 0.8M NaBr , $\text{pH} = 7$. Filled circles: 0.8M NaBr and 0.15M δ -gluconolactone, $\text{pH} = 9$; Filled squares: 0.8M NaBr and 0.15M δ -gluconolactone, $\text{pH} = 6$; Open squares: 0.8M NaBr and 0.15M δ -gluconolactone, $\text{pH} = 4.5$.

results indicate that: (i) at the normal cathodic operating potential in the packed-bed flow reactor (-2.1V vs. SCE), the current densities for lactone reduction (30 mA/cm^2 at $\text{pH} 4.5$ and 20 mA/cm^2 at $\text{pH} 6$) are considerably higher than the current densities for glucose reduction (10 mA/cm^2 at $\text{pH} 6$) and H_2 evolution ($\text{ca. } 2.5\text{ mA/cm}^2$) and (ii) at $\text{pH} 9$, there is no measurable reduction current for the lactone, presumably because at this pH the hydrolysis to gluconic acid is fast and gluconic acid is nonelectroreducible [as established previously (4)].

The rate of δ -gluconolactone hydrolysis to gluconic acid can be increased by increasing the solution temperature. At 25°C and $\text{pH} 7$, $\text{ca. } 3.5\text{h}$ are required to fully hydrolyze the lactone. To determine the rate of hydrolysis at elevated solution temperatures a series of H-cell experiments were performed in which a 0.15M δ -gluconolactone and 0.8M NaBr solution ($\text{pH } 6.7 \pm 0.4$) was maintained at either 45° or 55°C for $\text{ca. } 30\text{ min}$. The Zn(Hg) cathode was periodically polarized to -2.1V vs. SCE and the current measured; these current density values are plotted vs. the hydrolysis time (at 55°C) in Fig. 5. After 8–10 min, the current density decreased from an initial value of 55 mA/cm^2 to the normal background (H_2 evolution) current density of $\text{ca. } 2.5\text{ mA/cm}^2$. The decreasing currents correspond to the decreasing concentration of lactone. At 45°C , 20 min were required to convert the lactone to gluconic acid. Thus, the parasitic lactone/glucose redox couple can be

eliminated by performing the paired syntheses at elevated temperatures.

To ensure the absence of δ -gluconolactone in the cathode compartment of the packed bed flow reactor, the electrolyte exiting the anode was kept in a constant temperature ($\text{ca. } 58^\circ\text{C}$) holding tank for approximately 10 min. The size of the holding tank was dictated by the volume (1.5 liter) and volumetric flow rate (0.15 liter/min) of electrolyte in the circulation loop. The packed bed flow reactor operated at a temperature of 58°C with the solution residence time of 10 min outside the reactor. The initial electrolyte composition was 0.8M glucose and 0.8M NaBr . The solution pH was continuously monitored and maintained at 6.8 ± 0.3 by addition of NaHCO_3 during constant cathode potential (-2.1V vs. SCE) electrolysis.

Typical results of sorbitol and gluconic acid current efficiencies are given in Table I. For comparison purposes, current efficiencies of a 25°C , 10s residence time experiment (the holding tank and temperature bath were removed from the recycle loop) are also shown in Table I. The magnitudes of the increase in the sorbitol and gluconic acid current efficiencies for the elevated temperature electrolysis indicate that the parasitic δ -gluconolactone/glucose redox couple had been eliminated. Sorbitol and gluconic acid product yields were very high. Cathodic current losses are ascribed to hydrogen evolution.

CaBr₂ supporting electrolyte.—In order to evaluate CaBr_2 as a supporting electrolyte at $\text{pH} 7$ and 55°C , a series of i-E potentiostatic polarization measurements and constant potential reduction experiments were performed in a divided H-cell using a Zn(Hg) cathode. The H-cell was immersed in a 55°C constant temperature water bath, and the catholyte pH was maintained at 7.2 ± 0.5 by addition of HBr . The i-E curves as well as cathodic polarization data for NaBr supporting electrolyte are shown in Fig. 6.

The initial i-E polarization experiments compare the rate of hydrogen evolution in NaBr and CaBr_2 solutions. Curves A and B in Fig. 6 show a decrease of $\text{ca. } 80\text{ mV}$ in the hydrogen overpotential for 0.4M CaBr_2 as compared to 0.8M NaBr . Upon addition of glucose to the 0.4M CaBr_2 solution, a large increase in current was observed (curve C). The apparent current efficiencies for glucose reduction, based on curves B and C, was 96% at -1.7V vs. SCE . However, the sorbitol current efficiency at 0.2 F/mol was only 32% for a constant potential electrolysis performed at -1.7V vs. SCE (55°C , $\text{pH} 7$, initial glucose concentration of 0.8M). The calculation of the 96% current efficiency did not take into account the increase in hydrogen evolution due to the presence of both glucose and sorbitol. Previous H-cell experiments had shown that glucose caused an anodic shift in the potential for the visual onset of H_2 evolution of Zn(Hg) (4); sorbitol, which is not electroreducible (4), also increases the rate of H_2 evolution (curve D, Fig. 6).

CaBr_2 was also examined as a supporting electrolyte in the undivided packed bed flow reactor (cf. Fig. 1) with a

Fig. 6. The effect of catholyte composition on hydrogen evolution and glucose reduction (divided H-cell, Zn(Hg) cathode; pH = 7; $T = 55^{\circ}\text{C}$). A: 0.8M NaBr. B: 0.4M CaBr_2 . C: 0.4M CaBr_2 and 0.8M glucose. D: 0.4M CaBr_2 and 0.5M sorbitol.

Zn(Hg) shot cathode and graphite chip anode. The initial electrolyte composition was 0.8M glucose and 0.4M CaBr_2 , the electrolyte temperature was 55°C , and the solution pH (≈ 7) was maintained constant by periodically adding $\text{Ca}(\text{OH})_2$. The volumetric flow rate (0.2 liter/min) and electrolyte volume in the batch recycle reaction loop (600 ml) were chosen to ensure a 3 min residence time in the holding tank (it was determined in separate H-cell experiments that only 3 min were required to hydrolyze δ -gluconolactone at 55°C when CaBr_2 is the supporting electrolyte).

The results of three constant cathode potential electrolyses are shown in Table II. High gluconic acid current efficiencies at both -1.70 and -1.95V vs. SCE indicate that the lactone oxidation intermediate is completely hydrolyzed in the holding tank. The low sorbitol current efficiencies (compared with the 40-60% efficiencies with NaBr) were not unexpected because of the results obtained in the H-cell experiments. The results of the H-cell and flow reactor experiments show that, while the use of CaBr_2 may simplify and reduce the cost of the separation scheme, there are significant losses in the energy efficiency of the paired syntheses with the Zn(Hg) cathode.

The electrohydrogenation of glucose on Raney nickel.—Sorbitol is currently manufactured by hydrogenation of glucose on Raney Ni and Raney Ni-Mo alloy catalysts at elevated temperatures and pressures (15). Previous work

has shown that low hydrogen overpotential electrocatalysts, such as Raney Ni, and platinum and rhodium black, can effectively hydrogenate organic compounds (16-21). For example, Miller and Christensen (20) obtained high product yields and current efficiencies for electrohydrogenation of phenol to cyclohexanol on rhodium black cathodes in H_2SO_4 ; Kirilyus *et al.* (19) report that Raney Ni is highly active and selective for electrohydrogenation of pyridine to piperidine in alkaline solution, while Belenkaya and Belozersky (16) obtained relatively high current efficiencies for electrohydrogenation of glucose on a Ni-Al alloy cathode. These results indicate that Raney Ni may be an effective electrocatalyst for the hydrogenation of glucose. [Note: according to Chiba *et al.* (21), electrohydrogenation of aliphatic aldehydes would not be expected; however, no data were provided to support this opinion.] Therefore, in order to improve the sorbitol current efficiencies with CaBr_2 as supporting electrolyte, the use of a Raney Ni powder cathode was investigated.

H-cell experiments were performed with the anode and cathode compartments each charged with 50 ml of a 0.4M CaBr_2 solution; the anode was a graphite rod and the cathode consisted of a nickel plate current collector (3.5 cm diam) covered with 2g of activity W-2 Raney Ni powder. The electrolyte temperature and bulk catholyte pH were maintained constant at 60°C and ca. 7.0 (by addition of HBr), respectively.

At first, a constant current of 100 mA was applied for 95 min and then stepped up to 200 mA for 20 min before the current was terminated. While the Raney Ni cathode was set at open circuit, glucose powder (14.4g) was added to the catholyte to make a 1.6M solution. After 3h of continuous stirring of the solution, HPLC analysis indicated the formation of 0.0019 mol sorbitol; this amount required 0.0038 g-atom of adsorbed hydrogen atoms. The latter value provides the basis for the estimate of 56.4 m^2/g for the Raney Ni surface.

Next, a series of experiments was performed in which glucose was present in solution during current passage; the anode and cathode compartments of the H-cell were initially charged with 50 ml of a 1.6M glucose-0.4M CaBr_2 solution. The results are given in Table III. The sorbitol current efficiencies are significantly higher than those obtained for glucose reduction on Zn(Hg) cathodes [Table II and Ref. (4)]. For the 200 mA experiments (Table III), the potential of the Raney Ni bed was -1.10V vs. SCE , which is a considerably lower overpotential than that found for high hydrogen overpotential cathodes, such as Pb, Zn, and Zn(Hg) (-1.7 to -2.2V vs. SCE), as shown in Fig. 6 and Ref. (4). The open-circuit experiment and the lower reduction potentials indicate an electrohydrogenation mechanism for glucose reduction on Raney Ni in which glucose reacts with adsorbed hydrogen atoms to form sorbitol.

Current losses for glucose reduction on Raney Ni at 0.2 F/mol are primarily due to the formation of 2-deoxysorbitol with some current (5-10%) consumed by hydrogen evolution. The selectivities in Table III are the relative amounts of product and by-product(s) detected in the

electrolytic solution after the passage of either 0.2 or 0.4 F/mol of glucose. Fructose is formed during an electrolysis by the base-catalyzed isomerization of glucose. 2-deoxysorbitol is formed by the subsequent reduction of fructose on Raney Ni. The pH excursions and fructose formation can be minimized by performing the reduction in a flow reactor, where the residence time in the nickel powder bed is short.

A series of constant current glucose paired syntheses experiments were performed using a Raney Ni powder cathode (10g), a graphite chip anode, and the flow-through packed-bed reactor shown in Fig. 2. In all electrolyses, the initial glucose concentration was 1.6M, the supporting electrolyte was 0.4M CaBr₂, and the electrolyte temperature was maintained constant at ca. 60°C. The solution pH was maintained between 5 and 7 during an electrolysis by addition of Ca(OH)₂. The electrolyte volume in the batch recycle reaction loop and the flow rate were chosen to ensure an adequate solution residence time outside the electrochemical flow reactor for complete hydrolysis of δ -gluconolactone to gluconic acid. Fresh Raney Ni was used in each flow reactor experiment. During an electrolysis, solution samples were periodically removed and analyzed for glucose, sorbitol, gluconic acid, and by-products by HPLC.

The results of the paired syntheses experiments are presented in Table IV. Finely divided Raney Ni powder was used as the cathode material in experiments 1-7. In experiments 8 and 9, the cathode was an industrial grade granular Raney Ni catalyst (kindly provided by S. R. Montgomery of the Davison Chemical Division, W. R. Grace and Company). Linear velocities through the Raney Ni bed, which are also given in Table IV, were determined from the cathode reactor diameter (6.7 cm) and the porosity of the Raney Ni powder (0.74).

The gluconic acid current efficiencies from the paired syntheses experiments are ca. 100% when the electrolyte flow rate was maintained at or above 35 ml/min. In experiments 1 and 2, the high currents and low flow rates

led to anodic current losses by back-diffusion and subsequent reduction of electrogenerated HOBr or oxidation of HOBr to HBrO₃ (bromate does not oxidize glucose, but, rather it circulates through the recycle loop and is reduced to Br⁻ at the cathode). Product yields for gluconic acid were very high.

The sorbitol current efficiencies in Table IV are significantly higher than those obtained when glucose is reduced on Zn(Hg) in a paired reaction using either CaBr₂ (20%; cf. Table II) or NaBr (40-60%, cf. Fig. 3) as supporting electrolyte. The sorbitol yields in all Raney Ni paired syntheses experiments were very high. Cathodic current losses in experiments for electrolyte flow rates \geq 100 ml·min⁻¹ are ascribed to hydrogen evolution. Cathodic current losses in \leq 35 ml·min⁻¹ flow rate experiments were due to hydrogen evolution and either the reduction of anodically generated Br₂, which back-diffused into the cathode compartment or the reduction of BrO₃⁻. The results in Table IV suggest that 100% reduction and oxidation current efficiencies may be obtained at applied currents higher than 250 mA per 10g of Raney Ni by increasing electrolyte flow rate and/or glucose concentration. The overall cell potential in experiment 4 (250 mA, 100 ml/min) was 2.2V, which is 0.8-1.3V less than those given in Table II for the paired syntheses with a Zn(Hg) cathode. The lower cell potential is attributed to the lower operating cathode potential of Raney Ni, as observed in divided H-cell experiments and discussed above.

High sorbitol and gluconic acid current efficiencies were also obtained when granular Raney Ni particles were used as the cathode material. The pressure drop through such a cathode bed is less than that for Raney Ni powder since the glass frit, which is used to trap the nickel powder, is not required for the granular catalyst.

Conclusions

The oxidation and reduction of glucose have been successfully paired in undivided flow-through electrochemical reactors with a graphite chip anode and either a Zn(Hg) shot or Raney Ni powder (activity W-2) cathode. Higher reduction current efficiencies and lower operating potentials have been obtained with the Raney Ni cathode. 100% current efficiencies and very high product yields at 0.2 F/mol for sorbitol (reduction) and gluconate (oxidation) were obtained with a Raney Ni cathode flow reactor under the following operating conditions: 1.6M glucose-0.4M CaBr₂ initial electrolyte composition; solution pH between 5 and 7; 60°C solution temperature; a constant applied current of 250 mA/10g of Raney Ni powder; and a solution flow rate of 100 ml·min⁻¹ (0.064 cm/s linear velocity). Current efficiencies for sorbitol formation in undivided flow reactor experiments with a Zn(Hg) shot cathode were only 9-20% at 0.2 F/mol.

When the flow reactor (Zn(Hg) or Raney Ni cathode) was operated in a batch recycle mode, current losses from a δ -gluconolactone/glucose parasitic redox couple were eliminated when the solution was kept in a holding tank

for ca. 10 min (NaBr supporting electrolyte at 58°C) or 3 min (CaBr₂ at 60°C).

Lower cathode potentials for glucose reduction on Raney Ni as compared to Zn(Hg) were observed in both divided H-cell and flow reactor experiments. In a divided H-cell, sorbitol was produced on a Raney Ni cathode at -1.1V vs. SCE (200 mA applied current), whereas the reduction potential for glucose on Zn(Hg) was between -1.7 and -2.2V vs. SCE. In the flow reactor experiments, the overall cell potential was reduced from 3.0-3.5V to 2.2V when the Zn(Hg) cathode was replaced with Raney Ni powder.

Anodic Oxidation Mechanism of Hypochlorite Ion on Platinum Electrode in Alkaline Solution

A. Tasaka and T. Tojo

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Imadegawa-Karasuma, Kamigyo-ku, Kyoto 602, Japan

ABSTRACT

The anodic oxidation of hypochlorite ion (ClO⁻) or chlorite ion (ClO₂⁻) on platinum (Pt) electrode was carried out at 30°C in 1.0M NaOH solution. A plateau was observed on the anodic polarization curve of ClO⁻ in the potential range of 0.90-1.20V and, in the case of ClO₂⁻, a plateau was observed in the potential range of 1.10-1.50V. When alkaline solutions with various concentration ratios of NaClO₂ to NaClO were electrolyzed at 1.20V over 50h, the Raman intensity ratio of ClO₂⁻ to ClO⁻ in the anolyte was found to be constant at a value of ca. 0.12 in every case. From the calibration curves obtained in ClO₂⁻-ClO⁻ system, the concentration ratio of ClO₂⁻ to ClO⁻ was estimated to be ca. 0.08, which is in good agreement with the theoretical value according to a first-order consecutive reaction. Based on these results, it is suggested that the mechanism of the anodic oxidation of ClO⁻ is ClO⁻ → ClO₂⁻ → ClO₃⁻.

The reactions involved in the synthesis of ClO₃⁻ were studied by various workers (1-4). Above all, the mechanism which was formulated by Foerster and Müller at the beginning of this century was fundamental (1). It is as follows

This mechanism well explains the total reaction in the electrolysis of ClO₃⁻. However, it does not pay attention to the elementary process. Especially, the question remains that ClO₂⁻ is neglected, since ClO₂⁻ was produced

industrially as a bleaching agent and the binding energy of Cl-O bond in ClO₂⁻ is larger than that in ClO⁻.

In order to detect the species which would exist in the process of the formation of ClO₃⁻, laser Raman spectroscopy was used. The quantitative analysis of ClO⁻-ClO₂⁻-ClO₃⁻ system in an alkaline solution was carried out, since ClO⁻ and ClO₂⁻ are stable in an alkaline solution (5). In this condition, the reaction of Eq. [4] does not proceed, so only the reaction of Eq. [5] can be investigated. The kinetics of anodic oxidation of ClO⁻ on Pt electrode in 1.0M NaOH was investigated using calibration line obtained by laser Raman spectroscopy.

Experimental

Mixed solutions of ClO⁻-ClO₃⁻ and ClO₂⁻-ClO₃⁻ were prepared in various concentration ratios by dissolving sodium hypochlorite (NaClO), sodium chlorite (NaClO₂), or sodium chlorate (NaClO₃) in 1.0M NaOH. All chemicals used were reagent grade and from Nakarai Chemicals

Limited. Raman spectra of these solutions were taken to determine the relationship between Raman intensity ratios of ClO^- to ClO_2^- or ClO_2^- to ClO_3^- and concentration ratios of those. Concentration of ClO^- was determined by iodometry. A calibration curve of ClO_2^- - ClO^- system was obtained by calculating from those of ClO^- - ClO_3^- and ClO_2^- - ClO_3^- systems. Raman spectra were taken on a 488 nm Ar-ion laser in a JEOL Limited Model JLG-A-04 spectrophotometer. Sample cells were about 2 cm³ of Pyrex tubing. Slit widths for all spectra were 14 cm⁻¹ at 488 nm, and laser output power was 70-100 mW.

The electrochemical cell made by Pyrex glass has a diaphragm of porous glass frits. Smooth Pt plate with a surface area of 2 or 12 cm² was used as an anode, and Pt plate with large surface area as the cathode. Before electrolysis, the working electrode was cleaned in nitric acid, washed with distilled water, and preelectrolyzed anodically at 10 mA·cm⁻² in 1.0M NaOH and cathodically at 100 mA·cm⁻² in another solution of 1.0M NaOH for 30 min. All potentials were measured against a mercury (II) oxide electrode (Hg/HgO, 1.0M NaOH) at 30° ± 0.5°C.

The electrical circuit of the electrochemical cell is shown in Fig. 1. With this circuit, the stationary anodic polarization curves of ClO^- and ClO_2^- in 1.0M NaOH were obtained. The electrolytic solutions were prepared from NaClO, NaClO₂, and 1.0M NaOH solution which was previously deaerated with nitrogen. Solutions of ClO_2^- - ClO^- system at various concentration ratios were electrolyzed at a constant potential, and the variation of concentration ratio of $C_{\text{ClO}_2^-}$ to C_{ClO^-} with time was measured by taking the Raman spectrum of anolyte samples at different times.

Potentiostatic experiments were performed with a Hokuto Denko Limited Model HA-201 potentiostat and a Toa Denpa Kogyo Limited Model CDR-11 recorder.

Results and Discussion

Laser Raman spectra of ClO^- , ClO_2^- , and ClO_3^- .—The Raman spectrum of a solution of commercial NaClO (Fig. 2a) shows six bands at 479, 613, 713, 786, 932, and 1063 cm⁻¹. The band at 713 cm⁻¹ was assigned to the Cl-O stretching vibration of ClO^- (6). In order to assign the other five bands, the Raman spectra of solutions containing 1.0M NaClO₂ + 1.0M NaOH and 1.0M NaClO₃ + 1.0M NaOH were observed. Two bands were observed in NaClO₂ solutions (see Fig. 2b) at 402 and 786 cm⁻¹. The band at 402 cm⁻¹ was assigned to the O-Cl-O symmetric deformation vibration, and the one at 786 cm⁻¹ was as-

Fig. 1. Experimental apparatus. W: Working electrode (Pt plate). C: Counterelectrode (Pt plate). Ref: Reference electrode (Hg/HgO, 1.0M NaOH). D: Diaphragm of porous glass frits. T: Thermometer. P: Potentiostat. R: Recorder.

Fig. 2. Laser Raman spectra of solutions of (a) commercial NaClO, (b) 1.0M NaClO₂ + 1.0M NaOH, and (c) 1.0M NaClO₃ + 1.0M NaOH. Excitation: 488 nm argon ion laser line. Slit: 14 cm⁻¹ · 10 mm. Sensitivity: 80 · 250 pulses per second (pps).

signed to the O-Cl-O symmetric stretching vibration of ClO_2^- (6). Three bands were noticed in NaClO₃ solutions (Fig. 2c) at 479, 613, and 932 cm⁻¹. The band at 479 cm⁻¹ was assigned to doubly generated deformation vibration; that at 613 cm⁻¹ was assigned to the symmetric deformation vibration; and that at 932 cm⁻¹ was assigned to the symmetric stretching vibration of ClO_3^- (6). Thus, the band at 786 cm⁻¹ was assigned to ClO_2^- , and those at 479, 613, and 932 cm⁻¹ were assigned to ClO_3^- . In addition, the band at 1063 cm⁻¹ was assigned to the symmetric stretching vibration of carbonate ion which formed by the dissolving carbon dioxide in alkaline solution from air (6, 7).

These results show that commercial solutions of NaClO contain ClO_2^- and ClO_3^- and suggest the formation of ClO_2^- intermediate during the oxidation of ClO^- to ClO_3^- .

Calibration curve of alkaline solution containing ClO_2^- - ClO^- system.—Raman intensity is proportional to the concentration of a given species, if temperature of the solution and intensity of incident laser beam is kept constant. During the course of the experiment, ClO^- is decomposed gradually by the irradiating laser beam. In addition, chemical reaction between ClO^- and ClO_2^- proceeds in alkaline solutions according to Eq. [6]

These factors would reduce the accuracy of the analytical data based on the spectrum of alkaline solution of ClO_2^- - ClO^- system taken directly. Hence, the calibration line for ClO_2^- - ClO^- system was calculated from the data of ClO^- - ClO_3^- and ClO_2^- - ClO_3^- systems. In both cases, the concentration of ClO_3^- was 0.50, 0.75, and 1.00M. Since the ratio of Raman intensity decreased with time in case of ClO^- - ClO_3^- system, the initial ratio of the Raman intensity was estimated by extrapolation to time zero (8).

Fig. 3. Calculated relationship between concentration ratio (NaClO_2 to NaClO) and intensity ratio (786 to 713 cm^{-1}).

The slopes for the obtained calibration lines of the ClO^- - ClO_3^- system and the ClO_2^- - ClO_3^- system were 0.60 and 0.97, respectively. Figure 3 shows the calculated calibration graph for the ClO_2^- - ClO^- , from which the concentration ratio of ClO_2^- to ClO^- was evaluated from the Raman intensity data. The slope of the calibration line for the ClO_2^- - ClO^- system was 1.63. Thus, it would be possible to decide the concentration of each ion from these three standardized curves if the total concentration of each ion in the system is known.

Potentiostatic oxidation.—Potentiostatic polarization curves in alkaline ClO^- and ClO_2^- solutions on a Pt anode

Fig. 4. Potentiostatic polarization curves of Pt anode at 30°C . Curve 1: $0.25\text{M NaClO}_2 + 1.0\text{M NaOH}$. Curve 2: $0.25\text{M NaClO} + 1.0\text{M NaOH}$. Curve 3: 1.0M NaOH .

at 30°C were shown in Fig. 4, where curves 1, 2, and 3 refer to the anodic polarization curves of $0.25\text{M NaClO}_2 + 1.0\text{M NaOH}$, $0.25\text{M NaClO} + 1.0\text{M NaOH}$, and 1.0M NaOH , respectively. A plateau was observed with NaClO_2 solutions in the potential range of 1.10 - 1.50V , and in case of NaClO solution a plateau was observed in the potential range of 0.90 - 1.20V . However, with 1.0M NaOH solutions (curve 3), the current increased beyond 1.10V because of the discharge of O_2 . This potential was less noble compared with those observed with solution containing ClO^- and ClO_2^- .

The anode potential during electrolysis of sodium chloride in industrial operation is about 1.308V vs. NHE , i.e., 1.210V vs. Hg/HgO , 1.0M NaOH (9). Hence, electrolysis of ClO^- or ClO_2^- in alkaline solutions was conducted at 1.20V vs. Hg/HgO , 1.0M NaOH at 30°C for 24h using Pt anode. Figure 5 depicts the Raman spectrum of the anolyte (curve a), along with the Raman spectrum of a synthetic NaClO solution (curve b). In these spectra, the bands were noticed at 713 cm^{-1} (ClO^-), at 786 cm^{-1} (ClO_2^-), and at 479 , 613 , and 932 cm^{-1} (ClO_3^-). Comparison of curves a and b shows that the intensity of the band at 932 cm^{-1} (ClO_3^-) was increased slightly in the spectrum of an electrolyzed solution, whereas the band at 786 cm^{-1} (ClO_2^-) was unaltered. Figure 6 shows the spectrum of a solution containing $0.25\text{M NaClO}_2 + 1.0\text{M NaOH}$ which was electrolyzed at 1.20V on Pt anode for 24h and that of a synthetic NaClO_2 solution (b). In spectrum a, new bands were observed at 479 , 613 , and 932 cm^{-1} which were all assigned to ClO_3^- . These results show that ClO_2^- was easily oxidized to ClO_3^- , and, hence, the concentration of ClO_2^- in the anolyte should approach zero during electrolysis. However, the concentration of ClO_2^- in the anolyte remained unaltered during electrolysis, as shown in Fig. 5.

Concentration dependence on a current density.—Plateaus were observed on the anodic polarization curves of ClO^- and ClO_2^- in alkaline solutions in the potential range of ca. 1.00 - 1.20V . Figure 7 shows the relationship between the concentration of ClO^- or ClO_2^- and the current at 1.20V , where straight lines 1 and 2 refer to ClO^- and ClO_2^- , respectively. In both cases, the current at 1.20V is proportional to the concentration of ClO^- or ClO_2^- . In case of ClO^- , the straight line extrapolated to zero ClO^- concentration did not pass through the origin owing to interference from oxygen evolution reaction. However, in case of ClO_2^- , the extrapolated straight line passed through the origin.

Fig. 5. Laser Raman spectra of 0.25M NaClO before and after electrolysis at 30°C . Curve a: after electrolysis at 1.20V vs. Hg/HgO , 1.0M NaOH . Curve b: before electrolysis. Laser excitation: 488 nm (argon). Slit: $14 \text{ cm}^{-1} \cdot 10 \text{ mm}$. Sensitivity: $40 \cdot 250 \text{ pps}$.

Fig. 6. Laser Raman spectra of 0.25M NaClO₂ before and after electrolysis at 30°C. Curve a: after electrolysis at 1.20V vs. Hg/HgO, 1.0M NaOH. Curve b: before electrolysis. Laser excitation: 488 nm (argon). Slit: 14 cm⁻¹ · 10 mm. Sensitivity: 40 · 250 pps.

Potentiostatic oxidation of an alkaline solution of ClO₂⁻-ClO⁻ system.—Analytical results employing laser Raman spectroscopy show the existence of ClO₂⁻ during the anodic oxidation of ClO⁻ to ClO₃⁻. Hence, the anodic oxidation of ClO⁻ can be described as

where k_1 and k_2 are the rate constants for the forward processes and k_1' and k_2' are those for the backward processes. Since ClO₂⁻ was oxidized anodically only to ClO₃⁻ and ClO₃⁻ cannot be reduced electrochemically (10), the rate constant for the backward processes can be neglected. Hence, the concentration variation of ClO⁻ and ClO₂⁻ with time can be written as

Fig. 7. Relationship between NaClO or NaClO₂ concentration and current density at 1.20V vs. Hg/HgO, 1.0M NaOH. Line 1: NaClO + 1.0M NaOH. Line 2: NaClO₂ + 1.0M NaOH.

$$-dC_{\text{ClO}^-}/dt = k_1 C_{\text{ClO}^-} \quad [8]$$

$$dC_{\text{ClO}_2^-}/dt = k_1 C_{\text{ClO}^-} - k_2 C_{\text{ClO}_2^-} \quad [9]$$

Solving Eq. [8] and [9], the concentrations of ClO⁻ and ClO₂⁻ at time t may be expressed as

$$C_{\text{ClO}^-} = C_{\text{ClO}^-}^{\circ} \exp(-k_1 t) \quad [10]$$

$$C_{\text{ClO}_2^-} = \{k_1/(k_2 - k_1)\} C_{\text{ClO}^-}^{\circ} \{\exp(-k_1 t) - \exp(-k_2 t)\} + C_{\text{ClO}_2^-}^{\circ} \exp(-k_2 t) \quad [11]$$

where $C_{\text{ClO}^-}^{\circ}$ and $C_{\text{ClO}_2^-}^{\circ}$ are initial concentrations of ClO⁻ and ClO₂⁻, respectively. From Eq. [10] and [11], the concentration ratio of ClO₂⁻ to ClO⁻ at time t is obtained as

$$C_{\text{ClO}_2^-}/C_{\text{ClO}^-} = k_1/(k_2 - k_1) - \{k_1/(k_2 - k_1) - C_{\text{ClO}_2^-}^{\circ}/C_{\text{ClO}^-}^{\circ}\} \exp\{-(k_2 - k_1)t\} \quad [12]$$

Since $k_2 > k_1$ (see Fig. 4) $C_{\text{ClO}_2^-}/C_{\text{ClO}^-}$ approaches $k_1/(k_2 - k_1)$ for $t \rightarrow \infty$. Thus, the ratio of $C_{\text{ClO}_2^-}/C_{\text{ClO}^-}$ in the anolyte would approach a constant value, when alkaline solutions of various concentration ratios of ClO₂⁻ to ClO⁻ are electrolyzed potentiostatically.

Alkaline solutions of various concentration ratios of ClO₂⁻ to ClO⁻ were electrolyzed at 1.20V and 30°C. Results illustrating the variation of the Raman intensity ratios of ClO₂⁻ to ClO⁻ (h_{786}/h_{713})¹ with time during electrolysis were shown in Fig. 8. In case of curves c and d, the solution of 0.70 and 0.50M NaClO were prepared and no ClO₂⁻ was added. The concentrations of ClO₂⁻ containing in the commercial solutions of NaClO were different; hence, the initial concentration ratios of ClO₂⁻ to ClO⁻ were different. In case of curves a and b, initial concentration ratios of ClO₂⁻ to ClO⁻ were 0.51 (0.34M/0.67M) and 0.33 (0.25M/0.75M), respectively. As seen in Fig. 8, the Raman intensity ratio (h_{786}/h_{713}) became constant at ca. 0.12, corresponding to a $C_{\text{ClO}_2^-}/C_{\text{ClO}^-}$ ratio of 0.08, after 50h. Since the electrochemical oxidation of ClO⁻ and ClO₂⁻ on Pt electrode is diffusion controlled and the number of electrons involved in both reaction are equal,² $k_1/(k_2 - k_1) = i_{d1}/(i_{d2} - i_{d1})$, where i_{d1} and i_{d2} are limiting current densities of ClO⁻ and ClO₂⁻ at the same concentration. The value of $i_{d1}/(i_{d2} - i_{d1})$ calculated from the value of limiting current density on the anodic polarization curves of 0.25M NaClO and 0.25M NaClO₂ at 1.20V (Fig. 4) was found to be ca. 0.12. Correcting for the O₂ evolution reaction during ClO⁻ oxidation by taking the value of i_{d1} at 1.20V on the anodic polarization curve of 0.25M NaClO + 1.0M NaOH and subtracting the value of the current density at zero ClO⁻ concentration from that at 0.25M NaClO

¹The notations h_{713} and h_{786} mean the height of the band at 713 cm⁻¹ (ClO⁻) and 786 cm⁻¹ (ClO₂⁻).

²The electrochemical oxidation of ClO⁻ and ClO₂⁻ in an alkaline solution are as

Fig. 8. Relationship between time and intensity ratio (786 to 713 cm⁻¹) in the mixed solution of NaClO₂ and NaClO. Initial concentration ratios ($C_{\text{NaClO}_2}^{\circ}/C_{\text{NaClO}}^{\circ} = M^{\circ}$). Curves a and e: $M^{\circ} = 0.51$. Curves b and f: $M^{\circ} = 0.33$. Curve c (no NaClO₂ added): $M^{\circ} = 0.08$. Curve d (no NaClO₂ added): $M^{\circ} = 0.06$. Curves a, b, c, and d: electrolyzed at 1.20V vs. Hg/HgO, 1.0M NaOH and 30°C. Curves e and f: without electrolysis.

(in Fig. 7), the value of $i_{a1}/(i_{a2} - i_{a1})$ was estimated at ca. 0.08. This value was in good agreement with the value of concentration ratio of ClO_2^- to ClO^- obtained from Raman intensity data. Curves e and f in Fig. 8 show the variation of the Raman intensity ratios of h_{786}/h_{713} with time at 30°C without electrolysis. Since the degree of the decrement of the Raman intensity ratios was obviously different from the results in curves a and b, the reaction of Eq. [6] did not interfere during the present electrochemical studies.

From these results, it is suggested that the anodic oxidation of ClO^- proceeds under the consecutive first-order reaction $\text{ClO}^- \rightarrow \text{ClO}_2^- \rightarrow \text{ClO}_3^-$.

ABSTRACT

Experimental conditions are discussed for the thermal growth of iron oxide photoanodes which promote $\alpha\text{-Fe}_2\text{O}_3$ formation. The photoelectrochemical (PEC) performance of iron oxide electrodes is compared as a function of surface modification procedure. Platinum was found to be an effective electrocatalyst when incorporated into the bulk of the thermally grown iron oxide during the latter's preparation. This procedure was found to increase the carrier density and to give a more negative flatband potential.

Photoanodes based upon iron oxide are potentially useful materials for the photodecomposition of alkaline aqueous solutions into hydrogen and oxygen (1-3). The nominal bandgap for $\alpha\text{-Fe}_2\text{O}_3$ of ≈ 2.2 eV allows, in principle, utilization of up to 40% of the incident solar radiation for the generation of excited carriers. Iron oxides are also relatively inexpensive and possess good stability in alkaline electrolytes. These materials do, in general, have low quantum yields (e.g., single crystals of $\alpha\text{-Fe}_2\text{O}_3$ at high anodic polarization only exhibit quantum yields of 20%) (4), and have poorly positioned flatband potentials relative to that desirable for hydrogen evolution in the absence of an externally applied bias (4-6). However, when n- and p-doped iron oxides are used to form the corresponding photochemical diode particle, the resulting two-photon process may eliminate the need for an externally applied bias. For such particles, the photogeneration of hydrogen and oxygen was achieved in the absence of an external bias (2).

The photoelectrochemical (PEC) characteristics of iron oxide photoanodes have been found to be highly dependent upon the method used for their preparation. Such preparation techniques have included spray pyrolysis of a methanolic solution of ferric oxalate (7), chemical vapor deposition of iron acetylacetonate (1), anodization of a previously reduced iron electrode (5), thermal oxidation (5, 8-10), and sintering of pressed $\alpha\text{-Fe}_2\text{O}_3$ powders (2, 3, 6, 10, 11). The majority of the literature dealing with iron ox-

ide photoelectrodes has involved the use of the latter two preparation methods. Although the thermal growth of oxides on iron has systematically been investigated in connection with the problem of corrosion (12-23), use of this information in the preparation of $\alpha\text{-Fe}_2\text{O}_3$ photoanodes has been overlooked.

Results presented in the corrosion literature relating to the thermal growth of iron oxides on iron substrates has shown that the formation of a single iron oxide phase may be somewhat difficult to obtain (12-23). From the iron-oxygen phase diagram (12, 17), three oxide phases are present: FeO (wustite), Fe_3O_4 (magnetite), and $\alpha\text{-Fe}_2\text{O}_3$ (hematite), with the FeO phase being thermodynamically unstable below 570°C. For iron heated in the atmosphere below 570°C, oxide growth typically consists of inner Fe_3O_4 and outer $\alpha\text{-Fe}_2\text{O}_3$ layers. Hence, it can be concluded that PEC measurements made on " $\alpha\text{-Fe}_2\text{O}_3$ " are undoubtedly being performed on mixed iron oxides. Since $\alpha\text{-Fe}_2\text{O}_3$ is the photoactive component in such iron oxides, there would be a strong incentive to delineate preparative procedures which maximize its presence. An extensive investigation has been performed on the dependency of thermally grown iron oxide composition on various experimental oxidation parameters and will be discussed in a future paper.

In addition to identifying reproducible methods for the preparation of $\alpha\text{-Fe}_2\text{O}_3$ electrodes, their modification with electrocatalysts was also investigated as an approach to improving PEC performance. Previous work has shown that both Pd (24) and Pt (25) can increase photocurrents realized from $\alpha\text{-Fe}_2\text{O}_3$ electrodes.

We wish to report here on PEC performance characteristics for thermally grown α -Fe₂O₃ photoanodes both with and without photoelectrocatalytic effects from platinum introduced during the growth procedure.

Experimental

Iron foil (0.25 mm thick) (Alfa 99.999%) was used for photoanode preparation. Samples were furnace oxidized in an atmosphere of ultrapure oxygen, which was slowly passed (≈ 25 cm³/min) through an appropriate bubbler to maintain a positive pressure of oxygen inside the alumina furnace tube. Most samples were brought to temperature under high purity argon or helium before the introduction of oxygen. The oxygen atmosphere was maintained during cool-down as well. Although several procedures were followed for the preparation of iron oxide, the greatest photocurrents (and thickest α -Fe₂O₃ layer) were obtained on those samples initially reduced under hydrogen at 600°C for 1/2h. Following this, the general oxidation procedures discussed above were followed.

Current-potential curves were recorded with and without illumination. The most frequently used voltage scan rate was 10 mV/s, which was expected to give current densities differing only slightly from steady-state values. Curves were also recorded under manually chopped illumination to detect transient currents, which have been frequently observed with iron oxide photoanodes. A single-compartment cell was used for all measurements, using a platinum foil counterelectrode and a SCE reference electrode connected via a saturated KCl/agar salt bridge. Illumination of the photoanodes was provided by a General Electric ELH quartz-halogen lamp with light intensity being measured with an Eppley 8-48 pyranometer. Current-voltage measurements were made at light intensities between 0 and 300 mW/cm² using a Stonehart BC 1200 potentiostat connected to a Linear Instruments 8036 X-Y recorder. A Commodore 64 PC interfaced to a HP 7470A plotter was used to reduce the light intensity/exchange current density data. Exchange current densities were obtained from the linear portion of the Tafel plot. Capacitance data for Mott-Schottky plots were obtained at 1000 and 10,000 Hz in 6N KOH electrolyte in a three-electrode cell using a platinum counterelectrode and a SCE reference electrode. A HP-4276A LCZ meter was used to apply a dc bias and to measure the resistance and the phase angle (θ). $1/C$ was then calculated from the relationship: $\theta = \tan^{-1} 1/\omega RC$.

The oxidized iron foil samples were analyzed by reflective powder x-ray diffraction (XRD) using a Phillips vertical powder x-ray diffractometer. The diffraction patterns were matched to ASTM file spectra as well as to spectra obtained from standards.

A cathodic stripping method was used to quantitatively determine the amount of α -Fe₂O₃ present in the thermally grown thin oxide layers. Fe₂O₃ is the most easily reduced Fe oxide, and the application of a cathodic current to an Fe oxide electrode causes the following dissolution reaction to occur

As current is passed, the electrode potential *vs.* a reference is maintained roughly constant until the Fe₂O₃ is consumed, at which time the potential rises to a value required to carry out the next most favorable reduction. This is similar to battery charge/discharge curves, where a potential plateau is generated which specifies the amount of charge utilized in carrying out a given reaction. In this case, the charge passed can then be related to the amount of Fe₂O₃ in the electrode via Eq. [1]

Experimentally, a 50 μ A constant cathodic current was applied to the 0.25 cm² Fe oxide electrodes using either a PAR 173 potentiostat/galvanostat on a Stonehart BC-1200 potentiostat/galvanostat. The iron oxide electrode's potential *vs.* SCE was then monitored as a function of time. The stripping was performed in a single-compartment cell with a Pt counterelectrode, and the cell was thoroughly deaerated with high purity Ar to eliminate the

possibility of the reduction of any dissolved O₂. 0.1M NH₄Cl was used as the electrolyte. The presence of Fe²⁺ was identified by the formation of a bright red complex with 1,10-phenanthroline.

Results and Discussion

From PEC current-voltage curves for α -Fe₂O₃ prepared by thermal oxidation at temperatures between 300° and 800°C under oxygen, it was found that experimental conditions conducive to optimizing α -Fe₂O₃ content required (i) oxidation of iron substrates below 570°C so as to avoid FeO formation, (ii) the maintenance of a high oxygen partial pressure, and (iii) the initial reductive (H₂) pretreatment of the iron substrate prior to its oxidation.

The largest photocurrents were obtained by initially reducing iron substrates under hydrogen at 600°C for 30 min followed by a helium flush prior to the introduction of pure oxygen. Substrate oxidation was typically performed over 6h at 500°C. Somewhat smaller photocurrents were obtained when the hydrogen pretreatment step was omitted (Table I). The growth of the α -Fe₂O₃ layer and the corresponding measured photocurrents correlated well with oxidation time. The samples pretreated with hydrogen and later oxidized for 3h gave higher photocurrents than samples oxidized for 8h with no pretreatment. Thus an increase in the amount of α -Fe₂O₃ (as shown by both the intensity of the α -Fe₂O₃ peaks in the XRD spectra and by cathodic stripping data) (Table II) leads to an increase in the PEC performance of the α -Fe₂O₃ electrodes prepared by controlled thermal oxidation.

Comparison of PEC characteristics for these photoelectrodes with the procedures used for their preparation was performed at three applied anodic potentials, *i.e.*, -300, 0, and +300 mV *vs.* SCE. These results are summarized in Table I. At the slow scan rates used, the light and dark

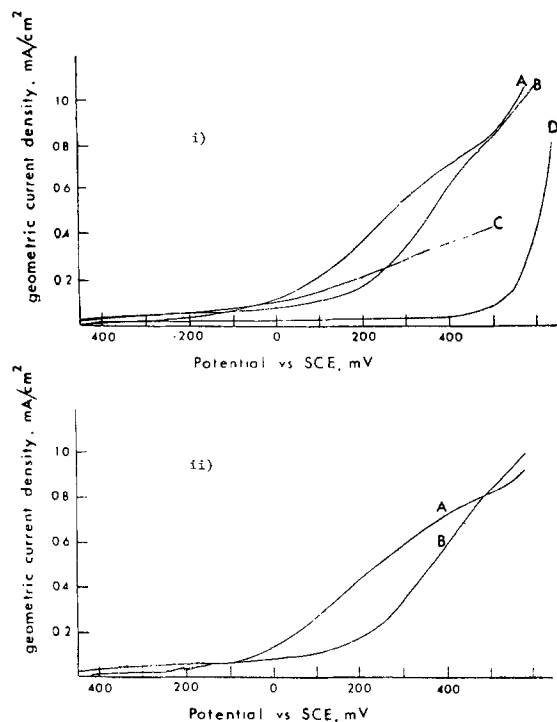

Fig. 1. Comparison of photocurrent-voltage curves for iron oxide photoanodes using various preparation procedures. Electrolyte: 1.0M KOH. Illumination ELH intensity: 100 mW/cm^2 . Scan rate: 10 mV/s . Geometric electrode area: 0.25 cm^2 . i: Furnace oxidized iron foil heated at 500°C for 8h (curve A), 3h (curve B), and 1h (curve C).

current densities were assumed to be steady-state values. A summary of current-voltage curves for iron oxides prepared following varying procedures is shown in Fig. 1.

Figure 1, part i shows the effect of increased oxidation time at 500°C on the photoresponse of the resulting iron oxides. As can be seen, extended oxidation times always gave an improved photoresponse corresponding to the increased presence of $\alpha\text{-Fe}_2\text{O}_3$. The largest photoresponses were observed from iron substrates which were initially reduced under hydrogen prior to furnace oxidation. Comparisons of photoresponse data obtained from an oxidized iron electrode both with and without this initial reduction treatment are shown in Fig. 1, part ii, curves A and B, respectively. The electrode subjected to initial reduction possessed approximately twice the photocurrent density at 200 mV vs. SCE than did the untreated substrate. XRD data indicated a particularly well-defined $\alpha\text{-Fe}_2\text{O}_3$ layer in the former sample. It thus appears that initial surface reduction of the iron substrate with hydrogen enhances the later growth of $\alpha\text{-Fe}_2\text{O}_3$, giving improved PEC performance.

From previously reported literature, flatband potential (3, 4, 26) measurements on $\alpha\text{-Fe}_2\text{O}_3$ photocurrents might be anticipated for electrode potentials up to -300 mV vs. SCE . But, as Table I shows, negligible values were observed in this potential region for all samples prepared. Thermally oxidized iron foils have shown the need for larger bias voltages to attain significant photocurrents when compared to sintered samples (5, 9, 10, 27).

For photoanodes subjected to chopped illumination, significant transient currents were observed. Figure 2 demonstrates this typical behavior for an iron substrate electrode oxidized for 8h at 500°C . Such current transients seem to be a common feature of thermally grown iron oxide films (5, 9, 10). These transients have been attributed to either recombination or cathodic back-reaction of the photogenerated species (10). If the observed transients are due to a cathodic back-reaction and the kinetics of the cathodic back-reaction could be reduced, improvement in overall PEC performance might be realized.

Another explanation for these transient signals is that the thermally grown oxides consist of a mixture of two or more oxides. Fe_3O_4 is reported to be a p-type semicon-

Fig. 2. Plot of exchange current density vs. light intensity for $\alpha\text{-Fe}_2\text{O}_3$ (squares) and platinum-modified $\alpha\text{-Fe}_2\text{O}_3$ (circles) in 6N KOH.

ductor (18, 21), and in all the oxide films investigated it was present along with $\alpha\text{-Fe}_2\text{O}_3$. Therefore, p-n junctions between Fe_3O_4 and $\alpha\text{-Fe}_2\text{O}_3$ may be present. Photo-produced electrons in the $\alpha\text{-Fe}_2\text{O}_3$ that are transferred to a Fe_3O_4 interface may cause an increase in the p-n potential barrier. Thus, the anodic transient currents observed may be sufficient to charge the p-n barrier before a significant photocurrent is obtained under steady illumination. Upon removal of illumination, the cathodic transients observed may be a result of discharging the potential barrier generated under illumination. It is significant that sintered $\alpha\text{-Fe}_2\text{O}_3$ photoanodes, where Fe_3O_4 is absent (1, 10), do not possess current transients proportional to light intensity as observed with thermally grown materials (10).

It has been previously shown that the presence of electrocatalysts of the platinum group metals can significantly improve the PEC performance of III-V photoelectrodes (28, 29). Surface modification of $\alpha\text{-Fe}_2\text{O}_3$ with palladium (24) or platinum (25) has also led to improvements in photoanode performance. In work performed here, the electrochemical deposition of platinum onto an iron substrate prior to the subsequent formation of $\alpha\text{-Fe}_2\text{O}_3$ was found to reduce these transient cathodic currents. Here electrode preparation involved the initial electrochemical deposition of $\approx 100\text{\AA}$ platinum from a 0.1M chloroplatinic acid solution followed by thermal oxidation. As previously discussed, the influence of incorporating platinum in this manner can be seen by reference to the current voltage curves in Fig. 3A and 3B for modified and unmodified electrodes, respectively.

To gain some insight into the electrocatalytic effect of platinum incorporated into the bulk of thermally grown iron oxide electrodes, current-voltage curves were obtained in 6N KOH. Figure 4 shows Tafel plots for $\alpha\text{-Fe}_2\text{O}_3$ (curve a) in the dark and (curve b) under 100 mW/cm^2 illumination. Under illumination, the equilibrium potential was shifted -70 mV cathodic of that in the dark. The electrode was initially potentiostated in the region of its illuminated open-circuit potential. The electrode potential was then adjusted until no current passed.

The hole exchange current densities are summarized in Table III and are shown in Fig. 5. For photoanodes

Fig. 3. A: Current-voltage curve for Fe_2O_3 flag in 6N KOH. B: Current-voltage curve for Fe_2O_3 with platinum in 6N KOH. (Platinum deposited on iron foil prior to oxidation.)

modified by platinum, larger hole exchange current densities were found. For both of these electrodes, a linear relationship was observed between light intensity and hole exchange currents. For photoanodes, the relationship between the hole exchange current density and corresponding overpotential is given by relationship [2] (30)

$$i_p = i_{p0} \left[\frac{p_s^*}{p_s} \exp\left(\frac{\alpha_v \rho_e \eta}{kT}\right) - \exp\left(-\frac{\alpha_v \rho_e \eta}{kT}\right) \right] \quad [2]$$

where i_{p0} is the valence-band exchange current, and ρ_s^* and ρ_s are the hole concentrations at the surface of the semiconductor at equilibrium and nonequilibrium, respectively.

Fig. 4. Mott-Schottky plot for (curve a) iron oxide photoanode prepared by initially depositing 200Å Pt onto Fe substrate followed by furnace oxidation at 500°C for 6h under oxygen and (curve b) iron oxide photoanode prepared by furnace oxidation of iron substrate at 500°C for 6h under oxygen without platinum pretreatment.

Table III. Exchange current densities as a function of light intensity for $\alpha\text{-Fe}_2\text{O}_3$ and platinum-modified $\alpha\text{-Fe}_2\text{O}_3$ electrodes

Electrode	Intensity (mW/cm ²)	i_0 (μA/cm ²)
$\alpha\text{-Fe}_2\text{O}_3$	0	0.313
	50	0.492
	100	0.663
	150	0.843
	200	—
Pt electrochemically deposited onto $\alpha\text{-Fe}_2\text{O}_3$	0	—
	50	1.12
	100	2.27
	150	3.2

Pt incorporated into $\alpha\text{-Fe}_2\text{O}_3$	0	3.42
	50	5.45
	100	8.15
	150	64.77
	200	44.96
	250	75.21

ρ is the IR overpotential associated with the electrolyte. From this relationship it is clear that an increase in the ratio ρ_s^*/ρ_s (via illumination) will result in an apparent increase in i_{p0} value. Thus, the linear relationship observed in Fig. 5 would be expected. The enhanced hole exchange currents seen for platinum-modified $\alpha\text{-Fe}_2\text{O}_3$ photoanodes are, therefore, expected to be due in part to the electrocatalytic effect of the incorporated platinum. It is not clear, however, why the slope of the hole exchange current line for the platinum-modified $\alpha\text{-Fe}_2\text{O}_3$ electrode is greater than that for the unmodified $\alpha\text{-Fe}_2\text{O}_3$ electrode. Thus, the question remains as to whether the role of the platinum introduced onto the iron oxide is mainly an electrocatalytic effect promoting the oxygen evolution reaction or whether such photoanode modifications also effect changes in their solid-state properties.

To gain some insight into this question, Mott-Schottky plots were performed on platinum-modified and unmodified $\alpha\text{-Fe}_2\text{O}_3$ electrodes. For platinum incorporated into the iron oxide lattice during the thermal growth procedure, it might be expected that the platinum would

Fig. 5. Plot of the hole exchange current density vs. light intensity for $\alpha\text{-Fe}_2\text{O}_3$ (squares) and platinum surface-modified $\alpha\text{-Fe}_2\text{O}_3$ (circles) in 6N KOH.

Fig. 6. Mott-Schottky plot for (curve A) iron oxide photoanode prepared by initially depositing 200Å Pt onto Fe substrate followed by furnace oxidation at 500°C for 6h under oxygen, and (curve B) iron oxide photoanode prepared by furnace oxidation of iron substrate at 500°C for 6h under oxygen without platinum pretreatment. Both electrodes measured at 1000 Hz in 6N KOH.

be in the +4 oxidation state. Under such circumstances, the number of carriers would be expected to increase. Mott-Schottky plots for the platinum-modified and -unmodified α -Fe₂O₃ photoanodes are compared in Fig. 6. Little frequency dispersion was observed for measurements taken between 100 and 10,000 Hz. In contrast to Mott-Schottky plots obtained by others (5, 11), the curves obtained here are linear over a relatively large voltage range and do not exhibit deviations ca. \approx 0.3V anodic of the flatband potential. It has been suggested that the observed curvature in polycrystalline α -Fe₂O₃ Mott-Schottky plots may be due to inhomogeneous doping concentration (2). It may be that, in the results discussed here, hydrogen pretreatment and subsequent controlled thermal oxidation may result in more homogeneous intrinsic doping, thus giving the observed linear Mott-Schottky plots.

Comparing the iron oxide-modified (Fig. 6A) and -unmodified (Fig. 6B) electrodes, we see an increase in the carrier density from 7.35×10^{16} to $7.59 \times 10^{17}/\text{cm}^2$ after incorporation of platinum. This is probably a consequence, as discussed earlier, of the Pt⁴⁺ acting as a donor when incorporated into a Fe⁺³ site. The flatband potential was also shifted to more negative values for platinum-modified electrodes. From current-voltage curves performed on this electrode, significantly higher exchange current densities were obtained (see Table III) than, for example, with iron oxide electrodes surface modified by the electrochemical deposition of platinum after thermal growth of the oxide. Of course, the predominant phenomenon here may still be electrocatalytic in nature, but certainly the incorporation of platinum within the bulk of the thermally grown iron oxide phase appears to give improved PEC performance over the surface-deposited catalyst.

Comparison of the α -Fe₂O₃ electrode current densities prepared by hydrogen pretreatment followed by controlled thermal oxidation under O₂ between 500° and 600°C with previous work by others is, however, somewhat difficult to achieve due to the disparity under which photocurrents are measured (i.e., different electrolytes, lack of light intensity data, noninclusion of current densities, etc.). However, Table IV compares photocur-

Table IV. Comparison of photocurrent densities for α -Fe₂O₃ photoanodes prepared under various conditions^a

Conditions	Photocurrent densities ($\mu\text{A}/\text{cm}^2$)
300°C/8h	100
500°C/1h	290
500°C/3h	450
500°C/8h	560
500°C/3h ^b	600
Flamed foils ^c	190

^a Experimental measurement of current densities were carried out in 1.0M KOH at 100 mW/cm² ELH intensity. Scan rate = 10 mV/s; electrode area = 0.25 cm².

^b Initial reduction under Hz at 600°C for 30 min prior to oxidation.

^c Foils were heated with a neutral gas/air torch until bright red for 5 min and then quenched in air.

rent densities for photoanodes prepared under various conditions during this work. From these results, it is clear that hydrogen pretreatment of the electrode at 600°C followed by oxidation at 500°C produces the highest current densities for thermally grown α -Fe₂O₃ electrodes. In addition, bulk modification of the thermally grown iron oxide with platinum during oxide growth seems to result in significant improvement in PEC performance. The incorporated platinum appears to act as a donor species, resulting in an increase in carrier density and a shift of the flatband potential to more negative values.

Raman Spectroscopy of Anodic Oxide Films on HgTe

Masao Sakashita,¹ Toshiaki Ohtsuka, and Norio Sato*

Faculty of Engineering, Hokkaido University, Sapporo, Japan

ABSTRACT

Laser Raman spectroscopic measurements of the anodic oxide film formed on HgTe in aqueous solutions reveal the characteristic Raman bands that appear at 422 and 684 cm^{-1} . These bands, which are different from those of crystalline HgTeO₃ and TeO₂ powders, may be attributed to a complex oxide of HgTe₂O₅ or an amorphous oxide of TeO₂ that might be formed in anodic oxidation. The heating effect on the anodic oxide film due to a focused laser beam is also discussed.

Surface passivation of compound semiconductors Cd_xHg_{1-x}Te (CMT) is of considerable importance in their utilization as photoconductive devices. One of the most common methods for surface passivation is anodic oxidation (1). In previous papers, the electrochemical reaction and the anodic oxide films of CMT and HgTe have been investigated by using x-ray photoelectron spectroscopy (XPS) and rotating ring-disk electrode (2-4). Furthermore, there have been a few papers dealing with composition of the anodic oxide (5-7). In recent years, laser Raman scattering spectroscopy has proved useful in studying the structure and composition of surface oxide films on metals. The Raman scattering spectra of bulk powder of HgTeO₃, CdTeO₃, and TeO₂ have been measured by Rhiger and Kvaas (8). In this work, a laser Raman backscattering technique is applied to the measurement of the anodic oxide films on HgTe.

Raman scattering measurements were made with a JASCO 800-T triple monochromator, and an Ar ion laser beam of 514.5 nm wavelength was used for excitation. All measurements were made in the backscattering geometry with an incidence angle of 70°. In order to minimize the effect of sample heating, a slightly defocused laser beam with an incidence power level of 25 mW was used for spectrum measurements. An attempt was, however, made to examine the heating effect on the spectra upon exposure of a focused beam with an incident power level of 50 mW.

The material studied was single crystal of HgTe with the surface of (100) plane. After electrochemical reduction of the mechanically polished surface, the material was anodically oxidized at a given electrode potential. The anodization was carried out in solution of sodium acetate-acetic acid, sodium borate-boric acid, and 0.1M KOH in 90% ethylene glycol-10% water. The procedure for cathodic reduction and anodic oxidation has been described in detail in a previous paper (2).

Figures 1 and 2 show the Raman scattering spectra of HgTe surfaces reduced at -0.6V vs. SHE (spectrum a) and oxidized at 3.0V (spectrum b) in a sodium acetate-acetic aqueous solution of pH 4.9. The thickness of the oxide film formed at 3.0V was found to be about 200 nm from electrochemical coulometric measurements. Spectrum a shows no characteristic bands, revealing that the reduced surface is free from any oxides and that HgTe is a weak scatterer for Raman effects. From spectrum b in Fig. 1 and 2, the Raman bands of the oxidized surface are found at the position of 422 and 684 cm^{-1} . These positions of the bands are not identical to those for TeO₂ shown in spectrum c. Furthermore, the characteristic band at 326 cm^{-1}

for HgO is not observed in spectrum b for the anodic oxide. The Raman bands at 422 and 684 cm^{-1} cannot be used to clearly identify the composition of the anodic oxide. It is, however, likely that the anodic oxide, which has previously been represented by TeO₂-0.5HgO (2), is not a mixture of TeO₂ and HgO, but is a complex oxide such as HgTe₂O₅. Such a complex oxide has been suggested from the results by XPS and ring-disk electrode measurements (2). One may also explain the Raman bands at 422 and 684 cm^{-1} to correspond to those of amorphous TeO₂, because the amorphous oxide may exhibit the Raman band different from that of the crystallized oxide.

The spectrum with the same Raman bands as those of spectrum b in Fig 1 and 2 was obtained for the anodic oxide films with the composition of TeO₂-0.7HgO formed in the sodium borate-boric acid aqueous solution of pH 8.4 and also for the film with the composition of TeO₂-1.0HgO formed in the basic ethylene glycol solution. It appears, therefore, that the Raman scattering spectrum is

Fig. 1. Raman spectra (10-240 cm^{-1}) for HgTe surfaces reduced at -0.6V vs. SHE (a) and oxidized at 3.0V (b) in pH 4.9, and for TeO₂ powder (c). The monochromator bandpass was 1.1 cm^{-1} . The peaks marked by asterisks are emission lines of Ar ion laser.

Fig. 2. Raman spectra (200-1000 cm^{-1}) for HgTe surfaces and TeO_2 powder. The monochromator bandpass was 4 cm^{-1} . Notation a, b, and c are those shown in Fig. 1.

incapable of distinguishing the composition difference in the anodic oxide films on HgTe. The characteristic positions of bands, however are markedly different from those reported for bulk powder of HgTeO_3 : 41, 59, 642, and 703 cm^{-1} (8). It is thus likely that the anodic oxide film on HgTe possesses a characteristic structure different from that of the thermally produced bulk oxide. Such a discrepancy of the Raman scattering spectrum was also observed between the oxide film on CdTe (9) and the bulk oxide CdTeO_3 (8).

Figure 3 shows the Raman scattering spectra of $\text{TeO}_2 \cdot 0.5\text{HgO}$ (or HgTe_2O_5) on HgTe measured after exposure of a focused laser beam of 50 mW. In addition to weak bands for the anodic oxide, the Raman scattering bands corresponding to TeO_2 are observed, indicating that TeO_2 is formed by the focused laser beam. This formation of TeO_2 may be represented by the following disproportionation reaction in analogy with the reaction between HgTeO_3 and HgTe

This thermal instability of HgTe_2O_5 and HgTeO_3 requires careful precaution in conducting the Raman spectroscopic studies of the oxide film on HgTe and CMT to eliminate the heating effects due to incident beam.

In summary, the characteristic Raman bands for the anodic oxide films on HgTe are found to be 68, 79, 422, and 684 cm^{-1} from determination by using a defocused laser beam with an incidence power level of 25 mW.

Fig. 3. Raman spectra of the anodic oxide on a HgTe surface after irradiation of a focused laser beam of 50 mW. Raman spectra were measured by using a defocused laser beam of 25 mW with the monochromator bandpass 1.1 cm^{-1} (a) and 4.0 cm^{-1} (b).

pH Measurements of High Temperature Aqueous Environments with Stabilized-Zirconia Membranes

S. Hettiarachchi,¹ P. Kedzierzawski,² and D. D. Macdonald*¹

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

A pH sensor has been developed for precise pH measurements of high temperature aqueous solutions based on a yttria-stabilized zirconia (9% Y_2O_3) membrane electrode with a Hg/HgO solid-state internal element. In these investigations, the use of calculated pH values in evaluating the performance of the sensor has been eliminated. The excellent one-to-one correlation obtained between the potential of the sensor and a hydrogen reference electrode measured against a Ag/AgCl, 0.1M KCl reference electrode confirms that the pH sensor behaves in a Nernstian manner. The sensor is capable of withstanding high temperatures and pressures and is unaffected by hydrogen and oxygen gases and chloride ion concentration. The electrode remains stable over long periods of time, thus showing its potential use in monitoring the pH of waters in nuclear reactors, geothermal brines, and other high temperature aqueous systems.

A considerable amount of research has been carried out during the past decade to develop electrodes to measure the pH ($= -\log a_{H^+}$) of high temperature aqueous systems (1-12). The failure of the glass electrode to operate at temperatures as high as 250°-300°C necessitated the development of pH sensors for use at elevated temperatures. Such a sensor, if developed, would have a tremendous practical impact in its applications, particularly in geothermal brines and nuclear and fossil-fueled power reactors.

Recently, Niedrach (13, 14) and Macdonald and Tsuruta (15) described the use of a yttria-stabilized zirconia (YSZ) membrane for the measurement of pH of aqueous solutions at temperatures as high as 300°C. In these studies, membrane electrodes with both aqueous and Cu/Cu₂O internal reference elements have been used. These membrane electrodes have been found to exhibit a Nernstian pH response at elevated temperatures, and appear to be ideally suited for the measurement of the pH of a wide variety of systems, including those containing other redox and/or easily reduced species.

Although the preliminary studies demonstrated the potential use of YSZ membranes as pH sensors, their apparent lack of high precision as demanded by many research and control applications of high temperature technology led us to investigate the possible use of Ag/Ag₂O and Hg/HgO as internal references in addition to Cu/Cu₂O. We have also attempted to eliminate the use of calculated pH values based on dissociation constant data to evaluate the performance of these membrane electrodes. In order to achieve this second objective, the potential of the sensor and the potential of a hydrogen reference electrode were measured against an external pressure balanced Ag/AgCl, 0.1M KCl reference electrode (RE) in systems containing known amounts of dissolved hydrogen. The one-to-one correlation obtained between these measurements (16) proves that the zirconia 9% Y_2O_3 pH sensors constructed by us follow a Nernstian behavior, as does the hydrogen electrode with respect to the hydrogen ion activity.

Experimental

Electrode system.—The electrode system (15) used in these studies consists of an external pressure-balanced Ag/AgCl, 0.1M KCl RE (17) a bright platinum electrode, and a pH-sensitive ZrO₂ (9% Y_2O_3) membrane electrode, all fitted to the autoclave containing the buffer solution. The solution was saturated with H₂ gas at 25°C before its entry into the autoclave. Thus the platinum electrode in equilibrium with H₂ served as an internal hydrogen electrode. A bright platinum electrode was used in these stud-

ies instead of a platinum black electrode because they both gave the same potential response with respect to RE.

The upper part of the reference electrode, where the Ag/AgCl active element is located, was cooled by air in order to avoid the thermal degradation of AgCl.

The zirconia membrane electrodes were constructed by filling about 1 in. of the zirconia tube (4 in. long, 1/4 in. od, and 5/32 in. id) with a metal/metal oxide mixture (Cu/Cu₂O, Ag/Ag₂O, or Hg/HgO). This acted as the internal reference junction of the sensor. A mild steel conducting wire embedded in this mixture served as the contact lead from the sensor. The upper part of the sensor was sealed with a Teflon insert and the sensor electrode was then introduced into a tightly fitting Teflon tube, leaving the bottom 1 in. of the sensor (active region) exposed. The sensor was then fitted to a Conax Type EG-125 Gland with a Teflon seal, followed by a steel ferrule. Care was taken to isolate the sensor from the Conax Gland to prevent any form of shunting.

A schematic of the autoclave test cell used in these studies appears elsewhere (15).

Test solutions.—Test solutions were prepared by mixing various amounts of boric acid and lithium hydroxide solutions of varying concentrations. Experiments were also performed with 0.01M H₃PO₄, 5×10^{-3} M and 5×10^{-4} M H₂SO₄, and 0.01M H₃PO₄ + 0.001M NaOH. Doubly distilled water and reagent-grade chemicals were used for the preparation of all solutions.

Before each test run, deaeration was accomplished by purging the solution in the reservoir with purified nitrogen gas for 2h. In experiments where a platinum electrode was used as a hydrogen reference, purified hydrogen gas was used for deaeration of the solution instead of nitrogen.

Experimental procedure.—All potentials were measured using a Keithley 614 electrometer having an input impedance of $5 \times 10^{13}\Omega$. Measurements were made on both the pH sensor electrode and the hydrogen electrode with respect to the same RE. Measured potentials were corrected for isothermal liquid junction potentials using the Planck-Henderson theory (18), and the data reported by Macdonald *et al.* (1). The correction terms varied between -5 and +25 mV. No corrections were made for the thermal diffusion potentials at this stage as this would not alter the slopes of the experimental plots reported in this paper.

Experiments were performed in the temperature range 125°-275°C at 25°C intervals. At each temperature, the potential was allowed to attain a stable value to within ± 2 mV at temperatures $>175^\circ\text{C}$ and ± 3 mV at temperatures $<175^\circ\text{C}$ about a mean value. At higher temperatures ($>175^\circ\text{C}$), this required less than a minute while at lower temperatures the stability was achieved within 5 min.

Since the system was found to be sensitive to static charge, all measuring cables and electrode assemblies were placed in a Faraday cage.

Results and Discussion

Figures 1 and 2 illustrate two of the typical potential pH (calculated) variations observed for sensors measured against RE for temperatures from 125° to 275°C. The calculated pH values used in these experiments were obtained from both published (1, 19) and unpublished data (20). It must be noted that these values have been calculated using dissociation constants for acids and bases and the mean activity coefficients for various ions (1, 5, 19-22).

The pH sensors used in the present studies contained either Ag/Ag₂O or Hg/HgO as internal references. Sensors with the Cu/Cu₂O internal reference showed irreproducible results. This is attributed to the poor electrical contact obtained with this mixture, as well as to the relative instability of Cu₂O when compared with Ag₂O and HgO. The stability of the Cu/Cu₂O and the Ag/Ag₂O mixtures was tested by using them as internal references inside the membranes under experimental conditions for ten test runs, and thereafter examining the resulting mixtures by x-ray diffraction and comparing these data with the x-ray diffraction data of Cu/Cu₂O and Ag/Ag₂O mixtures heated in a furnace at 275°C for 12h. These studies confirmed that Cu₂O underwent gradual thermal oxidation to CuO inside the membrane, while Ag₂O underwent gradual thermal decomposition to Ag. Hence, even though the sensors with Ag/Ag₂O internals performed well, all studies reported in this paper, unless otherwise stated, were conducted with sensors having Hg/HgO internal reference electrodes, because of the thermodynamic stability of HgO at temperatures below 500°C (23).

As is clearly seen from Fig. 1 and 2, the largest scatter in the results was observed in weakly acidic solutions (pH = 2.5-5.5): namely, for 5 × 10⁻⁴M H₂SO₄, 0.01M H₃PO₄, and 0.01M H₃PO₄ + 0.001M NaOH. It must be emphasized that, for these solutions, the available thermodynamic data are not sufficient to estimate their pH values to an accuracy better than ±0.5 of a pH unit. Even in the case of the LiOH-B(OH)₃ systems, recent work (1) indicates that the calculated pH values at elevated temperatures may also be in error due to uncertainties in the dissociation constant for boric acid. The 5 × 10⁻⁴M H₂SO₄ solution, in turn, suffers from the disadvantage that, being a poor buffer, corrosion processes occurring inside the autoclave could offset the pH of the system considerably. These two

Fig. 2. Variation of E_{sensor} with calculated pH at 275°C. Triangles: Ag/Ag₂O internal. Circles: Hg/HgO internal.

reasons possibly explain the observed deviation from the linear behavior in the $E_{\text{sensor}}/\text{pH}$ (calculated) diagrams for the above solutions.

The experimental slopes of the $E_{\text{sensor}}/\text{pH}$ plots over the temperature range 125°-275°C, calculated by linear regression analysis, are listed in Table I together with the theoretical values ($-2.303RT/F$). The linearity of this variation was established by the near-unity regression coefficients obtained. The experimental slopes with the Hg/HgO internal reference deviate from the theoretical slopes by about 11% at lower temperatures (e. g., 125°C), and gradually decrease to less than 5% at higher temperatures (e.g., > 225°C), the theoretical slopes being always greater than the experimental slopes.

The scatter observed in the $E_{\text{sensor}}/\text{pH}$ plots (Fig. 1 and 2) and the observed deviation in the experimental slopes of these plots are attributed to the uncertainty of the calculated pH values, rather than to the nature and the performance of the electrodes.

In order to test this hypothesis and to avoid uncertainties associated with the calculated pH values, experiments were repeated in which the potential of the sensor and the potential of an internal hydrogen reference electrode (H₂, Pt/H⁺_{ac}) were simultaneously monitored with respect to Ag/AgCl, 0.1M KCl RE. When these potential values were plotted one against the other, an excellent one-to-one correlation over the temperature range 125°-275°C was obtained. Figure 3 illustrates an example of

200	- 94	- 87.4	- 87.0
225	- 99	- 95.8	- 94.0
250	-104	- 97.4	-100.4
275	-109	-102.7	-107.9

Fig. 3. A typical example of a one-to-one correlation observed between the hydrogen electrode potential (E_H) and E_{sensor} at 250°C along with the actual pH of the system.

such a typical plot at 250°C. The one-to-one correlation obtained, resulting in a regression coefficient of almost unity (Table II), proves that the pH sensor behaves in a Nernstian manner, as does the hydrogen electrode with respect to hydrogen ion activity, thus enabling us to estimate the pH of high temperature aqueous solutions to an accuracy of ± 0.02 of a pH unit. Furthermore these findings also show that the lack of such accuracy apparent in Fig. 1 and 2 and Table I, is not due to a fault of the pH sensor, but can be traced to uncertainty in the calculated pH values of the buffer solutions used for the calibration.

In the present study, the pH value is evaluated using the internal reference hydrogen electrode potential in the following manner. For the hydrogen electrode, the electrode reaction is

The Nernst equation for this reaction can be written as

$$E_T = E_T^0 - \frac{2.303RT}{2F} \log P_{\text{H}_2, T} - \frac{2.303RT}{F} \text{pH}_T \quad [2]$$

where the subscript T refers to the temperature.

At 25°C, if the dissolved H_2 concentration in water is m mol-kg $^{-1}$, then, according to Henry's law, the effective partial pressure of H_2 is

Table II. Slopes of the plots of E_{sensor} vs. Ag/AgCl, 0.1M KCl against Pt, $\text{H}_2/\text{H}_{\text{aq}}^+$ vs. Ag/AgCl, 0.1M KCl

Temperature (°C)	Slope	γ^2
125	1.004	0.9984
150	0.983	0.9981
175	1.018	0.9993
200	1.012	0.9990
225	1.002	0.9999
250	1.002	0.9985
275	0.997	0.9997

N.B.: γ^2 is the regression coefficient.

$$P_{\text{H}_2, T} = m/K_T \quad [3]$$

where K_T is the Henry's law constant for H_2 at temperature T . Since the partial pressure of H_2 corrected for the vapor pressure of water at 25°C is 0.97 atm, from Eq. [3]

$$m = 0.97K_{25} \quad [4]$$

Thus from Eq. [3] and [4], the partial pressure of H_2 at any other temperature T is

$$P_{\text{H}_2, T} = 0.97K_{25}/K_T \quad [5]$$

From Eq. [2] and [5]

$$E_T = E_T^0 - \frac{2.303RT}{2F} \log [0.97K_{25}/K_T] - \frac{2.303RT}{F} \text{pH}_T \quad [6]$$

The potentials have been measured with respect to Ag/AgCl, 0.1M KCl, at elevated temperatures. Thus, a correction has to be carried out to convert the observed potential values (E_{obs}) to hydrogen scale (E_{SHE}) incorporating a correction for thermal junction potentials. These correction factors for various temperatures appear elsewhere (1). Thus

$$E_T = E_{\text{SHE}} = (E_{\text{obs}} + E_{\text{correct}}) \quad [7]$$

The term E_{correct} contains the thermal junction potential correction, while the term E_{obs} has been corrected for the isothermal liquid junction potential according to the procedure outlined in Ref. (1) and (18). The Eq. [6] now yields

$$\text{pH}_T = -\frac{F}{2.303RT} \cdot E_{\text{SHE}} - \frac{1}{2} \log (0.97K_{25}/K_T) \quad [8]$$

which can be used to calculate the pH at any temperature, knowing E_{SHE} and Henry's law constant for the hydrogen/water system at the required temperature (22). These pH values have been used to calibrate the pH sensor at various temperatures as appearing in Fig. 3, thus enabling a completely unambiguous measurement of pH by using an approach which has hitherto not been published elsewhere. The actual pH values thus evaluated for solution systems used in the present study are listed in Table III for temperatures up to 275°C.

The ability to measure pH to an accuracy of ± 0.02 of a pH unit in aqueous systems at elevated temperatures opens up a whole new area of solution chemistry, since we are now in a position to study hydrolysis reactions and activity coefficients of ions more accurately at these temperatures.

The influence of oxygen and hydrogen on the electrode potential of the sensor was investigated by either purging air or hydrogen, respectively, through the solution, and then monitoring the potential with respect to the Ag/AgCl, 0.1M KCl electrode. The results showed no influence of oxygen or hydrogen gases on the sensor potentials. Similarly, the pressure of the system showed no influence on the electrode potential of the sensor over the pressure range 200-1000 psi.

Figure 4 depicts the influence of chloride ion and its concentration on the sensor potential in 0.01M B(OH) $_3$ + 0.001M LiOH at 200°C. This was examined by introducing a known amount of NaCl into the solution tank. It is evi-

dent from Fig. 4 that the chloride ion has very little effect on the sensor potential at these concentrations. We attribute the general negative shift in potential to the increasing pH of the system due to the consumption of hydrogen ions by the all-metal loop. A similar shift is also evident in long-term stability tests, as shown in Fig. 5. Subsequent experiments with these membranes confirmed that their pH response is not affected by chloride ion concentrations up to 12 weight percent Cl^- and sulfide ion concentrations up to 780 ppm S^{2-} (24).

The results of long-term stability tests for three sensors with an Hg/HgO internal reference, performed in $0.01M LiOH$ solution at $200^\circ C$, are shown in Fig. 5. A gradual decrease of the potential of the sensor by 7-12 mV from the initial value occurs over a period of 27h. From Fig. 5, it is clearly seen that the electrodes show good reproducibility, in that the potentials obtained for each electrode did not deviate by more than ± 5 mV about a mean value. Thus, the small drift observed in these tests most likely arises from changes in the pH of the test solution stemming from the consumption of hydrogen ions by corrosion processes involving the all-metal loop and the random electrical noise pickup at these high impedances.

We previously surmised that the somewhat sluggish response exhibited by some membranes at low tempera-

Table IV. Electrical resistance of the exposed area of the $ZrO_2-9\% Y_2O_3$ membrane at various temperatures with Ag/Ag₂O and Hg/HgO internal elements

Temperature ($^\circ C$)	Electrical resistance ($M\Omega$)	
	Ag/Ag ₂ O	Hg/HgO
125	44.90	61.90
150	9.90	11.30
175	2.50	—
200	0.70	0.75
225	0.23	0.24
250	0.10	0.088

tures ($<150^\circ C$) might be due to their very high electrical resistance. For example, silica is sometimes added to the $ZrO_2-Y_2O_3$ mixture to "improve sinterability." It appears that this additive aids bonding by forming a glassy phase of very high electrical resistivity at the grain surfaces, thereby giving rise to very high matrix electrical resistance. If this hypothesis is correct, then a correlation should exist between the response of a membrane and its electrical properties, as reflected by the dc resistance.

The electrical resistance of the membrane was evaluated by measuring the EMF of the cell consisting of the sensor and the Ag/AgCl, $0.1M KCl$ electrode with and without a shunt connected across them. The resistance of the membrane wall was calculated according to the procedure outline by Niedrach (13). These results (Table IV) show that, with the Hg/HgO internal reference, the membrane resistance decreased from 61.9 $M\Omega$ at $125^\circ C$ to 0.088 $M\Omega$ at $250^\circ C$, thus showing that the membrane resistance is strongly temperature dependent. It is likely that the membrane is undergoing a reversible modification (change) during heating and cooling cycles, which is responsible for these drastic changes in membrane resistance. This factor probably explains the sluggish behavior of the membranes at lower temperatures (e.g., $T \leq 150^\circ C$), which disappears at higher temperatures owing to the high conductivity, that imparts a greater stability on the membrane potentials.

The membrane resistance data, plotted as the logarithm of specific conductivity (σ) of the membrane vs. the inverse of the absolute temperature, showed a linear re-

Fig. 6. Arrhenius plots for the specific conductivity (σ) of pH sensors with Ag/Ag₂O and Hg/HgO internal reference electrodes.

sponse with both Ag/Ag₂O and Hg/HgO internal references, as shown in Fig. 6. The activation energies of 20.7 kcal·mol⁻¹ with the Ag/Ag₂O internal, and 21.7 kcal·mol⁻¹ with the Hg/HgO internal, obtained from the above plot are in excellent agreement with those reported in the literature (25). These higher activation energies show that the sensors, in fact, behave as true membranes.

Conclusions

1. The yttria-stabilized zirconia membranes (9% Y₂O₃) with the Hg/HgO internal reference electrode used in these studies behave in a nernstian manner. Hence, they can be used for pH measurements of high temperature aqueous solutions.

2. A unique method, which has hitherto not been published elsewhere, is outlined for evaluating the pH of high temperature aqueous solutions from the sensor response.

3. Oxygen and hydrogen gases, chloride ion concentration, sulfide ion concentration, and pressure of the system have no influence on the sensor potential, and hence on the measured pH.

4. Experiments show that these pH sensors are capable of withstanding high temperatures and pressures over long periods.

ABSTRACT

The influence of supporting electrolytes upon the "heterogeneous" electron-transfer rate of the $MV^{2+/+}$ redox couple ($MV^{2+/+}$ and MV^+ are the dication and monocation of viologen sites, respectively, in polymer coatings) as poly(methylviologen) (PMV), poly(methylviologen)-Nafion complex (PMV-Nafion), and poly(methylviologen)-poly(p-styrenesulfonate) complex (PMV-PSS), which were attached to basal-plane pyrolytic graphite electrodes, as well as upon the "homogeneous" charge-transport rate within these polymer films was examined by the normal pulse voltammetry. The values of standard rate constant (k^0) and cathodic transfer coefficient (α) of the heterogeneous electron-transfer process changed with the supporting electrolytes used. The values of the apparent diffusion coefficient (D_{app}) for the homogeneous charge transport also changed with the supporting electrolytes. The relationship between the size of the counterion and D_{app} was found not to be simple. The D_{app} , k^0 , and α tended to decrease, though not monotonously, with an increase in $\Gamma_{Nafion}/\Gamma_{MV^{2+}^{obs}}$ or $\Gamma_{PSS}/\Gamma_{MV^{2+}^{obs}}$, irrespective of the kind of supporting electrolyte, where $\Gamma_{MV^{2+}^{obs}}$, Γ_{Nafion} , and Γ_{PSS} are the concentration of the electroactive viologen site as PMV and the concentrations of the sulfonyl group as Nafion and PSS, respectively. For a given supporting electrolyte and under the conditions of the same ratio of $\Gamma_{Nafion}/\Gamma_{MV^{2+}^{obs}}$ and $\Gamma_{PSS}/\Gamma_{MV^{2+}^{obs}}$, the D_{app} , k^0 , and α obtained with the PMV-Nafion system were different from those obtained with the PMV-PSS system. Furthermore, a linear correlation between $\log D_{app}$ and $\log k^0$ was observed. On the basis of the results obtained, the influence of the supporting electrolytes and the polymer morphology upon the heterogeneous electron transfer and the homogeneous charge transport is discussed.

The "poly(viologen)"-coated electrodes prepared by the various types of immobilization of polymeric viologen materials on the surfaces of conductors and semiconductors have been getting considerable interest as electron-transfer mediators or catalysts (1-4), as promising electrochromic materials (5), as a potential means of solar energy conversion via the photoelectrochemical reduction of viologen itself (6, 7, 9-11), and as electrode materials for electrochemical deionization (8). The immobilization of polymeric viologen materials on electrodes can be achieved by the formation of insoluble films of the reduced viologen on electrodes (12-15), the formation of the intermolecular polymer complexes (e.g., Nafion®-poly(methylviologen) (PXV) and poly(p-styrenesulfonate) (PSS) (1, 2, 16), the incorporation of monomeric methylviologen into anionic polyelectrolytes (such as Nafion and PSS) coated on electrode surfaces (1, 2, 16, 17), the physical adsorption of viologen polymer itself (3, 4, 11, 16), the chemical bonding of polymeric films of organosilane derivatives by metal -O-Si- linkages to electrode surfaces (9, 10, 18), and the formation of polymeric viologens prepared by electropolymerization of monomeric viologen derivatives possessing vinyl groups (e.g., Vinyldiquat®) (19). From the previous data (3, 4, 16) concerning the "homogeneous" charge transport within the poly(viologen) coatings on electrodes in these various cases, it is obvious that the apparent diffusion coefficients (D_{app}) characterizing the charge transport, actually described as a diffusion process, are functions of the polymer, solvent, electrolyte, concentration of viologen site in coatings, the conditions of coating preparation, temperature, etc. However, quantitative data are still relatively uncommon.

Recently, we (16) have reported that D_{app} as well as the kinetic parameters (i.e., standard rate constant [k^0] and transfer coefficient [α]) of "heterogeneous" electron-transfer reaction of the $MV^{2+/+}$ redox couple (MV^{2+} is the

dication of viologen site in polymer coatings) can vary substantially as the overall morphology of the polymers confining the viologen sites and the concentration of the viologen site are changed and that the empirical linear relationship between $\log D_{app}$ and $\log k^0$, which has been found in some redox complexes (20-23) incorporated electrostatically into the polyelectrolytes on electrodes, also holds for the monomeric methylviologen trapped in a perfluorinated ion-exchange polymer, Nafion. The more detailed examination of both the "homogeneous" charge-transport process through the poly(viologen) films on electrodes and the heterogeneous electron-transfer reactions at the electrode/poly(viologen) film interfaces is thus expected to lead to further insight into the homogeneous and heterogeneous charge-transport processes involved in the electrochromic process, electron-transfer mediation or catalysis, photoassisted hydrogen evolution, etc., when using poly(viologen)-coated electrodes.

Electron hopping between the neighboring redox sites in a polymer matrix, i.e., self-exchange electron-transfer process, has been proposed as the mechanism for transporting electrons through redox polymers (41, 42), since the redox sites are affixed to the polymer film matrix and all of these sites cannot directly contact with the underlying electrode. However, the rate-determining step of the electron transport is not always the intrinsic electron-transfer reaction between the neighboring redox sites. In many cases (3, 4, 16, 20-27, 41-49, 51-53), ion-transport processes such as the diffusion of the redox site itself, the motion of the charge compensating counterion, and the polymer chain motion have been considered to limit this electron-transport process. With the polymeric viologens, such fundamental data for the understanding of the mechanism of homogeneous charge transport are presently limited (3, 4, 16, 19). The influence of the electrolyte and the polymer morphology on the electrochemistry of the viologen polymer films attached to electrode surfaces

* Electrochemical Society Active Member.

should be examined in detail to elucidate the factors controlling homogeneous charge-transport kinetics in viologen polymer films as well as heterogeneous electron-transfer kinetics at electrode/viologen-polymer-film interfaces.

In this paper, the dependence of the D_{app} characterizing the homogeneous charge transport within poly(methylviologen) (PMV) (Fig. 1) and the kinetic parameters (k^0 and α) of heterogeneous electron-transfer reaction of the $MV^{2+/•}$ redox couple as PMV coated on a basal-plane pyrolytic graphite (BPG) electrode upon the supporting electrolytes will be examined by a normal pulse voltammetric procedure. This technique has successfully been applied to the determination of D_{app} , k^0 , and α for "electroactive polymer-coated electrodes" (16, 20-23). In addition, the results will be compared with those obtained with the PMV-Nafion and PMV-PSS intermolecular complexes coated on BPG electrodes under the various ratios of $\Gamma_{MV^{2+}^{obs}}$ to Γ_{Nafion} or Γ_{PSS} in various supporting electrolytic solutions, where $\Gamma_{MV^{2+}^{obs}}$, Γ_{Nafion} , and Γ_{PSS} are the surface concentration of the electroactive viologen site as PMV and the concentrations of the sulfonyl group as Nafion and PSS, respectively. The modification of electrode surfaces by coating the polymeric intermolecular complexes, which were produced by mixing two kinds of polymers having the opposite charges of each other, is a new useful means in the preparation of "polymer-coated electrodes," and the resulting electrodes could be expected to possess many potential applications [e.g., catalytic O_2 reduction at BPG electrodes coated with PXV-PSS or PXV-Nafion (1) and electrochromism of transparent electrode coated with PXV-PSS (5)]. Thus, a more detailed examination of the heterogeneous electron-transfer reaction between the electrode and the redox site confined in the blended-polymer coatings and homogeneous charge-transport process through these polymer coatings was undertaken in order to understand the electrochemical behavior of these intermolecular complex-coated electrodes.

Experimental

Materials.—The poly(methylviologen) (PMV), with average molecular weight of 9.8×10^3 , shown in Fig. 1, was prepared as described elsewhere (1, 6, 7, 16, 17). Nafion membrane 125® was obtained from E. I. du Pont de Nemours and Company (Wilmington, Delaware). According to a previous procedure (1, 6, 7, 17), the stock solution of Nafion was prepared from the membrane in order to facilitate the electrode coating, where ethanol-dimethylsulfoxide mixture (50:50 volume percent) was used as a solvent, and the concentration of Nafion was 2.55 mg·ml⁻¹. Poly(p-styrenesulfonate sodium salt) (PSS) used as an electrode coating film of polyelectrolyte was obtained from Polyscience, Incorporated (Warrington, Pennsylvania), and the average molecular weight was 6×10^6 . The water-soluble PSS used as a supporting electrolyte was prepared by the same procedure as described previously (1). Its average molecular weight was 1.2×10^6 .

The basal-plane pyrolytic graphite (BPG) (Union Carbide Company) disk electrodes (area of 0.17 cm²) were prepared and mounted into glass tube with heat-shrinkable polyolefin tube (24, 25). Fresh electrode surfaces were produced by cleaving the disk with a scalpel.

Fig. 1. Structure of the poly(methylviologen) used

Sodium chloride, sodium perchlorate, cesium chloride, sodium p-toluenesulfonate (NaPTS), and tetraphenylphosphonium chloride (TPPCl), which were reagent grade, were obtained from Wako Pure Chemical Industries, Limited (Osaka, Japan) and were used as supporting electrolytes without further purification. In each supporting electrolytic solution, the concentration of supporting electrolyte was 0.2M and the pH value was adjusted to 3.0 by an addition of an acid, which is composed of the same anion as that of the supporting electrolyte used, to the solution. In this process, no buffer solutions were used to avoid the complication of the interpretation (concerning the influence of supporting electrolyte on kinetics of electroreduction process of polymeric viologens) of the data obtained.

Electrode coating procedures.—The polymer film-coated electrodes were prepared by almost the same procedures as described previously (1). The PMV film and the polymer film obtained by mixing of the PMV and Nafion solutions on the electrode surface appeared homogeneous to the naked eye, while the polymer film obtained by mixing of the PMV and PSS solutions appeared less homogeneous.

PMV film coating.—Aliquots (1-10 μ liter) of methanolic stock solution containing 3 mg/ml methylviologen as PMV were spread by a microsyringe on the freshly cleaved electrode surface of BPG, and then the solvent was evaporated at room temperature.

PMV-Nafion film coating.—Aliquots of the stock solutions of PMV and Nafion were pipetted and mixed directly on the freshly cleaved surface and then air-dried to remove the solvent before use.

PMV-PSS film coating.—Aliquots of the stock solutions of PMV and PSS were mixed on the BPG electrode surfaces and dried.

Apparatus and procedures.—Normal pulse voltammograms and cyclic voltammograms were obtained with homemade instruments and were recorded with an X-Y recorder (Watanabe Corporation). Positive feedback circuitry was employed to compensate the resistances associated with the polymer coatings (these were typically ca. 20-50 Ω) as much as possible. In normal pulse voltammetric experiments, the pulse width of 10-100 ms and the interval of 30-60s between successive pulses were employed. Thus it can be safely considered that the depletion layer of reactants produced during the preceding pulse completely disappears before the following pulse starts. Normal pulse voltammetric measurements were confined to times (typically 1-10 ms) sufficiently short to ensure that semi-infinite linear diffusion prevailed (16, 20-23, 26).

The thicknesses of the coating films of PMV, PMV-Nafion, and PMV-PSS were measured as follows. Aliquots of the stock solutions of PMV, PMV and Nafion, or PMV and PSS were cast and then spread by a microsyringe on a glass slide in such a way that the area of the spread coating is equal to that (0.17 cm²) of BPG electrode used. They were then air dried. The resulting dry coatings were soaked for 30 min in the same aqueous solutions as those used in further electrochemical experiments (i.e., the concentration of supporting electrolyte = 0.2M, pH = 3.0), and the "wet" thicknesses were measured with a Surfcom 550A (Surface Texture Measuring Instrument, Tokyo Seimitsu Company). The wet thicknesses of the coating films were almost independent of the kind of the supporting electrolytic solutions used.

The quantities ($\Gamma_{MV^{2+}^{obs}}$ in units of moles per square centimeter) of the electroactive viologen site in electrode coatings were determined coulometrically (25) by integrating the current that passed when the electrode potential was stepped from a value where no current was flowing to a value where the dicationic viologen sites (MV^{2+}) were reduced to the corresponding radical monocations ($MV^{•+}$). The values of $\Gamma_{MV^{2+}^{obs}}$ were also determined by measuring the area of cyclic voltammograms (for the

Fig. 2. Variation of the thickness of the coating films with $\Gamma_{\text{Nafion}}/\Gamma_{\text{MV}^{2+}}^{\text{obs}}$ or $\Gamma_{\text{PSS}}/\Gamma_{\text{MV}^{2+}}^{\text{obs}}$. The constant quantity (6.2×10^{-8} mol-cm $^{-2}$) of PMV and the arbitrary quantities (2.0×10^{-8} – 2.0×10^{-7} mol-cm $^{-2}$) of Nafion or PSS were coated on glass slides (area of 0.17 cm 2) and then air dried. The resulting coating films were soaked in 0.2M NaClO $_4$ solution (pH 3.0) for 30 min, and then their thicknesses (ϕ) were measured. Circles: PMV-Nafion system. Squares: PMV-PSS system. Widths of error bars indicate uncertainties in thickness measurements.

oxidation-reduction of the MV $^{2+/+}$ redox couple) obtained at slow potential scan rates of 1–2 mV-s $^{-1}$. The $\Gamma_{\text{MV}^{2+}}^{\text{obs}}$ values estimated by these two procedures were the same within experimental error. The molar volume concentrations of the electroactive viologen site in electrode coatings were calculated by using the $\Gamma_{\text{MV}^{2+}}^{\text{obs}}$ values so obtained and the thicknesses of the coatings (Fig. 2).

Solutions were freed of air by using prepurified nitrogen. Potentials were measured and are reported with respect to a sodium chloride saturated calomel electrode (SSCE). Experiments were conducted at ambient laboratory temperature (25 $^{\circ}$ \pm 2 $^{\circ}$ C).

Results and Discussion

Electrochemical response of poly(methylviologen) (PMV)-coated electrodes.—The typical cyclic voltammetric response for a PMV-coated BPG electrode is shown in Fig. 3A. After several cyclings of the electrode potential, a steady-state cyclic voltammogram was obtained, indicating that the PMV coating becomes swelled relatively quickly. When the potential of this electrode was cycled in the range from 0 to –0.65V vs. SSCE, both anodic and cathodic peak currents of the cyclic voltammogram remained substantially unchanged even after 20h, showing that the PMV was stable and strongly attached to BPG electrode surface so long as the potential of the electrode is cycled within the range where the val-

Fig. 3. Panel A: Cyclic voltammogram for a PMV-coated BPG electrode in a 0.2M NaClO $_4$ solution (pH 3.0). Panel B: Cyclic voltammograms obtained when the electrode used in Panel A was washed with water and replaced in a 0.2M CsCl solution (pH 3.0). In both cases, the potential was scanned between 0 and –0.65V vs. SSCE at 200 mV-s $^{-1}$. The arrow indicates the direction of scan. The quantity ($\Gamma_{\text{MV}^{2+}}^{\text{T}}$) of the PMV coating coated originally on BPG electrode surfaces was 6.2×10^{-8} mol-cm $^{-2}$, and in this case the quantity ($\Gamma_{\text{MV}^{2+}}^{\text{obs}}$) of the viologen site detected electrochemically was 1.9×10^{-8} mol-cm $^{-2}$.

ence of the viologen site as PMV is changed between dication and monocation. However, when the potential scanning was extended to the region from 0 to –1.2V vs. SSCE, where the valence of viologen site changes from +2 to 0 (not shown in Fig. 3), the peak currents decreased gradually with the cycling. Such a loss of the electroactivity of the PMV film may be ascribed to the formation of the electroinactive materials via the dimerization reaction among the reduced viologen sites (28, 29) or any interaction between the reduced viologen sites and the original ones (30). Unless otherwise stated, the potential of the electrode was thus scanned only over the first wave (i.e., the reduction wave of the viologen dication as PMV to the radical cation) of the two reduction waves.

The above-mentioned decrease in electroactivity of PMV film with the cycling of the potential between 0 and –1.2V vs. SSCE seems to be different from that observed with the PXV-PSS or PXV-Nafion complex coated on electrodes (1). The PMV itself is water insoluble even in the dication state of viologen site, and thus this insolubility is not thought to decrease when the charge of the viologen sites of PMV is reduced to zero. However, in the case of the PXV-PSS and PXV-Nafion complexes, the PXV itself is water soluble, but the complex salt of PXV with PSS or Nafion is insoluble in water and when the charge of the viologen was reduced to zero the salts of both complexes again become water soluble, probably because of the loss in electrostatic interaction between PXV and PSS or Nafion. The same behavior as in the PXV-PSS or PXV-Nafion complex has been observed in the case of the monomeric dimethylviologen incorporated into Nafion film coated on electrodes (16).

After a steady-state voltammogram was obtained at the PMV-coated BPG electrode in a 0.2M NaClO $_4$ solution (Fig. 3A), this electrode was removed, washed, and transferred to a 0.2M CsCl solution and then the potential of the electrode was cycled between 0 and –0.65V vs. SSCE (Fig. 3B). In this case, the peak currents increased with the cycling of the electrode potential and after about 30 min another steady-state voltammogram was obtained (Fig. 3B), although the anodic and cathodic peak currents were smaller than those (represented by dashed line) obtained with the freshly prepared PMV-coated BPG electrode in a CsCl solution. It was also observed that the redox potential (estimated as the arithmetical mean of anodic and cathodic peak potentials) of the MV $^{2+/+}$ redox couple varied with the supporting electrolyte used. For example, in the case of NaClO $_4$ and CsCl solutions the potential difference was ca. 20 mV. This may reflect the difference in ion association interactions between the MV $^{2+/+}$ redox couple and these supporting electrolytes. Furthermore, the significant difference between the values of peak currents of the voltammograms obtained in the two kinds of electrolytes should be noted. Such a difference can be ascribed to the difference in rates of homogeneous charge transport through the PMV coating and/or heterogeneous electron-transfer reaction of the MV $^{2+/+}$ redox couple as PMV in the two electrolytes (16, 20–23). The details will be described below.

Figure 4 shows the correlation between the quantity ($\Gamma_{\text{MV}^{2+}}^{\text{obs}}$) of the viologen site detected electrochemically and the quantity ($\Gamma_{\text{MV}^{2+}}^{\text{T}}$) of PMV coated originally on BPG electrode surfaces. It is apparent from this figure that the fraction of the material that is electroactive varies with the film thickness, i.e., $\Gamma_{\text{MV}^{2+}}^{\text{obs}}$ decreases slightly with increasing $\Gamma_{\text{MV}^{2+}}^{\text{T}}$ and that the fraction of electroactive viologen site is about 30% of the quantity of the polymer originally deposited on BPG electrodes in the region examined of $\Gamma_{\text{MV}^{2+}}^{\text{T}}$ (3.1×10^{-8} – 3.1×10^{-7} mol-cm $^{-2}$). It can be surmised that about 70% of the quantity of viologen site was located in unswollen portions of the polymer, where it remained inaccessible to the supporting electrolytes and was thus electroinactive. Similar behavior has been observed with the PXV-coated BPG electrode in an aqueous NaClO $_4$ solution by Martigny and Anson (3). It has been sometimes observed (3, 7, 31) that all of the quantity of redox sites in the coating originally deposited

Fig. 4. Correlation between $\Gamma_{MV^{2+}}^{obs}$ and $\Gamma_{MV^{2+}}^T$. Supporting electrolyte was 0.2M NaClO₄ (pH 3.0). The values of $\Gamma_{MV^{2+}}^{obs}$ were measured as described in the Experimental section.

on electrodes is not usually electroactive, especially when an electroactive polymer itself was directly deposited on electrodes.

Effect of supporting electrolyte on effective diffusion coefficient for homogeneous charge-transport process within PMV coatings.—It has been shown that the rate of the charge-transport process through the polymer coating governs the rate of electrochemical and catalytic processes at polymer-coated electrodes (16, 19-27, 32-40). It has been demonstrated experimentally (4, 5, 16, 19-26, 32, 34-40, 43, 45) and theoretically (33, 46) that the charge transport can be treated as a diffusion of "electrons" which follows Fick's diffusion laws. Charge can be transported through the coating by the electron transfer between electroactive sites confined in polymer matrices [i.e., electron self-exchange reaction (41-44)] and/or the physical diffusion of the electroactive species itself (20-23,

45). Both processes will be followed, for charge neutrality, by concurrent uptake of counterions into the polymer matrix or expulsion of coions initially present in the film, and, in addition, the segmental motion of the polymer lattice. Thus the relative contribution of these effects to the overall charge transport is probably different for different kinds of polymer coatings. The apparent diffusion coefficient (D_{app}) for an electron-transfer process within the coatings has been considered as one of the parameters which characterize the charge-transport process through polymers and the evaluation of D_{app} has been mainly carried out by the use of transient chronoamperometry (27, 47), chronocoulometry and chronopotentiometry (25, 27), cyclic voltammetry (26, 48, 49), and normal pulse voltammetry (NPV) (16, 20-23), etc. In this study, NPV is employed for the determination of D_{app} . The D_{app} can be estimated from the dependence of the limiting current of the normal pulse voltammograms upon sampling time (16, 20-23).

In Fig. 5 are shown the typical normal pulse voltammograms for the reduction of the viologen dication (MV^{2+}) (to the corresponding radical monocation, $MV^{\cdot+}$) as PMV coated on BPG electrodes at various sampling times in various supporting electrolytes. In these cases, the concentrations of the electroactive viologen site were almost the same ($\Gamma_{MV^{2+}}^{obs} = 2 \times 10^{-8}$ mol-cm⁻²). Thus the difference in the values of the limiting current in different supporting electrolytes may reflect the difference in the rates of the charge-transport process within the PMV coatings. Plots of the cathodic limiting current (i_{lim}) of these normal pulse voltammograms against the inverse square root of the sampling time (τ) were found to be linear in the range used of τ (1 to ca. 10 ms) (Fig. 6), indicating that in these cases the limiting currents were diffusion controlled. Thus the values of the apparent diffusion coefficients, D_{app} , for the charge-transport process within the coatings were obtained from the slopes of the i_{lim} vs. $\tau^{-1/2}$ plots by using the Cottrell equation (50)

$$(i_d)_{Cott}^c = nFAC^o_p \sqrt{D_{app}/\pi\tau} \quad [1]$$

where $(i_d)_{Cott}^c$ denotes the cathodic limiting diffusion current for the cathodic electrode process, n the number of electrons involved in the heterogeneous electron-transfer reaction, F the Faraday constant, A the electrode area, and C^o_p the volume concentration of the electroactive site (i.e., the viologen dication) in PMV coatings.

The obtained values of D_{app} are summarized in Table I, together with the $\Gamma_{MV^{2+}}^{obs}$ values and the values of the kinetic parameters of heterogeneous electron-transfer reac-

Fig. 5. Typical normal pulse voltammograms for the one-electron reduction of viologen dication as PMV coated on BPG electrodes at various sampling times in aqueous solutions (pH 3.0) of 0.2M NaCl (A), TPPCl (B), and NaClO₄ (C). In all cases, $\Gamma_{MV^{2+}}^T = 6.2 \times 10^{-8}$ mol-cm⁻². $\Gamma_{MV^{2+}}^{obs}$, 2.2×10^{-8} (A) and 1.9×10^{-8} (B and C) mol-cm⁻². Sampling time (τ): (1) 2, (2) 4, and (3) 10 ms. The arrow indicates the direction of normal pulse voltammetric potential step.

All measurements were performed in 0.2M supporting electrolytes adjusted to pH = 3.0.

All electrodes were coated with PMV of $\Gamma_{MV^{2+}}^T = 6.2 \times 10^{-8}$ mol-cm⁻².

^a Poly(p-styrenesulfonate) sodium salt.

tion at the PMV-coated BPG electrodes in various supporting electrolytes. The $\Gamma_{MV^{2+}}^{obs}$ seemed to be almost independent of the kind of the supporting electrolyte used here. With any supporting electrolyte, about 30% of the total quantity of viologen dication in PMV coating originally deposited on electrodes was electroactive. However, it seems that D_{app} varies with the supporting electrolytes. That is, when the sodium salts [e.g., NaCl, NaClO₄, sodium p-toluenesulfonate (NaPTS) and poly(styrenesulfonate) sodium salt (NaPSS)] were used as supporting electrolytes, the values of D_{app} decreased in the order NaPTS ~ NaCl > NaClO₄ ~ NaPSS. Furthermore, when the counterions of the chloride salts as the supporting electrolytes were changed, the values of D_{app} seemed to decrease slightly in the order CsCl > NaCl > tetraphenylphosphonium chloride (TPPCl).

Previous studies (42, 51-53) have shown marked electrolyte effects on the electrochemistry of polymer films deposited on electrode surfaces. The rate limiting process of the charge transport through the swollen polymer films undergoing electrolysis (i.e., oxidation or reduction of electroactive polymer itself or electroactive species confined in electroinactive polymer) is the transport of counterions through the polymer phase. For example, in the case of tetrathiafulvalene polymer (42, 52) and poly(vinylferrocene) films (51) the oxidation of these films can be viewed as being "anion controlled." However, there is no clear relationship between the size of the counterion and the electrochemical oxidation-reduction rate of films. In the case of the PMV film, it is also of interest to examine whether or not there is some relationship between the size of the counterion and the charge-transfer rate, i.e., D_{app} . The actual size of the individual counterions used here is unknown. Thus, Stokes radii (γ_s) of these ions will be used for the discussion about a correlation between the obtained values of D_{app} and the size of the counterions. When the counterions of the chloride salts as supporting electrolytes were changed, the values of D_{app} seemed to decrease slightly in the order Cs⁺ > Na⁺ > tetraphenylphosphonium ion (TPP⁺). In this case, Stokes radii (γ_s) of these cations and Cl⁻ are in the order (54) $\gamma_s(\text{TPP}^+) > \gamma_s(\text{Na}^+) > \gamma_s(\text{Cs}^+) > 2\gamma_s(\text{Cl}^-)$. From this correlation between D_{app} and γ_s , it seems likely that D_{app} increases with a decrease in γ_s . Thus the reduction of PMV film may be considered to be "cation controlled."

However, when the sodium salts were used as supporting electrolytes, the values of D_{app} decreased in the order PTS⁻ \geq Cl⁻ > ClO₄⁻ ~ PSS⁻. Stokes radii of the corresponding anions and sodium ion decrease in the order (54) $\gamma_s(\text{Na}^+) \sim \gamma_s(\text{PTS}^-) > 2\gamma_s(\text{Cl}^-) \sim 2\gamma_s(\text{ClO}_4^-)$, where $\gamma_s(\text{PTS}^-)$ was assumed to be equal to γ_s (benzoic anion) or γ_s (picrate anion) [both are ca. 2.4 times larger than $\gamma_s(\text{Cl}^-)$] (54)]. In this case, the above-mentioned cation-controlled behavior and the correlation between D_{app} and γ_s (for anions) are not observed. The $\gamma_s(\text{Cl}^-)$ and $\gamma_s(\text{ClO}_4^-)$ are almost the same and are half smaller than γ_s of Na⁺. If the

$\gamma_s(\text{TPP}^+)$ is unknown, but is intuitively considered to be larger than γ_s (trimethyl-phenyl ammonium ion), which is ca. 1.4 times larger than $\gamma_s(\text{Na}^+)$ (54).

reduction of PMV film were cation controlled in aqueous NaCl and NaClO₄ solutions, then one could expect that the values of D_{app} are almost the same in both electrolytic solutions on the basis of size alone. However, the difference in D_{app} was observed in NaCl and NaClO₄ solutions. Thus, the difference in D_{app} cannot be only explained by the difference in Stokes radii. As can be seen from the comparison of $D_{app}(\text{PTS}^-)$ and $D_{app}(\text{PSS}^-)$, $D_{app}(\text{PTS}^-)$ is about ten times larger than $D_{app}(\text{PSS}^-)$. This may suggest the difference in the rates of the diffusion of PTS⁻ and PSS⁻ (which can be considered as the polymeric form of PTS⁻) through the swollen PMV film.

While the apparent diffusion coefficients obtained in various supporting electrolytes suggest a dependence on the size of the counterion, it is apparent from the above-mentioned discussion that a simple size relationship is not operative. Further, it should be noted that the rate-determining process of the charge-transport process within PMV coatings is not the intrinsic electron-transfer process between adjacent viologen sites confined in polymer matrix, but the process of charge compensating counterion motion which is necessarily coupled to electron transfer and/or the segmental motions of the polymer lattice.

Effect of supporting electrolyte on rate of heterogeneous electron-transfer reaction between electrode and viologen site.—As mentioned previously (16, 20-23), an analysis of the rising part of the current-potential curves shown in Fig. 5. allows us to estimate the kinetic parameters [i.e., standard rate constant (k°) and cathodic transfer coefficient (α)] of the heterogeneous electron-transfer reaction of the MV^{2+/+} redox couple as PMV. The relevant current-potential relationship for normal pulse voltammograms for the simple electrode process, Ox + ne \rightleftharpoons Red, has already been derived (55) and is given for the reduction by

$$E = E_{1/2}^r + \frac{RT}{\alpha nF} \ln \left\{ \frac{4}{\sqrt{3}} \frac{k^\circ \sqrt{\tau}}{\sqrt{D}} \right\} - \frac{RT}{\alpha nF} \ln \left\{ x \left[\frac{1.75 + x^2 [1 + \exp(\zeta)]^2}{1 - x [1 + \exp(\zeta)]} \right]^{1/2} \right\} \quad [2]$$

where E is the electrode potential, $E_{1/2}^r$ the reversible half-wave potential of the MV^{2+/+} redox couple, α the cathodic transfer coefficient, k° the standard rate constant, τ the sampling time, R the gas constant, T the absolute temperature, ζ the dimensionless parameter expressed as $\{(nF/RT)(E - E_{1/2}^r)\}$, D the diffusion coefficient expressed as $\{[D_{app}(\text{for cathodic process})]^2 [D_{app}(\text{for anodic process})]^{-1-\alpha}\}$,² and x the ratio of the current (i) at potential (E) to the cathodic limiting diffusion current [$(i_a)_{cat}$] expressed by Eq. [1].

Figure 7 shows the typical examples of the modified log plots of normal pulse voltammograms in which the logarithm of the third term on rhs of Eq. [2] is plotted

²It was assumed that $D \approx D_{app}$ (for cathodic process) $\approx D_{app}$ (for anodic process).

against E for the reduction of viologen dication to the corresponding radical monocations in polymer coatings. These plots gave the straight lines the slopes of which were constant at the different sampling times from 1 to 10 ms in each case. Thus, from the slopes $[(RT/\alpha nF)^{-1}]$ of the straight lines shown in Fig. 7 and the intercepts $(E_{1/2}^{\circ} + (RT/\alpha nF) \ln \{(4/\sqrt{3})(k^{\circ}\sqrt{\tau}/\sqrt{D})\})$ of these lines with the axis, the values of k° and α were estimated by using the known values of $E_{1/2}^{\circ}$, D_{app} , and τ . In this case, the values of $E_{1/2}^{\circ}$ were estimated as the average of the anodic and cathodic peak potentials of the cyclic voltammogram for the oxidation-reduction of the $MV^{2+/+}$ redox couple as PMV on BPG electrodes in a solution containing only supporting electrolyte. The results obtained are summarized in Table I. It is clear from this table that the kinetic parameters (k° and α) of heterogeneous electron-transfer reactions of the $MV^{2+/+}$ redox couple vary with the supporting electrolyte. The values of k° in the presence of NaCl or CsCl are $\sim 2 \times 10^{-4} \text{ cm}\cdot\text{s}^{-1}$ and those in the presence of TPPCl, PTSNa, NaClO_4 , or PSSNa are $(1 \sim 9) \times 10^{-5} \text{ cm}\cdot\text{s}^{-1}$. Particularly, one notice that k° in the presence of CsCl is *ca.* one order of magnitude larger than that in the presence of PSSNa. Thus, it is worth noting that the reduction of viologen dication to the corresponding radical monocation is markedly affected by the nature of the supporting electrolyte ions, although at the present stage it is impossible to find out a reasonable explanation for these results.

The effect of supporting electrolytes on the kinetics of heterogeneous electron-transfer reactions at a conventional "bare" electrode has been observed before, for example, for hydrogen ion reduction in the presence of halide ions (56, 57) and anion reduction in the presence of alkali metal cations at a negatively charged mercury electrode (58). In general, such an influence of supporting electrolytes on heterogeneous electron-transfer processes has been ascribed to a variation in the potential distribution in the double layer, usually termed the "double-layer effect" (59), and/or specific interaction between the reacting species and supporting electrolytic ions in the double layer (60, 61). Both of these effects should be taken into account in order to explain the above mentioned supporting electrolyte dependence of the kinetic parameters of heterogeneous electron-transfer reaction at the PMV-coated electrode. At the present stage, however, the related data are still rare. Thus we did not attempt to distinguish these two possibilities.

From Table 1, it is also clear that the values of α change with the supporting electrolyte. Especially, the α value (0.18) in the presence of PSSNa is significantly smaller than those (0.39 ~ 0.46) in the presence of other monomeric supporting electrolytes (*i.e.*, NaCl, NaClO_4 , PTSNa, CsCl, or TPPCl). Recently, we (16) have measured the kinetic parameters (k° and α) for the reduction of the viologen dication to radical monocation in various

Fig. 7. Modified log plots of normal pulse voltammograms for the one-electron reduction of viologen dication as PMV on BPG electrodes. Sampling time (τ): (1) 2, (2) 4, and (3) 10 ms. Other experimental conditions and the symbols used are the same as in Fig. 5 and 6.

Fig. 8. Typical normal pulse voltammograms for the one-electron reduction of viologen dication as PMV-Nafion (curve A) and PMV-PSS (curve B) intermolecular complexes on BPG electrodes at various sampling times. A: $\Gamma_{MV^{2+}}^{obs} = 6.8 \times 10^{-9} \text{ mol}\cdot\text{cm}^{-2}$ and $\Gamma_{Nafion} = 8.8 \times 10^{-8} \text{ mol}\cdot\text{cm}^{-2}$. B: $\Gamma_{MV^{2+}}^{obs} = 6.1 \times 10^{-9} \text{ mol}\cdot\text{cm}^{-2}$ and $\Gamma_{PSS} = 8.8 \times 10^{-8} \text{ mol}\cdot\text{cm}^{-2}$. In both cases, $\Gamma_{MV^{2+}}^T = 6.2 \times 10^{-8} \text{ mol}\cdot\text{cm}^{-2}$. Supporting electrolyte: 0.2M NaCl (pH 3.0). Sampling time (τ): (1) 2, (2) 4, and (3) 10 ms. The arrow indicates the direction of normal pulse voltammetric potential step.

polymer coatings of PMV, N, N'-dimethyl-4,4'-bipyridinium (MV)-Nafion and PXV-PSS-coated BPG electrodes in 0.2M NaClO_4 solution (pH 3.4). The values of α obtained with PMV, MV-Nafion, and PXV-PSS-coated BPG electrodes were 0.56, 0.58, and 0.20, respectively. These results demonstrate that the values of α vary with not only supporting electrolytes, but also the structure of the polymer coating. Further, note that the α value obtained with PMV-coated electrode in the presence of PSSNa as supporting electrolyte is almost the same as that obtained with PXV-PSS-coated electrode in the presence of NaClO_4 (16) and that these values are considerably smaller than those in the other systems.

Kinetics of electron-transfer processes at electrodes coated with PMV-Nafion or PMV-PSS intermolecular complex.—Figure 8 shows the typical normal pulse voltammograms for the one-electron reduction of the viologen dication (MV^{2+}) as PMV-Nafion and PMV-PSS intermolecular complexes on BPG electrodes at various sampling times. The reduction half-wave potentials of the normal pulse voltammograms shifted in the negative direction as the sampling time was reduced (Fig. 8), and their limiting currents were found to be diffusion-controlled from the Cottrell plots of (cathodic limiting current) *vs.* (sampling time) $^{-1/2}$. The kinetic parameters of the heterogeneous electron-transfer reaction of the $MV^{2+/+}$ redox couple as PMV-Nafion and PMV-PSS and the apparent diffusion coefficients for the charge transport process within polymeric coatings of these intermolecular complexes were evaluated by the same method as described in the previous section. The obtained values of D_{app} , k° , and α at the various ratios of $\Gamma_{MV^{2+}}^{obs}$ to Γ_{Nafion} and Γ_{PSS} under a constant amount ($\Gamma_{MV^{2+}}^T$) of the PMV originally deposited on electrodes are shown in Fig. 9, where Γ_{Nafion} and Γ_{PSS} are the concentrations of the sulfonyl group as Nafion and PSS, respectively.

Some correlations between D_{app} , k° , or α and the ratio $\Gamma_{Nafion}/\Gamma_{MV^{2+}}^{obs}$ or $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$ can be drawn on the basis of

Fig. 9. Dependence of D_{app} , k^o , and α on $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ or $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$. Supporting electrolyte (0.2M): NaCl (circles), CsCl (squares), NaPTS (deltae), TPPCl (dels). Open, solid, and half-solid symbols represent the data obtained for the PMV, PMV-PSS, and PMV-Nafion systems, respectively. $\Gamma_{MV^{2+}}^T = 6.2 \times 10^{-8} \text{ mol}\cdot\text{cm}^{-2}$. Widths of error bars indicate uncertainties in the measurements of D_{app} , k^o , and α .

the data shown in Fig. 9. (i) The D_{app} , k^o , and α tend to decrease, though not monotonously, with an increase in $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ or $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$, irrespective of the kind of supporting electrolytes. (ii) At a given ratio of $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ or $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$, D_{app} , k^o , and α change with the supporting electrolyte used. (iii) For a given supporting electrolyte and under the conditions of the same ratio of $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ and $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$, D_{app} , k^o , and α obtained with the PMV-Nafion system are different from those obtained with the PMV-PSS system.

It is of considerable interest to compare the above-mentioned results [especially (i)] with those (16) obtained with N, N'-dimethyl-4, 4'-bipyridinium (MV) incorporated into Nafion coatings (abbreviated as MV-Nafion) on electrodes, since the dependence of D_{app} and k^o on the concentration of viologen site in coatings is different in the MV-Nafion system and the PMV-Nafion or PMV-PSS system. In the latter system, D_{app} and k^o can be considered to increase with an increase in the volume concentration ($C_{MV^{2+}}$ in units of moles per cubic centimeter) of viologen dication site in polymer matrices, since $C_{MV^{2+}}$ increases

with decreasing the ratio $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ or $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$ under the conditions of constant $\Gamma_{MV^{2+}}$. However, in the case of the MV-Nafion system, as reported previously (16), D_{app} and k^o decreased with an increase in $C_{MV^{2+}}$. These different concentration dependences of D_{app} (and k^o) are considered to be associated with the different polymer morphology caused by the different interactions between the viologen sites and their surroundings (i.e., cationic polymer-anionic polyelectrolyte interaction in the PMV-Nafion or PMV-PSS system and cationic monomer-anionic polyelectrolyte interaction in the MV-Nafion system). In the case of the monomeric redox ions confined electrostatically in polyelectrolytes carrying the opposite charge [e.g., the $\text{Fe}(\text{CN})_6^{4-/3-}$ (22), $\text{Mo}(\text{CN})_8^{4-/3-}$ (20, 21), and $\text{IrCl}_6^{3-/2-}$ (23) incorporated into protonated poly(4-vinylpyridine), the $\text{MV}^{2+/+}$ (16), $\text{Co}(\text{bpy})_3^{3+/2+}$ (43) and $\text{Ru}(\text{bpy})_3^{3+/2+}$ (31, 41, 49) incorporated into Nafion], the degree of the electrostatic cross-linking of the polymer films by multiple ion pairing of redox ions with the surrounding sites having the opposite charge is thought to increase with increasing the concentration of the redox ion in polymer films. The increasing electrostatic cross-linking of the films causes the decrease in the rates of the diffusion of the redox ion itself, the charge compensating counterion motion which is necessarily coupled to the intrinsic electron transfer between the redox ions and/or the segmental motions of the polymer film. As a result, the decrease of D_{app} with increasing the concentration of the redox ion is observed. On the other hand, in the case of the PMV-Nafion and PMV-PSS systems, the electrostatic cross-linking between the cationic polymer (i.e., PMV) and the anionic polyelectrolytes (i.e., Nafion and PSS) is thought to be restricted to some extent by the constrained motion of the polymer backbones, which is attributed to the essential structure of the polymer itself. When the ratios of $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ for the MV-Nafion and PMV-Nafion systems and $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$ for the PMV-PSS system are the same, the degree of the electrostatic cross-linking in the PMV-Nafion or PMV-PSS system can be considered to be much smaller than that in the MV-Nafion system. As a result, the charge transport through the coatings of the PMV-Nafion and PMV-PSS intermolecular complexes seems to be controlled not only by the charge compensating counterion motion and the segmental motions of the polymers, but also by the electron hopping reaction between adjacent viologen sites, as can be demonstrated by the dependence of D_{app} on the kinds of the supporting electrolyte and the electroinactive polyelectrolyte blended with PMV at a constant $C_{MV^{2+}}$ and the increasing values of D_{app} with an increase in $C_{MV^{2+}}$.

A typical example of the charge-transport controlled by the rate of the intrinsic electron-transfer reaction between adjacent pairs of oxidized and reduced forms has been reported by Buttry and Anson with respect to effective diffusion coefficients of $\text{Co}(\text{bpy})_3^{2+}$ in the presence of $\text{Co}(\text{bpy})_3^+$ in Nafion coatings on BPG electrodes (43). Compared with this $\text{Co}(\text{bpy})_3^{2+/+}$ system, the charge transport for the PMV-Nafion and PMV-PSS systems seems to be more complicated and to be controlled by some other factors as mentioned above.

The result (ii) indicates that one of the factors controlling the charge transport is the diffusion of the supporting electrolyte which is necessarily coupled to the intrinsic electron-transfer reaction between the adjacent viologen sites. Note that the effect of the supporting electrolytes on the D_{app} values is larger in the PMV-Nafion and PMV-PSS intermolecular complexes than in the PMV alone. For example, at $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs} = 0$, $D_{app}(\text{NaCl})/D_{app}(\text{PTSNa}) = 0.95$, while at $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs} = 1.6$, $D_{app}(\text{NaCl})/D_{app}(\text{PTSNa}) = 32$. The different, swollen polymer morphology of the PMV-Nafion or PMV-PSS intermolecular complex and the PMV can be considered to cause the significant difference in the rates of the diffusion of supporting electrolytes and thus the difference in the D_{app} values.

For a given supporting electrolyte and at a given ratio of $\Gamma_{NaFion}/\Gamma_{MV^{2+}}^{obs}$ and $\Gamma_{PSS}/\Gamma_{MV^{2+}}^{obs}$, the values of D_{app} are dif-

Fig. 10. Correlation between $\log k^\circ$ and $\log D_{app}$. Supporting electrolyte (0.2M): NaClO_4 (diamond), water-soluble poly (p-styrenesulfonate) (sodium salt) (hexagon). The other symbols used are the same as in Fig. 9.

ferent in the PMV-Nafion and PMV-PSS systems. At the higher ratio of $\Gamma_{\text{Nafion}}/\Gamma_{\text{MV}^{2+}^{\text{obs}}}$ and $\Gamma_{\text{PSS}}/\Gamma_{\text{MV}^{2+}^{\text{obs}}}$, the difference in the D_{app} values becomes larger. Such a difference may be due to changes in overall swollen morphology of both intermolecular complexes. The differences in the diffusional behavior of ions in Nafion and sodium poly-(p-styrene sulfonate) (PSSNa) have been recently reported (62-64) to be due to the different structure of both polymers; i.e., Nafion is a polymer with an ion-cluster morphology, while PSSNa is a conventional cross-linked sulfonated ion-exchange resin.

The explanation for the dependence of the kinetic parameters of heterogeneous electron-transfer reaction of the $\text{MV}^{2+/+}$ redox couple upon the supporting electrolytes, the ratio of $\Gamma_{\text{Nafion}}/\Gamma_{\text{MV}^{2+}^{\text{obs}}}$ or $\Gamma_{\text{PSS}}/\Gamma_{\text{MV}^{2+}^{\text{obs}}}$ and the polyelectrolytes blended with PMV seems to be much more difficult compared with that for D_{app} values. However, it should be noted that there is a linear relationship between $\log k^\circ$ and $\log D_{app}$ (Fig. 10). Similar relationships have been obtained for the $\text{Mo}(\text{CN})_8^{4-\beta-}$, $\text{Fe}(\text{CN})_6^{4-\beta-}$, and IrCl_6^{3-2-} incorporated into the protonated PVP, the $\text{Fe}(\text{CN})_5^{3-2-}$ coordinated to PVP and the $\text{MV}^{2+/+}$ incorporated into Nafion (16, 23). The empirical relationship obtained suggests that the factors caused by changing the concentration of the viologen site in polymers, the supporting electrolytes, the polymer structure, etc., contribute in a similar manner to both the rate-determining process of the heterogeneous electron-transfer reaction at the electrode/film interface and the physical diffusion process of the electrochemical charge through the polymer films.

Incorporation of Complex Reaction Sequences in Engineering Models of Electrolytic Cells

I. Paired Synthesis of Propylene Oxide in an Undivided Cell

Richard C. Alkire* and James D. Lisius**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A reaction sequence involving 11 chemical species was incorporated into a mathematical model of an electrolytic cell consisting of an undivided parallel-plate reactor operating under steady, continuous flow conditions. The set of coupled, nonlinear, stiff differential equations was solved numerically by dynamic simulation. The technique was applied to the paired synthesis of propylene oxide from propylene-saturated bromide electrolyte. For this system, the eigenvalues associated with the jacobian ranged over ten orders of magnitude. The effect of pH, $[\text{Br}^-]$, mass transfer, space time, and current density were explored to understand their influence on yield, selectivity, conversion, current efficiency, and cell voltage.

Establishment of new electrochemical technologies requires engineering evaluation during early stages of development. The design of electrochemical cells, however, is intimately coupled to chemical transformations which occur within the cell. Robust engineering procedures are needed to evaluate cell design by utilizing scientific understanding of reaction mechanisms to predict cell performance.

Mathematical tools for simulating cell and process behavior are increasingly used in conjunction with experimental programs at the bench scale. Such tools, however, have to date incorporated relatively simple examples of process chemistry. The purpose of the present investigation was to model an electrochemical cell in which a complex sequence of reactions occurs. The method was used to study the paired electrosynthesis of propylene oxide in an undivided parallel-plate cell in which 11 chemical species appear as reactants, intermediates, product, and by-products. In this work, the space-time yield, power consumption, and current efficiency, and their dependence upon cell geometry, flow rate, reactant concentration, and pH, were obtained with use of a mathematical model of the reactor and chemical reaction sequence (1).

Pickett (2) reviewed chemical engineering reactor design concepts used for analysis of electrolytic reactors in terms of simple batch and continuous units. Such cell units can be interconnected to other units to form a process flowsheet. Cera (3) has recently described use of a computer-aided flowsheet simulator for design and optimization of electrochemical processes. In such treatments, the electrochemical reactor is simulated as a process unit which obeys mass, voltage, and thermal balances, but generally without specifying in detail the process chemistry which occurs within the cell.

Detailed models of the interior region of electrolytic cells have taken on a wide range of mathematical complexity (4, 5). Various electrochemical reactor configurations have been analyzed in order to clarify behavior in the presence of coupled mass-transport, potential field, and interfacial processes. Such configurations include, for example, parallel-plate cells (2, 6) and porous electrodes (7, 8), among others. Relatively few such studies,

however, include complex reaction sequences beyond a main electrode reaction plus a parasitic side reaction. Notable exceptions are surveyed in Ref. (6) and include treatment of coupled reactions in a laminar boundary layer and multiple homogeneous and heterogeneous reactions in a flow-through porous electrode.

The modeling of chemical reaction sequences by combination of reaction rate and equilibrium equations can be difficult when intermediate species react quickly or are present in very small concentration. In such cases the jacobian matrix of the model equations may exhibit eigenvalues which can be different by many orders of magnitude, and the equations are called "stiff." Because many engineering and scientific disciplines encounter stiffness in modeling, an extensive mathematical literature exists, and special algorithms have been developed for numerical integration of such equations (9, 10). In the present study, stiffness was encountered and efficient algorithms were identified for solving model equations describing the electrosynthesis of propylene oxide.

Baizer recently described advances in scientific understanding of reaction mechanism in the field of electro-organic chemistry (11). Swann and Alkire have indexed several thousand organic compounds which may be synthesized by electrolysis (12). Beck *et al.* discussed evaluation of several electro-organic process candidates (13). Propylene oxide was chosen for the present study because the reaction chemistry has been widely studied, and rate and equilibrium constants are known. Present chemical routes to propylene oxide include chlorohydrin and hydroperoxide processes; electrochemical routes have also been explored (14, 15). Several bench-scale investigations have been conducted with the bromohydrin route in undivided parallel-plate cells (16-19). The propylene oxide reaction, therefore, represents a convenient system for model studies.

System Chemistry

Desired reactions.—Consider an aqueous solution of sodium bromide saturated with dissolved propylene and contained in an undivided electrochemical cell. Bromine is formed by electrolysis at the anode

[1]

*Electrochemical Society Active Member.

**Electrochemical Society Student Member.

Because in saturated propylene solution the rate for addition of bromine to propylene is over 200 times larger than that for bromine hydrolysis (19, 20), the reaction of dissolved propylene was assumed to occur exclusively with molecular bromine to form propylene bromohydrin (20-24)

Electrolysis of water occurs at the cathode

Propylene oxide is formed by base-promoted dehydrohalogenation of the vicinal bromohydrin (25-28)

The desired overall cell reaction is

The desired cell reaction utilizes intermediate products from both anode and cathode, and therefore is called a "paired" synthesis. The halogen species does not appear in the overall reaction. Other halogens could be used. However, iodine reaction with propylene is slower and is reversible (28); also, reaction of bromohydrin to propylene oxide is more rapid than that of chlorohydrin, and is of comparable magnitude to that of iodohydrin (26).

Side reactions.—A detailed discussion of side reactions is available elsewhere (1) and will be summarized here. The following paragraphs include reactions of bromine species having higher oxidation states, and reactions involving organic propylene compounds.

Bromine may form polybromides and may also hydrolyze to form hypobromous acid (29). Hypobromous acid can hydrolyze to form the anion which can disproportionate to form bromate (30). Bromate ion can hydrolyze to form the corresponding acid. Electrochemical reactions can also interconvert the different bromine species (31, 32).

All bromine in valence states of 0 and above (positive) possess strong oxidizing capability and may oxidize organic species. High bromide ion concentrations are known to catalyze addition of molecular bromine to olefins (28). The sole kinetic study of bromine addition to propylene (20) shows no hypobromous acid addition. The speed of the bromine-propylene reaction in comparison to bromate ion formation (20, 33) suggests that essentially all bromine reacts with propylene to form bromohydrin. Reactions of bromine in valence states of 0 and above have thus been neglected in model presented below.

Side reactions involving organic propylene compounds also occur since the carbonium ion intermediate is available for nucleophiles other than water. The major by-product is propylene dibromide (dibromopropane) which is formed by nucleophilic (Br^-) attack on the carbonium ion intermediate formed from reaction of propylene with bromine

The relative proportion of propylene bromohydrin to propylene dibromide depends in a nonlinear manner upon the concentration of bromide ion (20). To an insignificant extent, based upon reactant concentrations, bromohydrin may serve as the nucleophile to yield dibromo-isopropyl ether. Hydrolysis of bromohydrin may occur to form propylene glycol (34, 35), but the rate is slow in comparison with attack of hydroxide ion on bromohydrin to form propylene oxide.

Propylene oxide is susceptible to attack by water since the epoxide ring is readily attacked even by weak nucleophiles. In basic solutions, the $\text{S}_{\text{N}}1$ uncatalyzed and $\text{S}_{\text{N}}2$ hydroxide ion-catalyzed reactions are the dominant mechanisms of glycol formation (36-39)

The foregoing summary indicates clearly that the chemistry of the system has been extensively studied by others. The purpose of the next section is to embody this knowledge in a mathematical model of an electrolytic cell.

Theoretical Formulation

Electrolytic cell and process chemistry.—The electrolytic cell is illustrated in Fig. 1. The cell is an undivided parallel-plate continuous flow unit having a well-mixed core region of uniform composition described by the space-time variable τ . The cell operates with a current of I_{app} . Convective mass-transfer processes are characterized by a diffusion layer at each electrode, represented by the length δ , of equal value at both electrodes. The cell is assumed to operate under isothermal conditions at 25°C and atmospheric pressure. The cell model corresponds to turbulent flow with negligible conversion per pass.

The feed is sodium bromide electrolyte saturated with propylene. The reaction chemistry within the cell is summarized in Fig. 2. The desired reactions are indicated by the heavy arrows. The side reactions are indicated by the light arrows, and account for all unwanted product yields in excess of 1%. The reaction sequence includes 11 chemical species; in addition, the potential is included as a variable. The reaction sequence does not include bromine species of higher oxidation states (+1, +3, and +5).

Rate equations.—Values of thermodynamic data and rate constants which appear in the following equations are tabulated in Table I. Equilibrium constants were calculated from free energies of formation of the reacting species. The standard free energies of formation of all species have been compiled (1).

Fig. 1. Schematic diagram of electrolytic cell

Fig. 2. Model reaction sequence

The electrochemical reaction of the Br^-/Br_2 couple follows a modified Butler-Volmer rate equation (40, 42) which was found to fit experimental data

$$j_1 = i^\circ_{\text{cathodic}} \exp \left[-\frac{anF}{RT} (E - E_{\text{eq}}) \right] - i^\circ_{\text{anodic}} \exp \left[\frac{bnF}{RT} (E - E_{\text{eq}}) \right] \quad [8]$$

where

$$E_{\text{eq}} = E_1^\circ + \frac{RT}{nF} \ln \left[\frac{C_2^*}{(C_1^*)^2} \right]$$

Br_2 which contacts the anode was assumed to reduce back to Br^- and thus lower cathode current efficiency.

The reduction of water at the cathode was expressed by

$$j_2 = \left\{ i^\circ \exp \left[-\frac{anF}{RT} (E - E_{\text{eq}}) \right] - \exp \left[\frac{bnF}{RT} (E - E_{\text{eq}}) \right] \right\} \quad [9]$$

where

$$E_{\text{eq}} = E_2^\circ - \frac{RT}{nF} \ln \{C_8^*\}$$

At each electrode the magnitude of the cell current was equal to the sum of the electrochemical reactions j_1 and j_2 . Hydrogen gas was assumed to be carried out of the cell by convective action and to be present at its saturation value in the bulk solution. The back reaction of dissolved hydrogen occurs at the anode, and serves thus to lower anode current efficiency.

The reaction of bromine with propylene was expressed by a rate equation based on experimental data (20), which were fit by second-degree polynomial regression to the form

$$R_{3,4} = fk_{3,4} \left[C_2C_3 - \frac{C_4C_1}{K_{3,4}C_8} \right] \quad [10]$$

where

$$f = 0.967178 - 0.583315C_1 - 0.367902C_1^2$$

and where

$$k_{3,4} = \frac{k'_{3,4} + k''_{3,4}K'_{3,4}C_1}{1 + K'_{3,4}C_1}$$

Reaction of propylene to propylene dibromide was, in a similar manner, expressed by a rate equation based on experimental data (20) fit by second degree polynomial regression

$$R_{3,5} = (1 - f)k_{3,4} \left[C_2C_3 - \frac{C_5}{K_{3,5}} \right] \quad [11]$$

and f and $k_{3,4}$ are defined as above.

The reaction of propylene bromohydrin to propylene oxide obeys the rate equation (26)

$$R_{4,6} = k_{4,6}C_4C_8 - k_{6,4}C_1C_6 \quad [12]$$

Reaction of propylene oxide to propylene glycol obeys the rate equation (38, 39, 44)

$$R_{6,7} = k'_{6,7} \left[C_6 - \frac{C_7}{K_{6,7}} \right] + k''_{6,7}C_8 \left[C_6 - \frac{C_7}{K_{6,7}} \right] \quad [13]$$

Conservation equations and voltage balance.—This section presents equations for conservation of 11 chemical species plus a voltage balance. The conservation equations were based on the dilute solution approximation (45); while more rigorous expressions could be used in principle, it is unlikely that such refinements would be either cost effective or appropriate to the present level of analysis. In addition, migration terms have been ignored for charged species on the basis that they introduce significant mathematical complexity by coupling the potential and concentration variables, while introducing only modest gains in the expected accuracy of analysis. Finally, the transport coefficients have been assumed to remain constant throughout the concentration fields under study. Table II lists the transport coefficients used in the calculations carried out below; the "calculated" diffusion coefficients were estimated by the correlation of Wilke and Chang (50) with use of the LeBas molar volume correlation (51).

The conservation of species equations are summarized in Table III. The conservation equations were applied in both anolyte and catholyte boundary regions and represent transport by diffusion with simultaneous homogeneous chemical reaction. The central well-mixed core region

is of uniform concentration throughout and therefore enters only as a boundary condition upon the two sets of ordinary differential equations. The boundary conditions of the electroactive species are governed by the sum of the two electrode reactions, where the parasitic reaction occurs at the mass-transfer-limited current. The nonelectroactive species have zero-flux conditions at the electrode and mass balance boundary conditions at the edge of the boundary layer.

The voltage balance across the cell was expressed by Ohm's law based on mobilities and concentrations of ionic species in solution. The effect of hydrogen gas bubbles was ignored. The potential field in the well-mixed core region was therefore

$$\frac{dE}{dx} = - \frac{I_{app}}{F^2 \{u_1 C_1 + u_8 C_8 + u_{10} C_{10} + u_{11} C_{11}\}} \quad [14]$$

The cathode potential was set arbitrarily at zero

$$E = 0 \quad [15]$$

The anodic boundary layer and cathodic boundary layer conditions were

$$E_{abl} = E_{cbl} + \frac{I_{app}}{F^2 \{u_1 C_1 + u_8 C_8 + u_{10} C_{10} + u_{11} C_{11}\}_{cbl}} \quad [16]$$

Method of solution.—The model equations were solved by first isolating those equations which could be solved independently of the remaining set, *i.e.*, for H⁺, H₂, Na⁺, and E. The central problem thus was obtaining a solution for the remaining equations, which were stiff.

In this investigation, the method for converging to the steady-state solution of the boundary value system was to introduce time derivatives and convert the ordinary differential equations (ODE's) into partial differential equations, which were integrated in time until the time derivatives became negligible (52, 53). That is, the problem was solved by dynamic simulation.

The Forsim VI numerical code was used for integration of model equations (53). This package consists of a set of subroutines which contain general procedures for integration of systems of initial value differential equations. Detailed discussion of computation details is available (1).

Two difficulties were encountered in the solution of the equations. The first problem resulted from the range of variables over the spatial interval. The Forsim VI package uses a modified Newton method for convergence of boundary conditions which required scaling of variables. The unscaled problem had a range of variables over ten orders of magnitude with use of reference concentrations presented in Table IV. The variables were scaled such that the range of values between the smallest and largest was reduced three orders of magnitude. The large range

of variable values was the result of fast reaction kinetics. The rapid bromine-propylene reaction, for example, caused sharp gradients at the reaction interface within the anode diffusion layer. The propylene and bromine concentrations exhibited large values on one side of the reaction zone, while values on the opposite side were approximately seven orders of magnitude smaller.

The second problem concerned slow convergence to steady state arising from stiffness of the differing transport time scales. That is, the relaxation time of the diffusion layers was significantly smaller than the space time of the central core. Integration typically proceeded to the stage where all time derivatives across the diffusion layers were essentially zero, while the time derivatives associated with the central region were still significant. The problem was remedied by choosing improved initial guesses for the central core concentrations, which accelerated convergence to steady state. The new initial guesses were determined through a Newton-Raphson technique. The jacobian was assumed to be diagonal, which allowed easy calculation of improved central core concentration estimates.

The set of dependent ODE's were scaled, cast into partial differential equation form, and then solved with use of the Forsim VI package on a CDC Cyber 175 computer. Typical execution times were 150s per case, excluding preliminary evaluation of initial guesses. The local truncation error was set at 1.0×10^{-5} . Five node points were used per diffusion layer. The solution was assumed to have converged when the time derivatives at every point within the spatial interval satisfied the criterion

$$\frac{dC_i}{dt} \leq 5.0 \times 10^{-3} \frac{C_i}{C_i} \quad [17]$$

Decreasing the convergence criteria to 5.0×10^{-5} resulted in a solution different by less than 1% for every variable. The uncoupled variables were then calculated from the coupled variable solutions.

The potential profile was found by solving the finite difference form of Eq. [14] at the discretized points across the diffusion layer. The kinetic overpotentials of each electrode were found by solving nonlinear equations and using a bisection technique. The convergence criterion for the overpotential determination was that the difference of the current predicted from the overpotential equation and the ODE solution agree within 1.0×10^{-4} (A/cm²).

Results and Discussion

The model was used to calculate yield, product selectivities, potential field, and concentration profiles across the cell. A series of test calculations summarized in Table IV was used to explore the response of the system to variation in reactor design parameters and chemical concentration variables.

The following definitions were used. "Conversion" was the fraction of the key limiting reactant which was consumed. "Yield" was the moles of a particular product generated per mole of key reactant consumed. "Selectivity" was the moles of a particular product generated per mole of another coproduct.

The results of one calculation are discussed in order to describe the general features which influence behavior of the electrolytic cell. The example situation had $\tau = 10$ s, $Sh = 2000$, $w = 1.0$ cm, and a feed stream composition of 0.500M NaBr at pH 14, saturated with propylene. The Sherwood number is defined by the ratio of diffusion layer thickness to the equivalent diameter, which for infinite parallel plates is twice the plate spacing $Sh = (2W/\delta) = (2i_s W/mFC_i D_i)$. Experimental measurement of the Sherwood number would be defined using the bromide ion diffusion coefficient. The spatial distributions of all variables except H⁺, OH⁻, and Na⁺ are presented in Fig. 3.

A listing of the reference quantities for scaling of variables appears in Table IV. The reference concentrations for the organic species is the saturation concentration of

propylene in aqueous solution at 25°C and 1 atm pressure. The reference concentration for bromine is the saturation concentration, and for hydrogen is 100 times the saturation concentration in aqueous solution at 25°C and 1 atm pressure.

The reaction pathway represents, in essence, an indirect oxidation via electrochemically generated reactants.

Fig. 3. Spatial variation of chemical species

That is, the electrochemically active species transfer the driving force, via bromine and hydroxide ion, to the propylene species.

Bromide ion entered the cell in the feed stream at a concentration of 0.500M. Bromide ion diffused to the anode, where it was oxidized to form bromine according to Eq. [1]. The Br₂ concentration at the anode surface had a value of 0.157 with respect to its saturation concentration. Within the anode mass-transfer boundary layer, Br₂ reacted with propylene to form propylene bromohydrin by Eq. [2]. The major cathodic reaction was electrolysis of water to form H₂ and OH⁻ ions according to Eq. [3]. Hydrogen concentrations, which were scaled against 100 times the saturation concentration, indicated values of 13 times the saturation concentration, indicated values of 13 times saturation at the cathode surface. The reaction of dissolved H₂ at the anode was found to cause an 8% loss of current efficiency under the conditions shown.

The propylene enters the cell in the feed stream at a dimensionless concentration of 1.0 and was reduced to a value of 0.371 by homogeneous reaction with Br₂. The largest rate of bromine-propylene reaction occurred where propylene contacted Br₂ within the anode diffusion layer. The propylene concentration decreased to essentially zero at the anode.

Bromohydrin and dibromide were formed at the reaction interface of propylene and Br₂. Both species exhibited maximum formation rates in the anodic diffusion layer at the bromine-propylene interface. In contrast to the sharp reaction zone formed by the bromine-propylene reaction, propylene oxide formation occurred over the entire reactor volume. Dibromide was formed in the anodic diffusion layer.

Propylene oxide had a spatial distribution with maximum concentrations near each electrode because the maximum rates of the oxide formation Eq. [4], occurred

near each electrode. The maximum near the anode was from the presence of high concentrations of bromohydrin; the maximum rate near the cathode was from the high concentrations of OH^- .

Glycol had behavior similar to that of propylene oxide, though it was less extreme since the reaction rate of oxide to glycol is four orders of magnitude slower than propylene oxide formation. The maximum near each electrode was caused by a different mechanism in the two-pathway route from oxide to glycol. The maximum rate of glycol formation near the anode was caused by uncatalyzed hydrolysis of oxide and thus exhibited a maximum rate in the regions of high oxide concentration. The cathodic glycol peak was from the base-catalyzed reaction pathway of glycol formation, and occurred from the high concentrations of OH^- within the cathodic diffusion layer.

For the particular case under discussion, the variation of potential across the cell is shown in Fig. 4. The potential drop was the result of IR drop across the cell, reversible electromotive force of the electrode reactions, and the overpotential of each electrode reaction. The example results show that the anodic overvoltage and the IR loss in solution were comparable and that the cathodic overvoltage was small. The conductivity used for this calculation was that which corresponds to dilute solution theory. The actual conductivity of a 0.500M NaBr solution is 32% less than the value predicted by dilute solution theory. Therefore, the IR drop is also in error by this amount.

The foregoing model was also used to investigate the response of the parallel-plate electrochemical cell to design variables. The most sensitive variables in the chemistry were $[\text{Br}^-]$ and pH. $[\text{Br}^-]$ controlled the yield of propylene oxide by determining the fraction of propylene converted to the bromohydrin. pH controlled the rate of propylene oxide generation.

Effect of pH.—The effects of feed-stream pH are summarized for three cases in Fig. 5. Additional data are provided in Table V as well as in the original reference (1). The effect of hydroxide ion concentration was chiefly upon the bromohydrin-oxide reaction, Eq. [4], and, to a lesser degree, on the oxide-glycol reaction, Eq. [7]. The decrease in the feed-stream pH caused the bromohydrin not to be converted to propylene oxide owing both to thermodynamics and also to pH dependence of the reaction rate. At lower feed-stream pH, the hydroxide ions re-

Fig. 4. Spatial variation of potential

Fig. 5. Effect of feed-stream pH

mained unreacted and served to increase sizably the central region pH above that of the feed. The selectivity of oxide-glycol was decreased through the increase in basicity; glycol formation was not significant at any pH considered. The decrease in hydroxide ion concentration also influenced the cathodic overpotential and decreased the solution conductivity, resulting in increased cell voltage.

Efficient conversion of bromohydrin to oxide was dependent on the pH in the electrolyzer. The equilibrium constant for the oxide formation reaction is 1.03×10^9 at unit concentrations and pH 14, but only 1.01×10^{-5} at pH 1. One method of accomplishing bromohydrin conversion was to force the reaction to completion with large hydroxide ion concentrations; 98% of the bromohydrin was converted to oxide at pH 14.

The operation of the cell at extremely high pH conditions may cause other reactions, not included in the model, to influence the reaction sequence. The hydrolysis of bromine to form $\text{Br}(+1)$ species, and further reaction to $\text{Br}(+5)$, may influence the rate of the propylene-bromine reaction. $\text{Br}(+1)$ formation would cause a decrease in the yield of propylene oxide with increasing pH. Increased basicity may cause other electrode reactions to occur in addition to bromine formation at the anode and water electrolysis at the cathode.

Effect of bromide ion concentration.—The effects of variation in the feed-stream bromide ion concentration are presented in Fig. 6; additional data are given in Table V. Decreasing $[\text{Br}^-]$ did not affect the rate of propylene consumption by bromine, but changed the ratio of bromohydrin to dibromide produced. Higher fractions of bromohydrin are formed when the bromine-propylene reaction occurs at low $[\text{Br}^-]$. Dilute bromide solution allows greater likelihood of hydroxide ion attacking the cation intermediate vs. the bromide ion which forms propylene dibromide. Decreased $[\text{Br}^-]$ thus resulted in increased selectivity of oxide/dibromide. High pH conditions allow the additional bromohydrin to be reacted further to form propylene oxide. The maximum yield observed was 90.4% at 0.100M $[\text{Br}^-]$. Higher yields could be achieved by decreasing $[\text{Br}^-]$ further. The decrease in bromide and sodium ion concentrations increased the cell voltage through IR resistance and the slightly larger anodic overpotential; the possibility of adding inert supporting electrolyte was not explored.

Greatest yields of propylene oxide are formed when low concentrations of Br^- were present at the propylene-bromine reaction interface. Decreased $[\text{Br}^-]$ also minimized formation of dibromide by-product.

Effect of mass transfer.—The effect of mass transfer is shown in Fig. 7 and in Table V. The variation of mass-

transfer conditions was done while holding all other parameters constant. Mass-transfer variation by this procedure corresponds experimentally to modification of turbulence promoters within the flow channel; changing the flow rate would influence reactor space time.

The decrease in mass-transfer rates caused higher conversion of propylene by 4%. The decreased transport of H₂ to the anode reduced the rate of side reaction, Eq. [3], and thus increased the current efficiency, generating more bromine for reaction. Slight increase in the oxide/dibromide selectivity with decreasing mass-transfer rates came about because the bromine-propylene reaction interface was shifted to regions having lower bromide ion concentrations.

Decreasing mass-transfer slightly increased the selectivity of oxide over dibromide, and also increased the cell

voltage. The yield of propylene oxide was not sensitive to mass transfer over the range of conditions studied.

Effect of space time.—The results of reactor space-time variation under conditions of constant stoichiometry are presented in Fig. 8 and in Table V. The propylene/Br₂ stoichiometric ratio was kept constant by increasing the current with decreasing space time to achieve the same theoretical conversion of propylene; therefore, the decrease in space time caused increased potential drop from IR and overpotential losses owing to the increased current. Decreased space time promoted propylene conversion by increasing anodic current efficiency. The variation in space time affected the conversion of bromohydrin to propylene oxide; the incomplete conversion was from the slowness of the bromohydrin-oxide reaction, Eq. [4], which decreased the oxide/bromohydrin selectivity. The conversion of bromohydrin to propylene oxide decreased with decreasing space time.

The dominant region for the bromohydrin to oxide and oxide to glycol reactions was in the central stirred core, and both reactions were affected by the variation in space time. The faster propylene-bromine reaction was unaffected since the reaction zone was within the anode diffusion layer.

The results of the reactor space-time variation with constant current are also presented in Table V. The decrease in space time with constant cell current decreased the theoretical conversion of propylene. Although the yield of propylene oxide was not significantly influenced, the decreased conversion of propylene gave better selectivity of oxide to dibromide and oxide to glycol. The potential field across the cell was virtually unaffected.

Fig. 6. Effect of feed-stream bromide ion concentration

The synthesis for propylene oxide was found to be more efficient by producing less dibromide under lower conversions of propylene. Additional advantages would be gained in the oxide/dibromide selectivity by operating the reactor at lower conversions and increased propylene concentration (pressure).

Conclusions

This work demonstrates procedures for incorporating realistic reaction mechanisms into models of electrolytic cells. Limitations on computational feasibility were encountered owing to stiffness of the differential equation describing the reactor. It was found that dynamic simulation with the Forsim VI algorithm gave good results. By this procedure, the dependence of space-time yield, conversion efficiency, and power consumption upon variation of design variables were predicted for paired synthesis of propylene oxide in an undivided cell.

The example of propylene oxide synthesis has been useful for the purpose of illustrating the general procedures involved in this study, but the central contribution of this work should be recognized to be applicable to many other specific process candidates, including inorganic syntheses. For the propylene oxide system, the effect of an increase in pH is to facilitate the in-cell conversion of bromohydrin to propylene oxide owing both to

Fig. 7. Effect of mass transfer

Fig. 8. Effect of space time of constant Br_2 /propylene stoichiometric ratio.

the appearance of OH^- in the reaction and also to the pH dependence of the rate constant. The bromide ion concentration influences reaction of bromine and propylene in the anodic diffusion layer, giving dibromide at high concentrations and bromohydrin at low concentrations. The variation of mass-transfer coefficient was found not to influence selectivity or yield significantly. An increase in space time, however, was found to enhance the in cell conversion of bromohydrin to propylene oxide which occurs throughout the cell volume. Variation in space time had an insignificant effect on the dibromide/bromohydrin ratio, which is determined by conditions in the anodic diffusion layer.

As the level of sophistication of mathematical simulation increases, the accuracy of supporting knowledge of mechanism and of data base must also increase. In the present study, it was necessary to have specific rate equations, rate constants, thermodynamic equilibrium constants, transport properties, reaction stoichiometry, knowledge of reaction intermediates, and mass-transfer coefficient. Models of electrolytic cells can also be extended to include economic balances in order to identify reactor designs and operating conditions which optimize economic objectives. The extent to which such auxiliary data are available will determine, to a large degree, the accuracy with which model predictions can simulate realistic cell behavior.

The Wetting Behavior of Dialkylimidazolium Chloroaluminate, a Room Temperature Molten Salt

J. G. Eberhart¹

The Frank J. Seiler Research Laboratory, U.S. Air Force Academy, Colorado Springs, Colorado 80840

The wetting behavior of a battery electrolyte can have a dramatic effect on the internal resistance of the battery as well as its cycle life (1). Good wetting of battery separators by electrolyte is essential for the easy passage of ions through the separator pores during charge and discharge. Porous, gas diffusion electrodes require, on the other hand, a lesser degree of electrolyte wetting, so that the line of contact of the three phases (reactive gas/liquid electrolyte/porous electrode or current collector) can be maintained within the porous electrode through a balance of capillary and hydrostatic pressures.

For several years, a room temperature molten salt system composed of 1-methyl-3-ethylimidazolium chloride ($C_6N_2H_{11}Cl$ or MeEtImCl) plus aluminum chloride has been under study at the Frank J. Seiler Research Laboratory (2-5). The most promising application of this novel liquid solution is as a battery electrolyte. Analysis of available physical and electrochemical data suggests that cells with a chlorine positive electrode reactant and a magnesium, aluminum, or zinc negative electrode material are likely candidates (6).

To assess wetting behavior in this electrochemical system, a study was undertaken of the contact angles of various room temperature molten salts on candidate battery separator and porous electrode materials. The factors examined in the study were the effects on wettability of (i) the melt composition, (ii) chemical constitution of the solid, (iii) chlorination of the organic component of the melt, (iv) replacement of the $AlCl_3$ component by other inorganic compounds, and (v) cleaning procedure for the solid.

Theory

The wettability of a solid surface is defined in terms of the contact angle, θ , made by a liquid drop resting on the solid surface (7); see Fig. 1. The angle θ can take on values ranging from 0° to 180° . The contact angle made by a liquid on a solid can have either one value or a range of possible values, depending on the nature of the solid surface.

If the solid surface is idealized as smooth, chemically homogeneous, isotropic, and nondeformable, and there is no mutual solubility or chemical reaction between the two phases, then there is only one stable, equilibrium contact angle which is given by Young's equation (7)

$$\gamma_{LV} \cos \theta = \gamma_{SV} - \gamma_{SL} \quad [1]$$

where γ_{LV} is the liquid surface tension, γ_{SV} is the solid surface tension, and γ_{SL} is the interfacial tension between the solid and liquid phases.

A real solid surface, on the other hand, may be rough, chemically heterogeneous, and anisotropic and the contacting liquid will have a range of allowed contact angles rather than a single value (7). The maximum angle is called the advancing contact angle, θ_A , while the minimum angle is called the receding contact angle, θ_R . The difference $\theta_A - \theta_R$ is the contact-angle hysteresis. The

¹Permanent address: Department of Chemistry, University of Colorado, Colorado Springs, Colorado 80933-7150

range of contact angles in these systems leads to three categories of wetting behavior (8). If $\theta_R < \theta_A < 90^\circ$, then the solid is easy to wet by the liquid and the liquid will spontaneously penetrate pores of the same solid. If $\theta_R < 90^\circ < \theta_A$, then the solid is difficult to wet by the liquid and the liquid will not spontaneously penetrate pores of the same solid. However, if the liquid is forced into these pores by the application of a hydrostatic pressure, it will remain in the pores after the pressure is removed. Finally, if $90^\circ < \theta_R < \theta_A$, then the solid is impossible to wet by the liquid and the liquid will not spontaneously penetrate pores of the same solid. If the liquid is forced into these pores, it will spontaneously leave the pores when the force is removed.

The advancing and receding contact angles were determined from observations of a tilting sessile drop (7). If the angle of tilt of the substrate is increased, then the upper and lower contact angles of the drop, θ_U and θ_L , will approach their limiting or extreme values of θ_R and θ_A , respectively; see Fig. 2.

Experimental Methods

The 1-methyl-3-ethylimidazolium chloride and aluminum chloride are reactive with moisture, so the preparation of their solutions at various compositions and the determination of contact angles on various solid surfaces was carried out entirely within a helium glove box having moisture and oxygen concentrations of less than 10 ppm (3). The MeEtImCl was prepared from vacuum-distilled 1-methylimidazole (obtained from Aldrich Chemical Company) as previously described (3). The $AlCl_3$ (obtained from Fluka Chemical Corporation) was sublimed (9) before mixing with the MeEtImCl. The salt solutions were prepared at $AlCl_3$ mole fractions, N , of 0.333, 0.500, 0.600, and 0.667. This choice covers the range of basic ($N < 0.5$), neutral ($N = 0.5$), and acidic ($N > 0.5$) behavior and was selected to show the effect of melt composition on wetting behavior.

Solutions were also prepared using the chlorinated imidazolium salt, 4,5-dichloro-1-methyl-3-ethylimidazolium chloride ($C_6N_2H_9Cl_2$), with $AlCl_3$ mole fractions of 0.375, 0.600, and 0.650, to determine the effect of chlorination on wetting behavior.

A solution of the imidazolium salt with lithium chloride was also prepared with a $LiCl$ mole fraction of 0.376 to examine the effect of the $AlCl_3$ on wetting behavior.

A simple tilting stage was fabricated in order to observe upper and lower contact angles as a function of the substrate tilt angle. The stage can hold substrates of interest

Fig. 1. The contact angle of a liquid on a solid surface

Fig. 2. The upper and lower contact angles of a liquid drop on an inclined solid surface.

(whether rigid or film) in any orientation from horizontal to vertical. The contact angles and tilt angles were observed through the glove box window with a Gaertner telemicroscope equipped with a goniometer and two X-Y positioning micrometers.

The substrates examined were soda-lime glass microscope slides, Teflon (Berghof/America, Incorporated), Celgard 2500 and 3501 polypropylene film (Celanese Corporation) with 45% porosity and 0.04 μm pore size, and reticulated vitreous carbon or RVC (Energy Research and Generation, Incorporated) with a 97% porosity and 70-90 pores per inch.

The substrates were cleaned in various ways. The soda-lime glass was washed either with Alconox solution (Alconox, Incorporated) or with Chromerge chromic-sulfuric acid solution (Manostat), and then rinsed with water and with ethanol. Residual ethanol and water were removed from the samples by evacuation while they were transferred into the glove box. The Celgard films and the RVC were washed in ethanol. Although the two Celgard films have the same mechanical properties and pore structure, the Celgard 3501 is hydrophilic because of treatment with proprietary surfactant. As a result, the Celgard 3501 is more wettable by aqueous systems than the hydrophobic Celgard 2500. This difference could be observed during cleaning of the two films with ethanol. The films are white and opaque, but when the 3501 was cleaned with ethanol it became momentarily transparent. A Celanese technical representative attributed this behavior to the pore filling of the 3501 film and the resultant change in optical properties.

Experimental Results

The advancing and receding contact angles for a number of different room temperature, dialkylimidazolium chloroaluminate molten salts were determined on the substrates described above using the tilting drop technique at temperatures in the range of 27°-28°C. The results of these measurements are summarized in Table I.

The advancing and receding contact angles for the 1-methyl-3-ethylimidazolium chloride plus aluminum chloride melts on glass, Teflon, polypropylene, and RVC surfaces are shown in the first portion of Table I. All of the substrates except the RVC are easy to wet by the melt with spreading observed for several acidic melts on glass. RVC is difficult to wet by basic and neutral melts.

The contact angles for chlorinated melts of 1-methyl-3-ethylimidazolium chloride plus aluminum chloride on glass surfaces are shown in the second part of Table I. As with the nonchlorinated melts, glass is easy to wet by the chlorinated melt.

The last portion of Table I shows the results of replacing AlCl_3 by LiCl in the 1-methyl-3-ethylimidazolium chloride melts. Glass and Celgard 2500 substrates were difficult to wet by a basic melt of this system.

Conclusions

An examination of the data presented suggests the following. 1. The 1-methyl-3-ethylimidazolium chloride plus aluminum chloride melts show easy-to-wet behavior on all substrates tested except RVC. The RVC is difficult to wet by basic or neutral melts and easy to wet by acidic

^a N is the mole fraction of the inorganic melt component.

melts. 2. With only one exception (Celgard 3501), wetting behavior improves as the mole fraction of AlCl_3 increases. 3. On glass surfaces, the chlorination of the 1-methyl-3-ethylimidazolium chloride has relatively little effect on the melt's wetting behavior. 4. When aluminum chloride is replaced by lithium chloride the easy-to-wet behavior changes to difficult-to-wet behavior on the surfaces tested. 5. The treatment of polypropylene film with a surfactant to change the surface from a hydrophobic to a hydrophilic nature has little effect on the wettability of the surface by the molten salts studied here. 6. The way in which a surface is cleaned can have a dramatic effect on its wettability.

These results indicate that AlCl_3 plays a key role in the good wetting of these molten salt solutions. This view is supported by the previously reported effectiveness of LiAlCl_4 as a battery-separator wetting promoter for LiCl-KCl molten salt solutions (1, 10).

Based on the above observations, a number of conclusions can be drawn regarding the wetting behavior of battery electrolyte containing AlCl_3 and dialkylimidazolium chloride. 1. It is not expected that any serious problems will be encountered with the wetting of battery separators and porous electrodes, especially in the acidic range of concentrations. 2. It is possible that electrolyte wetting may be better than desired in the case of gaseous electrode reactants. If such problems should occur, it is likely they could be remedied by a decrease in the AlCl_3 mole fraction without serious impairment of separator and current-collector wettability. 3. If chlorinated melts are used in original cell designs or produced as a result of a chlorine gas positive electrode, their wetting behavior is likely to be about the same as that of the nonchlorinated melts. 4. If electrolytes are considered without AlCl_3 as the inorganic component, then the generally favorable wetting picture presented here could change dramatically for the worse.

Electroplating of Tungsten Carbide from Molten Fluorides

Kurt H. Stern* and M. L. Deanhardt*,¹

Naval Research Laboratory, Chemistry Division, Washington, DC 20375-5000

In previous work (1), it was shown that adherent coatings of tungsten carbide could be deposited on nickel substrates from the molten ternary fluoride eutectic (Li,Na,K)F (FLINAK) containing several weight percent

(w/o) each of Na_2WO_4 and K_2CO_3 . In these preliminary studies, the plating was carried out between a tungsten anode and the nickel cathode at an applied voltage of 1.5V, and solute concentrations of 1-10 w/o. It was found that the coating composition (W_2C , WC), current efficiency (c.e.), and structure of the deposit depends both on the concentration of each solute as well as the so-

Fig. 1. Electrodeposited W_2C coatings. 3 w/o Na_2WO_4 , 1 w/o K_2CO_3 ; 500°C. a(top left): -1.0V. b(top right): -1.5V. c(left): -2.2V.

lute concentration ratio. For example, at higher C:W ratios (> 2), if the concentrations are also high, the coating is WC, the c.e. is low and the coating structure is unsuitable for a wear coating.

Subsequent to these studies, voltammograms and chronopotentiograms for tungstate reduction were obtained (2). These and the work described above were used to refine and improve the deposition process, using a three-electrode rather than a two-electrode cell arrangement. With this arrangement, the potential of the nickel cathode is controlled relative to a separate platinum quasi-reference electrode. Since essentially no current passes through the quasi-reference electrode, its potential will remain constant, and the potential of the nickel cathode can be accurately controlled. This was not possible in

the previously used two-electrode arrangement since the potential of the nickel cathode varies with the magnitude of current. Since voltammetric studies of WO_4^{2-} reduction (2) had shown that no tungsten deposition occurred more positive than -0.7V , and that below -2V the reduction probably occurred indirectly through the prior reduction of Li^+ , most of the experiments were carried out in the range -1.0 to -1.5V . Furthermore, based on the previous deposition study (1), the concentrations were restricted to 3 w/o Na_2WO_4 and 1-3 w/o K_2CO_3 .

Experimental

The general procedure used has been described previously (3). It was modified in this study by being carried out in a O_2 - and H_2O -free (a few parts per million of each)

Fig. 2. Electrodeposited W_2C coating. 3 w/o Na_2WO_4 , 2 w/o K_2CO_3 ; 500°C . a(top left): -1.0V . b(top right): -1.25V . c(middle left): -1.25V , cross section. d(middle right): -1.5V . e(left): -2.2V .

glove box with recirculating purification system (Vacuum Atmospheres Corporation) and using 100-200g of melt. After pre-electrolysis, the melt was filtered through a silver gauze into a nickel reaction vessel. Electrodes were positioned in the melt through holes in a lava block. The solutes were added (Na_2WO_4 was prepared by vacuum dehydration of its dihydrate at 200°C), and electrolyses carried out at 750°C using a potentiostat (PAR Model 173), and the amount of charge followed with an electronic coulometer (PAR Model 179). At the end of each run, the nickel electrodes were quickly withdrawn from the reaction vessel, freed of adherent melt and loose deposit by ultrasonic cleaning in water, and examined by scanning electron microscopy (SEM) and x-ray diffraction. In some cases the cross sections were examined also.

Results

Figures 1-3 show the surface structures of deposits, all of which were found to be W_2C by x-ray diffraction, obtained at different voltages and K_2CO_3 concentrations at a constant Na_2WO_4 concentration of 3 w/o. The total amount of charge passed in each case was 500C to plate an area of $\sim 2\text{ cm}^2$.

Figures 1a-1c show the surface of the coating obtained at 1 w/o K_2CO_3 and three different voltages. All voltages are given with respect to the platinum reference electrode. At -1.0V , the surfaces of the individual crystallites are nearly flat and densely packed, whereas with increasing voltage the individual crystals are irregularly shaped and the overall surface becomes increasingly rough.

At 2 w/o K_2CO_3 , the surface structure appears highly dependent on relatively small changes in voltage. At -1.0V (Fig. 2a), the W_2C surface is densely covered with crystal-

lites of varying shapes and sizes. However, beneath this debris the surface appears to consist of a uniform distribution of very small ($<1\ \mu\text{m}$), densely packed crystallites. A change of voltage to -1.25V produces a more uniform surface of densely packed, irregularly shaped crystals (Fig. 2b). A cross-sectional view of this coating (Fig. 2c) indicates that it is dense and columnar (the coating was lightly etched with a $\text{KMnO}_4\text{-NaOH}$ solution to bring out the carbide structure) and that the surface view is probably dominated by the arrangement of crystals on the surface. As was also found previously (1), there appears to be no interdiffusion zone at the coating-substrate boundary. In contrast, an extensive interdiffusion zone was evident for coatings of tantalum carbide (3). However, the adherence of W_2C appears to be excellent, although no tests were carried out to test the adherence of the coating. At -1.5V (Fig. 2d), the crystals are rounded, indicative of nuclei which may grow together on further plating. The structure again changes markedly at -2.2V (Fig. 2e), consisting of an interconnected, serpentine network with a rather smooth overall surface.

A further increase in K_2CO_3 concentration to 3 w/o produces a new set of structures. At -1.0V (Fig. 3a), the underlying surface is quite smooth, with a few large angular crystals and many smaller ones at the surface. At -1.25V (Fig. 3b), the structure of the coating strongly resembles that obtained at 1 w/o and -1.0V (Fig. 1a), whereas at -2.2V (Fig. 3c) there are no distinct crystallites at all, but a fairly smooth, almost glassy looking surface.

The ability of the coating to follow complex surfaces is illustrated, at a much lower magnification, by a comparison of coated and uncoated engravings (Fig. 4). Figure 4a shows some details of an unplated, engraved nickel plate. The lines of the grid are $\sim 60\ \mu\text{m}$ wide and $25\ \mu\text{m}$ deep;

Fig. 3. Electrodeposited W_2C coating. 3 w/o Na_2WO_4 , 3 w/o K_2CO_3 , 500°C . a(top left): -1.0V . b(top right): -1.25V . c(left): -2.2V .

Fig. 4. Engraving plated with W_2C . 3 w/o Na_2WO_4 , 3 w/o K_2CO_3 , $1000^\circ C$. a(top left): Unplated. b(top right): Plated. c(bottom left): Cross sections of plated, engraved line. d(bottom right): Cross section of plated, engraved letter.

the grooves of the letters are $\sim 150 \mu m$ wide and $30 \mu m$ deep. After plating with W_2C (Fig. 4b), the engraved lines and letters are still clearly visible, though somewhat narrowed and fuzzy. The cross sections of both lines and letters show that the coating conforms very well to the metal surface but the coating surface shows some unevenness (Fig. 4c and 4d).

Discussion

The modification of the plating process from two-electrode (1) to three-electrode appears to have improved the coating structure considerably with respect to density, surface smoothness, and conformity to substrate. Presumably, control of the potential of the nickel electrode results in plating conditions such that better coating structure is obtained. In addition, better atmospheric control and melt pre-electrolysis may also have contributed to the improvement.

The optimal voltage range for W_2C deposition, -1.0 to $-1.5V$, is consistent with the reduction of $W(VI)$ to $W(0)$ (2). It is very noticeable, however, that whereas the coating structure of metallic tungsten obtained in this range is quite poor and the current efficiency is $\sim 10\%$, the addition of 1-3 w/o K_2CO_3 and plating in the same voltage range gives very good coatings with current efficiencies of 50%. We do not know how the coreduction of CO_3^{2-} and the subsequent chemical reaction between tungsten and carbon affect the overall deposition; neither of these processes has been studied yet. It does seem that Senderoff and Mellors (4) are correct and oxyanions are detrimental to the metal plating process (current efficiency is poor, and the deposit does not adhere to the substrate).

As is obvious from Fig. 1-3, and also from earlier work (1, 5), the surface structure of the coating is markedly dependent on plating conditions: melt composition, voltage, and even total charge passed (5). However, as can be seen from the cross sections (e.g., Fig. 2c), the coating structure overall is dense and no porosity is visible, even when the surface structure appears to have holes or irregularities. Since the surface is just the coating being formed at the time the plating stops, it follows that the coating being formed undergoes further regrowth and densification as surface becomes bulk. Thus, if a coating were to be polished, one would expect to obtain a smooth, continuous layer of W_2C . From a practical point of view, e.g., for producing wear coatings, one would need to consider whether the cost of such a procedure was justified or whether further research should be done to improve the "as-grown" surface structure.

Acknowledgment

We would like to thank Michael McCollum for the x-ray analyses and SEM photographs.

The demand for chlorine for water and waste treatment is increasing because of the increase of water consumption, a large amount of waste water discharge, and governmental regulations. Transportation and handling of chlorine cylinders and containers are strictly controlled to avoid hazard. As a result, on-site electrolytic production of hypochlorite becomes important for disinfection of drinking water, oxidation of sewage, chlorination of cooling water in process plants, and other uses. There are now a number of publications and patents on hypochlorite cells and the electrodes to be used (1-13).

A hypochlorite cell must be simple in operation with minimum maintenance for a year or more. The energy consumption is also an important factor.

In an electric power station located by the sea, saline water containing some 3% NaCl is fed to the hypochlorite cell and is chlorinated prior to being sent to the heat exchangers in the plant. Because of the low salt concentration, oxygen evolution occurs, and this reduces chlorine current efficiency. Also, sea water contains Mg and Ca ions, which deposit at the cathode, resulting in high cell voltage. Periodic acid cleaning removes the scale, but affects the electrodes, especially the anode coating, and in some cases the electrode activity is not restored.

Pretreatment of sea water prior to electrolysis is preferable, but it is expensive and complicated. Therefore, durable anodes having such characteristics as low chlorine overvoltage and high oxygen overvoltage in sea water must be developed to improve the operating performance of hypochlorite cells.

Experimental Procedure

Two types of the platinized Ti anodes were used as controls. One was Pt-plated Ti sheet prepared by conventional electroplating (hereafter referred to as "regular Pt/Ti"). The other was also a Pt-plated Ti sheet and had a large surface area ("modified Pt/Ti") (14). The average thickness of the Pt coating was 3 μm .

The modified Pt/Ti sheet was painted with a solution containing a metal chloride, such as RuCl_3 or IrCl_3 , depending on the oxide catalyst proposed, dried in air, and then fired at 500°C for few minutes to deposit the oxide on the Pt layer (MODE®). In this work, the Ir oxide-loaded material was used mostly.

Full-scale experiments were conducted in an electric power plant located at Tokyo Bay. The flowsheet is illustrated in Fig. 1. Eight cells were operated in series and parallel connections; the sea water was fed to the top end of the cell series, electrolyzed, and mixed together at the outlet. The chlorinated sea water was sent to the heat exchangers in the plant. Each hypochlorite cell employed was equipped with five anodes and six cathodes (carbon steel plate) in parallel. There were no separators. The design capacity of the cell is as follows. The effective area of

electrode was 80 cm wide and 45 cm high each. The anode-to-cathode gap was 5 mm. The current density was 15 A/dm² at 5.4 kA total current load. The cell voltage was 5.5 \pm 0.5V. The solution flow rate was 60 m³/h. The chlorine generation was 5 kg/h. The conditions of the sea water varied with season in the following ranges: for temperature, 9°-28°C; for electrical conductivity, 42-50 mmhos/cm; for Cl⁻ concentration, 15.5-18.5 g/liter; for pH, 7.6-8.4; for suspended solids, 9.0-22.0 ppm; and for chemical oxygen demand (COD), 0.2-3.2 ppm. Since the COD level was low in winter, the electrolytic current was lowered to avoid residual chlorine in the discharged water.

A small cylinder cell was also operated with various anodes as reference. The nameplate capacity was 150A, producing 160 g-Cl₂/h at 80% current efficiency.

Results and Discussion

Life test of the modified Pt/Ti anode were conducted for 3 years. The thickness and condition of the Pt layer were measured several times. The consumption rate of Pt was large at the beginning, and became smaller with time. Warren *et al.* reported similar behavior for platinized Ti anodes in copper electrowinning cells (15). Since the water hardness in the first cell was high, heavy scales deposited and affected the Pt coating.

The Ti substrate was also attacked by oxygen evolution, affecting the Pt to Ti bond. The service life of the regular Pt/Ti was estimated to be ca. 3 years. However, a tight oxide film just under the Pt layer of the modified Pt/Ti anode (the MODE), prevented further oxidation of the Ti substrate. This resulted in long life for these anode materials.

From the results of the field tests together with practical operations for 6 years, the average consumption of the Pt layer of the modified Pt/Ti anode was estimated to be ca. 0.4 $\mu\text{m}/\text{yr}$ in thickness under normal conditions.

The field test of the MODE was started at the end of November 1982, and is being continued without serious trouble.

Brine flow rate, current, cell voltage, chlorine current efficiency, solution temperature, salinity, COD, electrical conductivity of saline water, and other factors were measured intermittently at intervals of about one month.

The cell was operated at the rated amperage (5.4-5.5 kA) in summer, and at lower currents in other seasons, to

Fig. 1. Flowsheet of the field test with large scale hypochlorite cells in an electric power station.

* Electrochemical Society Active Member.

Fig. 2. Terminal voltage of a large scale hypochlorite cell

meet the COD level in the sea water. The cell voltage varied with the season, mainly because of the solution temperature and hence the electrical conductivity. Heavy scaling and fouling on the working electrodes were also factors.

175 data points obtained from the field test for 10 months were processed by desk computer. The variations of the electrical conductivity of sea water with temperature was calculated. The cell voltage with the MODE was about 0.4-0.5V lower than that with the modified Pt/Ti anode, depending on the amperage, as shown in Fig. 2.

The chlorine current efficiency on the MODE was in the range 85-90% compared to less than 80% with the Pt/Ti anodes. The chlorine current efficiency decreased slightly with increase of current density.

Table I shows the breakdown of the terminal voltage of a cylindrical cell with different anode materials at 150A or 8.9 A/dm² in current density. The decomposition voltage is an extrapolation of the volt-ampere curve to zero current. The solution IR drop is the largest factor because the electrical conductivity of sea water is low and the electrode gap is relatively large (ca. 20 mm). This factor may be reduced by adequate design of the cell configuration. The cathode overvoltages for the two cells are equal, so that the cell voltages reflect the anode overvoltage in both cases.

Figure 3 illustrates the polarization curves of various anode materials in 300 g/liter NaCl solution saturated with chlorine at 30°C. The overvoltage of the MODE increased by 150 mV at 10 A/dm² after 4 months of electrolysis with a cylindrical cell in comparison with the virgin sample. Even so, the overvoltage of the MODE was still lower than that of the platinized anodes. The polarization measurements were also conducted in dilute solution (30 g/liter NaCl), and the overvoltage was almost the same as in the concentrated solution. Some oxygen is generated.

The saving in energy consumption by using a low overvoltage anode is represented as follows

Table I. Breakdown of the cell voltages at 150A

	With MODE	With modified Pt/Ti
Decomposition voltage (V)	2.42	2.42
Anode overvoltage (V)	0.60	1.21
Cathode overvoltage (V)	0.61	0.61
Solution IR drop (V)	4.30	4.30
Terminal voltage (V)	7.93	8.54

Fig. 3. Polarization curves of the platinized titanium anodes in 300 g/liter NaCl saturated with chlorine at 30°C.

$$\Delta W = \frac{W - W_1}{V\xi_1} = 1 - \frac{V_1\xi}{W\xi_1} \quad [1]$$

where V is the cell voltage in volts, W the energy consumption in kWh/kg-Cl₂, and ξ is the current efficiency. The subscript 1 indicates the test cell.

For a current of 15 A/dm², $V = 6V$, $V_1 = 5.5V$, $\xi = 70\%$, $\xi_1 = 80\%$, and the energy saving is about 20%, which agrees with the data of the field tests.

In conclusion, since physical degradation of the platinized Ti anode was troublesome in the hypochlorite cells, a modified Pt/Ti anode was developed. This was treated further to improve the overvoltage characteristics by coating with iridium oxide by thermal decomposition of an Ir compound. The chlorine overvoltage for this material, MODE, was low, and the chlorine current efficiency was high compared to uncoated platinized titanium. A 10 month field test at an electric power station gave energy saving of ca. 20%.

Chiral Polypyrroles from Optically Active Pyrrole Monomers

Manuel Salmón*

Instituto de Química de la Universidad Nacional Autónoma de México, Circuito Exterior, Ciudad Universitaria, Coyoacán 04510, México

Gerard Bidan

Laboratoire d'Electrochimie Organique et Analytique, Laboratoires de Chimie, Département de Recherche Fondamentale, Centre d'Etudes Nucleaires de Grenoble, F-38041 Grenoble Cedex, France

Previous reports have shown that the use of electrochemically prepared polypyrrole-coated electrodes further coated with polyaminoacids by the dipping method introduces asymmetry to the electrode surface (1).

Electrodes modified with chiral groups have shown potential as asymmetric inductors in electro-organic synthesis (2). However, in spite of the stability improvements in this class of chiral electrodes, the loss of the asymmetry inducing power is a major problem (3).

Recently, we have shown that N-alkyl- and N-phenyl-substituted pyrroles produced by anodic oxidation result in stable electroactive polymer films which can be used as modified electrodes (4). From among these compounds, we have selected the hydroxy derivatives I and II (5) to synthesize optically active pyrrole monomers (6) III [$\alpha]_D^{18} + 25.4$ and IV [$\alpha]_D^{18} + 11.4$ (Fig. 1) which contain the (+) camphor-10-sulfonate ester as a chiral group.¹ The chiral pyrrole monomers used were ester derivatives of camphorsulfonic acid. This last compound was chosen as the asymmetric chromophore because it is well known that it exhibits circular dichroism.² The results of an electrochemical study have shown that chiral centers can be easily incorporated into polymeric materials.

Cyclic voltammetry of the monomeric pyrrole units III and IV showed one irreversible peak at 0.93 and 1.02V (*vs.* Ag/10⁻²M Ag⁺), while thin polymer films derived from the monomers using a total charge of 2.0 and 3.0 mC/cm² gave a reversible redox system with defined E_{pa} and E_{pc} peaks as shown in Fig. 2. The electrochemical properties of these polymeric materials are not affected by exposure to air and a color change is observed when the oxidized form is driven (brown) to the neutral (yellow) state resembling the polypyrrole matrix (4).

The films are smooth and adhere strongly to the Pt electrode in spite of the large substituent which had very little effect on the redox values (Table I) when compared with other N-alkyl pyrrole polymers (4).

Thin polymer films were obtained from the environmentally stable monomers III and IV on Pt (3×10^{-2} cm²) and on indium-oxide-glass (1 cm²) electrodes by controlled potential at 0.80V *vs.* Ag/10⁻²M Ag⁺ reference electrode. Argon purged acetonitrile solutions containing 0.1 or 0.7M anhydrous LiClO₄ and 3×10^{-2} M optically active pyrrole monomer derivatives were used to grow the films on the electrode surface in a one compartment cell. Pt wire and Ag/10⁻²M Ag⁺ were the counter and reference electrodes, respectively.

*Electrochemical Society Active Member.

¹All new compounds gave correct spectroscopic and combustion data.

²D-(+) camphor 10-sulfonic acid contains a carbonyl chromophore absorbing at $\lambda_{max} = 290$ nm; the keto group is located in a dissymmetric surrounding and so is optically active.

Table I. Summary of data for monomers and polymers *vs.* Ag/10⁻²M Ag⁺

		E_{pa}		E_{pa}	E_{pc}	E_n
Monomer	III	0.93	Polymer	0.28	0.24	0.27
	IV	1.02		0.16	0.26	0.21

Thin polypyrrole films from the optically active monomers were easily prepared in spite of the large camphor-sulfonate ester substituent and were stable when cycled from -0.4 to 0.6V *vs.* Ag/10⁻²M Ag⁺ (Fig. 2) in dry and oxygen-free electrolyte.

The optical activity of the chiral monomers and polymers was evaluated by circular dichroism (CD) measurements using a Dichrographe III Roussell-Jouan instrument. The instrument was calibrated before each measurement using (+)-camphor-10-sulfonic acid solutions, as was suggested by Krueger and Pshigoda (7).

The c.d. study was performed with different quantities of chiral polypyrrole deposits in their oxidized or reduced state. The total charge applied to form these films was in the range of 50 to ca. 90 mC/cm² (Fig. 4a-4f). The stability of the chiral polypyrrole materials as coated electrodes can be compared with those of N-alkyl or N-phenylpolypyrroles (4), which are far more stable than those asymmetric poly(amino acid)-coated electrodes prepared by the dipping method (1).

Fig. 1. N-alkylpyrrole (+) camphor-10-sulfonate ester derivatives

Fig. 2. Cyclic voltammograms with 2 and 3 mC/0.3 cm²/Pt films of chiral polypyrroles derived from monomers III (curve b) and IV (curve a) at 100 mV/s in CH₃CN containing 0.1M LiClO₄.

Figure 3 shows the gaussian-type c.d. curves of the pyrrole monomers compared with dc curves of camphorsulfonic acid and its sulfonyl chloride.³ Positive Cotton ef-

³(+)-Camphor-10-sulfonyl chloride, puriss. from Fluka.

⁴The Cotton effect exhibited by a molecule is associated with the presence of a chromophore (light absorbing group), which is either chiral or in which the dissymmetric vicinity makes the transition optically active (8).

Fig. 3. The circular dichroism curves of (+) camphor-10-sulfonyl chloride (diamond-shaped point), (+) camphor-10-sulfonic acid (solid line), pyrrole monomer derivatives III (dotted line), and (IV) (open circles) reveal positive Cotton effect.

fect⁴ was observed in all samples at $\lambda_{\max} = 290$ nm for (+)-camphor-10-sulfonic acid, $\lambda_{\max} = 293$ nm for (+)-camphor-10-sulfonyl chloride and pyrrole camphorsulfonate IV, and the $\lambda_{\max} = 294$ nm band for the pyrrole monomer camphorsulfonate III.

The c.d. measure was also employed to identify the asymmetric material deposited as a film onto an indium-oxide-glass electrode. No c.d. effects were observed with either a bare indium-oxide-glass electrode or unsubstituted polypyrrole perchlorate film (51 mC/cm²) deposited in the same electrode (Fig. 4a-4b).

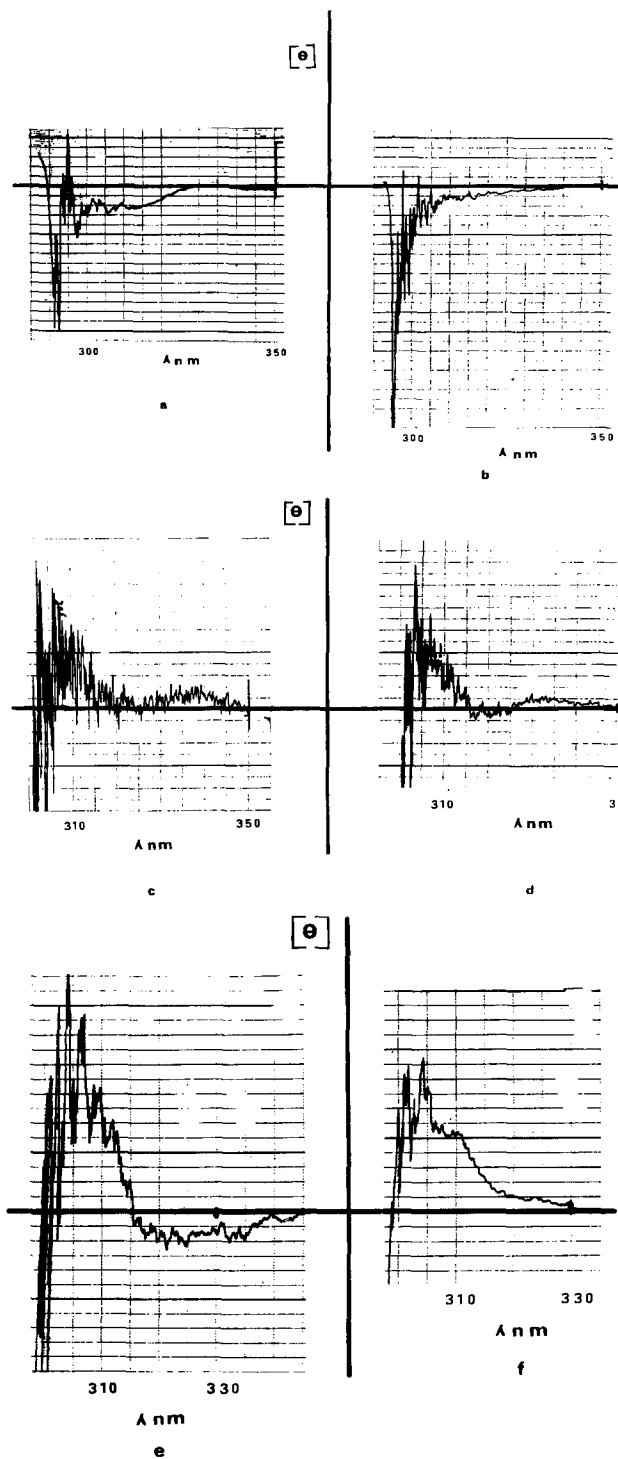

Fig. 4. Circular dichroism curves of bare indium-oxide-electrode (a) and polypyrrole/CIO₄ film-coated electrode 51 mC/cm² (b). Circular dichroism curves of indium-oxide-electrode coated with chiral polymer obtained by oxidation of monomer IV in its oxidized (c) (66 mC/cm²) and reduced state (d) (87 mC/cm²). Circular dichroism curves of indium-oxide-electrode coated with chiral polymer obtained with pyrrole monomer III in its oxidized (e) (70 mC/cm²) and reduced form (f) (50 mC/cm²).

The experience (9) in polymerizing pyrrole monomers substituted with functional electroactive groups showed that the electroactive properties of these groups are not affected by polymerization. Moreover, the polypyrrole matrix also remains stable when cycled from negative to positive potentials. Consequently, the c.d. study of the optically active polymer prepared here shows that the oxidation and the reduction of the polypyrrole matrix do not affect the chiral center of the camphorsulfonate substituent.

As shown in Fig. 4c-4f, the asymmetric polymers give a positive Cotton effect in either the oxidized or the reduced state. These measurements were made on polymer films deposited on the indium-oxide electrode; the films were copiously rinsed with spectroscopic grade acetone and methanol to eliminate any monomeric or electrolyte salt residue.

The c.d. wavelength absorption of these polymers at ca. 305 nm showed a bathochromic shift in comparison with the c.d. absorption maximum of monomers. This variation should be attributed exclusively to the change of solvent, since there is no other obvious reason to be considered.

The electrosynthesis of other chiral polypyrrole derivatives and their use as electrodes is in progress, and the results will be published elsewhere.

ABSTRACT

We have developed a technique for growth of thin oxides (80-90Å) with an intermediate annealing step. The oxides exhibit a tight distribution in breakdown voltage measurements leading to defect density less than $5/\text{cm}^2$, intrinsic breakdown field of 12 MV/cm, and a value of less than $1 \times 10^{10}/\text{cm}^2\text{-eV}$ for interface trap density in midgap. The inferior electrical properties of thin oxides grown by conventional methods in dry oxygen with Ar dilution have been correlated with Si-SiO₂ interface roughness using high resolution transmission electron microscopy. The intermediate annealing process may be used to improve the endurance and retention properties of EEPROM devices and alleviate the degradation of thin oxides in short-channel MOS devices.

This study investigated the use of an intermediate annealing step to eliminate the failure causing defects that develop in thin oxides during the oxidation process. The principal failure causing mechanism for thin oxides has been attributed to the presence of conducting channels arising from various defects (1) or local crystalline regions (2) in the amorphous oxide. The method of growth and the thickness of the film greatly influence the electrical properties of an oxide film. High defect densities in an oxide film lower the median breakdown field and lead to reliability problems which are associated with time-dependent breakdown phenomenon (3).

There have been detailed reports in the literature on the composition of the very thin interfacial region between the oxide and silicon. The thin interfacial region of maximum thickness less than 30Å has been investigated extensively by ellipsometry, infrared spectroscopy, Auger electron spectroscopy, and etch-rate determination (4, 5). It has been suggested that the near-interface oxide has a silicon-rich composition SiO_x where $x < 2$. Recent work (6) has shown that the interfacial layer is stoichiometric SiO₂ to within one monolayer of the substrate. It has also been demonstrated that compressive stresses (7) exist in thermal oxides depending on the oxidation temperature and growth conditions.

We have characterized the electrical properties of thin oxides ($\approx 80\text{Å}$) grown under various processing conditions by performing oxide breakdown voltage measurements, current vs. voltage measurements, and both high and low frequency capacitance vs. voltage measurements. The nature of the Si-SiO₂ interface has been studied for each processing condition using high resolution transmission electron microscopy.

Sample Preparation

For electrical measurements on the properties of thin oxides, polysilicon gate capacitors were fabricated using the LOCOS process (8). The capacitors had three different areas (0.002, 0.008, and 0.032 cm²) and two different geometries (circular and rectangular). This device variety al-

*Electrochemical Society Active Member.

lowed the effect of area and geometry on the electrical properties of thin oxides to be studied. We did not observe any geometry dependence on the oxide breakdown voltage characteristics for capacitors of the same area. In all cases, electrical contact was made on a pad over the field oxide to avoid any mechanical damage of the thin oxide layer.

The starting material was 4-6 Ω-cm p-type <100> Si wafers. The wafers were subjected to a standard cleaning process consisting of H₂SO₄/H₂O₂ clean followed by a 1:10 HF dip to remove any native oxide. The wafers were loaded immediately in the furnace with argon flowing only. The thin oxides were grown by the following processes.

The first was a standard process: growth of thin oxides of thickness between 80 and 90Å in a single oxidation step at 900° or 950°C.

The second was a two-step oxidation process: growth of $\approx 30\text{-}40\text{Å}$ of oxide at 900° or 950°C followed by an annealing treatment in Ar at 1050°C for 1h and then followed by the growth of additional oxide at 900° or 950°C to a final thickness between 80 and 90Å.

The third and last was the postoxidation anneal process: growth of thin oxides of thickness between 80 and 90Å in a single oxidation step at 900° or 950°C followed by an annealing step at 1050°C for 1h. After metallization, the wafers were annealed in forming gas at 450°C for 30 min.

Structural analysis of the thin oxide interfaces that resulted from the different processing sequences was performed by high resolution transmission electron microscopy (HREM). The instrument used was a Philips 400ST, operated at 120 keV. Cross-sectional specimens were prepared using a standard technique (9), and viewing the samples along <110>-type directions in many-beam conditions allowed structure images to be obtained. Point-to-point resolution was on the order of 3.3Å.

Results and Observations

Oxide thickness measurements.—The thickness of the thin oxides grown by the different processes was measured by three different techniques: (i) by a Rudolph

Auto El II Ellipsometer, (ii) by TEM cross-sectional studies, and (iii) by high frequency capacitance vs. voltage measurements. The oxide thickness measured by the three different techniques agreed within 5%.

Oxide breakdown voltage measurements.—To compare the electrical properties of the thin oxides, we performed breakdown voltage measurements using an automatic prober stepper and a Keithley test system. The test program used a ramp rate of 10 V/s and detected breakdown voltage by measuring the voltage at which a threshold current of 10 μ A occurred. The dielectric breakdown measurements yield the defect density (10). One can also estimate the high field capability of thin oxides as required in EEPROM devices (11).

For each wafer, we collected 110 data points for each type of capacitor. The data was collected for three wafers (330 data points) of similar processing conditions before any statistical analysis was performed. The results of the breakdown voltage measurements were analyzed using the extreme value statistics (3). The cumulative probability of failure $P(E)$ at a field E is given by

$$\ln(\ln[1 - P(E)]^{-1}) \propto E \quad [1]$$

Figure 1 shows a plot of the cumulative probability of failures (corresponding to the left term of Eq. [1]) vs. electric field for the 84Å thin oxide grown under standard process at 900°C. We note that each of the curves has three distinct regions.

In the first region, from 0 to 4 MV/cm, the breakdown can be due to possible contamination control related to the cleanliness of the wafers, furnace, etc. In this region, the cumulative probability of failures is low (less than 2% for the 0.002 cm² capacitors).

In the second region, from 4 to 10.5 MV/cm, the probability of failures increases with the electric field. In this region, the breakdown phenomenon is related to defects in the oxide incorporated during the growth process. In this region, one can calculate the defect density/area (10) from the relation

$$\rho = (-\ln[1 - P])/A \quad [2]$$

where ρ is the defect density per unit area, P is the cumulative probability of failures, and A is the area of the capacitor.

In the third region, at ≈ 10.5 MV-cm, the probability of failures increases sharply as it is related to the intrinsic breakdown characteristics.

For electric fields between 0 and 10.5 MV/cm, the probability of failures increased with the area of the capacitor, as expected from the extreme value statistics (3).

Figure 2 shows a similar plot for circular capacitors for thin oxides of thickness 85Å that underwent two-step oxidation at 900°C with intermediate anneal at 1050°C for 1h in Ar.

Comparing Fig. 1 (standard process) to Fig. 2 (two-step oxidation process), we observe some noticeable differences.

Fig. 1. Plot of cumulative probability of failures (percent) vs. electric field for thin oxides grown under a standard process at 900°C.

Fig. 2. Plot similar to Fig. 1 for thin oxides grown under a two-step oxidation process.

For the two-step oxidation process, the cumulative probability of failures remains fairly constant for electric field between 0 and 10 MV/cm, independent of capacitor area. This is a marked improvement from the condition observed with the standard process, where, in the range 0-10 MV/cm, the probability of failures increases steadily with electric field. Since the probability of failures is related to defect density, one can deduce that the two-step oxidation process leads to oxides with much lower defect density than those from the standard process (see Table I).

At the intrinsic breakdown field, the cumulative probability of failure does not depend on the area of the capacitor. The defect density per unit area is calculated from the probability of failure at the onset of intrinsic breakdown and thus gives an upper limit value.

We have also observed (Fig. 3) that the postoxidation annealing treatment does improve the electrical breakdown properties of thin oxides somewhat. However, as shown in Fig. 2 for the two-step oxidation process, the intermediate annealing step produces thin oxides with the best electrical breakdown voltage characteristics.

We also note from Fig. 4 that the breakdown characteristics of thin oxides grown at 950°C are better than those grown at 900°C (Fig. 1) for circular capacitors of area 0.002 cm². Also, the two-step oxidation process is more effective in reducing the defect density of thin oxides grown at 950° than 900°C (compare Fig. 4 with Fig. 2).

Table I summarizes the various parameters of thin oxides such as defect density and intrinsic breakdown field as a function of the oxide growth conditions for circular capacitors of area 0.002 cm². Similar tables can be obtained for the other areas.

We have performed high frequency and quasi-static capacitance vs. voltage measurements to determine the oxide thickness, fixed oxide charge density, and the density of interface traps. Figure 5 shows a plot of the density of interface traps (D_{it}) as a function of bandgap position for thin oxides grown at 950°C with an intermediate annealing at 1050°C for 1h. The value of D_{it} at midgap is $8 \times$

Table I. Summary of the oxide breakdown voltage characteristics

Process variable	Oxide thickness (Å)	Defect density (ρ/cm^2)	Breakdown field (MV/cm)
Standard 900°C	84	300	10.5
Two-step oxidation Anneal at 1050°C for 1 h (900°C process)	85	20	11.5
Postoxidation Annealing at 1050°C for 1 h (900°C process)	85	255	10.5
Standard 950°C	82	50	10.5
Two-step oxidation Anneal at 1050°C for 1 h (950°C process)	86	4	12.0

Fig. 3. Plot similar to Fig. 1 for thin oxides grown under a postoxidation anneal process.

Fig. 4. Plot of cumulative probability of failures (percent) vs. electric field for thin oxides grown under a standard process at 950°C and a two-step oxidation process.

Fig. 5. Interface trap density vs. bandgap position for thin oxides grown at 950°C with a two-step oxidation process.

$10^9/\text{cm}^2\text{-eV}$, compared to a value of $2 \times 10^{10}/\text{cm}^2\text{-eV}$ for oxides grown by the standard process at 950°C.

The intermediate annealing step reduces not only the defect density in the oxides, but also the density of interface traps.

HREM Structural Observations

Figure 6a illustrates the thin oxide interface morphology for the sample that had undergone the standard process. It is evident that considerable atomic-scale roughness exists at the interface between the substrate and the oxide. The height of the individual crystalline protrusions above the single-crystal region may be as much as 20Å or more. The irregular, mottled pattern in the oxide is typical of the appearance of amorphous materials when viewed at high magnification using HREM (12).

The results for the sample which had undergone the intermediate annealing at 1050°C for 1h are quite different. As illustrated in Fig. 6b, both interfaces in this sample are found to be atomically smooth. No sizable silicon protrusions

Fig. 6. High resolution electron micrographs illustrating the thin oxide interface morphologies for samples that had undergone: the standard process (a), the two-step oxidation process (b), and the post-oxidation anneal process (c).

are observed, and the degree of interface roughness never exceeds the width of a single monolayer.

Material which received a postoxidation anneal only (Fig. 6c) shows a morphology that is intermediate between those observed in the other two cases. Si/SiO₂ interface roughness existed, but not nearly on the scale of that encountered in the standard process specimen.

Discussion and Conclusion

As seen from the results of the electrical breakdown voltage measurements, the intermediate annealing step is more effective than the postoxidation annealing step in reducing the defect density in thin oxides. Moreover, thin oxides grown at 950° compared to 900°C produce reduced defect density. There seems to be a definite correlation between the electrical properties of thin oxides and the nature of the Si-SiO₂ interface as observed by HREM. The smoothest interface is obtained with the intermediate annealing step, which gives the best electrical properties for the thin oxides.

Stress at the Si-SiO₂ interface is caused by the mismatch between silicon lattice spacings and the restricted range of interatomic separations and bond angles in the amorphous thermal oxide. This molecular mismatch is expressed (13) by the thermodynamic "free volume supply condition," and the release of stress requires the operation of viscous flow in the oxide film. It has also been firmly established, through *in situ* wafer curvature measurements (7), that the viscous flow point of thermally grown SiO₂ on Si is between 950° and 975°C. The dominant free energy term in the initial growth regime is expected to be that associated with defects and strain (13, 14). In the absence of viscous flow (as in our samples oxidized at 900°C), strains that accumulate in the oxide are not easily relieved. Thus, the additional energy required to create strained oxide near any small interface perturbation slows down the oxidation reaction locally and leads to continued growth of the asperity.

With the increase in strain energy as the oxidation continued (15), these protrusions grew to considerable size. Postoxidation annealing at 1050°C allowed viscous flow and relaxation to take place, resulting in a reduction of the interface roughness. Intermediate annealing at 1050°C was even more effective. Its effectiveness is gained by stopping the process before considerable roughness has had time to develop and annealing out the oxide strain before completing the oxidation. Both lower temperature steps (900° or 950°C) were kept short enough to prevent appreciable interfacial asperities from forming. Since the viscous flow point of SiO₂ is between 950° and 975°C (7), the thin oxides grown at 950°C showed a smoother interface than that grown at 900°C.

Substantial interface roughness for the standard process at 900°C leads to a local intensification of the electric field. This leads to a lower value of the oxide breakdown electric field, leading to a higher value of the defect density as observed from the electrical data.

Acknowledgments

It is a pleasure to acknowledge Juanita Sneed and Gerard DeGroot for help with processing the wafers, and W. T. Stacy, S. W. Mylroie, J. C. Bravman, and R. Sinclair for helpful discussions and suggestions.

Acceleration Factors for Thin Oxide Breakdown

J. W. McPherson and D. A. Baglee

Texas Instruments, Incorporated, Houston, Texas 77001

ABSTRACT

Time-dependent dielectric breakdown (TDDB) data for 100Å of thermally grown SiO₂ have been analyzed using an Eyring model. The model has been found to describe the general features of the data: (i) an apparent activation energy which is a function of the stressing electric field, and (ii) a field acceleration parameter that is a function of temperature. Quantitatively, the model suggests the proper field dependence for the activation energy and the observed temperature dependence of the field acceleration in the 100Å oxide material. Because of a decrease (with increasing stress) in the spread (σ) of the time to fail data, acceleration factors derived from $t_{10\%}$ and $t_{50\%}$ are quite different. In the case of $t_{50\%}$, the apparent activation energy is found to decrease from > 1 eV at low field stressing [Eb(50%) - Es > 5 MV/cm] to < 0.3 eV at higher fields [Eb(50%) - Es < 3 MV/cm]. Also, the field acceleration was found to be approximately 5 decades/MV/cm at room temperature, but it reduces to 2 decades/MV/cm at 150°C.

When insulators such as SiO₂, commonly used in VLSI circuits, are stored at a fixed voltage and temperature, they are observed to breakdown with time. This time-dependent dielectric breakdown (TDDB) is judged to be a potential failure mode for MOS integrated circuits and has captured the attention of many investigators. Early investigations centered around the effects of mobile ions (particularly Na⁺) on enhanced conduction via ionic drift to the Si-SiO₂ interface (1-3), or around the effects of radiation damage on dielectric breakdown (4, 5). More recently, with improved processing, oxides have become relatively free from both Na contamination and radiation damage; thus, TDDB attention has turned to intrinsic breakdown (6, 7).

While general agreement seems to exist in that the TDDB data for intrinsic breakdown (6-10) is lognormal in nature, the reported activation energy seems to vary greatly; e.g., Crook (6) reported 0.3 eV, while Anolick (7) gave a value of 2 eV. More recently, TDDB data by Hokari (8) for thin oxides (100Å) suggested an activation energy of 1 eV, while Baglee (9) reported 0.3 eV. Also, the electric field acceleration factors for thin oxides were reported to be < 2 decades/MV/cm (8,9), while the values for thicker oxides (> 400Å) are given (6, 10) to be > 6 decades/MV/cm.

Based on the recent TDDB results reported here for thin oxides, it would seem that many of the above differences are virtual and can be explained by an apparent activation energy which is electric field dependent and a field acceleration factor which depends on temperature. In the next section, we describe the specifics of thin oxide growth and the characterization techniques used in our study. This is followed by a description of the Eyring model used to analyze the results. Acceleration factors for thin oxide stressing are determined with special emphasis given to the impact that the spread (σ) in the time to fail can have on the acceleration factor. The paper is concluded with a discussion and summary of the results.

Oxide Growth and Characterization

Sample preparation.—The basic test structure used to model oxide reliability is the MOS capacitor. However, care must be taken in ensuring that this structure accurately represents the state of oxide in an actual VLSI circuit. For this reason, the test structures reported in this paper were fabricated using a full double-level polysilicon and advanced VLSI process flow and were subjected to all of the standard implants, sputtering, and etch sequences to which typical devices would be subjected.

After initial cleaning of the p-type ($N_A = 10^{15}/\text{cm}^3$) silicon, a pad oxide of 35 nm was grown and a nitride layer of 120 nm was deposited. The thick field oxide was grown using local oxidation of silicon (LOCOS) techniques to a thickness of 600 nm. After removal of the nitride layer, a 40 nm sacrificial oxide was grown in steam and then immediately stripped. The purpose of this is to reduce the Kooi or "white ribbon" effect (11). The pregate oxidation cleanup was a RCA-type cleanup (12). Following the spin-rinse and drying cycle, the slices were immediately loaded into the gate oxidation furnace. The 100Å oxide was grown at 900°C in dry O_2 with 4% HCl and annealed for 20 min in nitrogen. 450 nm LPCVD polysilicon was then deposited and doped from a POCl_3 source. The test capacitors were then patterned and etched.

Following removal of the photoresist, the slices were subjected to a second gate oxidation, a second level of polysilicon deposition and etch, arsenic source-drain implant, deposition and etching of interlayer oxide, deposition and etching of aluminum and compressive silicon nitride was used for the protective overcoat. The samples were then scribed and bonded into ceramic packages.

Initial characteristics.—Before proceeding with a discussion of our initial characterization results, a brief explanation of breakdown in oxides and our measurement techniques will be given.

Care must be exercised in the collection of breakdown data on very thin oxides due to their ability at high electric fields to pass large current densities without actually shorting. In this paper, when we talk about oxide failure we are not referring to the self-healing type of events that can often occur and may cause "soft" errors in memories, but rather to the hard failure due to rupturing of the oxide causing a conducting filament between the anode and cathode. It is beyond the scope of this paper to discuss the actual breakdown mechanisms in silicon dioxide, but there have been many papers written on this subject which provide excellent insight into this phenomenon (*e.g.*, 13-16).

In measuring the breakdown voltage of an oxide, the usual technique is to choose a high current level (say 10 μA) and ramp the voltage until the current through the capacitor reaches this level. Thick oxides (400Å) are always shorted at this point, but this is not necessarily the case for thin oxides, due to the reasons mentioned above. After each stress voltage is applied, the capacitor is subjected to a low reference voltage, V_{ref} (approx 1V). If the capacitor has become shorted, then a large current flows even at the low V_{ref} voltage. This ensures that only shorted devices are monitored.

Using the above technique, we measured the initial breakdown distribution of our oxides after processing was completed. A typical distribution for these 100Å oxides is shown in Fig. 1. There are a few points that should be made about these results. There are two apparent breakdown distributions: those devices which breakdown at approximately 11V and those that are shorted even at 0 V. The breakdowns at 11V are due to intrinsic breakdown, while those seen at 0 V are attributed to pinholes or particulate contamination during processing. It is interesting to note that in this case there is no intermediate distribution between the two. This distinctive distribution for 100Å SiO_2 allows one to investigate very high (8 MV/cm) electric field stressing and still obtain well-behaved TDDB results over a relatively long period of time.

In Fig. 1, the low voltage breakdowns are shaded. This part of the distribution is screened out at multiprobe and would not form part of the actual distribution seen in a real device. The I-V and C-V curves for these thin dielectrics have been reported previously (9).

TDDB testing.—This section will briefly discuss the details of the life testing performed on the packaged capacitors. The polysilicon capacitors (area = 0.01 cm^2) were bonded out, with eight per ceramic package. Each package was then inserted into a life-test board containing 200

Fig. 1. Bimodal distribution typically seen in 100Å oxides. After a low voltage screen (to eliminate defects causing 0 V breakdowns), the remaining distribution shows $E_b(10\%) = 10 \text{ MV/cm}$ and $E_b(50\%) = 11 \text{ MV/cm}$. Capacitor area is 0.01 cm^2 .

such packages. A 200Ω resistor was placed in series with each capacitor in order to limit the current drawn by each device upon failing and to indicate failed devices (a voltage is dropped across the resistor if the capacitor is shorted). Before beginning the life test, all devices were checked for shorts and continuity. Bad capacitors were removed from the sample population. Four voltages were applied to each package (8, 7, 6, and 5V). The units were then monitored periodically to look for failing devices. This test was repeated at three temperatures: 150°, 85°, and 25°C. Data obtained from these tests will be given in the TDDB Results for Thin Oxide Stressing section.

Eyring Model for Oxide Stressing

The thin oxide TDDB results reported in this investigation seem to be described well by a simplified Eyring model.

Eyring model.—The Eyring model is a theoretical model based on exponential reaction rate theory and free energy considerations (17, 18). The model for TDDB has been written in the form (see Appendix)

$$TF(f\%) = A \exp\left(\frac{\Delta H}{K_B T}\right) \exp[\gamma(T) \mathcal{S}] \quad [1]$$

where $TF(f\%)$ is the time to failure for $f\%$ of the units, ΔH is the enthalpy associated with the activated dielectric breakdown, $\gamma(T)$ is the field acceleration parameter, and \mathcal{S} is the electric field stress function given by

$$\mathcal{S} = E_B(f\%) - E_S \quad [2]$$

Here $E_B(f\%)$ represents the field at which $f\%$ of the capacitors are expected to "instantaneously" break down at room temperature; E_S is the constant electric field applied across the dielectric during TDDB data collection, and the expected temperature variation of $\gamma(T)$ is of the form

$$\gamma(T) = B + \frac{C}{T} \quad [3]$$

where B and C are constants.

Effective activation energy and electric field acceleration parameter.—The "effective" activation energy $(\Delta H)_{\text{eff}}$ is a useful parameter which allows one to relate the time-to-fail data taken at temperature T_1 to data taken at T_2 (with the assumption that the electric field stress function is held fixed). Mathematically, this is expressed as

$$(\Delta H)_{\text{eff}} = K_B \left(\frac{\partial \ln TF(f\%)}{\partial (1/T)} \right)_{\mathcal{S}} = \Delta H + K_B C \mathcal{S} \quad [4]$$

Similar to the activation energy, the electric field acceleration parameter γ allows one to relate the time to failure data taken at one stressing field, \mathcal{S}_1 , to the data taken at another, \mathcal{S}_2 (with the assumption being that the temperature is fixed)

$$\gamma = \left(\frac{\partial \ln TF(f\%)}{\partial \mathcal{S}} \right)_T = - \left(\frac{\partial \ln TF(f\%)}{\partial E_s} \right)_T \quad [5]$$

Acceleration factors for thin oxide stressing.—For reliability estimations, the acceleration factor, AF , is of primary importance. The AF allows one to project the time-to-failure data taken under a given set of stress conditions (ST_2) to some other set of conditions (ST_1), i.e.

$$[TF(f\%)]_{ST_1} = AF * [TF(f\%)]_{ST_2} \quad [6]$$

Normally, it is assumed that the dispersion [$\sigma = \ln(t50/t16) = \ln(t84/t50)$] in the lognormal time-to-fail data is independent of the stress conditions. Under the assumption of a constant σ , any arbitrary $f\%$ of failures may be used for the determination of a unique value of AF .

However, if σ does show a dependence on stress conditions, then the value determined for AF will no longer be unique, but will depend on the $f\%$ of failures used for the AF determination. The impact of σ can be illustrated by comparing AF based on $f = 10\%$ and $f = 50\%$

$$(AF)_{10\%} = (AF)_{50\%} \exp [1.28(\sigma_{ST_2} - \sigma_{ST_1})] \quad [7]$$

This last equation shows that the acceleration factors AF based on 10% and 50% are identical only if σ is independent of stressing conditions.

TDDB Results for Thin Oxide Stressing

Observed time to failure.—Details of the lognormal TDDB data for these 100Å SiO₂ films have been shown elsewhere (9). The TDDB results are summarized here in Table I. One will note that σ is rather sensitive to the stress conditions, decreasing with increasing electric field stress or increasing temperature. This would imply, according to Eq. [7], that the determined value of AF will depend on the failure percent ($f\%$) used for its determination. Therefore, in Fig. 2-4, we show the time-to-failure data as a function of the stressing electric field in two forms: one based on $f = 10\%$ and the other based on $f = 50\%$.

Field acceleration parameter.—The determination of γ is based on the slope of the linear fits to the data shown in Fig. 2-4. The results are shown in Fig. 5. We note that the fit for the data is quite good at $f = 10\%$ and reasonably good for the $f = 50\%$ data. The equations for the lines are

$$(\gamma_e)_{f=10\%} = -3.0 + \frac{0.21}{K_B T} (\text{mV/cm})^{-1} \quad [8]$$

and

Table I. Summary of time-to-failure results for 100Å SiO₂. The values for $t_{50\%}$ and σ were obtained from best lognormal fits to each data set.

TEMP	FIELD (MV/cm)	t _{50%} (HRS)	t _{10%} (HRS)	σ
25 DEG C	6	4x10 ¹¹ *	2.0x10 ⁴	13.1
	7	1.1x10 ⁶ *	2.5x10 ²	6.6
	8	90	1.5	3.2
85 DEG C	6	—	—	—
	7	1.7x10 ⁴	25	5.1
	8	12	.66	2.3
150 DEG C	6	7x10 ⁵ *	50	7.5
	7	2.7x10 ²	5	3.1
	8	2.5	.4*	1.4

* AN EXTRAPOLATION OF MORE THAN ONE DECADE REQUIRED

Fig. 2. Room temperature time-to-failure data vs. the stressing electric field. Two data sets are shown: one using $f = 10\%$ and the other using $f = 50\%$.

$$(\gamma_e)_{f=50\%} = -6.0 + \frac{0.43}{K_B T} (\text{mV/cm})^{-1} \quad [9]$$

The electric field acceleration parameters shown in Eq. [8] and [9] are subscripted with an "e" as a reminder to the reader that natural logarithms and exponentials have been used in this work, e.g.

$$TF \propto \exp (\gamma_e \mathcal{S}) \quad [10]$$

However, many authors prefer to express γ in decades/MV/cm, which we will represent as γ_{10} , e.g.

$$TF \propto 10^{\gamma_{10} \mathcal{S}} \quad [11]$$

Fig. 3. 85°C time-to-failure data vs. stressing electric field

Fig. 4. 150°C time-to-failure data vs. stressing electric field

The relationship between Eq. [10] and [11] is straightforward

$$\gamma_{10} = \gamma_e / \ln_e(10) \quad [12]$$

Effective activation energy.—The effective activation energy $(\Delta H)_{\text{eff}}$ can be determined, according to Eq. [4], from the slope of the Arrhenius plots of the time-to-fail data. These are shown in Fig. 6. The determined activation energy is shown in Fig. 7 and Fig. 8. The equations for the best linear fit to the data become

Fig. 5. Observed temperature dependence of the electric field acceleration parameter. Data for two characteristic failure percentages are shown.

Fig. 6. Arrhenius plot of time to failure data. Results for 6, 7, and 8V are shown for two characteristic failure percentages.

$$(\Delta H)_{\text{eff},10\%} = -0.30 + 0.20\mathcal{F} \text{ (eV)} \quad [13]$$

and

$$(\Delta H)_{\text{eff},50\%} = -0.71 + 0.35\mathcal{F} \text{ (eV)} \quad [14]$$

Note that, in accordance with the observed breakdown distribution (Fig. 1) for the 100Å oxide tested, $E_b(10\%) = 10 \text{ MV/cm}$ and $E_b(50\%) = 11 \text{ MV/cm}$ were used in Eq. [13] and [14], respectively.

Discussion of Results

Before the simplified Eyring model can be used to properly model TDDB data, two basic requirements for the data must first be satisfied: (i) the observed activation energy $(\Delta H)_{\text{eff}}$ should be a linear function of the electric field stress $\mathcal{F} = E_b(f\%) - E_s$ and (ii) the observed electric field acceleration parameter should be a linear function of reciprocal temperature. The results reported here for 100Å oxides suggest that both requirements are met for Eyring model use.

The electric field acceleration factor determined in this study

$$(\gamma_{10})_{f=50\%} = -2.6 + \frac{0.19}{K_b T} \text{ (decades/MV/cm)} \quad [15]$$

Fig. 7. Observed electric field dependence of the activation energy. $E_b(10\%) = 10 \text{ MV/cm}$ for the SiO_2 material under investigation. $f = 10\%$ was used as the characteristic failure percentage.

Fig. 8. Observed electric field dependence of the activation energy. $E_b(50\%) = 11$ MV/cm for the SiO_2 material tested. $f = 50\%$ was used as the characteristic failure percentage.

is consistent with the 1.7 decades/MV/cm result reported by Hokari at 250°C for thin oxides. While a slight divergence of the two data sets seems to exist at room temperature (see Fig. 9), at normal operating temperature (55°C and above), good agreement seems to exist with Berman's data (10) for thicker oxides ($\geq 400\text{\AA}$). Also, the functional form of γ is consistent with that suggested by Anolick for thick oxides.

As for the observed activation energy $(\Delta H)_{\text{eff}}$ being a function of the electric field stress function \mathcal{S} (Eq. [13] and [14]), this seems to be required for a unified explanation of the results reported here, in addition to the results of Crook, Anolick, and Hokari. Crook reports an activation energy of 0.3 eV for gate oxides stressed at 3-5 MV/cm and $f = 10\%$. Assuming that $E_b(f = 10\%) = 7$ MV/cm for his oxide tested, then the stress function \mathcal{S} would have ranged from 2-4 MV/cm. Equation [13] would predict an average observed activation energy of 0.3 eV.

Anolick's reported activation energy was based on $f = 50\%$ and low field stressing ($E_s = 1-3$ MV/cm). Assuming that $E_b(f = 50\%)$ was about 9 MV/cm for his material

Fig. 9. Observed temperature dependence of the electric field acceleration parameter. Data shown represent (i) the 100\AA SiO_2 results obtained in this work plus the single datum of Hokari (also for 100\AA SiO_2), and (ii) the data of Berman for much thicker SiO_2 ($\geq 400\text{\AA}$).

tested, then \mathcal{S} would have ranged from 6-8 MV/cm during stressing. Equation [14] predicts an average value of 1.8 eV over this stress range and seems to agree with Anolick's reported value at 2 eV.

Also, Hokari's data for thin (100\AA) SiO_2 suggest an activation energy of 1 eV with the stressing field at $E_s = 6$ MV/cm and $f = 50\%$. This again is quite consistent with the results shown in Fig. 8.

Conclusions

In this paper, we have presented TDDB data for 100\AA silicon dioxide films. These data have been found to be fit well by a simplified Eyring model. We have found that the activation energy measured depends upon the electric field stress and that the field acceleration factor is temperature dependent. Both results are in good agreement with the proposed model. We have shown that the acceleration factors derived from $t_{50\%}$ and $t_{10\%}$ can be quite different and that care must be taken with the manipulation of TDDB data in order to get meaningful results. Finally, we have shown that other published data on oxide wearout can be fit with our model, thus removing many of the apparent discrepancies between the results of the various workers.

Acknowledgments

The authors would like to thank George Punter for preparing some of the samples and Ron Parker for much of the data collection.

APPENDIX

Thermodynamic Model for Dielectric Breakdown

Thermodynamics of dielectrics.—The internal energy ϵ for a dielectric material under the influence of an external electric field E will be a function of the system entropy S , volume V , mole number N , and polarization P (19)

$$\epsilon = \epsilon(S, V, N, P) \tag{A-1}$$

The polarization P represents the total dipole moment produced (either induced or oriented) by the applied electric field E . The Gibbs free energy as a function of the intensive parameters temperature T , electric field E , chemical potential μ , and pressure p , can be obtained through the Legendre transformation of ϵ giving

$$G(T, E, \mu) = H_0 - TS - \mu N - EP \tag{A-2}$$

where H_0 is the enthalpy. Since the pressure p is constant during dielectric stressing, its impact on the free energy G will not be shown explicitly. We attempt to write the last three terms of the free energy as

$$-TS - EP - \mu N = K_b T f(T) g(E) h(\mu) \tag{A-3}$$

where f , g , and h are functions only of T , E , and μ , respectively. Using the standard thermodynamic relationships

$$S = -\left(\frac{\partial G}{\partial T}\right)_{E, \mu} = -K_b g h \left[f + T \frac{df}{dT} \right] \tag{A-4}$$

$$P = -\left(\frac{\partial G}{\partial E}\right)_{T, \mu} = -K_b T f h \frac{dg}{dE} \tag{A-5}$$

$$N = -\left(\frac{\partial G}{\partial \mu}\right)_{T, E} = -K_b T f g \frac{dh}{d\mu} \tag{A-6}$$

and insertion into Eq. [A-3], we obtain the defining ordinary differential equation

$$\frac{T}{dT} \frac{df}{f} + \frac{E}{dE} \frac{dg}{g} + \frac{\mu}{d\mu} \frac{dh}{h} \tag{A-7}$$

The solution to Eq. [A-7] gives for the free energy

$$G(T, E, \mu) = H_0 + K_b T \sum_m \sum_n C_{mn} \frac{E^m \mu^n}{T^m} \tag{A-8}$$

At breakdown, the dielectric undergoes an irreversible phase transition in which the material is transformed from an insulating phase to a conductive phase. While the driving force for this change is a free energy difference between the two phases, the rate at which the change takes place is controlled by the free energy of activation associated with the conductive poly filament growth shorting the gate to substrate. Equation [A-8] suggests that the free energy of activation ΔG^* associated with dielectric breakdown can be written as

$$\Delta G^* = \Delta H_o^* + K_B T \sum_m \sum_n C_{mn} \frac{(E_B^n - E_s^n) \mu^{m-n}}{T^m} \quad [\text{A-9}]$$

Where H_o^* is the free enthalpy of activation, E_s is the electric field applied during stress, and E_B represents the "time-zero" breakdown strength of the dielectric.

Simplified Eyring model for breakdown reaction rate.—The assumption is made that the time-dependent dielectric breakdown is an activated process obeying standard chemical reaction rate theory (17, 18), with the reaction rate constant given by

$$k \propto \exp \left(- \frac{\Delta G^*}{K_B T} \right) \quad [\text{A-10}]$$

In order to simplify the theory for dielectric breakdown, we keep only the linear terms in Eq. [A-9], giving

$$\Delta G^* = \Delta H_o^* + K_B T \left[B + \frac{C}{T} \right] \mathcal{S} \quad [\text{A-11}]$$

where $\mathcal{S} = E_B - E_s$ and B and C are constants. For capacitors with identical breakdown strengths, the characteristic time-to-failure can be expressed as

$$TF = A \exp \left(\frac{\Delta G^*}{K_B T} \right) \quad [\text{A-12}]$$

where A is a constant. However, in practice, the breakdown strengths of individual capacitors will not be identical (dispersion in breakdown strength). The dispersion in breakdown strength can be taken into account by writing

$$TF(f\%) = A \exp \left(\frac{\Delta H_o^*}{K_B T} \right) \exp [\gamma(T)\mathcal{S}] \quad [\text{A-13}]$$

where

$$\gamma(T) = B + \frac{C}{T} \text{ and } \mathcal{S} = E_B(f\%) - E_s$$

Please note that the model predicts an electric field-dependent activation energy

$$K_B \left(\frac{\partial \ln TF}{\partial(1/T)} \right)_{\mathcal{S}} = \Delta H_o^* + K_B C \mathcal{S} \quad [\text{A-14}]$$

and a temperature-dependent field acceleration parameter

$$\left(\frac{\partial \ln TF}{\partial \mathcal{S}} \right)_{\tau} = - \left(\frac{\partial \ln TF}{\partial E_s} \right)_{\tau} = \gamma(T) \quad [\text{A-15}]$$

Also, note that, according to Eq. [A-13], the observed dispersion σ in the time to failure data should have a temperature dependence given by

$$\sigma = \ln \left[\frac{TF(50\%)}{TF(16\%)} \right] = \gamma(T)[E_B(50\%) - E_B(16\%)] \quad [\text{A-16}]$$

A Simplified Viscoelastic Model for the Thermal Growth of Thin SiO₂ Films

G. Camera Roda, F. Santarelli, and G. C. Sarti

Istituto di Impianti Chimici, Università di Bologna, I-40136 Bologna, Italy

ABSTRACT

Recently, thermal dry oxidation of silicon was quantitatively described by the present authors in a model accounting for the relaxation phenomena occurring in the oxide film. Clarity about the underlying physical mechanisms and satisfactory matching with existing data both make the model rather appealing; also, the well-known anomalous behavior encountered in the thin film region appears to be adequately predicted. The resulting numerical problem is rather complex when compared with other existing models. A simplified mathematical formulation of the mentioned model is proposed here. The viscoelastic relaxations occurring in the oxide layer are lumped into a time-dependent effective diffusivity for which an explicit expression was found in terms of the parent model parameters. A deviation of, at most, 2.3% in the oxidation rate was obtained by comparing the results from rigorous and simplified approach. The simplified model proposed requires numerical procedures as simple as for some previously existing models; it has the additional advantage of being written in terms of quantities which all have precise physical meanings and can be measured independently of the oxidation process.

Modern microelectronic technology for LSI and VLSI demands highly reliable although very thin passivating layers. A widely used passivating agent is found in thermally grown silicon dioxide. In the present work, we will only refer to SiO₂ layers grown in dry atmospheres.

The operating conditions at which SiO₂ layers are grown involve a temperature range usually between 800° and 1100°C. The film thickness of practical interest typically does not exceed a few hundred angstroms. In this case, all experimental data (1-9) show marked deviations from the behavior predicted by the so-called linear-parabolic equation (10). The latter equation, however, successfully describes the thermal growth of SiO₂ layers for higher temperatures and/or for oxide thickness larger than 200-300Å. The physical picture underlying the linear-parabolic theory can be summarized as follows (10): (i) molecular oxygen dissolves into the SiO₂ phase and diffuses through the SiO₂ layer; (ii) the oxygen concentration in the SiO₂ layer at the gas-solid interface obeys the thermodynamic phase equilibria requirements; (iii) diffusion of molecular oxygen occurs according to Fick's law, with constant diffusivity, and convective contributions are completely neglected and the diffusion process is assumed to occur under pseudosteady-state conditions; (iv) chemical reaction takes place at the oxide-silicon interface, according to a first-order kinetics with respect to the molar oxygen concentration.

In spite of the crude simplicity embodied by the above assumptions, it is nevertheless apparent that a rather wide variety of physical phenomena simultaneously takes place during the oxidation process.

The crude simplicity embodied by the above assumptions is paralleled by the rather wide variety of physical phenomena which have been found experimentally to occur during the oxidation process.

The mentioned failure of the linear-parabolic theory to predict the experimental behavior and the increasing demand for a satisfactory quantitative description both are the origins of the wide research interest devoted to this field.

Indeed, several different merely mathematical models have been proposed recently which adequately describe experimental data (1, 3, 11-13); owing to their pure phenomenological origin, however, the intervening parameters are just data fitting variables, with no particular meaning. Important questions such as (i) what the main physical and chemical phenomena which govern the observed growth rate are, and (ii) what their suitable mathematical description is, are left unanswered by the purely empirical models.

Thus, the need of quantitative models obtained through a suitable physical schematization of the process is self-evident.

Only very recently Fargeix *et al.* (14-16) proposed a physical based mathematical model of the oxidation pro-

cess suitable also to represent the behavior for thin oxide layers. Their basic assumptions are related to the stress dependence of the oxygen diffusivity and to the viscoelastic behavior of the newly formed oxide film.

The aim of the present work is to develop another physically based mathematical model for the dry oxidation process adequate to represent both thin and thick oxide film formation. To that extent, it is convenient to first recall some relevant features to the experimental observations.

Some experimental evidence (3, 11) suggests that the oxygen transport through the SiO₂ layer occurs through molecular oxygen diffusion at higher temperatures, while at significantly lower temperatures diffusion of atomic oxygen seems to be more plausible. The existence of different parallel paths for O₂ transport was also claimed due to spatial nonuniformities [*viz.*, channeling (17)] in the very early stages of SiO₂ formation.

A significant role seems to be played by the mechanical stresses originated during the process, which can be schematically understood as follows.

Indeed, the oxidation which occurs at the oxide-silicon interface causes a significant increase in the Si-Si interatomic distance, or, in other words, the silicon atomic concentration is higher in the Si single crystal than in the SiO₂ phase. However, adhesion and material continuity at the Si/SiO₂ interface prevent any slipping motion along the interfacial surface. As a consequence, strain and stresses are built in both phases during the oxidation process. The oxide layer is under compression in the directions parallel to the interface; unconstrained displacements can take place only in the oxidation direction, *i.e.*, perpendicularly to the Si/SiO₂ interface; correspondingly, the underlying silicon is under tension in the directions parallel to the oxidation plane (13, 20).

The stress and strain levels in both phases decrease with the distance from the Si/SiO₂ interface according to the mechanical properties of both phases. In this respect, it is worth noting that Si single crystals behave as elastic materials with Young moduli of about 1.7×10^{12} dyn/cm² (18), while the oxide properties show peculiar behavior. Dilatometric measurements (19) indicate that at temperatures lower than about 960°C density is a time-dependent quantity which eventually relaxes toward a final value; at temperatures higher than 960°C, however, the relaxation rate is so high that no relaxation response was observed. An analogous conclusion was drawn on the basis of direct mechanical measurements of the relaxation times (20). Apparently, the value of 960°C plays the role of a transition temperature separating regions of practically instantaneous response, at higher temperatures, from regions of viscoelastic response at lower values.

Undoubtedly, the stress or strain level will influence the overall process kinetics. As a matter of fact, the diffusion through the compressed oxide layers is expected to

be slower than through an unstrained film. However, the oxidation reaction will occur with a pure Si concentration which is altered by the deformation (13); moreover, the rate constant is increased by the strain, as can be qualitatively expected from Eyring kinetic theory (21).

A comprehensive description of the oxidation process thus appears rather complex since the strain, stress, and concentration fields as well as oxide thickness should be simultaneous unknowns of the problem. Additional complexity derives also from the viscoelastic behavior of the SiO₂ phase, whose physical properties must be regarded as time dependent.

As a matter of fact, a detailed analysis of the oxide region, based on the relative intensity of the binding energy (26, 27), showed that there is a SiO₂ layer, about 40Å thick, adjacent to the oxide-silicon interface, with a structure different from the oxide core. More precisely, the amorphous SiO₂ phase is mainly formed by six Si atom rings, with small fractions of four Si atom rings, while close to the Si-SiO₂ interface the oxide is mainly formed by four Si atom rings. As a consequence, during its lifetime the oxide phase experiences significant morphological changes, moving from a lower free volume to a higher free volume state; in other words, the phenomenon can be viewed as a relaxation from a high free energy towards a lower free energy state. Such a relaxation certainly involves stress relaxation, although it does not simply coincide with such.

In spite of the discouraging complexity we are faced with, not all the above mechanisms seem to be equally effective on the oxidation kinetics. Indeed, the existing deformations will be typically in the order of a few percent in the single-crystal phase, so that the pure silicon concentration change induced by the stress presence can be disregarded. Moreover, the strain energy is three orders of magnitude smaller than the activation energy of the reaction so that the influence produced on the kinetic constant is also actually negligible.

More significantly, decoupling the mass transfer from the mechanical stress distribution problem seems to be a reasonable approximation. In fact, parallel to what is currently recognized in polymer physics, e.g., Ref. (22), all mechanical and transport properties are directly related to the free volume associated to a given structure. Thus, as a first approximation, diffusivity does not depend on the stress *per se*; it rather depends on the free volume associated to the existing structure. The free volume relaxes in time toward a final equilibrium value, typically according to an exponential decay (22).

Based on the above observations, a shorthand though satisfactory quantitative description of the oxidation process was recently proposed by the present authors (23). The resulting mathematical formulation will be briefly summarized in the next section for the sake of clarity.

The resulting computational model appears rather cumbersome to be easily used for simulation purposes. The aim of this work is to analyze a simplified formulation of the model proposed in Ref. (23). This simplified model involves lower computational requirements than the parent one without any significant loss of accuracy in representing experimental data.

The Viscoelastic Kinetic Model

The mathematical model developed in Ref. (23) is given by a two moving boundaries diffusion problem since oxygen diffusion takes place within the oxide layer whose interfaces are both moving with respect to the silicon core. The oxygen concentration at the oxide-vapor phase is assumed to obey the equilibrium conditions.

The crucial assumption of the model is related to the constitutive equation for the diffusive flux across the oxide phase. Instead of the usual Fick's law, a viscoelastic-like linear constitutive equation was assumed, given by (24)

$$J_{O_2}(t, \mathbf{x}) = - \rho \int_0^t \mu(t-t') \nabla \omega(t', \mathbf{x}) dt' \quad [1]$$

where ρ is the oxide density and ω the oxygen mass fraction. The memory function $\mu(s)$ was given the following expression

$$\mu(s) = D_1 \delta(s) + \frac{D_x - D_1}{\tau} e^{-s/\tau} \quad [2]$$

where δ is the Dirac function

Equations [1] and [2] were first studied to represent the mass-transfer behavior in relaxing polymers. Qualitatively, they represent a time-dependent diffusive flux: for oxide lifetimes very short with respect to the relaxation time τ , the diffusive flux is roughly equivalent to Fick's law with constant diffusivity D_1 , while at lifetimes much larger than τ it is equivalent to a fickian diffusion with the "relaxed" constant diffusivity D_x . At intermediate lifetimes, we can say that apparent diffusivity relaxes from the value D_1 to the value D_x , according to the relaxation time τ .

Since it can be easily shown that the convective contributions can be disregarded, the mathematical formulation of the problem can finally be written as follows. The distribution of the oxygen mass fraction ω , as a function of time t and of the distance y from the vapor-solid interface, is governed by

$$\frac{\partial \omega}{\partial t} = D_1 \frac{\partial^2 \omega}{\partial y^2} + \frac{D_x - D_1}{\tau} \int_0^t e^{-\frac{t-t'}{\tau}} \frac{\partial^2 \omega}{\partial y^2} dt' \quad [3]$$

with the associated initial and boundary conditions

$$t = 0 \quad \omega = 0 \quad [4]$$

$$t > 0, y = 0 \quad \omega = \omega_e \quad [5]$$

$$t > 0, y = \delta(t) \quad -D_1 \frac{\partial \omega}{\partial y} = k_r \omega \quad [6]$$

The problem must be solved for $y \in (0, \delta(t))$, where $\delta(t)$ represents the thickness of the oxide layer, ω_e is the equilibrium oxygen concentration, while k_r is the kinetic constant of the oxidation reaction.

As shown in Ref. (23), the oxide thickness is governed by the following equation

$$\frac{d\delta}{dt} = \frac{J_{O_2}(t, 0)}{\rho(1 - \omega_e)} + k_r \frac{M_{Si}}{M_{O_2}} \omega(t, \delta(t)) \quad [7]$$

to be solved with the proper initial condition.

It is worth noting, in passing, that Eq. [7] properly reduces to the usual equation reported by Deal and Grove (10) in the special case of fickian diffusion with constant diffusivity.

In Ref. (23), the problem represented by Eq. [1]-[7] was solved in dimensionless terms by using $t_0 = D_1/k_r^2$ and $l_0 = D_1/k_r$ as characteristic time and length, respectively. The dimensionless time, t^* , and the dimensionless relaxation time, τ^* , were consequently defined as

$$t^* = tk_r^2/D_1 \quad [8]$$

$$\tau^* = \tau k_r^2/D_1$$

The comparison with several existing experimental data has shown the satisfactory ability of the model to represent the observed behavior.

The Simplified Viscoelastic Model

The complete model outlined in the previous section is adequate to describe the thermal oxidation of silicon also in the range of relatively low temperatures and of very thin oxide thickness. However, one disadvantage of the model may be represented by the computational requirements involved in its solution. The question then arises of what simplified calculation schemes could be followed to reach in a more straightforward way thickness vs. time relationships which are essentially the same as those resulting from the original model.

First of all, it was observed that the pseudosteady-state approximation, obtained by setting the lhs of Eq. [3] equal to zero, is very reasonable. Actually, for the cases of practical interest, the oxide thickness obtained under this approximation differs from the value given by the original problem at most in the seventh significant digit.

Within the pseudosteady-state approximation, the introduction of a suitable time-dependent effective diffusivity allows, on the one hand, bypassing the solution of the boundary value problem for the oxygen concentration and, on the other hand, accounting for the linear viscoelastic relaxation of the diffusive properties.

The time-dependent effective diffusion coefficient, $D_e(t)$, is defined as

$$J_{O_2}(t) = -\rho D_e(t) \frac{\omega_\delta - \omega_e}{\delta} \quad [9]$$

where J_{O_2} is the time-dependent flux, which is independent of the spatial position in view of the pseudosteady-state approximation, and ω_δ is the oxygen mass fraction at the oxide-silicon interface $y = \delta$.

In view of Eq. [9], Eq. [7] for the thickness growth rate becomes

$$\frac{d\delta}{dt} = \frac{k_r D_e(t)}{D_e(t) + \delta k_r} \omega_e \left(\frac{M_{Si}}{M_{O_2}} + \frac{1}{1 - \omega_e} \right) \quad [10]$$

A suitable expression for the effective diffusivity was found to be

$$D_e(t) = D_x + (D_i - D_x) \exp \left[-a \frac{t^*}{\tau^{*n}} \right] \quad [11]$$

with $a = 0.16$ and $n = 0.9$.

The procedure followed to obtain Eq. [11] is outlined in the Appendix.

Confidence in the use of Eq. [10] and [11] was gained through the comparison of the results from the simplified model with those from the complete one: for the parameters of practical interest, the value of the oxide thickness obtained under the two situations differs typically less than 1%. A maximum deviation of 2.3% was found in the case of $\tau^* = 10^8$.

It is important to notice that Eq. [10] can be reduced to an expression which is formally very similar to the one resulting from the linear parabolic theory.

This is not surprising, since when transport through the layer and chemical reaction at the interface are considered as the significant steps of the process, it is easy to prove that in pseudosteady state the equation

$$\frac{dt}{d\delta} = \frac{1}{K_{L,e}} + \frac{2\delta}{K_{P,e}} \quad [12]$$

formally holds, when both the linear and the parabolic coefficients assume different expressions as the result of the physical assumptions made on the material behavior.

In the present case the effective parabolic coefficient $K_{P,e}$ is then given by

$$K_{P,e} = K_{P,e}(t) = 2D_e(t) \phi \quad [13]$$

where, for the sake of simplicity, use has been made of the following position

$$\phi = \omega_e \left(\frac{M_{Si}}{M_{O_2}} + \frac{1}{1 - \omega_e} \right) \approx \omega_e \frac{M_{SiO_2}}{M_{O_2}} \quad [14]$$

The effective linear coefficient, $K_{L,e}$, is defined as

$$K_{L,e} = k_r \phi \quad [15]$$

and it has the same physical meaning as in the linear-parabolic theory.

Thus, according to the simplified model presented here the slope in the Hopper diagram ($dt/d\delta$ vs. δ) is related to reciprocal effective diffusivity, which changes during oxidation from the value D_i to the value D_x .

From Eq. [12] and [15], it is apparent that the reaction rate constant k_r is related to the reciprocal of the actual intercept, for $\delta = 0$, in the Hopper diagram. In this respect, it can be noticed that the usual practice, e.g. Ref. (3), to evaluate k_r appears to be misleading, insofar as the intercept is not obtained by the true $dt/d\delta$ curve but rather on the straight line which extrapolates down to small thickness the linear behavior observed in the thick oxide region.

In the simplified model proposed so far, use is made of five physical properties, i.e., D_i , D_x , τ , k_r , and ω_e , all of which have a precise physical meaning and can be measured independently of each other as well as independently of the oxidation process.

The same model, however, could also be simply regarded as a mathematical correlation between oxide thickness and oxidation rate. In the latter case, only four independent parameters enter the model. Indeed, in view of Eq. [11] and [8], Eq. [13] can be rewritten as

$$K_{P,e}(t) = 2 \phi D_x \left\{ 1 + \left(\frac{D_i}{D_x} - 1 \right) \exp \left[-\frac{at}{\tau^n} \left(\frac{D_i}{k_r^2} \right)^{n-1} \right] \right\} \quad [16]$$

Therefore, the resulting model parameters turn out to be

$$K_{L,e} = k_r \phi; \quad K_{P,x} = 2 \phi D_x$$

$$A = D_x/D_i; \quad \bar{\tau} = \frac{\tau^n}{a} \left(\frac{k_r^2}{D_i} \right)^{n-1} \quad [17]$$

Accordingly, the model equation for the oxidation rate, Eq. [12], can be rewritten as

$$\frac{dt}{d\delta} = \frac{2\delta}{K_{P,x} \left\{ 1 + \left(\frac{1}{A} - 1 \right) \exp \left(-\frac{t}{\bar{\tau}} \right) \right\}} + \frac{1}{K_{L,e}} \quad [18]$$

In view of the presentation of the results, it may be convenient to solve Eq. [18] in its dimensionless form obtained by using the characteristic time and length defined previously.

Results and Discussion

The dimensionless form of Eq. [18] has been solved for different sets of the relevant variables in order both to assess the role of the significant parameters and to fit some of the published oxidation rate data.

It must be noted that, in all the runs, $\omega_e = 10^{-6}$ has been assumed as a plausible value for the equilibrium oxygen concentration in the silicon dioxide at the gas-solid interface (25).

The effect of the diffusivity ratio $A = D_x/D_i$ is shown in Fig. 1 for a typical value of the relaxation time τ^* . The $A = 1$ case properly coincides with the linear parabolic theory, while increasing values of the diffusivity ratio lead to more pronounced slope changes in the Hopper diagram. At different A values, the slope changes all occur at almost the same time for a given value of the relaxation time.

The role played by the relaxation time τ^* can be grasped from Fig. 2, where curves at different values of this parameter are given for a typical diffusivity ratio. As expected, for higher relaxation times, the slope change occurs at higher oxide thicknesses, as due for the physical meaning of τ^* . Noteworthy is the fact that the two limiting cases of infinite and negligible relaxation time coincide with the classical linear parabolic theory. Indeed, when $\tau \rightarrow \infty$, the effective diffusivity is always unrelaxed at the initial value, i.e., $D_e(t) \approx D_i$. For very small relaxation times ($\tau \rightarrow 0$), on the contrary, the effective diffusivity is always given by its relaxed value, i.e., $D_e(t) \approx D_x$.

On the other hand, experimental data show that the linear-parabolic model does not hold for intermediate temperatures while at higher temperature, say above 1000°C, and at lower temperatures, say below 750°C, much smaller deviations from it are observed.

Fig. 1. The reciprocal of the growth rate vs. oxide thickness for $\tau^* = 10^7$ and different values of the diffusivity ratio.

Therefore, the two limiting cases discussed above for the model behavior appear consistent with the trends shown by experimental data, especially if one remembers that relaxation time is a quantity which is strongly dependent on temperature, being rather high at low temperature and quite small at higher temperature values.

The ability of the proposed simplified model to represent experimental data is apparent from Fig. 3, in which a comparison is made between the model behavior and the experimental data reported in Ref. (1, 6, 14): the curves' matching is self-evident and definitely satisfactory.

However, since other existing models (phenomenological and physically based ones) also give a satisfactory representation of the observed behavior, some comments and comparisons are now in order.

As a purely mathematical correlation between oxide thickness and oxidation rate, the present model appears very similar, in many respects, to the phenomenological models presented in Ref. (3) and (12).

Actually, in the Supreme III model (3), two exponential terms and six model parameters enter the complete formulation. However, one exponential term can be neglected since it contributes to the solution for no more than 5%. The resulting four parameters model is usually written as

$$\frac{d\delta}{dt} = \frac{B}{2\delta + A} + C_2 \exp\left(-\frac{\delta}{L_2}\right) \quad [19]$$

The coefficients used merely obey a data-fitting requirement; no precise physical meaning is associated with them. The ability to represent experimental data is known, and the set of parameter values was given for several different temperatures (3).

The model proposed by Ellis *et al.* in Ref. (12) can be reduced to Eq. [12] with

Fig. 2. The reciprocal of the growth rate vs. oxide thickness for $A = 2.5$ and different values of the relaxation time.

Fig. 3. Comparison of the model results to published experimental data from Ref. (14).

$$K_{L,e} = K_L \left[1 + \delta_r \exp\left(-\frac{\delta}{\delta_r}\right) \right]; K_{p,e} = \text{const.} \quad [20]$$

Apparently, this associates an exponential variation to the linear coefficient. Roughly speaking, such is equivalent to considering an exponential decay in the chemical reaction rate, although, in this case too, the purely phenomenological nature of the model does not attribute a precise physical meaning to all the coefficients. For this model too, a satisfactory agreement between model results and experimental data has been reported (12).

The mathematical relationships between oxide growth rate and oxide thickness given by Supreme III, by Eq. [20], and by the present simplified model, Eq. [10] and [11], have some common features. As a matter of fact, all of them have four adjustable parameters, all of them show comparable complexity of the required numerical solutions, and, finally, all of them can represent experimental data with satisfactory accuracy.

The physically based models, on the contrary, have the advantage of being the mathematical representation of a clearly defined set of assumptions on the basic physical mechanisms. Different models of this type will thus present, in addition to intrinsic differences, several analogies as far as the gross physical picture is concerned.

Both our approach and the one followed by Fargeix *et al.* consider oxygen transport through the oxide and the oxidation reaction localized the Si/SiO₂ interface; in view of what was observed in the previous section, Eq. [12] formally holds true in either theory. Furthermore, in both cases, the origin of the deviations from the linear-parabolic theory is associated to the existence of a very narrow SiO₂ layer in the proximity of the pure silicon phase, endowed with properties very different from those encountered in the bulk SiO₂ phase. In that layer, a non-equilibrium structure is observed, which relaxes towards an equilibrium state; the relaxation process ultimately results in an increase in the effective oxygen diffusivity.

In Ref. (15, 16), the mass flux is given by a fickian constitutive equation in which the diffusion coefficient is changing only as a consequence of a change in the deviatoric stress level. The latter is calculated via a maxwellian fluid constitutive equation in which the deformation rate term is neglected. In our model, on the contrary, the diffusive flux is described by a nonfickian integral type constitutive equation, Eq. [1], [2], the nature of which parallels exactly that of the momentum flux equation in linear viscoelasticity. The viscoelastic response is thus asso-

ciated to the relaxation of the newly formed oxide structure, which may or may not be described by the deviatoric stress. Although it appears useless at the present stage to argue in favor of either approach, we want only to point out that the simplified version of our model, as presented above, results in a quite different mathematical expression for the oxide growth rate which is rather simpler than the one obtained in Ref. (15, 16), while the ability to represent the experimental data is the same for both models.

Conclusions

A simplified viscoelastic model for the thermal dry oxidation of silicon was formulated which accounts for the anomalous behavior observed for the very thin oxide region. The basic assumption of the model is related to the constitutive equation for the oxygen diffusive flux which is represented by a viscoelastic-type equation instead of the usual Fick's law. Qualitatively, the proposed equation can be viewed as an exponential relaxation from an initial fickian behavior with a lower diffusivity D_1 toward a final fickian behavior with a higher diffusivity D_x .

The model was found to provide a satisfactory description of several available experimental data. Furthermore, the model, while it does not require a mathematical formulation more complex than other currently used models, has the important feature that all the intervening parameters have a physical meaning.

APPENDIX

For any set of the relevant parameters the effective diffusivity $D_e(t)$ can be calculated through its definition, Eq. [9], once all the other quantities entering Eq. [9] itself have been calculated from the solution of the complete model recalled in the viscoelastic kinetic model section.

The time dependence of $D_e(t)$ has therefore been obtained for several sets of the two most significant parameters, namely, the dimensionless relaxation time $\tau^* = \tau k_1^2/D_1$ and the diffusivity ratio $A = D_x/D_1$ which were allowed to range between 10^5 and 10^8 and between 1 and 10, respectively.

For each of the cases examined the resulting values of the $D_e(t)$ distribution have then been fitted with the analytical exponential form

$$\frac{D_e}{D_1} = \frac{D_x}{D_1} + \left(1 - \frac{D_x}{D_1}\right) \exp(-\beta t^*) \quad [\text{A-1}]$$

where t^* is the dimensionless time and D_x and D_1 maintain the same physical meaning and numerical values as

in the complete original model. The dimensionless time constant β was calculated through a least mean squares procedure.

A set of β values was originated through successive application of Eq. [A-1] to all the cases considered; the resulting values showed a very weak dependence on A , which has thus been neglected, while a significant dependence on τ^* was apparent. The calculated β values were, therefore, required to satisfy a τ^* dependence given by

$$\beta = a (\tau^*)^{-n} \quad [\text{A-2}]$$

The two numerical constants which appear in Eq. [A-2] were then evaluated through a least mean squares procedure and turned out to be $a = 0.16$, $n = 0.9$.

Titanium Silicide Formation on Boron-Implanted Silicon

T. P. Chow,* W. Katz, R. Goehner, and G. Smith

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Thin film interaction between Ti and boron-implanted silicon substrates at 650°-900°C was investigated. The compositional properties were examined with Rutherford backscattering spectrometry and secondary ion mass spectrometry, the structural properties with x-ray diffraction, and the electrical properties with sheet resistance measurements. At 650°C, incomplete Ti/Si reaction led to significant amounts of intermediate silicide phases (Ti_5Si_3 and $TiSi$) and hence higher sheet resistance. Annealing at 700°C or higher resulted in conversion of the titanium film into predominantly $TiSi_2$ and a lower sheet resistance. Boron was found to redistribute into the silicide layer during annealing, leading to an accumulation on the surface and a depletion at the silicide/silicon interface. The diffusion kinetics of boron through titanium silicide are compared with those of other p- and n-type dopants.

Refractory metal silicides have recently attracted much attention as MOS gates and interconnects in silicon integrated circuits because of their low resistivities and MOS process compatibility (1, 2). Among the disilicides studied, $TiSi_2$ has the lowest resistivity ($\sim 15 \mu\Omega\text{-cm}$) (3). Usually, the silicide is formed by cosputtering, coevaporation, or sintering titanium on silicon. For self-aligned silicide structures, the last technique is used. Also, the silicide formation is performed after the source/drain regions are heavily doped by implantation (4, 5). Thin film interaction of Ti with various n-doped silicon substrates, as well as on heavily phosphorus- and boron-doped poly-Si films, has been studied (7-12). However, the reaction with p-doped substrates has not been investigated in detail. We have recently studied titanium silicide formation and boron and fluorine redistribution on BF_2^+ -implanted silicon (13). In this paper, the Ti/Si reaction on boron-implanted, (100) silicon substrates is reported. The compositional, structural, and electrical properties of the silicide layer formed as well as the kinetics of boron redistribution are discussed. Furthermore, the redistribution behavior of boron is compared with those of n-type dopants such as phosphorus and arsenic.

Experimental Procedure

Various doses (5×10^{14} - $6 \times 10^{15} \text{ cm}^{-2}$) of boron ($^{11}B^+$) were implanted at 25 keV ($R_p = 820\text{\AA}$ and $\Delta R_p = 330\text{\AA}$) into (100), 300-500 $\Omega\text{-cm}$, boron-doped silicon substrates and then activated at 900°C in N_2 for 30 min. Low implantation energy and minimum heat-treatment were used to keep

* Electrochemical Society Active Member.

Fig. 1. Sheet resistance of the boron- and BF_2^+ -implanted layers vs. dose after annealing at 900°C for 30 min.

the implanted layer shallow so as to represent typical source/drain junction of short-channel MOS devices. The sheet resistance measured after activation, shown in Fig. 1, varies between 70 and 225 Ω/\square . For comparison, BF_2^+ was also implanted at 40 keV and the same dose range and then similarly activated. Its resistance ranged between 110 and 270 Ω/\square (13). Then, after a dip in 10% HF to remove the surface native oxide, nominally 1000 \AA thick titanium films were electron-beam evaporated onto the silicon substrates at room temperature. The background pressure before evaporation was always 1×10^{-6} torr or lower. The heat-treatment was performed in UHP H_2 at 650°-900°C for 30 min. To minimize the contamination from the ambient, a clean silicon wafer was always used as a cover during annealing.

The compositional and structural properties were studied with Rutherford backscattering spectrometry (RBS), secondary ion mass spectrometry (SIMS), and x-ray diffraction, while the sheet resistance was monitored with a four-point probe. RBS was performed with a 2 MeV $^4He^+$ beam from a linear accelerator. SIMS was done with a Cameca IMS 3-f ion microscope. The in-depth profiles of various negative ion species (namely, $^{11}B^-$, $^{16}O^-$, $^{19}F^{2-}$, $^{30}Si^-$, and $^{48}Ti^-$) were obtained using a mass-analyzed beam of Cs^+ primary ions with an impact energy of 10.5 keV. The concentrations of various ion species in silicon were calibrated with implanted standards. X-ray diffrac-

tion was done in a Rigaku horizontal diffractometer equipped with a Cr tube and a receiving beam graphite crystal monochromator and also checked with a REED thin film camera using Cr $K\alpha$ radiation and a glancing angle of 15° .

Results and Discussions

Sheet resistance.—As deposited, the sheet resistance was about $10 \Omega/\square$ for the unimplanted sample and ranged from 8 to $10 \Omega/\square$ for the boron-implanted ones (Fig. 2). After annealing at 650°C for 30 min, the sheet resistance dropped to $0.9\text{-}3 \Omega/\square$, as shown in Fig. 2. The scatter in the resistance values can be attributed to the difference in silicide content (see below) and appears to relate to the varying presence of native oxide and not to the boron dosage. The effect of a thin native oxide layer on titanium silicide formation has been previously studied in an UHV system (14). After a 700°C anneal for 30 min, the sheet resistance ranged between $0.8\text{-}0.9 \Omega/\square$ for all cases. Annealing at higher temperatures up to 900°C changed the sheet resistance only slightly. For example, in Fig. 3, the sheet resistance of Ti on unimplanted and $6 \times 10^{15} \text{ B}^+ \text{ cm}^{-2}$ -implanted silicon substrates is shown as a function of annealing temperature for a period of 30 min. It is clear from the figure that the presence of boron has little influence on the sheet resistance and the major reduction

Fig. 5. X-ray diffraction spectra of a Ti/Si sample ($6 \times 10^{15} \text{ B}^+ \text{ cm}^{-2}$) after annealing at (a, top) 650°C and (b, bottom) 700°C for 30 min

Fig. 6. Peak boron ($^{11}\text{B}^-$) concentration in silicon after titanium deposition but before Ti/Si reaction as determined from SIMS.

in sheet resistance occurs in the temperature range of 650°-700°C. Furthermore, the BF_2^+ -implanted samples yielded very similar values of sheet resistance (13). For example, values of 0.75-2.5 Ω/\square were measured after annealing at 650°C for 30 min and 0.70-0.86 Ω/\square after a 700°C anneal.

Film composition.—From RBS spectra, both the Si/Ti ratio and silicide thickness are obtained. The Si/Ti ratio for unimplanted and $6 \times 10^{15} \text{ cm}^{-2}$ samples are shown in Fig. 4 as a function of annealing temperature. When the Ti/Si films were annealed at 700°C or higher, a Si/Ti ratio between 2.0 and 2.1 was measured. The resulting TiSi_2 thickness after high temperature annealing was 2200-2300Å (close to the theoretical estimate of 2.27 times the

original Ti thickness) and insensitive to the boron doping. For the samples annealed at 650°C, a thin (~650Å) surface region of titanium-rich silicide (Si-Ti ~1.8) was detected together with a near-stoichiometric disilicide underneath. This indicates incomplete conversion of titanium into the end phase of TiSi_2 . As will be pointed out in the next section, the titanium-rich surface layer has been found to contain significant amounts of intermediate silicide phases (Ti_5Si_3 and TiSi).

Film structure.—X-ray diffraction revealed that only the (002) peak (at 2.34Å) of β -titanium (15) was detected in as-deposited films. After annealing at 650°C or higher temperatures for 30 min, no titanium peak was left. These results are similar to those reported for Ti on heavily

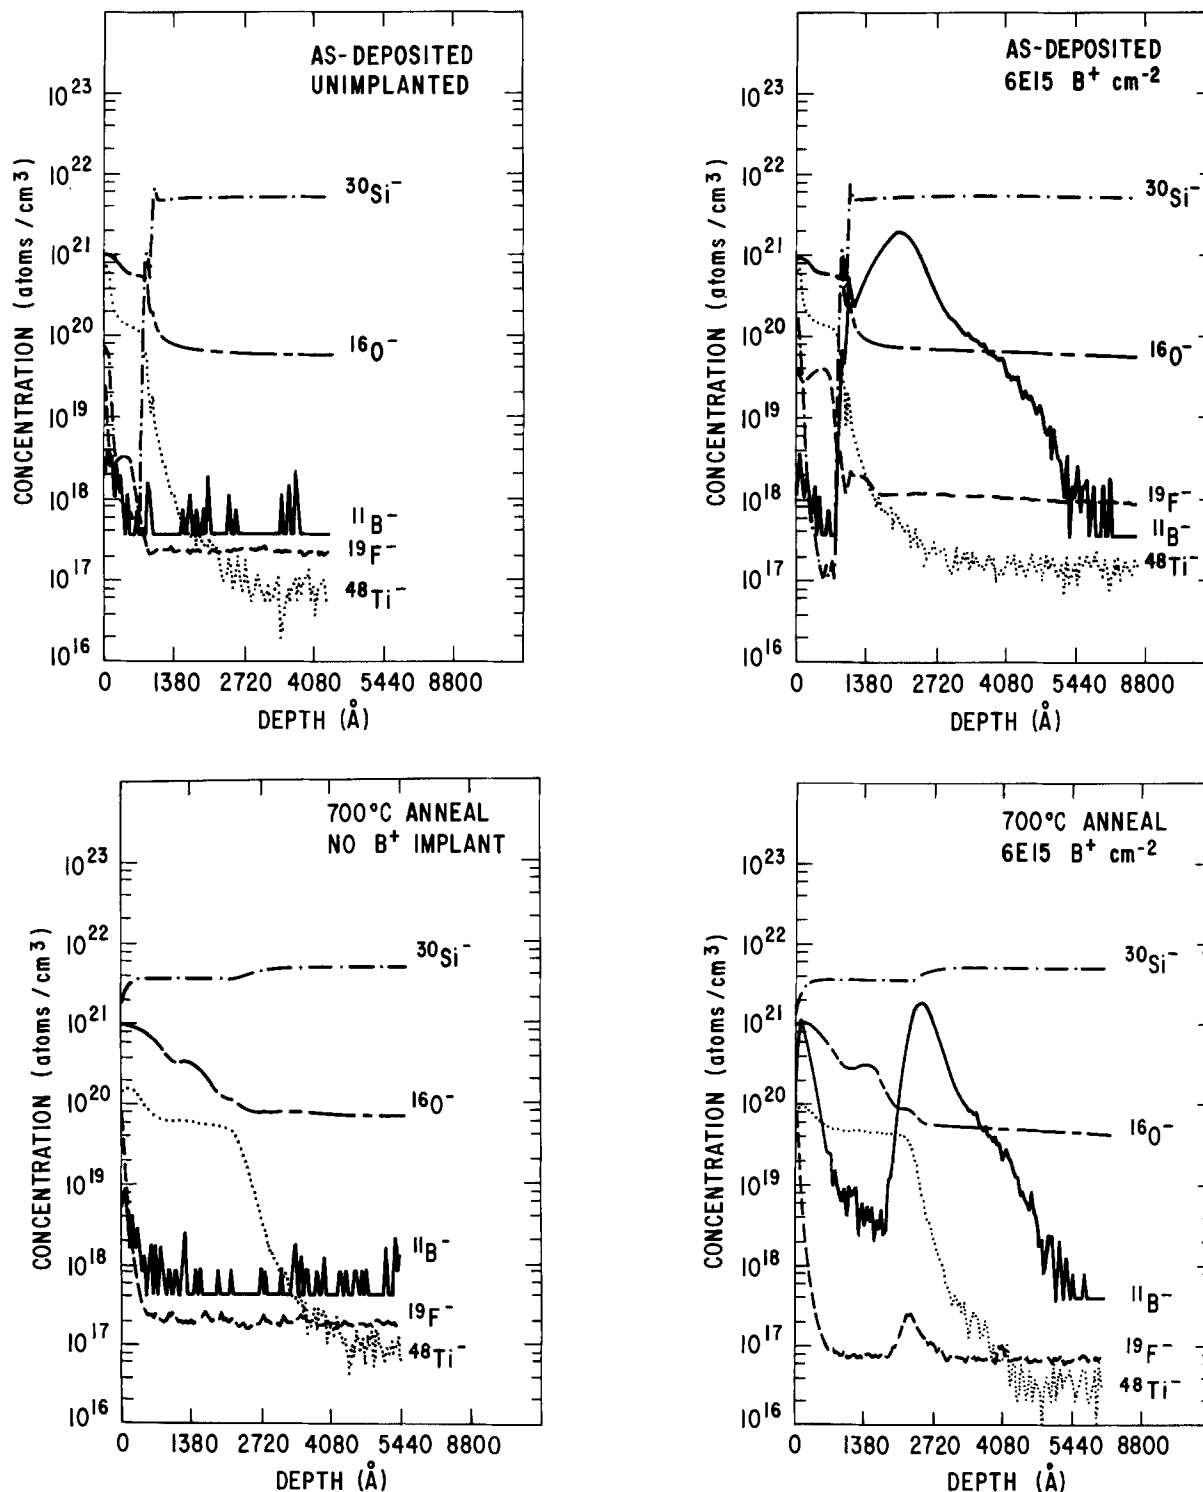

Fig. 7. SIMS depth profiles for two Ti/Si samples (unimplanted and implanted with boron at $6 \times 10^{15} \text{ cm}^{-2}$) before [a (top left) and b (top right)] and after [c (bottom left) and d (bottom right)] annealing at 700°C for 30 min.

Fig. 8. Peak concentration of boron ($^{11}\text{B}^-$), as determined from SIMS, for Ti/Si samples with a $6 \times 10^{15} \text{ B}^+ \text{ cm}^{-2}$ implant as a function of annealing temperature.

phosphorus-doped (from PBr_3) poly-Si (7). The films annealed at 650°C exhibited three titanium silicide phases. Figures 5a and 5b show the x-ray diffraction spectra of a Ti/Si sample with $6 \times 10^{15} \text{ B}^+ \text{ cm}^{-2}$ after annealing at 650° and 700°C , respectively. Face-centered-orthorhombic TiSi_2 (16) is the major phase formed, with several peaks observed. The main ones were at 2.30, 2.14, 2.09, and 1.83\AA , corresponding to the (311), (004), (022), and (313) peaks, respectively. From the (311) line broadening, a grain size of 550\AA was calculated. Also, for the films with higher sheet resistance, three other peaks (not attributable to TiSi_2) at 2.72, 2.44, and 2.20\AA were enhanced. While the first one can be assigned to the (201) peak of TiSi (17), the last two can be, respectively, from either the (210) and (211) peaks of TiSi or the (120) and (121) peaks of Ti_5Si_3 (18). Since the peak at 2.20\AA has a sharper profile and is narrower than those of the 2.72 and 2.44\AA peaks, it was assigned to Ti_5Si_3 , whereas the latter two to TiSi . (To index all the three peaks to TiSi would require the TiSi grains to have a peculiar orientation.) Grain sizes of 500 and 100\AA were estimated for Ti_5Si_3 and TiSi from breadths of the 2.20 (2θ of 63.0°) and 2.44\AA (2θ of 56.0°) lines, respectively. Similar diffraction spectra (not shown) were also obtained for the unimplanted sample. It was found that a stronger intensity of the intermediate silicide peaks was usually detected on films with a higher sheet resistance. This is consistent with the higher resistivity (two times or higher than that of TiSi_2 , $36\text{--}63 \mu\Omega\text{-cm}$ for TiSi and $55\text{--}350 \mu\Omega\text{-cm}$ for Ti_5Si_3) of these intermediate phases (3). Furthermore, no diffraction peak traceable to any Si-O, Ti-O, or Ti-B phase was found.

After annealing at 700°C or higher, there is no substantial structural difference among the unimplanted (control) and boron-implanted samples. TiSi_2 was the major phase formed with a small amount of TiSi also detected.

Boron diffusion—Boron diffusion after heat-treatment was monitored with SIMS depth profiling. To check the accuracy of boron concentration from SIMS, besides the routine calibration with implanted standards as mentioned earlier, the ion intensity of $^{11}\text{B}^-$ in the Ti/Si

Fig. 9. SIMS depth profiles for Ti/Si films without (a, left) before and with (b, right) $6 \times 10^{15} \text{ P}^+ \text{ cm}^{-2}$ after annealing at 700°C for 30 min

samples after titanium deposition but before thermal annealing was measured and is plotted as function of the implantation dosage in Fig. 6. A linear relationship can be readily seen, confirming that the boron concentration is proportional to the $^{11}\text{B}^-$ signal intensity within the dosage range studied. In Fig. 7, the boron profiles for two Ti/Si samples—one unimplanted and one implanted (at $6 \times 10^{15} \text{ cm}^{-2}$)—before and after annealing at 700°C for 30 min are shown. After Ti deposition, the boron ($^{11}\text{B}^-$) level in the silicide was very low. Then, after annealing at 650°C or higher, the redistribution of boron into the silicide was very significant. At 700°C , it can be seen from comparing Fig. 7b and 7d that about half of the initial boron layer has outdiffused into the silicide layer formed and accumulated on the outer surface of the silicide layer and eventually was lost into the ambient. When the annealing temperature was raised, the decrease of boron concentration in silicon was enhanced, as indicated in Fig. 8, where the boron peak concentration of the $6 \times 10^{15} \text{ B}^+ \text{ cm}^{-2}$ sample was shown against annealing temperature up to 900°C . A 40% decrease in peak concentration (from 2×10^{21} to $1.2 \times 10^{21} \text{ cm}^{-3}$) can be observed. Such a dopant redistribution during silicide growth has been reported for high dosage BF_3^+ (13) and for antimony (8) (but not for arsenic) in TiSi_2 . However, unlike boron and arsenic in PtSi and Pd_2Si (19, 20), no significant snowplow effect is apparent. The absence of the snowplow effect has also been observed earlier for higher dosage arsenic in TiSi (21). Such a characteristic is particularly undesirable for shallow junctions like those studied here because of the significant loss of dopants.

To compare the boron diffusion with n-type dopants in TiSi_2 , we have also annealed titanium on phosphorus- and arsenic-implanted silicon substrates. Phosphorus was found to diffuse like boron while arsenic apparently reacted with titanium or silicon during silicide formation. The SIMS depth profiles of Ti/Si films with and without phosphorus (at the dosage of $6 \times 10^{15} \text{ cm}^{-2}$) after annealing at 700°C for 30 min are shown in Fig. 9. It can be seen that only a small amount (<50%) of the implanted phosphorus was left in the silicon with peak concentration still at the silicide/silicon interface. On the other hand, for arsenic (its SIMS depth profile not shown here), its concentration was constant in the silicide, and, still, a large percentage was retained in the silicon. More on arsenic diffusion during titanium silicide formation will be published later (22).

Summary

Thin film interaction between titanium and boron-implanted, (100) silicon substrates was investigated. X-ray diffraction indicated that the (002)-oriented Ti films was converted into mainly TiSi_2 after annealing at 650°C – 900°C , with intermediate silicide phases (TiSi , Ti_5Si_3) significantly present at 650°C . A higher intermediate silicide content was correlated with a higher sheet resistance. Boron redistributes into the silicide layer during annealing, leading to an accumulation on the surface. Then it was lost into the ambient. Phosphorus, but not arsenic, was found to outdiffuse through the silicide like boron.

Characterization of the Dual E-Beam Technique for Recrystallizing Polysilicon Films

J. R. Davis,¹ R. A. McMahon, and H. Ahmed

Department of Engineering, Cambridge University, Cambridge, England IP5 7RE

ABSTRACT

Detailed materials properties of silicon on insulator films produced by dual electron-beam recrystallization of polysilicon films are reported. By scanning a line electron beam parallel to the edges of an array of narrow seeding windows, large areas (several square centimeters) of precisely oriented single-crystal silicon have been formed. The optimum beam conditions and substrate geometry to achieve the best recrystallization have been investigated, and it has been found that using a fast scan speed (~ 35 cm/s) allows seeded regrowth without melting the substrate below the isolating oxide. Using these conditions, complete wafers may be recrystallized in around 30s without introducing strain or wafer warping. Remaining crystallographic defects include dislocations midway between seeding windows and an occasional twinning of the regrowth when the windows are aligned along $\langle 110 \rangle$.

There is now considerable interest in the production of single-crystal silicon films on amorphous insulators (SOI), in which advanced electronic devices may be fabricated (1). One of the most promising methods is the recrystallization of deposited polysilicon films by moving a localized molten zone across the specimen surface. Many heat sources have been used to produce this zone, including graphite strip heaters (2), radiant lamps (3), lasers (4), and electron beams (5). The use of a dual E-beam technique capable of producing single-crystal silicon films has been reported previously (6-8). In this paper, recent improvements to the technique and the detailed materials properties of the resulting recrystallized films are described. Also, the dependencies of these properties on the specimen preparation conditions and geometry, and on electron-beam parameters such as speed, power, and scan direction, are investigated. The characterization techniques employed include defect etching, TEM and SEM, x-ray topography, and RBS and ion channeling. Electrical properties of CMOS transistors and circuits fabricated in the films are reported elsewhere (9).

The dual E-beam technique has several desirable features, particularly when the films are required for VLSI applications. One important requirement is that when the substrate is in the form of an oxide-covered wafer the recrystallization technique does not cause any damage to it, either microscopically in the form of slip dislocations or macroscopically as wafer warpage. Production of stacked-layer or three-dimensional circuits calls for a technique in which the silicon beneath the isolating oxide is not melted. For production of more conventional devices, however, limited melting of the underlying silicon is permissible as long as the oxide remains intact and flat and the silicon film on top of it maintains a uniform thickness and smooth surface. To be commercially acceptable, the recrystallization system should have a high throughput, and it must have a large window of recrystallization conditions, thus ensuring that the process is controllable and the yield is high. Finally, the positions in which active devices may be placed must not present unreasonable constraints to the circuit designer. No recrystallization technique, or any other SOI method, has yet fully achieved all these objectives, but the progress with the dual E-beam technique reported here allows most of them to be met.

Method

The dual E-beam system has been described previously (10). The wafer is supported in thermal isolation so that both its surfaces are accessible to the beams. The lower column produces a background temperature of around 1000°C by the multiple-raster-scanned, isothermal heating technique. This uniform temperature is achieved in a few seconds, and is maintained during recrystallization.

¹Present address: British Telecom Research Laboratories, Ipswich, England IP5 7RE.

The upper column images a line beam on the specimen surface, producing a localized molten zone in the polysilicon film which is swept across the wafer. In the present version of the machine, this line beam is synthesized by scanning a 60 μm focused spot with a 100 kHz triangular signal applied to the X-direction electromagnetic deflection coils. This frequency is sufficient to prevent the polysilicon from solidifying between passes of the beam because of the high background temperature and the large amount of energy stored as latent heat. The length of the line in these experiments was typically 2 mm, and was limited only by the power available from the high voltage supply (60W at 20 keV). Recrystallization was performed by scanning the line beam across the wafer at speeds in the range 3-300 cm/s by means of the Y-deflection coils, producing a 2 mm wide recrystallized stripe. Larger areas were recrystallized by stepping the wafer, together with the area scanned by the bottom beam, between sweeps, and with the line blanked. Complete wafers can be recrystallized in around 30s using this technique with a typical scan speed of 35 cm/s. This time is virtually independent of the wafer size, being determined principally by the background heating time constant.

The choice of accelerating voltage for the line beam is a compromise between a low value to maximize the power deposition in the polysilicon, rather than in the substrate, and a high value for ease of producing a high power density. Only 3.3% of the beam power penetrates to the substrate with a 20 keV beam for a structure in which the underlying oxide, the polysilicon, and the capping layer are each 1 μm thick (7).

Previous work (7, 8) has shown that for line-scan speeds of > 10 cm/s, which are used to control the depth of melting, seeding of the regrowth from a single-crystal substrate through holes ("seeding windows") cut in the isolating oxide is necessary to achieve an (001) surface. There is a choice of two obvious directions for the scan relative to the orientation of the seed windows. These have been termed "perpendicular scanning" and "parallel scanning" and are illustrated in Fig. 1. The relative advantages of the two schemes originate from the fact that the seed windows fulfill two roles; not only do they select the crystal orientation of the regrown layer, but they also control the flow of heat during resolidification. Perpendicular scanning, which we originally used (6, 8), produces a slightly wider defect-free zone, but we have recently obtained improved surface flatness and control of the process by using parallel scanning; all the results described in this paper employed parallel scanning.

Specimens for recrystallization were prepared by growing a thermal oxide of between 0.5 and 2.0 μm on (001) silicon wafers. Seeding windows were normally produced by wet etching, giving an oxide edge slope of $\sim 70^\circ$, but some specimens were prepared with an approximately coplanar surface by a LOCOS process. The seed

Fig. 1. Schematic diagram of two possible seeding strategies. a: Perpendicular scanning. b: Parallel scanning.

windows were aligned either with the $\langle 110 \rangle$ direction (parallel to the wafer flat and the normal processing orientation), or with the $\langle 100 \rangle$ direction, at 45° to the flat. A 10s dip in dilute HF immediately prior to the low pressure deposition of the 0.5 or 1.0 μm thick polysilicon layer ensured good contact with the substrate in the seeding windows. A capping layer of 1 μm of deposited oxide and 50 nm of silicon nitride was employed.

Results and Discussion

General.—Figure 2 is a set of Nomarski micrographs of several regions taken from a typical recrystallized stripe after removal of the capping layers and Secco etching to reveal any crystallographic defects. Recrystallization in this instance was achieved with a background temperature of 985°C and a scan speed of 35 cm/s. In the central region, the recrystallized film is free of any line features, indicating perfect regrowth. At the start of the scan, the unmelted polysilicon has been removed by the etch, and this is followed by a short region of unseeded growth, with associated grain boundaries, until the polysilicon in the seed windows melts. The contraction of the polysilicon as it initially melts gives rise to a row of small holes, penetrating the film, when the beam first hits the specimen, but once the sweep is underway there are no discontinuities in the mass flow to cause any further loss of surface flatness. This is in contrast to the perpendicular scanning case, where the oxide steps present periodic constrictions to the flow, and the heat sinking effect of

Fig. 2. Secco-etched regions from a 2×8 mm recrystallized stripe, with an $\langle 001 \rangle$ substrate and the seed windows aligned along $\langle 110 \rangle$. The narrow lines are the 4 μm wide seeding windows.

the exposed substrate lowers the temperature and increases the viscosity of the molten silicon, producing the ripples observed in our earlier results (8). At the end of the scan, expansion of the silicon leads to a row of small mounds as the now stationary molten pool solidifies. The extent of the recrystallization beyond these mounds gives an indication of the instantaneous size of the molten zone, with typical values being in the range 50-150 μm , depending on the beam power; that is, they are comparable with the width of the line beam. In a production recrystallization system, the beginning and end of the scan would be arranged to occur either off the wafer or in the scribe lanes between chips, thus removing all evidence of mass flow from the device areas. At the extreme edge of the stripe, the beam power is insufficient to cause melting in the seed windows, leaving a narrow zone of large-grained material. Once again, this zone would be placed outside the active device region.

Figure 3 is a series of SEM micrographs of specimens Secco-etched after cross sectioning, and in which recrystallization was produced by increasing beam powers. The unrecrystallized polysilicon has a columnar grain structure, with grains $\sim 0.1 \times 1 \mu\text{m}$ (Fig. 3a). After recrystallization at the lowest beam power (Fig. 3b) the polysilicon on the oxide shows a dramatic increase in grain size, but the extra heat sinking in the seed window has prevented complete melting there and the regrowth is unseeded. A small increase in the beam power (Fig. 3c) causes the melt to penetrate into the substrate at the sides of the seed window, even though melting in the center is incomplete. This effect, which arises from the lateral heat

Fig. 3. SEM cross sections of recrystallized films after Secco etching. Pictures a to d are at increasing beam powers. Scan direction is into the plane of the paper.

flow from the oxide-isolated region into the seed area, means that proper seeding can be achieved from windows of submicron widths at powers only very slightly above those needed to melt unseeded films. In Fig. 3d, complete epitaxial growth has occurred in the seed regions, and only a few etch pits at the original polysilicon/substrate interface remain, probably caused by the breakup of the thin native oxide present before polysilicon deposition; these defects do not propagate into the oxide-isolated regions. The difference in beam power between Fig. 3b and 3d is about 15%.

The orientation of the regrown films has been investigated with a variety of techniques. For example, Fig. 4 shows an array of anisotropically etched pits (11) which, by their square shape, show the surface to be (001) oriented. The sides of these squares are accurately aligned parallel to the $\langle 110 \rangle$ seeding window direction, which is to be expected of a pit defined by the intersection of the [111] planes with the (001) surface. Correct orientation of much larger regions is shown by the electron channeling picture of Fig. 5. Two separate recrystallized stripes show the standard (001) channeling pattern, and this pattern is continuous across the vertical scribe lane where the polysilicon is in direct contact with the substrate and has regrown epitaxially. No patterns are seen in the nonrecrystallized regions.

Macroscopic wafer flatness and the possibility of internal stresses in the substrate created by the recrystallization procedure were investigated by means of x-ray topography. The wafer shown in the topographs of Fig. 6 was unseeded and was recrystallized over its entire area by a number of sweeps of the line beam parallel to the wafer flat. After recrystallization, the wafer underwent a full CMOS processing schedule, in the course of which the recrystallized film was etched into small islands. It can be seen that there are no slip dislocations in the substrate, and the evenness of the image intensity indicates that there is no appreciable stress. This is in contrast to graphite strip heater-recrystallized wafers, where the slow

movement of a much larger molten zone may cause complex two-dimensional stresses (12). The introduction of seed windows does not produce significant changes to the temperature profile in the substrate, and hence it is expected that seeded wafers will also be stress free.

Crystal defects.—Dual E-beam recrystallized films, although essentially single-crystal sheets, at present show three main types of crystallographic defects. First, with parallel scanning, there is a defect in the center of each oxide bar where the growth fronts from the two seeding windows meet. This defect was not usually revealed by Secco etching, but transmission electron microscopy (Fig. 7) shows the presence of a number of threading dislocations. These dislocations were almost always confined to within $1 \mu\text{m}$ of the geometrical center of the oxide bar by the symmetry of the heat flow, and so could be avoided by the active region of devices fabricated in the films. It is worth noting that no dislocations were found at other positions.

The second form of defect observed was an occasional twinning of the regrowth which, once initiated, could propagate for hundreds of microns in the scan direction. This twinning is shown by the anisotropic etch pits in Fig. 8, where the pits along one half of the central oxide bar are hexagonal. X-ray texture camera studies showed that these regions have a $(2\bar{2}\bar{1})$ surface, resulting from twinning on a (111) plane. Twinning was usually observed on specimens with the seed windows aligned along the $\langle 110 \rangle$ direction. In this case, the {111} twin planes lie along the seed direction, which is also the direction of the maximum temperature gradient produced by the line beam.

Fig. 7. TEM of dislocations running along the center of a recrystallized stripe.

Fig. 8. Anisotropic etch pits in a recrystallized film with the seed windows aligned along $\langle 110 \rangle$, showing hexagonal pits along half of the middle bar indicating twinning and a $(2\bar{2}1)$ surface.

The final form of crystal defect observed was stacking faults, which are shown in the optical and TEM micrographs of Fig. 9. The most common faults were found in twinned regions with $\langle 110 \rangle$ -aligned seed windows. These faults, which again lie on (111) planes, originate at the seed window edge and grow at 56° in towards the center of the oxide bar. In untwinned regions, the traces of the (111) planes make an angle of 90° to the seed edge, and these faults were observed far less frequently, with about one fault per centimeter of seed edge. For seed windows aligned along $\langle 100 \rangle$, where the traces of the (111) planes are at 45° to the seed edge, the stacking fault density was typically two faults per millimeter. Stacking faults on higher-order planes, particularly $(\bar{2}11)$, (311) , and (221) , were sometimes observed in regions where poor photolithography had led to very rough edges to the seed windows. In general, the larger the angle a fault made with the seed edge, the less frequently it was observed, confirming that the driving force for the propagation of the defect is the stress produced by the temperature gradient behind the beam. A more detailed investigation of the defects will be published elsewhere.

Overall crystal quality.—The effects of the various crystal defects described above on the overall perfection of the film have been investigated by Rutherford backscat-

Fig. 10 $^4\text{He}^+$ ion backscattering spectra from recrystallized films. a: Direct contact between the polysilicon and the substrate (equivalent to the seeding region). b: 82% of the recrystallized film separated from the substrate by $1 \mu\text{m}$ of oxide.

tering and ion channeling studies. Figure 10a shows the random and $[001]$ -channeled spectra obtained from an epitaxially regrown polysilicon layer deposited directly onto an (001) substrate, corresponding to the seed area of an SOI specimen. A value of 3.9% is obtained for the minimum channeling yield χ_{min} , approaching that of bulk silicon and indicating good quality regrowth. There is no sign in the channeled spectrum of the original polysilicon/substrate interface, showing that good mixing has occurred. The beam power in this experiment had been optimized for the regrowth of the SOI area, and so even

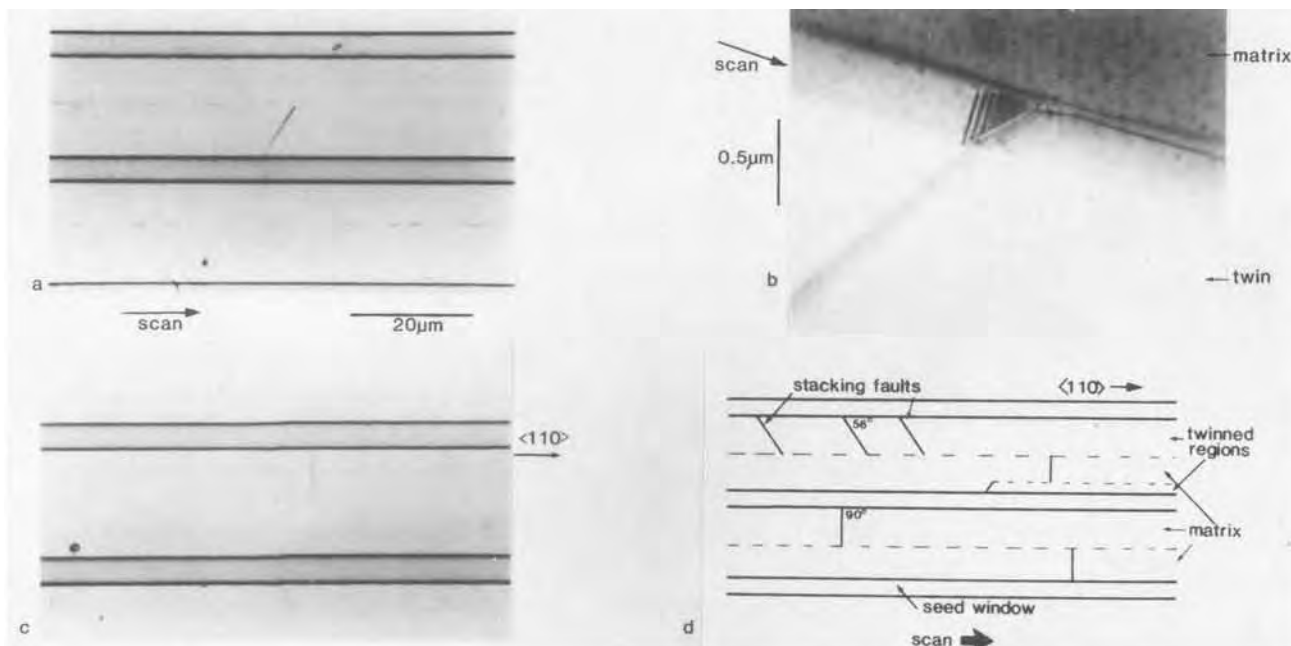

Fig. 9. Stacking faults in a film recrystallized on an (001) substrate with seed windows aligned along $\langle 110 \rangle$. Pictures a and c are Nomarski micrographs of Secco-etched regions in which the recrystallization is twinned and untwinned, respectively. Picture b is a TEM of a single stacking fault. The various types of common faults are shown schematically in d.

better results could be expected for slightly higher powers.

The spectra of Fig. 10b were obtained on the same specimen as used for Fig. 10a without changing its orientation, but in a region where a repetitive array of oxide bars 18 μm wide and spaced 4 μm apart isolated 82% of the silicon film from the substrate. The 1.5 MeV $^4\text{He}^+$ beam used in this study had a diameter of 1 mm, so these spectra represent averages over many separately seeded regions. The specimen, which had $\langle 110 \rangle$ -oriented seed windows, had been lightly Secco etched to reduce the silicon film thickness and to allow the degree of twinning to be estimated optically at around 15% of the total area. This twinning, and the associated stacking faults, have increased the value of χ_{min} to 10.2%, which is similar to values often observed for silicon on sapphire films (13). The increase in the channeled signal with increasing depth is much smaller here than in the case of SOS, however, as the density of defects is largely independent of depth for the recrystallized films, whereas for SOS many microtwins are nucleated at the back interface, giving rise to a gradually increasing defect density with depth. That the recrystallized silicon has good crystal qualities throughout its thickness is confirmed by the electron and hole mobilities at the back interface, which have values comparable to bulk silicon (9). Thus for specimens in which the twinning is reduced, for example by the $\langle 100 \rangle$ alignment of the seed windows, much improved crystal quality should result. Also, it will be possible to provide thinner films, required for small-geometry devices, without degrading the crystal quality.

Choice of regrowth parameters.—Optimum regrowth with the dual E-beam technique depends on the correct choice of the beam conditions and the thicknesses of the various layers. The relationship between the power required in the line beam and the scan speed for a typical experiment is shown in Fig. 11. Along the line marked "partial melting," the beam power raises the polysilicon temperature to the melting point but is insufficient to provide the latent heat requirement of the whole film, resulting in a slush of mixed solid and liquid. For beam powers above the value required for complete melting, there is a window in which good recrystallization occurs, until eventually the liquid silicon is raised to a temperature at which damage is caused. This damage takes the form of dewetting and agglomeration of the silicon into islands ("beading up") at low speeds and a cracking of the cap at high speeds. The increasing window of satisfactory conditions with scan speed makes it attractive to work with as fast a scan as possible, especially as the reduced diffusion of heat into the specimen with the short dwell times minimizes the possibility of substrate melting. The upper limit to the speed is set by the necessity to provide adequate beam power, and by the ability of the seed windows to keep the position of the solidification front under control, preventing random nucleation of grains. This latter effect is also a function of the substrate or background temperature. It is desirable to work with a

high background temperature in order to minimize (i) the difference in power densities required to melt the polysilicon on the thermally insulating oxide and that on the substrate, (ii) the stress produced by the high temperature gradients, and (iii) the total line beam power. The window of beam powers allowing seeded recrystallization (i.e., the minimum power required to melt the polysilicon in the seed window without causing melting under the isolating oxide) is shown in Fig. 12 for a fixed scan speed. As expected, the two lines converge towards the melting point, where the whole specimen is melted without any power input from the line beam. For temperatures above $\sim 1270^\circ\text{C}$, the seed windows, which were widely separated in this experiment, are unable to keep the solidification front close to the line beam and random solidification proceeds vertically from the underlying oxide in small ($\sim 50 \mu\text{m}$ diam) regions, leading to a $\{111\}$ -textured film. Thicker polysilicon or oxide layers or more closely spaced seed windows all result in the polysilicon being in better lateral thermal contact with the substrate, and hence allow seeded regrowth to be maintained to higher scan speeds or substrate temperatures.

Seeded regrowth naturally requires melting to penetrate into the substrate in the seed window, but it is desirable for the substrate below the isolating oxide to remain solid. The depth of melting has been investigated by observing the motion of an As marker implant (1.0^{16} cm^{-2} at 40 keV) positioned in the substrate prior to the low temperature growth of the oxide. Bevel-and-stain and cross-sectional SEM techniques have both been used. The depth of melting, both under the center of an oxide stripe and at the edge of a seed window, is shown in Fig. 13 as a function of the line beam power. There is a window of beam power between 24 and 26 W/mm, or 8%, for seeded regrowth without substrate melting. The size of this window is expected to increase with increasing sweep speed. Increases in the beam power above the melting threshold give a linear increase in the melt depth. The slope of the line indicates that, to a first approximation, there is no change in the amount of heat lost from the sur-

Fig. 11. Power required in the line electron beam as a function of speed, for dual-beam recrystallization.

Fig. 12. Dependence of the window of line beam powers for seeded recrystallization on the background temperature.

Fig. 13. Dependence of the depth of substrate melting, both under the isolating oxide and in the seed windows, on the line beam power.

face region and that the extra power above threshold is simply absorbed as latent heat. The substrate under the oxide can be melted to a depth of several microns without loss of surface flatness or damage to the oxide stripes, and hence substrate melting should not necessarily be regarded as catastrophic, except, of course, for the case of recrystallization of partially processed wafers. Finally, for beam powers substantially above the melting threshold, molten silicon flows over the oxide stripes which remain intact but sink into the substrate.

The thicknesses of the various layers determine the heat flow in the system and hence the process window. Increasing the thickness of the underlying oxide increases the thermal isolation of the polysilicon film, making it easier to melt it without substrate melting. This means, however, that when the beam power is sufficient to cause melting in the seed window the polysilicon on oxide has been heated well above the melting point and hence it exerts a large stress on the capping layer, sometimes causing it to fracture. Although no problems were experienced in obtaining seeded regrowth up oxide edges 2 μm high, optimum results were usually achieved with 1 μm oxides.

SOI films intended for VLSI applications will probably have thicknesses of 0.5 μm or less. The dual E-beam technique was found to be successful for polysilicon thicknesses down to 0.2 μm , below which dewetting occurred. The uniformity of the crystal structure throughout the film allows it to be thinned after recrystallization (by etching, or by growing and stripping off an oxide, for example) without any loss in crystal quality, and hence a thicker film than is finally required can be chosen for recrystallization. Increasing the polysilicon thickness increases the lateral component of the heat flow compared to the vertical one through the oxide, providing better control of the solidification front. Thus thicker polysilicon layers show a reduced tendency to random nucleation at high scan speeds and also allow a wider spacing of the seed windows without allowing the solidification front to facet and produce sub-boundaries. The maximum window spacing which still produced boundary-free recrystallization with parallel scanning was 50 μm for 0.5 μm films and 70-100 μm for 1 μm thick films. As the spacing was increased towards these maximum values, the severity of the defect above the center of the oxide bar (that is, the number of individual dislocations required to accommodate the mismatch between the two sides) increased.

Conclusions

It has been demonstrated that the dual electron-beam recrystallization technique is capable of producing precisely oriented films of single-crystal silicon on oxide. The films are essentially free of major defects, except for an occasional twinning of the growth on {111} planes which occurs particularly when the seed windows are aligned in the $\langle 110 \rangle$ direction. By arranging for the scan direction of the line beam to be parallel to the seed windows, there are no discontinuities in the mass flow of molten silicon, and so the recrystallized films remain flat.

The optimum beam and specimen parameters for achieving a wide process window have been investigated. Oxide and polysilicon films $\sim 1 \mu\text{m}$ thick produce the best recrystallization, particularly when recrystallized with a background temperature of 1000°C and a scan speed of $> 30 \text{ cm/s}$. Under these conditions, there is a process window of $\sim 8\%$ in beam power between achieving proper seeded regrowth and the onset of substrate melting beneath the isolating oxide. Substrate melting of several microns can be tolerated without degrading the SOI film as long as there are no device structures present, giving a much larger window.

Future work will concentrate on a scaling up of the E-beam equipment and on methods of eliminating the problems of twinning. The speed with which the technique can recrystallize a wafer and the quality of the films that it produces will make it a strong contender for producing SOI substrates for VLSI device fabrication.

Acknowledgments

We would like to thank Dr. G. F. Hopper (GEC Hirst Research Centre) for the supply of the polysilicon specimens. The x-ray topographs were produced by Mrs. M. Halliwell (British Telecom Research Laboratories). Dr. C. Jaynes (University of Surrey) is thanked for his help with the RBS spectra. J. Davis and R. McMahon acknowledge a Research Scholarship and a Research Fellowship, respectively, from British Telecom Research Laboratories.

Plasma Organosilicon Polymers

Deposition, Characterization, and Application in Multilayer Resist

V. S. Nguyen, J. Underhill, S. Fridmann, and P. Pan

IBM General Technology Division, Essex Junction, Vermont 05452

ABSTRACT

Divinyl tetramethyl disiloxane (DVS), hexamethyl disilazane (HMDS), and methyl trimethoxysilane (MTS) polymer films were deposited on p-type silicon substrates using plasma-enhanced chemical vapor deposition (PECVD) processing. The deposition process was implemented in a parallel-plate, capacitively coupled plasma deposition system. Excellent film thickness and refractive index uniformity (std dev = 2-3%) were obtained. The deposition kinetics were studied as a function of process parameters such as pressure, power, density, and substrate temperature. The polymer film's physical properties were characterized by Fourier transformed infrared (FTIR), electron spectroscopy for chemical analysis (ESCA), Auger spectroscopy, electron spin resonance (ESR), and plasma etching. These polymer films were used as an intermediate oxygen etch resistance layer in trilevel resist lithography to produce submicron image patterns ($\approx 0.7 \mu\text{m}$ lines and spaces) using step and repeat photolithography.

The formation of polymeric organosilicon compounds by radio frequency (RF) glow discharge as a thin dielectric film for optics (1-2) and other microelectronic applications (3-9) has been reported widely in several recent publications. Plasma polymer films with unique physical and chemical characteristics can be produced by the passage of organosilicon monomers through low pressure plasma. The polymers are usually amorphous and highly cross-linked with stoichiometric ratios which typically do not relate to those of the starting monomers in a simple way. In microelectronic applications, siloxane, silazane, and silane monomers are the most frequently used compounds for plasma polymerization because of their low toxicity (10) and compatibility with both organic resists and silicon materials. Furthermore, low temperature dry processing in a vacuum minimizes exposure to contamination and is a low cost and attractive technique for VLSI fabrication.

It is well known that properties of plasma-deposited polymers are influenced by process parameters, including power density, pressure, substrate temperature, position of substrate, and type of plasma reactor coupling (capacitive or inductive) (11-13). The complexity of the plasma polymerization mechanism has also been discussed by Haller and others (11, 14-17). Organosilicon polymer tends to have lower internal stress and greater freedom from pinholes, as compared to thermally grown or deposited silicon films, due to the low deposition temperature, highly cross-linked structure, and better thermal matching and compatibility with organic resist. Therefore, the organosilicon polymer films can be used as an intermediate plasma oxygen etch barrier, in place of thin oxide or nitride films, in trilevel resist photolithography.

Recently, Sachdev *et al.* (4) studied some physical properties of organosilicon polymers deposited in a barrel-type inductively coupled plasma system. In this paper, we report the deposition, characterization, and application of divinyl tetramethyl disiloxane (DVS), hexamethyl disilazane (HMDS), and methyl trimethoxysilane (MTS) polymers in a parallel-plate, capacitively coupled, plasma system.

The deposition kinetics were investigated by studying the variation in film deposition rates as a function of process parameters such as power, system pressure, and substrate temperature. The physical properties of deposited polymers were characterized by Fourier transformed infrared (FTIR) spectroscopy, electron spectroscopy for chemical analysis (ESCA), Auger analysis, and electron spin resonance (ESR) techniques. Film properties were studied as deposited, after thermal annealing up to 300°C, and after surface treatment with oxygen or nitrogen plasma. The etch rates of these polymers in CF_4 plasma and in O_2 plasma in reactive ion etching modes were also investigated. The deposited polymers were used as intermediate plasma oxygen etch barriers in trilevel resist

photolithography (18-20). Submicron images with vertical profiles ($\approx 0.7 \mu\text{m}$) were obtained from this multilayer resist technique using step and repeat photolithography.

Experimental

The plasma polymerization and deposition processes were implemented in a high frequency (13.56 MHz), parallel-plate, capacitively coupled, plasma deposition system. The monomers DVS, HMDS, and MTS were purchased from Petrarch Chemical, Limited, and used without further purification. The chemical structure, molecular weight, and boiling point of the monomers are shown in Table I. Polymer films were deposited on bare p-type silicon wafers for process and physical characterization. The monomer liquids were heated to a constant 70°C during the deposition process. The reactor chamber pressure was controlled by gas input and vacuum pump throttle valves. The radius of the electrode is about 31 cm. The volume of the system is about 45 dm³. Since the gas input is controlled by monomer evaporation, exact flow rate calculation is not possible. Approximate flow rates for all monomers is in the range of 300-500 sccm. The centerline process parameters for the best film thickness and refractive index uniformities (std dev = 2-3%) are given in Table II. We also studied the variation

Batch Thickness Uniformity $3\sigma = 6 - 10\%$

of deposition rates as functions of substrate temperature (25°-300°C), power density (0.08-0.24 W/cm²), and reactor pressure (110-1000 mtorr).

Film thickness and refractive index were measured using a He-Ne laser ellipsometer (wavelength = 632.8 nm) and a Talystep.

FTIR studies were performed with 500 nm polymer films deposited on a bare silicon substrate. Background absorption of the substrate was subtracted from the spectra to obtain bulk film spectra. The maximum resolution of the spectrometer was 0.5 cm⁻¹ wave number. FTIR studies of liquid monomers were also performed to detect Si-H and Si-OH bonds which may result from water vapor contamination. However, none of these bonds was detected in the liquid monomer adsorption spectra.

Auger analysis for compositional depth profiles was performed with 100 nm films on a silicon substrate surface. The films were sputtered by 1 keV Ar⁺ ion to determine the composition as a function of depth. The detection limit of the Auger tool was 0.5 atomic percent (a/o). The polymer films were examined as deposited and after annealing in a nitrogen atmosphere for 30 min at 300°C.

The ESCA technique was used to analyze the film surface composition as-deposited, and after either nitrogen or oxygen plasma surface treatment. The surface compositions were also analyzed as a function of RF power. Surface analysis was performed on a Hewlett-Packard HP 5950B photoemission spectrometer. Scans were made in both survey and high resolution modes: survey to detect the possible presence of unexpected elements on the surface, and high resolution to quantify the known elements and help establish their bonding environments.

ESR analysis for unpaired electrons (spin density) in the polymer films was performed with 2 μm films deposited on a bare silicon substrate surface. The measurements were performed both at room and near liquid helium temperatures (≈ 8-9 K). Double integrals were computed for all observed resonance and compared with standardized thin Si₃N₄ film samples with known spin density. The reproducibility of the integrals is about ±15-20%, and, within this limit, integrals can be compared from one sample to another. Bare Si substrates were subjected to similar plasma deposition, and the deposited films were then removed by wet etching in a buffered HF solution. The substrates were measured for any spin resonance that might have arisen from plasma irradiation. The detection limit of the ESR tool is about 1 × 10¹¹ spin-cm⁻³.

The plasma etching experiments were carried out in a parallel-plate, radial flow, etching reactor in a reactive ion etching (RIE) mode. The reactor has a radio fre-

quency of 13.56 MHz. The grounded substrate electrode of the reactor was maintained at 40°C during the etching process. The conditions for RIE were 0.55 W/cm² RF power density, 25 mtorr pressure, and 22 sccm CF₄ flow rate. Etch rates of deposited polymers were studied as deposited and after annealing at 200°C in a nitrogen atmosphere. Etch rates were calculated using laser interferometer end-point traces. (Etch rate $R = \lambda/2nt$, where λ is the wavelength of the laser, n is the film's refractive index, and t is the etch time that changes reflected intensity by one cycle.)

Trilayer resist structures were fabricated using the PECVD organosilicon films for the midlayer oxygen etch barrier (see Fig. 12). The bottom layer was a novalak-based photoresist, 1-2 μm thick, baked to 200°C. The top imaging resist was a positive photoresist approximately 0.5 μm thick. The image resist was exposed using a 0.3 NA lens and 405 nm exposing wavelength and developed in the normal manner. The image was transferred by RIE, first through the organosilicon with CF₄, then through the base polymer with O₂.

Scanning electron microscopy (SEM) was used to study the resulting profiles in multilayer resist structures.

Results and Discussion

Film deposition.—Table II shows the process parameters, deposition rates, and refractive indexes of DVS, HMDS, and MTS polymers. The film thickness and refractive index uniformity is good (std dev = 2-3%). The refractive indexes of all three polymers varied from 1.48 to 1.51 within each batch, and had average deposition rates of 15, 27, and 6 nm/min for HMDS, DVS, and MTS polymers, respectively. It appears that DVS has a higher deposition rate than HMDS under the same process conditions. Since both monomers have comparable molecular weight and boiling points (Table I), the higher deposition rate of the DVS polymer is attributed to the double bond structure of DVS monomer vinyl groups.

Increased substrate temperature substantially reduced the deposition rate of all three polymers (Fig. 1). From this data, we obtain the reversed activation energies (E_{ra}) of 0.55, 0.49, and 0.41 kcal·mol⁻¹ for DVS, HMDS, and MTS, respectively. Here, the reversed activation energy (E_{ra}) is defined as the energy difference between the activated (reactive) species and film product. In general the plasma deposition of polymer primarily involves the bonding and energy transfer deactivation of reactive species A* with a substrate surface to form a polymer film. When the substrate temperature increases, it becomes more difficult for reactive species A* to transfer its energies to, and bond with, the substrate surface due to the process exothermic reaction pathways. This results in lower deposition rates with increased substrate temperature.

Fig. 1. Variation of deposition rate vs. temperature

Fig. 2. Variation of deposition rate with power density

Fig. 3. Variation of deposition rate vs. pressure

Figure 2 shows the variation in deposition rates with power density. A minimum power density of 0.08 W/cm^2 is required to initiate significant polymerization and deposition for all three polymers under the indicated process conditions. Optimum film thickness and refractive index uniformity was observed in the $0.12\text{--}0.18 \text{ W/cm}^2$ ($300\text{--}450\text{W}$) power density range. This indicates that the plasma glow discharge to form a polymer is relatively stable, *i.e.*, the distribution of reactive species is more uniform in the $0.12\text{--}0.18 \text{ W/cm}^2$ ($300\text{--}450\text{W}$) power density range. The significant increase in deposition rate with increased power beyond 450W is attributed to increased reactive species concentration in the glow discharge. When the pressure was increased, the deposition rate dropped sharply for all three polymers (Fig. 3). However, the deposition rate of DVS does not drop significantly until the pressure reaches 1 torr. This reduction may cause more frequent deactivation collisions between reactive species and monomers when the pressure is increased. The results also indicate that these deactivation collisions become significant when system pressure is above 500 mtorr.

Physical characterization of polymer films.—The infrared transmission spectra of as-deposited DVS, HMDS, and MTS polymers are shown in Fig. 4-6. The spectra indicate normal bonding characteristics of organosilicon polymers. The spectrum for the DVS polymer contains the following bonding characteristics.

Table III. Positions and intensity of various Si-CH₃ vibrational bands

1. Only small amounts of residual vinyl groups (C=C) at $\approx 1600 \text{ cm}^{-1}$ wave number remain in the polymer structure. This indicates that most of the double bonds in the vinyl group of the DVS monomer were opened during the polymerization and deposition process.

2. The siloxane backbone band structure (Si-O-Si at 1050 cm^{-1}) for DVS remains almost the same after the deposition. This indicates that the siloxane group (Si-O-Si) is also the backbone structure of the DVS polymer.

3. The vibrational bands of Si-CH₃ are located at 840 and 800 cm^{-1} . As shown in Table III, the Si-CH₃ groups in DVS polymers must exist in two forms

4. Si-H (2130 cm^{-1}) and Si-OH (800 cm^{-1}) are present in the DVS polymer.

From the combination of the above bonding characteristics, band position and intensity, the most probable structure of the DVS polymer is

Fig. 5. FTIR of plasma-deposited HMDS polymer.

Fig. 6. FTIR of MTS polymer

where n is an integer.

The spectrum of the HMDS polymer is shown in Fig. 5. The presence of strong Si-O bands ($1000-1050\text{ cm}^{-1}$) indicates oxygen contamination in the film's bulk structure. This oxygen probably came from the desorption of water vapor from the cool-wall reactor during the deposition process. The infrared transmission spectrum of the HMDS polymer also showed the presence of Si-CH₃ (800 , 840 , and 1250 cm^{-1}), Si-N ($900-950\text{ cm}^{-1}$), and other bending and stretching bands (2960 , $1360-1400$, 1250 cm^{-1}). The oxygen contamination makes the determination of the exact HMDS polymer structure more difficult. However, the most probable structure of the HMDS polymer, which corresponds well with the band positions and intensity is

where m and n are integers.

The spectrum of the MTS polymer with its band structures is shown in Fig. 6. The presence of a strong and a small overlap (at $900-1050\text{ cm}^{-1}$) range, together with a small amount of nitrogen ($\sim 2\text{ a/o}$) detected by Auger in

the film bulk, leads us to assign this band as an overlap of Si-O-Si and possibly Si-N bonds. The existence of nitrogen indicates that some air contamination may have occurred during the deposition process. From the spectrum band structure, it appears that the MTS polymer was formed from various fragments of the monomer. No clear structure of the MTS monomer can be identified from the spectrum. In summary, FTIR results revealed that most of the DVS polymer and a large portion of the HMDS polymer were made up primarily of their monomer units, while the MTS polymer was formed mostly from its monomer reactive fragments. Although we could not identify cross-linking bonds in these polymers, they may still exist in substantial quantities in all three polymers. The identified polymer structures are only the most probable structures derived from our FTIR results.

Auger depth profiles through $\sim 0.1\text{ }\mu\text{m}$ of polymer films deposited on p-type silicon wafers showed good compositional uniformity with depth for all three polymers (Fig. 7-9). A small amount of oxygen contamination has also been observed in all three polymer surfaces and polymer-silicon interfaces. The oxygen contamination in polymer-silicon interfaces is attributed to the initial desorption of water vapor from the reactor sidewalls. The oxygen in the polymer surfaces is due to oxidation after the polymer was exposed to air.

ESCA results for all three plasma-deposited polymers showed a general trend of increased surface composition for all elements relative to carbon and to monomer compositions (Table IV). It was found that oxygen was incorporated into the polymer surfaces, even when it was not present in the monomer, as in the case of HMDS. This is

Fig. 7. Auger depth profile of DVS polymer

Fig. 9. Auger depth profile of MTS polymer

consistent with the Auger, infrared data, and other published results (21). The variation of substrate temperature produces notable changes in composition. For HMDS and MTS polymers, an increase in substrate temperature from 100° to 300°C further enhanced the silicon and oxygen surface concentration, especially for the MTS polymer. Conversely, for the DVS polymer, the most notable changes were slight reductions in silicon and oxygen. This suggests that the DVS polymer surface may be less sensitive to air oxidation. Although nitrogen was found in the film bulk (2-3% a/o) of MTS polymer, less than 1 a/o of nitrogen was observed in its surface. This must be due to the substitution of oxygen for nitrogen in the film surface as observed by Auger depth profile data.

In marked contrast to their sensitivities to substrate temperature, all three polymer film surface compositions remain about the same with increased power density (Table V). Since the deposition rate increased almost fourfold with increased power under the same process conditions (Fig. 2), the above results suggest that the deposition rate is limited by the concentration of radical reactive species in the glow discharge.

For postdeposition plasma treatment, there is no difference in the effect of using oxygen *vs.* nitrogen plasma among polymer systems: all plasma-treated polymer surfaces become like SiO₂ (Table VI). The similarity between nitrogen and oxygen plasma treatment may be due to (i) the presence of background oxygen in nitrogen plasma with induced surface oxidation, and/or (ii) the generation of an "activated" surface by nitrogen plasma treatment which immediately oxidized upon exposure to air.

Fig. 8. Auger depth profile of HMDS polymer

Finally, bonding features discernable from high resolution scans show (i) the presence of pronounced carbon-oxygen single bonds in MTS polymer as in the methoxy groups of monomer structures (Fig. 10), and (ii) the presence of low but measurable levels of carbon-carbon double bonds in the DVS polymer. (These were determined by reanalyzing by ESCA after bromination of the surface with a bromine solution.) This is consistent with FTIR data and suggests that some vinyl groups still existed in the DVS polymer.

ESR studies revealed that all polymer films have very low spin density (few unpaired electrons and dangling bonds) except for the as-deposited DVS polymers at 100°C. This DVS film showed a signal 8G wide ($g = 2.0065$) at a magnetic field of 3360G (Fig. 11). As compared to reference thin Si₃N₄ film samples ($\approx 3 \times 10^{16}$ spin/cm³), the integrated spin density of the DVS polymer is 2×10^{17} spin/cm³. The broad signal of the DVS polymer corresponds to the carbon dangling bonds in the polymer structures. This appears to be consistent with the open double bond of DVS monomer vinyl groups during the deposition process. After annealing at 300°C in nitrogen for 30 min, the spin signals disappeared. This is due to the recombination of carbon dangling bonds by thermal excitation. It should be noted that the bare Si substrate subjected to the described plasma deposition and removal of deposited films shows only a small amount of spin density (1×10^{13} spin/cm³). The effect of plasma radiation on the generation in the silicon substrate is therefore minimal.

Reactive ion etching of three polymer films with CF₄ gas at 400W, 22 sccm flow rate, and 25 mtorr pressure yielded etch rates of 41-48 nm/min (Table VII). No significant differences in the etch rate of the polymer film were

observed between the as-deposited and postanneal (30 min, 200°C in a nitrogen atmosphere) films. These results, together with the small variation range of RIE etch rate (41-48 nm/min) suggested that the as-deposited polymers may have a stable cross-linking structure that has not been detected by our analytical method. When all three polymer films were exposed in oxygen plasma, their surface compositions became silicon dioxide-like

and any further etching, after about 5 nm of the surface was oxidized, stopped.

Application to multilayer resist (MLR).—The process steps for MLR are shown in Fig. 12. The actual scanning electron micrographs of submicron patterns are shown in Fig. 13. These structures result after O_2 RIE of the base polymer. The organosilicon film remains, but the top

layer imaging photoresist was removed by the O₂ plasma. The rough surface in Fig. 14 (1 μm line and spaces) is a polysilicon silicide and the 0.8 and 0.5 μm wide lines span 0.35 μm high steps in the oxide pattern under the polysilicon. The uniformly thin imaging resist has resulted in replicating patterns with smaller dimensions than could be obtained with single-layer resist and with the same optics. The stand-alone 0.5 μm line and the vertical profiles in the line/space pattern indicate MLR process extendability to replication of 0.5 μm minimum dimensions.

Conclusion

HMDS, DVS, and MTS polymer films with excellent uniformity have been deposited on p-type silicon substrates using PECVD processing in a parallel-plate reactor. The backbone structure of DVS and HMDS polymers was made up primarily of their monomer units. The polymer film compositions have good depth thickness uniformity. However, the polymer film surfaces and interfaces are slightly contaminated by oxygen. ESCA showed that surface compositional changes are less sensitive to deposition power density as compared to substrate temperature variation. ESR studies revealed that all polymer

films have low spin density, except for as-deposited DVS polymer. Both ESCA and ESR data appear to be consistent with open double bond of the vinyl group's monomer polymerization for the DVS polymer.

Reactive ion etching of these polymer films with CF₄ gas yielded etch rates of 41-48 nm/min for all polymers. When these polymer films are exposed to oxygen (or nitrogen) plasma, their surface composition becomes silicon dioxide-like and ceases etching. Utilizing these properties, the polymer films were implemented as an intermediate oxygen etch resistance layer in trilevel resist lithography to produce submicron image patterns using step and repeat photolithography.

The Sensitivity of CVD Calculations to Physical Property Values

Helen Rebenne* and Richard Pollard**

Department of Chemical Engineering, University of Houston, Houston, Texas 77004

ABSTRACT

A mathematical model that describes chemical vapor deposition in an impinging jet reactor has been used to assess the sensitivity of theoretical predictions to physical property values for intermediate species. Uncertainties in thermochemical data for a species have greatest impact on predicted deposition rates when the composition level of that species near the surface is comparable to the local compositions of the reactants. Under these circumstances, relatively small changes in the values of thermodynamic quantities used for the species can produce significant differences in deposition rates calculated under equilibrium conditions. Also, with the modified property values, different values of the kinetic parameters may be required to fit available experimental data, and this can lead to different interpretations of the rate-limiting steps in the process. Quantitative information for chemical vapor deposition of boron from boron trichloride and hydrogen is presented.

Chemical vapor deposition (CVD) is a processing technique that is widely used in the manufacture of electronic materials and in the formation of surface coatings for high temperature applications. Several theoretical models of CVD have been proposed (1-12). Each analysis requires physical property values for the species taken into consideration. This information is usually obtained from one or more data compilations (13-28). However, there is often considerable uncertainty in the reported values, particularly for less common species such as intermediates in CVD reactions. In some cases, the tabulated results are estimated using information for similar compounds or are calculated using other physical quantities and statistical thermodynamics, group contribution theory, or empirical rules. Even when experimental data are available, different interpretations or treatments of the measurements can lead to a range of possible values for the property studied. Also, discrepancies between sets of experimental results can exist. The sensitivity of CVD model predictions to these uncertainties in property values has not yet been assessed.

In this paper, a previously developed model (11, 12) which describes CVD in an impinging jet apparatus is used to investigate quantitatively the relationship between theoretical results and values used for thermodynamic and transport properties. The model includes hydrodynamics, multicomponent heat and mass transfer, simultaneous homogeneous and heterogeneous reactions, and variable physical properties. Chemical vapor deposition of boron from BCl_3 and H_2 is treated as an example because sufficient experimental data are available to evaluate the impact of changes in physical property values on both equilibrium calculations and results obtained for actual, nonequilibrium conditions. Specifically, changes in compositions, fluxes, and deposition rates are examined for conditions under which reaction rates are so fast that the system is locally at equilibrium and the deposition rate is limited only by the mass-transfer rate to the surface. Additional sensitivity studies are made for conditions under which rate constants are finite, and new sets of kinetic parameters which give agreement between experimental and predicted deposition rates are determined for different sets of physical property values. Furthermore, the effects of

the changes on rate-limiting reactions for the process are evaluated.

The subject of sensitivity analyses for chemically reacting systems has been considered previously (29-36), but has been restricted to sets of homogeneous reactions. The governing equations treated in these studies are highly simplified material balances; this facilitates the use of numerical techniques that are designed for situations where the reaction mechanism or the magnitudes of uncertainties in parameter values are not known. For example, sensitivity coefficients can be determined which indicate the relative effects of arbitrary changes in inlet concentrations and rate constants on species concentrations. This approach is not suitable for CVD of boron because (i) the complexity of the governing equations precludes the evaluation of sensitivity coefficient, (ii) it is not necessary to generate sensitivity coefficients since only specific uncertainties in physical property values need to be considered and the validity of the reaction mechanism has already been established (11), and (iii) sensitivity coefficients do not yield any information on the new sets of kinetic parameters required to match theoretical and experimental results.

Model Description

The details of the mathematical model used to describe CVD in an impinging jet reactor have been presented previously (11) and are not repeated here. However, to explain the sensitivity of model calculations to physical property values, it is necessary to know how the values are incorporated into the model and to understand the significance of the kinetic parameters. These aspects of the model are described below.

For CVD of boron from a mixture of boron trichloride and hydrogen, the elementary reaction steps are taken to be

where reactions [I] and [II] can occur in the gas phase as well as at the deposition surface.

The net rate of each reaction is given by

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

$$\tau_1 = \left[k_{1f} \prod_{i \atop \nu_{i1} > 0} x_i^{\nu_{i1}} - k_{1b} \prod_{i \atop \nu_{i1} < 0} x_i^{-\nu_{i1}} \right] (\theta_{v1})^{\nu_1} \quad [1]$$

The parameters k_{1f} and k_{1b} are rate constants for forward and backward reactions, respectively. An Arrhenius temperature dependence is assumed for k_{1b}

$$k_{1b} = A_1 e^{-E_{a,1}/T} \quad [2]$$

For elementary reactions, the forward rate constant k_{1f} is related to k_{1b} by

$$K_1 = \frac{k_{1f}}{k_{1b}} \quad [3]$$

where K_1 is the equilibrium constant for reaction 1. The coefficients θ_{v1} in Eq. [1] represent the interactions between gas phase molecules and the surface; they are unity for homogeneous reactions. For surface processes, θ_{v1} may be regarded as the fraction of active surface sites that is available for adsorption of reactants. It can be related to compositions in the gas phase immediately adjacent to the surface by an expression of the form (37)

$$\theta_{v1} = \frac{1}{1 + \sum_i K_{s,i,1} (x_i)^{\nu_{i,1}}} \quad [4]$$

where

$$K_{s,i,1} = A_{s,i,1} e^{-E_{s,i,1}/T_s} \quad [5]$$

Values for the parameters $\nu_{i,1}$, $q_{i,1}$, $A_{s,i,1}$, A_1 , $E_{s,i,1}$, and $E_{a,1}$ in Eq. [1]-[5] can, in principle, be obtained by matching experimental and theoretical results. For a system with five gas phase species, two homogeneous reactions, and three heterogeneous reactions, this treatment would give 58 adjustable kinetic parameters. However, only a few of these parameters have a significant effect on the deposition process. To obtain a physical understanding of CVD systems from model predictions, it is advantageous to use the smallest number of kinetic constants necessary to fit the experimental data.

For CVD of boron from BCl_3 and H_2 , a single expression for $(\theta_{v1})^{\nu_1}$

$$(\theta_{v1})^{\nu_1} = \frac{1}{K_{s,j}(x_j)^{q_j}} \quad ; \quad j = \text{BCl}_3 \quad [6]$$

for all three heterogeneous reactions is sufficient to match theoretical predictions and experimental data (11). As a result, only one activation energy, E_s , is required for adsorption (see Eq. [5]). A physical explanation is that reaction [II] is the dominant heterogeneous reaction; reaction [I] occurs primarily in the gas phase, and reaction [III] is essentially at equilibrium (11). Also, reaction [I] is the only important homogeneous step and, therefore, one activation energy E_a in Eq. [2] is adequate. With the above simplifications, the system can be described by the independent parameters E_a , E_s , q_{BCl_3} , and θ_1 to θ_5 where (11)

$$\theta_1 = \frac{k_{2b}}{k_{1b}} = \frac{A_2}{A_1} \quad [7]$$

$$\theta_2 = \frac{k_{3b}}{k_{1b}} = \frac{A_3}{A_1} \quad [8]$$

$$\theta_3 = \frac{k'_{2b}}{k'_{1b}} = \frac{A'_2}{A'_1} \quad [9]$$

$$\theta_4 = \frac{k_{1b}^2 e^{-(2E_s - E_a)/T_s}}{c_{\infty} \nu_{\infty} k'_{1b} (K_{s,\text{BCl}_3})^2} = \frac{A_1^2}{A'_1 c_{\infty} \nu_{\infty}} \quad [10]$$

$$\theta_5 = \frac{c_{\infty} a e^{-E_a/T_s}}{k'_{2b}} = \frac{c_{\infty} a}{A'_2} \quad [11]$$

The dimensionless ratios θ_1 and θ_2 describe the relative rates of the surface reactions, and θ_3 is a ratio of rate con-

stants for the homogeneous reactions. The dimensionless quantity θ_4 represents the relative rates of homogeneous and heterogeneous reactions and includes the adsorption term from Eq. [6]. The quantity θ_5 can be regarded as the absolute rate of homogeneous BCl production relative to the mass transfer rate in the process because the hydrodynamic parameter a in Eq. [11] is proportional to the mass flow rate of the jet stream that enters the CVD reactor (38). With this formulation of the kinetic parameters, all are independent of inlet gas composition and surface temperature, and all except θ_5 are independent of jet mass flow rate.

The previous analysis (11) provided some insight into the relative importance of the kinetic parameters described above. It was found that any value for θ_3 may be used because, under typical operating conditions, the extent of homogeneous BCl production is unimportant. Also, any value for θ_2 was acceptable provided it was large enough to ensure that reaction [III] remained essentially at equilibrium under all operating conditions. Without this restriction, the correct dependence of deposition rate on the hydrodynamic parameter a could not be obtained. Consequently, it was only necessary to choose specific values for the remaining six kinetic parameters in order to match theoretical and experimental results.

In the model, thermochemical properties are used to calculate the equilibrium constant K_1 defined by Eq. [3]. For ideal gases, K_1 is related to a pressure-independent equilibrium constant K_{p1} by

$$K_{p1} = p^{m_1} K_1 = p^{m_1} \prod_i x_{i,e}^{-\nu_{i1}} \quad [12]$$

Here, the activity of any solid phase is taken to be unity, and m_1 represents the net number of moles produced by reaction 1. Values for K_{p1} are obtained from the relation

$$\left[\frac{\partial \ln K_{p1}}{\partial (1/T)} \right]_p = - \frac{\Delta H_{r1}(T)}{R} \quad [13]$$

The temperature dependence of each heat of reaction $\Delta H_{r1}(T)$ is estimated using specific heats for the reactants and products

$$\tilde{C}_{p1} = \left[\frac{\partial \tilde{H}_1}{\partial T} \right]_p = d_1 + e_1 T + f_1 T^2 \quad [14]$$

Integration of Eq. [13] gives (39)

$$\ln K_{p1} = \alpha_1 + \beta_1/T + \gamma_1 \ln T + \delta_1 T + \epsilon_1 T^2 \quad [15]$$

The standard changes in enthalpy and entropy for each reaction, which are required to evaluate the constants of integration, are obtained from $\Delta H_{f,298}^\circ$ and S_{298}° . Table I lists these properties for the species involved in CVD of boron. Values from a compiled data source (26, 27) are included for all the species. For BCl_3 and BHCl_2 , results based on experimentally determined heats of reaction are also given. These results are calculated using compiled $\Delta H_{f,298}^\circ$ and S_{298}° information (26) for the other reactants and products involved in each experiment. No experimentally determined properties for BCl are available and, hence, only calculated values are given. Since the thermodynamic properties of H_2 and HCl are well known, only values from the compiled source are listed. All the entries in Table I are based on the same reference state.

In this paper, four cases are considered (see Table I). The thermodynamic properties for case A were used previously (11) and, therefore, this example may be regarded as a base case. Case B uses the lowest reported standard heat of formation for BHCl_2 . This value represents a 3% reduction from the base case. Case C uses an independent set of properties for BHCl_2 . The changes correspond to a 5% increase in $\Delta H_{f,298}^\circ$ and a 4% decrease in S_{298}° compared to case A. In case D, $\Delta H_{f,298}^\circ$ for BCl is 33% larger than in case A.

The effect of these variations on the coefficients for the equilibrium constants (see Eq. [15]) is illustrated in Table

Table I. Standard enthalpies of formation and entropies at 298 K. ^a This represents a lower bound obtained from a recalculation of $\Delta H_{f, 298}^\circ$ from previously reported experimental data.

II. Only the coefficient α_i is altered by changes in S_{298}° while changes in $\Delta H_{f, 298}^\circ$ affect only β_j . The coefficients γ_i , δ_i , and ϵ_i are determined from d_i , e_i , and f_i , respectively, in Eq. [14]. Values for d_i , e_i , and f_i have been reported previously (11).

Analysis of the momentum, heat, and mass transport phenomena requires a knowledge of viscosity, thermal conductivity, and binary diffusion coefficients as a function of temperature and composition. These properties may be evaluated using the Chapman-Enskog kinetic theory of gases (46). This theory yields expressions for the transport coefficients μ_i , and \mathcal{D}_{ij} in terms of Lennard-Jones force constants and temperature. The thermal conductivity k_i is obtained from the Eucken equation (47). Force constants are generally determined from experimental viscosity or second virial coefficient data. Methods of calculation based on corresponding states theory are also available (48), but these require critical constants and vapor pressure or boiling point data. Force constants for the species used in the analysis of CVD of boron are presented in Table III.

Results and Discussion

The sensitivity of model calculations to standard thermodynamic quantities and Lennard-Jones force constants for the intermediate species BHCl₂ and BCl has been analyzed. The investigation was restricted to these compounds because, in contrast to BCl₃, there are significant uncertainties in the values of their properties.

The effects of altering thermodynamic properties for the intermediates on predicted composition profiles are presented in Fig. 1. These profiles are for the region close to the deposition surface and were obtained for the limiting condition of equilibrium in the gas phase.

A change in either $\Delta H_{f, 298}^\circ$ or S_{298}° for a species alters the equilibrium constants for the reactions in which that species participates. Hence, equilibrium compositions are modified. For example, when $\Delta H_{f, 298}^\circ$ is made less negative or more positive, the species becomes less stable and its equilibrium mole fraction is reduced (compare cases A and B or A and D in Fig. 1). A change in the properties for one species has a direct effect on the composition of that species. There is also an effect on the compositions of the other species, in accordance with the equilibrium constant relationships in Eq. [12] and the requirement that the mole fractions sum to unity. In case C, $\Delta H_{f, 298}^\circ$ for BHCl₂ differs from the case A value by a larger amount than in case B. On this basis, a larger change in x_{BHCl_2} from the case A result might be anticipated. However, the reduction of S_{298}° in case C lowers the stability of BHCl₂. This offsets the increase in stability caused by the change in $\Delta H_{f, 298}^\circ$ and attenuates the increase in x_{BHCl_2} . Figure 1 also shows that the mole fraction for BCl is always much smaller than the compositions of the other compounds.

In the analysis, the multicomponent diffusion equations link compositions and composition gradients to the species fluxes. For the mechanism given by reactions [I]-[III], the sum of the dimensionless surface fluxes N_m for the boron compounds gives the dimensionless deposition rate

Fig. 1. Gas phase composition profiles in region adjacent to reaction surface. Values are calculated at the thermodynamic mass transfer limit. The outer edge of the diffusion layer occurs at $\zeta \approx 9$. Solid line: case A. Long-short dashed line: case B. Dotted line: case C. Dashed line: case D. Curves A to D are obtained with different values of $\Delta H_{f, 298}^\circ$ and S_{298}° for BHCl₂ and BCl (see Table I). Deposition conditions: $T_s = 1373$ K, $T_x = 298$ K, $p_x = 1.013 \times 10^5$ N/m², $x_{\text{BCl}_3}^0 = 0.4$. Curves A and D coincide for BCl₃.

$$S = -\sum_m N_m \quad [16]$$

Changes in physical property values that alter composition profiles near the surface, and hence surface fluxes, also alter the deposition rate. Figure 2 shows the dependence of dimensionless deposition rate on inlet gas composition for the four cases considered in Fig. 1. Each curve in Fig. 2 is a locus of maximum deposition rates predicted when all kinetic restraints are removed. In the model, this is achieved by increasing the rate constants until the forward and backward rates of each reaction are essentially equal and all compositions are locally at equilibrium. A deposition rate calculated under these conditions is controlled by mass transfer rates between the surface and the inlet and, hence, may be regarded as a thermodynamic mass transfer limit (3).

A substantial change in $\Delta H_{f,298}^0$ for BCl (compare cases A and D) does not influence the predicted deposition rate. This can be attributed directly to the low mole fraction for BCl which ensures that the BCl flux is several orders of magnitude lower than N_{BCl_3} or N_{BHCl_2} . Therefore, a change in x_{BCl} or N_{BCl} has a negligible effect on S . In contrast, cases B and C lead to significantly different predictions for the deposition rate, particularly at high inlet compositions of BCl_3 . At $x_{\text{BCl}_3}^0 = 0.6$, the deposition rate for case B is 19% larger than for case A, while the case C result is 12% smaller than the case A result. Changes in deposition rate are caused by changes in both N_{BCl_3} and N_{BHCl_2} , though N_{BCl_3} is larger in magnitude for the $x_{\text{BCl}_3}^0$ values shown in Fig. 2. At low inlet compositions, changes in N_{BCl_3} and N_{BHCl_2} counteract each other, and this reduces the dependence of deposition rate on physical property values. The results presented in Fig. 1 and 2 are for a surface temperature of 1373 K. If T_s is changed, the deposition rate predicted in the thermodynamic mass transfer limit changes in response to the temperature dependences of the binary diffusion coefficients. However, the differences between cases A, B, C, and D are not altered significantly.

The results presented above demonstrate that, at equilibrium, the sensitivity of deposition rate to the thermodynamic properties of a species is directly associated with

the species composition. A compound with a composition level that is much lower than the other species is expected to have a negligible effect on the deposition rate in the thermodynamic mass transfer limit. This result, shown here for CVD of boron, has also been obtained for CVD of silicon from SiCl_4 in excess hydrogen (49).

The dimensionless deposition rates predicted in Fig. 2 exceed experimental results (50-52) because they do not consider the finite rates of the chemical reactions. In a previous study (11), rate-limiting reactions were identified and a set of kinetic parameters that gave a match between theory and experiment was obtained. Curve A in Fig. 3 shows the agreement between predicted and actual deposition rates obtained with the base-case thermodynamic properties. When the kinetic parameters for case A are used and thermodynamic properties are varied, predicted deposition rates no longer agree with experimental results. Curves B, C, and D in Fig. 3 indicate that the effects of the property changes are not the same as those obtained in the thermodynamic mass transfer limit. This is because the compositions are determined by material balance relationships that include local production terms from the chemical reactions and they are not related directly by the equilibrium constants. One consequence of the more complex interactions obtained with finite kinetic parameters is that a given change in properties can reduce the predicted deposition rate under some circumstances but can increase it under others (see curves A, B, and C).

In contrast to results obtained in the thermodynamic mass transfer limit, the heat of formation of BCl has a marked effect on the deposition rate calculated with finite kinetic parameters (see curve D). This can be attributed to an order of magnitude decrease in N_{BHCl_2} which, under the conditions in Fig. 3, is the dominant surface flux in Eq. [16]. This change can be related to the reduction in stability of BCl, which makes decomposition of BHCl_2 to BCl less favorable and changes the surface composition gradient of BHCl_2 .

Figure 4 shows the dependence of dimensionless deposition rate on surface temperature at two different mass flow rates. Changes in the thermodynamic properties al-

Fig. 2. Influence of inlet gas composition on the dimensionless rate of boron deposition calculated at the thermodynamic mass transfer limit. $S = \text{actual deposition rate}/c_{\infty} \sqrt{\nu_{\infty} a}$. Physical property values and deposition conditions are as in Fig. 1.

Fig. 3. Influence of inlet gas composition on the dimensionless rate of boron deposition. Experimental data (51): triangles $\sim a = 102 \text{ s}^{-1}$ at $x_{\text{BCl}_3}^0 = 0.4$, $L/d = 0.375$. Curves are theoretical predictions with the case A kinetic parameters (see Table IV). Physical property values and deposition conditions are as in Fig. 1.

Fig. 4. Influence of substrate temperature on the dimensionless rate of boron deposition. Experimental data (51): $x_{\text{BCl}_3}^0 = 0.4$, squares $\sim a = 310 \text{ s}^{-1}$, dots $\sim a = 626 \text{ s}^{-1}$, $L/d = 0.375$. Curves are theoretical predictions with kinetic parameters as in Fig. 3, except for θ_5 . Dotted line: $a = 310 \text{ s}^{-1}$, therefore $\theta_5 = 3.3 \times 10^{-7}$. Solid line: $a = 626 \text{ s}^{-1}$, therefore $\theta_5 = 6.6 \times 10^{-7}$. Deposition conditions: $T_x = 298 \text{ K}$, $p_x = 1.013 \times 10^5 \text{ N/m}^2$.

ter the theoretical predictions in each case. The results presented in Fig. 3 and 4 indicate that when different values for $\Delta H_{f,298}^0$ or S_{298}^0 are used, it becomes necessary to obtain a new set of kinetic parameters to fit the experimental data.

The sensitivity of kinetic parameters to thermochemical properties is illustrated in Table IV. The set of parameters for each case was obtained by matching the experimentally observed dependence of deposition rate on inlet gas composition, jet mass flow rate, and surface temperature. The original set, used in case A, was changed as little as possible to refit the data in cases B and D. It should be noted that, with the exception of θ_5 and θ_3 (see above), small variations of the parameter values listed for each case would lead to a noticeably poorer fit of the data.

A comparison of cases A and D shows the effect of a 33% increase in $\Delta H_{f,298}^0$ for BCl. A small adjustment in E_s is required to give the correct dependence of deposition rate on surface temperature. This adjustment is needed to offset the changes in the temperature dependences of the equilibrium constants (see β_i values in Table II), since effective activation energies for heterogeneous forward rate constants are $E_s - E_a + \beta_i$. However, a change in the value of $E_s - E_a + \beta_i$ does not produce an identical change in the

Table IV. Values of kinetic parameters used to match experimental data. Superscripts: $a \sim$ values are for $x_{\text{BCl}_3}^0 = 0.4$; $b \sim$ value is for $a = 102 \text{ s}^{-1}$; $c \sim$ based on $n = 1$.

Case	A	D	B
θ_1	2.3×10^5	1.2×10^7	7.7×10^3
θ_2	8.0×10^1	8.0×10^1	8.0×10^1

Fig. 5. Gas phase composition profiles in region adjacent to reaction surface. Solid line: case A. Long-short dashed line: case B. Dashed line: case D. Curves A, B, and D are obtained with the kinetic parameters listed in Table V. Deposition conditions: $T_s = 1373 \text{ K}$, $T_x = 298 \text{ K}$, $p_x = 1.013 \times 10^5 \text{ N/m}^2$, $x_{\text{BCl}_3}^0 = 0.4$, $a = 102 \text{ s}^{-1}$. Curves A and D coincide for BCl_3 .

magnitude of the slope in Fig. 4. This is because variations in local compositions with T_s also influence the slope and the compositions are dependent on thermochemical property values (see Fig. 5).

The parameter θ_4 in Table IV influences the relative importance of the parallel heterogeneous and homogeneous pathways for reaction [I]. This quantity must be altered to counteract the change in E_s . The change required for θ_4 cannot be determined exactly from Eq. [10] due to the effects of local compositions on the slope in Fig. 4.

The most noticeable difference between cases A and D is the value of θ_1 . This parameter relates the rates of heterogeneous reactions [I] and [II], in accordance with Eq. [7]. Combination of Eq. [1] and [7] gives

$$\frac{r_{\text{II}}}{r_{\text{I}}} = \theta_1 \frac{x_{\text{BCl}}}{x_{\text{BHCl}_2}} \left(\frac{1 - r_{\text{IB}}/r_{\text{IF}}}{1 - r_{\text{IB}}/r_{\text{IF}}} \right) \frac{r_{\text{IB}}/r_{\text{IF}}}{r_{\text{IB}}/r_{\text{IF}}} \quad [17]$$

where r_{IF} and r_{IB} are the forward and backward rates for surface reaction I. Values for $r_{\text{IB}}/r_{\text{IF}}$ obtained with refitted kinetic parameters are presented in Table V. A small value of $r_{\text{IB}}/r_{\text{IF}}$ indicates that the reaction is far from equilibrium. Table V shows that the magnitudes of $r_{\text{IB}}/r_{\text{IF}}$ are almost identical in cases A and D. In contrast, Fig. 5 shows that the surface compositions of BCl in the two cases differ by nearly two orders of magnitude. The change in the value for θ_1 more than compensates for this difference and gives similar values for the ratios $(r_{\text{II}}/r_{\text{I}})_A$ and $(r_{\text{II}}/r_{\text{I}})_D$.

Overall, the large change in $\Delta H_{f,298}^0$ for BCl results in relatively small changes in the rates of the reactions. There is a slight shift in the importance of heterogeneous reaction [I] (compare values for r_{I} in Table V). Nevertheless, the departures from equilibrium, as indicated by the ratios $r_{\text{IB}}/r_{\text{IF}}$ and $(r'_{\text{int},i})_{\text{B}}/(r'_{\text{int},i})_{\text{I}}$ for all the reactions are essentially unchanged. The homogeneous reaction rates given in Table V are integrals over the diffusion layer. Therefore, values for the homogeneous and heterogeneous reaction rates (r_{I} and $r'_{\text{int},i}$) may be compared directly. However, it should be noted that not all the BHCl_2 produced homogeneously is able to reach the deposition surface. Table V shows quantitatively that, in both cases A and D, reaction [I] occurs predominantly in the gas phase, whereas reaction [II] takes place at the solid surface. The

Table V. Theoretical reaction rates and departures from equilibrium calculated using $T_s = 1373$ K, $T_x = 298$ K, $p_x = 1.013 \times 10^5$ N/m², $a = 102$ s⁻¹, $x_{\text{BCl}_3}^0 = 0.4$. Kinetic parameters for each case are listed in Table IV. Note that $S = r_{\text{III}}/c_x \sqrt{\nu_x a}$.

Case	Reaction	$\frac{r_1}{c_x \sqrt{\nu_x a}}$	$\frac{r_{\text{Ib}}}{r_{\text{I}}}$	$\frac{r'_{\text{int.1}}}{c_x \sqrt{\nu_x a}}$	$\frac{(r'_{\text{int.1b}})}{(r'_{\text{int.1}})}$
A	[I]	0.78×10^{-2}	0.45	0.88×10^{-1}	0.64
	[II]	0.54×10^{-1}	0.87	-0.74×10^{-3}	1.00
	[III]	0.54×10^{-1}	1.00	0.0	—

	[II]	0.55×10^{-1}	0.89	-0.18×10^{-5}	1.00
	[III]	0.55×10^{-1}	1.00	0.0	—
B	[I]	0.16×10^{-1}	0.61	0.61×10^{-1}	0.86
	[II]	0.54×10^{-1}	0.53	0.17×10^{-3}	1.00
	[III]	0.54×10^{-1}	1.00	0.0	—

values for $r'_{\text{int.1}}$ indicate that a small amount of conversion of BCl to BHCl₂ can take place in the gas phase. This is due to the large decrease in the magnitude of K_{II} that occurs at small distances from the surface. Finally, it is emphasized that the small difference in deposition rate in the two cases is insignificant in terms of the overall fit of the data.

A comparison of cases A and B (see Tables IV and V) indicates the influence of a 3% decrease in $\Delta H_{f,298}^0$ for BHCl₂ on the model predictions. Although this percentage change is significantly smaller than the one for the A/D comparison, it has a larger effect on the reactions. As in case D, the values of θ_1 , θ_4 , and E_s had to be altered to refit the data. In addition, changes were required for θ_5 and q_{BCl_3} . The empirical parameter q_{BCl_3} determines the relationship between deposition rate and inlet gas composition, and its value is chosen to give the correct shape of the curves in Fig. 3. If the change in q_{BCl_3} in case B were interpreted physically, it might imply that a different mechanism is involved in adsorption and desorption of species at the surface. The parameter θ_5 links the absolute magnitudes of the chemical reactions to the gas phase hydrodynamics. The change in θ_5 needed to match the data cannot be related to a single factor: variations in local compositions, equilibrium constants, and the other kinetic parameters are involved.

In order to interpret the results presented in Table V from the standpoint of rate-determining steps, it is necessary to consider the reaction pathways in the system. The homogeneous and heterogeneous pathways for reaction [I] are in parallel. Consequently, the magnitudes of r_1 and $r'_{\text{int.1}}$ rather than the extents to which the reactions depart from equilibrium, should be compared to assess the relative importance of the parallel routes. Reactions [II] and [III] may be regarded as consecutive steps, since reaction [II] does not occur to an appreciable extent in the gas phase and reaction [III] is restricted to the surface. Hence, the departures from equilibrium (i.e., $r_{\text{Ib}}/r_{\text{I}}$) for these two heterogeneous reactions can be used to indicate which step is more rate determining. With the parallel pathways for reaction [I], it is difficult to specify the relative importance of reactions [I] and [II]. One approach that could be used to provide an indication of the rate-limiting step is to neglect heterogeneous reaction [I] and to compare departures from equilibrium for the two most important reactions, homogeneous reaction [I] and heterogeneous reaction [II]. On this basis, homogeneous reaction [I] would be the rate-determining step in case A, but heterogeneous reaction [II] would be the limiting step in case B. An additional change in case B is the shift in the relative importance of the pathways for reaction [I]: the heterogeneous rate r_1 is increased and gas phase conversion to BHCl₂ is reduced. This can be attributed, at least in part, to the stronger temperature dependence of the equilibrium constant K_1 (see Table II).

It is emphasized that the results in Table V are for one set of process conditions. If the mass flow rate is increased or the surface temperature is decreased, the reactions are shifted further from equilibrium: i.e., the values

of $r_{\text{Ib}}/r_{\text{I}}$ and $(r'_{\text{int.1b}})/(r'_{\text{int.1}})$ are reduced. These changes tend to make the deposition process more kinetically controlled. However, for the range of operating conditions considered, changes caused by varying thermochemical properties are essentially the same as those described above.

The sensitivity of model predictions to independent variations in S_{298}^0 was also studied. When the value of S_{298}^0 for BHCl₂ was arbitrarily reduced by 3%, results similar to curves B in Fig. 2-4 were obtained. These results emphasize that the system behavior is influenced by changes in equilibrium constants. The origin of the changes, i.e., uncertainties in either $\Delta H_{f,298}^0$ or S_{298}^0 , is not in itself important.

The effects of changes in transport properties on model predictions were tested by varying the Lennard-Jones force constants for BHCl₂ and BCl. Each force constant was independently varied by $\pm 10\%$. At $T_s = 1473$ K, a 10% increase in σ_{BHCl_2} reduced the viscosity and thermal conductivity for BHCl₂ by 17% and lowered the binary diffusion coefficients by 7-10%. However, the corresponding changes in deposition rate are small. For example, at $a = 102$ s⁻¹, and with the case A thermodynamic properties and kinetic parameters, the increase in σ_{BHCl_2} does not alter S at $x_{\text{BCl}_3}^0 = 0.1$ and only increases it by 1.4% at $x_{\text{BCl}_3}^0 = 0.6$. Similar results are obtained for changes in ϵ_{BHCl_2} . Also, the deposition rate showed no sensitivity to σ and ϵ for BCl over the range of inlet compositions used in this work.

Conclusions

A model that describes the coupled multicomponent transport phenomena and reaction kinetics for CVD in an impinging jet reactor has been used to assess the sensitivity of theoretical predictions to uncertainties in physical property values. Results for intermediate species involved in CVD of boron from BCl₃ and H₂ illustrate the trends in behavior that can be expected in general.

An intermediate species with a composition level near the surface that is much lower than the local compositions of the reactants will generally have a small surface flux and, hence, will make a negligible contribution to the deposition rate. Consequently, uncertainties in property values for a species of this kind will not have a significant effect on the deposition rate in the thermodynamic mass transfer limit and can only change the interpretation of rate-limiting steps if the reactions in which the species participates are far removed from equilibrium. For an intermediate species with a gas phase mole fraction comparable to the reactant compositions, small changes in physical properties such as $\Delta H_{f,298}^0$ and S_{298}^0 can lead to noticeable changes in the deposition rates calculated under equilibrium conditions. These changes are more significant when concentrated inlet gas mixtures are used. Also, with modified property values, different values for the kinetic parameters may be required to fit available experimental data and this can lead to different interpretations of the rate-limiting steps in the process. Changes in Lennard-Jones force constants give relatively small variations in the transport properties and these generally have a negligible effect on predicted deposition rates.

LIST OF SYMBOLS

a	hydrodynamic parameter, proportional to mass flow rate of jet stream (s ⁻¹)
A_1	pre-exponential factor for backward rate constant for heterogeneous reaction 1 (mol/cm ² -s)
A'_1	pre-exponential factor for backward rate constant for homogeneous reaction 1 (mol/cm ² -s)
$A_{s,1}$	pre-exponential factor for adsorption/desorption equilibrium constant for species i in reaction 1 (see Eq. [5])

C	total concentration (mol/cm ³)
C_{pi}	molar heat capacity of species i (J/mol-K)
d	nozzle diameter (cm)
d_i	coefficient in Eq. [14] (J/mol-K)
\mathcal{D}_{ij}	diffusion coefficient for binary interactions (cm ² /s)
e_i	coefficient in Eq. [14] (J/mol-K ²)
$E_{a,i}$	activation energy for backward reaction i (see Eq. [2]) (K)
E_a	kinetic parameter representing activation energy for rate-limiting step (K)
$E_{s,i,l}$	activation energy for adsorption/desorption of species i in reaction l (see Eq. [5]) (K)
E_s	kinetic parameter representing activation energy for adsorption/desorption of BCl ₃ (K)
f_i	coefficient in Eq. [14] (J/mol-K ³)
H_i	enthalpy of species i (J/mol)
ΔH_{r1}	enthalpy change of reaction l (J/mol)
$\Delta H_{f,298}^{\circ}$	standard enthalpy of formation at 298 K (J/mol)
k	Boltzmann constant (1.3806×10^{-23} J/K)
k_i	thermal conductivity of species i (W/m-K)
k_l	rate constant for heterogeneous reaction l (mol/cm ² -s)
k'_l	rate constant for homogeneous reaction l (mol/cm ³ -s)
K_l	equilibrium constant for reaction l
K_{pi}	equilibrium constant defined by Eq. [12]
$K_{s,i,l}$	equilibrium constant for adsorption/desorption of species i in reaction l
$K_{s,l}$	equilibrium constant for adsorption/desorption of BCl ₃ (see Eq. [6])
L	distance between end of nozzle and substrate surface (cm)
m_l	net number of molecules produced by reaction l
n_l	exponent in Eq. [1]
N_m	= flux/ $c_s \sqrt{\nu_x a}$, dimensionless surface flux for species m
p	gas pressure (N/m ²)
$q_{i,l}$	exponent in Eq. [4]
r_l	= $r'_{lf} - r'_{lb}$, net rate of heterogeneous reaction l (mol/cm ² -s)
r'_l	= $r'_{lf} - r'_{lb}$, net rate of homogeneous reaction l (mol/cm ³ -s)
$r'_{int,l}$	net rate of homogeneous reaction l , integrated across diffusion layer (mol/cm ² -s)
R	universal gas constant (8.3143 J/mol-K)
S	= deposition rate/ $c_s \sqrt{\nu_x a}$, dimensionless boron deposition rate
S_{298}°	standard entropy at 298 K (J/mol-K)
T	temperature (K)
$x_{BCl_3}^0$	inlet mole fraction of BCl ₃
x_i	mole fraction of species i
z	axial distance from deposition surface (cm)

Greek symbols

$\alpha, \beta, \gamma, \delta, \epsilon$	coefficients in Eq. [15]
ϵ	energy of interaction for Lennard-Jones potential (J)
ζ	= $z\sqrt{a/\nu_x}$, dimensionless axial distance coordinate
θ_{v1}	parameter defined by Eq. [4]
θ_k	dimensionless kinetic parameter ($k = 1-5$) defined in Eq. [7]-[11]
μ_i	viscosity of species i (g/cm-s)
ν_{ii}	stoichiometric coefficient for species i in reaction l (positive for reactants)
ν_x	bulk kinematic viscosity (cm ² /s)
σ	collision diameter for Lennard-Jones potential (cm)

ABSTRACT

The photoexcitation effects on the growth rate have been demonstrated in the vapor phase epitaxial growth of GaAs. The growth rate is enhanced by irradiating the substrate zone with a 249 nm (KrF) excimer laser over the whole of temperature range 480° ~ 700°C and increases in proportion to the incident power. However, the growth rate is reduced by irradiating the source zone with a 249 or 222 nm (KrCl) excimer laser at low temperatures below 650°C. These effects have been concluded to be caused not by thermal-induced reactions but, rather, by photoinduced reactions because of sharp wavelength dependence. Infrared absorption analyses have shown that the reduction of AsCl₃ by H₂ is promoted by irradiation with a 249 or 222 nm laser. This photodissociation of AsCl₃ causes the growth rate reduction in the case of source zone irradiation.

The development of low temperature processing techniques is increasingly required in the manufacture of semiconductor devices. This requirement comes about because defect generation and propagation, thermal warpage, and impurity redistribution occur at high temperatures. Photoexcited technique has been receiving increasing attention as low temperature processing. One of the authors (J. N.) first proposed the photoexcited process in 1961 (1), and applied this technique to the vapor phase epitaxial growth of Si (2). High quality Si epitaxial layers were grown at low temperatures by irradiating the substrates with UV light.

In photoexcited processes, reactions are less complex and fewer defects are generated due to excess energies, unlike plasma excitation, because a sort of specific radical or ion can be selectively formed by selecting the photon energy. Moreover, photoexcited processes have the possibility that each elementary process can be individually controlled among the competitive processes by using monochromatic light whose wavelength is suited to activate the process. Photoexcited processes can be carried out at low temperatures and are expected to be easily monitored and controlled. Therefore, photoexcited processes are more promising techniques for achieving precise control. Another advantage of photoexcited processes is the ability to localize spatially the reaction region by using a tightly focused laser beam. This paper describes the initial results of an application of photoexcited technique to the vapor phase epitaxial growth of GaAs.

Experimental

The growth of GaAs epitaxial layers was carried out by using a conventional AsCl₃-Ga-H₂ system. A schematic diagram of the growth apparatus is shown in Fig. 1. The apparatus consists of a controlled two-zone furnace, a quartz reactor tube, a Ga source boat, a substrate holder, and an

AsCl₃ bubbler. The furnace has two window ports to introduce light beam into the reactor tube, and the ports are closed with evacuated quartz plugs to keep the thermal condition. The reactor tube has an inside diameter of 34 mm. The hydrogen carrier gas was passed through an absorption-type purifier. The temperature of the AsCl₃ bubbler was kept at 0°C, and the flow rate of hydrogen through the AsCl₃ bubbler was kept at 100 cm³/min by a mass flow controller. The substrates were Cr-O doped semi-insulating GaAs crystals, oriented 4° off (100) toward (110). The substrates were cut in 1 × 1 cm² rectangles and were first etched by 4H₂SO₄:1H₂O₂:1H₂O solution followed by dipping into concentrated HF solution, then slight etching by 10H₂SO₄:1H₂O₂:1H₂O, and finally another concentrated HF dipping prior to epitaxial growth. An excimer laser was mainly used as a light source for irradi-

Fig. 1. Schematic diagram of the growth apparatus

ation during crystal growth. The excimer laser which emits $10 \times 20 \text{ mm}^2$ sheet beam was operated with KrCl (222 nm), KrF (249 nm), XeCl (308 nm), or XeF (350 nm) line at repetition rate of 5 ~ 70 pps. The light was introduced into the substrate zone or the Ga source zone without any focusing. The growth rate was derived from the growth time, and the thickness of the grown layer was measured by the cleavage and stain technique on the assumption that it is a linear function of time.

The gas analysis by infrared absorption spectroscopy was carried out in order to clarify the photoexcitation effect on the reduction of AsCl_3 by H_2 . There are two methods for infrared spectroscopy measurements (3); they are sampling and direct (*in situ*) observation methods. Although the sampling method was used in the present experiment, the direct observation method could have also been used. The measurement system is nearly similar to that used in a previous paper (4). A capillary is introduced into the reactor tube to lead reactants into a gas cell for analyzing by an infrared spectrometer. Hydrogen gas was introduced into the reactor tube after passing through the AsCl_3 bubbler and then irradiated with an excimer laser.

Experimental Results

Substrate zone irradiation.—Figure 2 shows the growth rate as a function of incident excimer laser wavelength for an incident average power of $\sim 1.7 \text{ W}$ in the case of substrate zone irradiation. The source temperature and substrate temperature were 720° and 600°C , respectively. The growth rate was increased by the 249 nm laser irradiation but scarcely changed by other wavelength irradiation. Moreover, no enhancement of growth rate was obtained by irradiation with a visible argon-ion laser.

The growth rates are plotted in Fig. 3 as a function of the reciprocal substrate temperature. In this experiment, the temperature difference between the source and the substrate zone was kept to 50°C . In the absence of irradiation shown by curve a, the growth rate monotonically decreased with lowering the substrate temperature to 600°C and then slightly increased, followed by decreasing below 550°C with further temperature decrease. No crystal growth was obtained below 500°C . In the case of substrate zone irradiation with the 249 nm laser shown by curve b, the growth rate slightly decreased with lowering the substrate temperature to 500°C and then rapidly decreased to a small value at 480°C . The growth rate was found to be enhanced over the whole of temperature range of $480^\circ \sim 700^\circ\text{C}$ by the substrate zone irradiation with the 249 nm laser.

Fig. 2. Wavelength dependence of growth rate for GaAs epitaxial layers grown by the substrate zone irradiation with an excimer laser.

Fig. 3. Temperature dependence of growth rate for GaAs epitaxial layers. Curves a, b, and c show no irradiation, substrate zone irradiation, and source-zone irradiation, respectively.

Figure 4 shows the incident laser power dependence of growth rate in the case of substrate zone irradiation with the 249 nm laser. Since the growth rate increases in proportion to the incident power, the growth rate can be controlled by changing the incident laser power.

Source zone irradiation.—Figure 5 shows the growth rate as a function of incident excimer laser wavelength in the case of Ga source zone irradiation. The source temperature and substrate temperature were 600° and 550°C ,

Fig. 4. Incident 249 nm laser power dependence of growth rate for GaAs epitaxial layers.

Fig. 5. Wavelength dependence of growth rate for GaAs epitaxial layers grown by the source zone irradiation with an excimer laser.

respectively. The growth rate was markedly reduced by irradiation with the 249 nm laser irradiation and with the 222 nm irradiation but scarcely changed by other wavelength irradiation.

The growth rate in the case of source zone irradiation with the 249 nm laser was comparable to the value without irradiation at the source temperature above 650°C but was smaller than that without irradiation below 650°C, as shown by the curve c in Fig. 3.

Photodissociation of AsCl₃.—Figure 6 shows the temperature dependence of AsCl₃ decomposition measured by infrared absorption spectroscopy. In order to estimate the

Fig. 6. Temperature dependence of the reduction of AsCl₃ by H₂. *Arsenic was deposited on the irradiated region at low temperatures below 325°C.

concentration of reactants, we used the absorbance at 398 and 2926 cm⁻¹ for AsCl₃ and HCl, respectively. In the absence of irradiation, AsCl₃ is completely reduced by H₂ and HCl is produced at high temperatures above 700°C, but AsCl₃ is scarcely reduced by H₂ at low temperatures below 600°C. In the case of irradiation with the 249 nm laser, on the other hand, AsCl₃ is reduced by H₂ even at low temperatures below 600°C. The activation energies for reduction reaction of AsCl₃ are 49 and 2.2 kcal/mol without and with irradiation, respectively. The activation energy decreased dramatically with irradiation. However, the activation energy does not necessarily show the energy for the individual process step because there is the possibility that the reaction involves multistep processes.

Figure 7 shows the wavelength dependence of AsCl₃ reduction by irradiation with an excimer laser. The reduction of AsCl₃ is promoted by irradiation with the 222 and 249 nm laser.

Discussion

Although the detailed mechanism of GaAs epitaxial growth by the chloride method has not been clarified, the following processes are generally considered for the reactions (5).

At high source temperatures above 700°C where the growth is usually carried out, introduced AsCl₃ is reduced by H₂ and HCl is produced by

HCl produced by reaction [1] reacts with the GaAs crust formed on the surface of the Ga melt at the source to form GaCl and As₄ by

These gases are carried by H₂ onto the substrate at a low temperature, where GaAs is deposited by

At low source temperatures below 600°C, on the other hand, AsCl₃ is not efficiently reduced by H₂ and the source reacts directly with AsCl₃ by reaction [4] and not with HCl (6)

In the deposition region, reaction [3] or reaction [5] should take place

By taking account of the above-mentioned mechanism, we discuss the irradiation effects on the growth rate. In the case of substrate zone irradiation, the sharp wavelength dependence of growth rate enhancement indicates

Fig. 7. Wavelength dependence of the reduction of AsCl₃ by irradiation with an excimer laser.

that it is caused not by thermal-induced reactions but by photoinduced reactions. GaCl has an absorption band at around 248 nm (7). The mechanism of the growth-rate enhancement by the substrate zone irradiation is not clear yet, but it is presumably associated with excitation or decomposition of a sort of gallium chlorides by the 249 nm laser irradiation.¹

The temperature dependence of growth rate in the absence of irradiation seems to be related with the degree of AsCl₃ decomposition. At $T_{\text{source}} < 700^{\circ}\text{C}$, AsCl₃ is not completely decomposed, and the Ga source reacts not only with HCl but also directly with AsCl₃ with lowering of the source temperature below 700°C. Therefore, the growth rate behavior as shown by curve a in Fig. 3 is based on the difference of the source reaction mechanism.

Infrared absorption analysis indicates that the AsCl₃ reduction by H₂ can be caused even at low temperatures below 700°C by irradiation. Therefore, the growth rate reduction by the source zone irradiation at low temperatures must be associated with the photodissociation of AsCl₃. At high temperatures above 650°C, AsCl₃ is thermally reduced and then the Ga source reacts with HCl regardless of irradiation. At low temperatures below 650°C, on the other hand, the Ga source reacts directly with AsCl₃ in the absence of irradiation, whereas the Ga source reacts with HCl in the presence of irradiation because of the photodissociation of AsCl₃. The reaction velocity of direct reaction with AsCl₃ is larger than that of the reaction with HCl at low temperatures (6). Therefore, the growth rate is decreased by the source zone irradiation at low temperatures.

Conclusion

We have demonstrated the photoexcitation effects on the growth rate in the vapor phase epitaxial growth of

¹Results will be reported in the next paper.

GaAs. The growth rate can be enhanced by irradiating the substrate zone with the 249 nm laser over the whole of temperature range of 480° ~ 700°C, whereas it is reduced by irradiating the source zone with the 249 or 222 nm laser at low temperatures below 650°C. Infrared absorption analysis showed that the reduction of AsCl₃ by H₂ is promoted by irradiation with the 249 or 222 nm laser. This photodissociation of AsCl₃ causes the growth-rate reduction in the case of source zone irradiation. Further investigations are extended to clarify the detailed mechanism of photoexcitation effects. In future, the crystal growth will be performed by identifying the radicals or ions which participate in the reactions by infrared absorption spectroscopy and then by forming selectively the radicals and ions with photoexcitation.

ABSTRACT

Lateral autodoping is encountered if silicon wafers with heavily doped areas are subjected to silicon epitaxy. The characteristics of the autodoping profile are determined by the pre-epitaxial bake conditions and by the identity of the impurities. Lateral autodoping originating from arsenic- or antimony-implanted silicon substrates can be suppressed by reduction of the total pressure during the epitaxial process. In contrast, autodoping is enhanced at reduced pressure if boron-doped buried layers are employed. These phenomena can be accounted for if chemical processes in the gas phase, which involve the dopant, are considered. Thermodynamic computations have been carried out in order to explain the influence of process conditions such as temperature, total pressure, and the presence of chlorine on the autodoping behavior or antimony, arsenic, phosphorus, and boron. Evaporated dopant atoms are converted to stable gaseous compounds such as SbCl for antimony, AsH and As₂ for arsenic, PH₃, PH₂, and P₂ for phosphorus, and BHCl₂ for boron. The reincorporation of the dopant in the epitaxial layer is governed by the partial pressure of monoatomic species in the gas phase. Mass action law describes the influence of total pressure on the efficiency of the autodoping process.

During epitaxial deposition of silicon, impurities present in the substrates are redistributed in the epitaxial layer. Transport of dopant atoms can take place by means of solid-state diffusion (1) or according to a two-step mechanism involving impurity evaporation from the substrate and reincorporation into the growing layer (2, 3). The latter phenomenon is usually referred to as autodoping. The result of autodoping is an unintended impurity profile in the epitaxial layer. This may give rise to unwanted device characteristics in schemes where wafers with buried layers or heavily doped substrates are used.

A considerable amount of work on the topic of autodoping has been done in recent years. Most authors pay attention in particular to the physical aspects of the process, such as gas phase diffusion (4), the retainment of impurities in the boundary layer (5, 6), and the adsorption of impurities at the surface (7). Quantitative treatments of gas flow effects have been published (8, 9).

The characteristics of the autodoping profile are determined to a large extent by the pre-epitaxial bake conditions, such as temperature, bake time, and total pressure (10). An important observation is the fact that, in the case

of arsenic, autodoping can be suppressed by low pressure epitaxy (11, 12), which is in agreement with theoretical expectations. However, in the case of boron, enhancement of autodoping at reduced pressure has been reported (13). It seems that in order to explain this and other anomalies, the influence of chemical processes on the autodoping mechanism should be taken into account. This approach has been successfully pursued for the description of intentional doping during epitaxial deposition of silicon, especially for arsenic (14) and phosphorus (15), for epitaxy at both atmospheric and reduced pressure (16). At present, physicochemical models for the incorporation of dopants in epilayers are available (17).

The purpose of this paper is to compare the autodoping behavior of Sb, As, P, and B buried layers and to study the influence of chemical processes in the gas phase on the reincorporation of these dopants.

Experimental Procedure

Epitaxial silicon layers were grown in an AMC7800 radiant-heated barrel reactor. Silicon sources used were dichlorosilane, trichlorosilane, and tetrachlorosilane. The silicon growth rate amounted to $0.43 \mu\text{m}/\text{min}$ during most experiments. Diborane and phosphine were used as dopant gases. Hydrogen was used as a carrier gas; the total gas flow was about 170 standard liter/min. The deposition temperature was varied within the range 1050°C – 1200°C .

The samples for the investigation of autodoping profiles were prepared as follows. Heavily doped substrates were used in order to facilitate CV measurements.

Fig. 1. Doping profiles in epilayer on a substrate with P buried layer. The figure shows the heavily doped substrate, the buried layer (open circles), and the autodoping profile (darkened circles). Shaded area: autodoping peak.

Antimony-doped silicon wafers (resistivity $0.02 \Omega\text{-cm}$) were used as N^+ substrates, and boron-doped wafers ($0.02 \Omega\text{-cm}$) were used as P^+ substrates. The slices were (100) oriented and of 3 in. diam; they were supplied by Wacker. The P^+ substrates were backsealed with $2 \mu\text{m}$ of undoped silicon. The N^+ and P^+ slices were coated on the front side with N^- or P^- epitaxial layers, respectively (carrier concentration of 10^{14}cm^{-3} ; thickness of $5 \mu\text{m}$), in order to separate the buried layers from the substrate doping. Next, the wafers were subjected to ion implantation (dose $3 \times 10^{15} \text{cm}^{-2}$; energy 50 keV) in order to create buried layers doped with antimony, arsenic, phosphorus, or boron. The buried layers were rectangular with dimensions of $6.6 \times 8.8 \text{mm}^2$; the active region was 52% of the total surface area.

Subsequently, a 100 min diffusion drive was performed at 1200°C for Sb and As, and at 1100°C for B and P. Due to differences in the diffusivities of these elements in silicon, this resulted in approximately equal doping profiles in these four types of substrates prior to the epitaxy step. A second epilayer was deposited onto the substrates, doped intentionally to about 10^{14}cm^{-3} n- or p-type.

The autodoping phenomena caused by the presence of the buried layers during epitaxy were investigated with the aid of spreading resistance (SR) measurements on beveled samples. To this end, an SSM two-probe measuring system, Type ASR-100, was used. The uncorrected SR profiles were compared with impurity profiles obtained with an MSI 894 capacitance-voltage (C-V) profiler provided with a mercury probe. Qualitative agreement was observed. The SR data were converted to carrier concentrations with the aid of a series of values of four-point probe resistivities obtained on calibration samples.

Experimental Results

The redistribution of dopant atoms originating from the buried layers was investigated by measuring the spreading resistance profile in between two buried layer (BL) regions. A comparison of the doping profile obtained in this way and a doping profile determined over a buried layer is shown in Fig. 1. The extent of autodoping is indicated by the magnitude of a concentration maximum in the second epilayer, formed during the initial stage of epitaxial growth. The variation of the lateral autodoping peak as a function of distance from the BL edge is shown in Fig. 2. It is seen that the maximum is only slightly dependent on distance in the region within several millimeters from the BL edge. The repetitious pattern of buried layers causes an averaging effect on the off-BL profiles. In investigations where only a single

Fig. 3. Influence of pre-epitaxial bake time and temperature, total pressure, and HCl on lateral autodoping peak height (corrected for background doping).

buried layer on an entire wafer was used, the direction of the gas flow affected autodoping (8).

The off-BL profiles presented below were always determined at 2.2 mm from the BL edge, *i.e.*, in the middle between two buried layers. Minor deviations in distance do not affect the profile significantly.

Influence of pre-epitaxial bake conditions on lateral autodoping.—Native oxide, present on the silicon surface, is removed by the action of hydrogen during the pre-epitaxial bake step. Simultaneously, dopant atoms are released from the buried layer, to be reincorporated during the deposition step. The lateral autodoping maximum is affected by the conditions of the pre-epitaxial stage. The following experimental parameters were studied.

Total pressure.—Experiments were done at atmospheric pressure (AP) or at reduced pressure (RP, *i.e.*, 65 torr).

Pre-epitaxial bake temperature.—Pre-epitaxial bake was performed at 1080° and 1200°C. The temperature during growth was the same as the pre-epitaxial temperature.

Pre-epitaxial bake time.—The time required for attaining the set-point temperature was about 3 min. This was des-

Fig. 4. Influence of silicon source gas on lateral autodoping peak height. Deposition conditions: reduced pressure (65 torr); temperature of 1080°C; growth rate of 0.41 $\mu\text{m}/\text{min}$. (Corrected for background doping.)

Fig. 5. Boron incorporation from the gas phase at atmospheric and reduced total pressure. Epitaxy conditions: 1.4% SiHCl_3 , 1080°C.

ignated as "No Bake." Alternatively, and additional pre-epitaxial bake (B) was allowed for the duration of 30 min.

The influence of these conditions on the autodoping profile was studied for epitaxial layers deposited onto wafers implanted with Sb, As, P, and B, respectively. The lateral autodoping profiles which result for different conditions for each of the dopant types were published elsewhere (18). The results can be summarized as follows.

For antimony, the Sb lateral autodoping peak was found always below 10^{15} cm^{-3} . The maximum decreased with (i) reduction of the total pressure, (ii) extension of the pre-epitaxial bake time, and (iii) increase of temperature.

For arsenic, the As lateral autodoping peak was strongly affected by the experimental conditions. The highest maximum was found at low temperature and atmospheric pressure. The maximum decreased with (i) reduction of the total pressure, (ii) extension of the pre-epitaxial bake time, and (iii) increase of temperature.

For phosphorus, the P lateral autodoping peak was always larger than 10^{16} cm^{-3} . The maximum decreased with (i) increase of the total pressure, and (ii) decrease of temperature. The maximum was not notably affected by the duration of the pre-epitaxial bake time.

Fig. 6. Boron incorporation from the gas phase. Influence of chlorine on doping efficiency. Epitaxy with SiH_2Cl_2 and 1 ppb B_2H_6 at 1080°C.

Fig. 7. Dimensionless diagram showing the effect of pre-epitaxial bake time on autodoping.

For boron, the B lateral autodoping peak was found within a large range from 10^{14} to 10^{17} cm^{-3} . The maximum decreased with (i) increase of the total pressure, (ii) shortening of the pre-epitaxial bake time, and (iii) decrease of temperature.

A graphic representation of these results is given in Fig. 3. In addition to the pre-epitaxial conditions mentioned above, the effect of the presence of HCl (1 volume percent) during the pre-epitaxial stage was studied. This resulted in the removal of the top layer (about $0.5 \mu\text{m}$) of the substrate, including part of the implanted region. This caused a reduction of the autodoping maximum for As and P by a factor of four, and by somewhat less for Sb. Etching during the pre-epitaxial bake did not influence the magnitude of the autodoping peak of boron.

Influence of the silicon source on lateral autodoping.—In addition to the experimental conditions prior to the epitaxial process, the identity of the silicon source gas present during deposition appeared to be of importance. In order to avoid possible interpretation difficulties introduced by surface kinetics, the same growth rate ($0.41 \mu\text{m}/\text{min}$) was imposed for the preparation of all samples. This was attained by the choice of appropriate growth gas partial pressure: 0.4% SiH_2Cl_2 , 2.4% SiHCl_3 , and 4% SiCl_4 , respectively, for epitaxial deposition under reduced pressure at 1080°C . The influence of the silicon source on the lateral autodoping peak height is depicted in Fig. 4. For arsenic and phosphorus, the variations of the autodoping maximum were within the uncertainty of the measurement, which was about 15%. This indicates that P and As autodoping is not affected by the identity of the silicon source. The effect on antimony autodoping is

Fig. 8. Dimensionless diagram showing the effect of pre-epitaxial bake temperature on autodoping.

somewhat ambiguous; a decline of the peak height by 25% was observed if tetrachlorosilane was used instead of dichlorosilane. For boron, a clear reduction of the autodoping efficiency was found. If SiH_2Cl_2 was replaced by SiCl_4 , the autodoping maximum decreased with a factor of more than two.

Doping with diborane.—In order to study the influence of the experimental conditions on the mechanism of dopant incorporation from the gas phase, a number of experiments were executed in which the epitaxial layers were intentionally doped with boron. This is the more interesting dopant because of its divergent behavior. The incorporation of arsenic and phosphorus has been described in several publications (14, 15).

When diborane was used as a dopant source, the relationship between the boron concentration in the epilayer N_B and the diborane fraction in the gas $X_{\text{B}_2\text{H}_6}$ during deposition could be expressed by a straight line with slope ϕ

$$\phi = \frac{d(\log N_B)}{d(\log X_{\text{B}_2\text{H}_6})} \quad [1]$$

Experimentally, the following values for ϕ were found (cf. Fig. 5). At atmospheric pressure and 1080°C , $\phi = 0.95$ for 0.4% SiH_2Cl_2 (growth rate $0.43 \mu\text{m}/\text{min}$), and $\phi = 0.98$ for 1.4% SiHCl_3 (growth rate $0.36 \mu\text{m}/\text{min}$). At reduced pressure, similar results were obtained: $\phi = 0.98$ for SiCl_4 at 50 torr, $\phi = 1.01$ for SiCl_4 at 370 torr, and $\phi = 1.00$ for SiHCl_3 at 60 torr.

The influence of the total pressure on the doping process can be studied by comparing these results. The dependence of the impurity concentration in the epitaxial layer on the total pressure P_{tot} (for a constant diborane fraction in the gas phase and hydrogen as a carrier gas) is expressed by

$$\psi = \frac{d(\log N_B)}{d(\log P_{\text{tot}})} \quad [2]$$

The value $\psi = -0.52 \pm 0.07$ was found when SiCl_4 was used as a silicon source. For the case of SiH_2Cl_2 , $\psi = -0.43 \pm 0.10$ was measured. Clearly, the efficiency of the boron incorporation process is enhanced by reduction of the total pressure. In spite of the fact that the total concentration of boron in the gas phase is reduced, the concentration of boron in the solid increases!

In view of the observation that boron autodoping was influenced by the chlorine content of the silicon source (preceding section), the effect of the amount of chlorine present in the gas phase on the boron doping process was also studied. The chlorine fraction was varied by adjustment of the dichlorosilane and trichlorosilane partial pressures. The relationship between the boron concentra-

Fig. 9. Dimensionless diagram showing the relationship between autodoping and total pressure.

tion in the epitaxial layer and the chlorine fraction in the gas phase X_{Cl} is given by the equation

$$\xi = \frac{d(\log N_B)}{d(\log X_{Cl})} \quad [3]$$

For SiHCl_3 at atmospheric pressure, $\xi = -0.96$ was found, whereas for SiH_2Cl_2 at 65 torr the value $\xi = -0.86$ was obtained (cf. Fig. 6). It can be shown that the decrease of the boron concentration in the solid with increasing SiH_2Cl_2 and SiHCl_3 partial pressure is not caused by kinetic limitations. If the incorporation of impurities during deposition of silicon is governed by quasi-equilibrium conditions, the number of boron atoms incorporated in silicon is less than the amount of boron atoms arriving at the surface. Essentially, this implies that the effective segregation coefficient, defined at

$$k_{\text{eff}} = \frac{N_B/N_{Si}}{X_B/X_{Si}} \quad [4]$$

must be smaller than unity (19). In Eq. [4], N_{Si} is the concentration of silicon atoms in the solid, X_B is the total boron fraction in the gas phase, and X_{Si} is the total silicon fraction in the gas phase. The theoretical upper limit of k_{eff} (which points to an incorporation process governed by kinetic laws) may be even larger than unity if chlorine is present in the gas phase, since not all silicon arriving at the surface is used for crystal growth in this case. Table I gives a number of values for k_{eff} calculated from the experimental results for trichlorosilane. The figures show that the doping experiments were done well within the regime where equilibrium conditions may be assumed to be present.

Finally, the temperature dependence of boron doping was studied in the range 1050°–1200°C for 0.4% SiH_2Cl_2 and 1 ppb B_2H_6 at atmospheric pressure. For a constant diborane partial pressure, the doping level tended to increase with increasing temperature. An activation energy $E'_{\text{act}} = 0.84$ eV was found.

Discussion

Lateral autodoping is caused by evaporation of impurities from the buried layer area during the pre-epitaxial bake stage. Srinivasan (20) showed that the surface concentration of the dopant source at the end of the pre-epitaxial bake stage can be described by the expression

$$N(T, t)/N_0 = \exp(\beta^2 t) \operatorname{erfc}(\beta t^{1/2}) \quad [5]$$

where $N(T, t)$ is the surface concentration after a bake process with duration t at temperature T , and N_0 is the initial surface concentration. The parameter β contains the mass transfer coefficient for evaporation K , expressed in centimeters per second and the dopant diffusivity in the solid D , expressed in square centimeters per second

$$\beta(T) = K(T) \{D(T)\}^{-1/2} \quad [6]$$

The Arrhenius behavior for β is described by

$$\beta(T) = \beta_0 \exp(-\Delta E/kT) \quad [7]$$

where ΔE represents the activation energies for impurity diffusion and evaporation. The most important experimental parameters influencing the evaporation process are the pre-epitaxial bake time and temperature. These

Table I. Effective segregation coefficient k_{eff} for the incorporation of boron with constant diborane partial pressure and variable trichlorosilane partial pressure. Experimental conditions: $T = 1080^\circ\text{C}$, $X_B = 10^{-9}$, $P_{\text{tot}} = 1$ atm.

X_{Si}	N_B (cm^{-3})	k_{eff}
0.0144	1.6×10^{15}	0.47
0.0396	7.4×10^{14}	0.59
0.0652	4.7×10^{14}	0.61
0.0990	3.2×10^{14}	0.63

relationships are presented graphically in Fig. 7 and 8. As expected, the surface concentration decreases with increasing bake time and temperature, due to enhancement of the evaporation rate. Since the lateral autodoping level is directly proportional to the surface concentration of the dopant source (20), the magnitude of the lateral autodoping peak is influenced in an analogous way. According to this model, lateral autodoping can be suppressed by extension of the pre-epitaxial bake time or by an increase of the bake temperature.

A third experimental parameter that influences the lateral autodoping process is the total pressure. The surface concentration at the end of the pre-epitaxial stage determines the dopant concentration in the gas phase, and this quantity, in turn, governs the dopant reincorporation during epitaxial growth. For dilute solid solutions, the concentration of impurities in the solid phase N_i is directly proportional to the partial pressure P_i of impurities in the gas phase, as given by Henry's law (14)

$$N_i = K_i P_i \quad [8]$$

where K_i is the equilibrium constant. A part of the total amount of evaporated impurities will not be used for reincorporation, but is removed to the main gas stream. This fraction is determined by the magnitude of the diffusion coefficient D_i of species i in the gas phase. The diffusion coefficient is related to the total pressure according to

$$D_i = D_{0,i} P_{\text{tot}}^{-1} \quad [9]$$

where $D_{0,i}$ is the diffusion coefficient at atmospheric pressure. Thus, it can be shown that the effective partial pressure P_i is inversely proportional to the diffusion coefficient and directly proportional to the total pressure.

Consequently, the magnitude of the lateral autodoping maximum is directly proportional to the total pressure. This is depicted schematically in Fig. 9.

In summary, the lateral autodoping model based on the concept of successive evaporation, diffusion, and reincorporation implies that the pre-epitaxial bake conditions influence the autodoping process in the following way: (i) lateral autodoping is reduced by extension of the pre-epitaxial bake time, (ii) lateral autodoping is reduced by elevation of the pre-epitaxial bake temperature, and (iii) lateral autodoping is reduced by reduction of the total pressure.

In the foregoing, it was assumed implicitly that the evaporated impurity is always present in the gas phase as a monoatomic gas. This appears not to be in the case in every instance. In order to obtain a detailed view of the gas phase composition, it was necessary to perform a number of thermodynamic computations, based on data reported in the literature. A survey of the chemical species used in these calculations is given in Table II. The computer program was based on the minimization of the Gibbs energy for each set of input values. The standard conditions chosen for the calculation were an input com-

position of 1% Cl, 1 ppm O₂, and 10 ppb dopant in a hydrogen ambient, in equilibrium with a condensed silicon phase. The standard temperature was 1350 K. Equilibrium compositions were calculated for several sets of input values of the parameters dopant concentration, total pressure, chlorine concentration, and temperature. The results are presented in a series of diagrams, Fig. 10 to 23. In equilibrium, most chlorine is present in the form of HCl and most oxygen is converted to SiO. Some silicon compounds were included in the calculations, but were omitted in the plots for the sake of clarity. The influence of the partial pressure of hydrogen chloride on the equilibrium composition of the silicon-hydrogen-chlorine system has been reported by several authors (21, 22).

Antimony autodoping.—Autodoping originating from antimony buried layers (cf. Fig. 3) is roughly in agreement with the expected behavior. The influence of the pre-epitaxial bake conditions on autodoping is relatively small, which may be explained by the low evaporation rate of antimony. In order to determine whether the chemical composition of the reaction mixture has any effect on the autodoping mechanism, the results of the equilibrium calculations are considered. Figure 10 gives the gas phase composition as a function of the total amount of antimony present in the reaction mixture. It

Fig. 11. Equilibrium composition of the Sb-Si-H-Cl system as a function of the total pressure. Mass balance: 1% Cl; 10 ppb Sb. Temperature: 1350 K.

appears that, in the presence of HCl, or, which is equivalent, in the presence of a chlorine containing silicon source, virtually all evaporated antimony is converted to antimony monochloride, SbCl. This is the case within a wide concentration range of evaporated antimony. The influence of the total pressure on the composition is shown in Fig. 11. The dependence of the monoatomic Sb partial pressure on the total pressure is governed by the equilibrium

The mass action law implies that a plot of $\log P_{\text{Sb}}$ vs. $\log P_{\text{tot}}$ yields a straight line with slope equal to 1/2. From the experimental data, it follows that

$$\frac{\Delta(\log N_{\text{Sb,max}})}{\Delta(\log P_{\text{tot}})} = 0.08$$

If all antimony were present in the gas phase as monoatomic Sb, the expected slope would be equal to unity. Clearly, the observed figure is more in agreement with the supposition that the stability of monoatomic Sb is affected by the occurrence of chemical reactions in the gas phase.

The influence of the total amount of chlorine on the gas phase composition is shown in Fig. 12. An increase of the chlorine content tends to reduce the stability of

Fig. 12. Equilibrium composition of the Sb-Si-H-Cl system as a function of the Cl atomic fraction. Mass balance: 10 ppb Sb. Total pressure: 1 atm. Temperature: 1350 K.

monoatomic Sb. However, the effect of the Cl concentration on the autodoping maximum cannot be deduced unequivocally from the empirical data (Fig. 4). The fact that an increase of the Cl concentration does not significantly reduce the autodoping maximum seems to indicate that, in the case of antimony, surface kinetics of the incorporation process should be taken into account if a comprehensive description of the antimony autodoping mechanism is to be given.

The temperature dependence of the equilibrium composition is given in Fig. 13. It is seen that the stability of the monoatomic Sb increases slightly with increasing temperature. The activation energy, defined as

$$E''_{\text{act}} = - \frac{d(\ln P_1)}{d(1/kT)} \quad [10]$$

is approximately +2.01 eV. The apparent activation energy for the autodoping process, defined as

$$E'_{\text{act}} = \frac{d(\ln N_{1,\text{max}})}{d(1/kT)} \quad [11]$$

is equal to -0.66 eV. Hence, a net value for the activation energy E_{act} is found equal to -2.67 eV.

Arsenic autodoping.—Autodoping due to arsenic buried layers and heavily doped substrates has been studied extensively by a number of authors (5, 10, 11, 23, 24). The experimental results presented here are in agreement with most of these publications and are consistent with the autodoping model described in the preceding section.

A computation of the equilibrium gas phase composition as a function of the total amount of arsenic present (Fig. 14) shows that either AsH or As₂ is the dominant spe-

Fig. 13. Equilibrium composition of the Sb-Si-H-Cl system as a function of temperature. Mass balance: 1% Cl; 10 ppb Sb. Total pressure: 1 atm.

Fig. 14. Equilibrium composition of the As-Si-H-Cl system as a function of the As atomic fraction. Mass balance: 1% Cl. Total pressure: 1 atm. Temperature: 1350 K.

cies. If the arsenic atomic fraction due to evaporation is relatively low, most of the arsenic is converted to AsH. For a higher evaporation rate, virtually all As is converted to As₂. The species AsCl appears to be relatively unimportant. The graphic representation of the relationship between the chemical composition and the total pressure (Fig. 15) shows that the monoatomic As partial pressure is governed by a rather complicated equilibrium, which may be simplified, however, to the equation

The slope of $\log P_{\text{As}}$ vs. $\log P_{\text{tot}}$ is equal to +1/2. (If As₂ is assumed to be the prevailing species, the same result is obtained.) Experimentally, the following relationship between the autodoping maximum and the total pressure was found

$$\frac{\Delta(\log N_{\text{As,max}})}{\Delta(\log P_{\text{tot}})} = +0.62$$

This is in good agreement with the behavior that is predicted according to the thermodynamic analysis. The fact that the empirical slope is larger than 0.5 could be explained by the assumption that the partial pressure of monoatomic As is larger than the value that follows from the equilibrium calculations (24).

In Fig. 16, it can be seen that the stability of monoatomic As increases only to a small extent with temperature. The activation energy E'_{act} amounts to +1.06 eV. The apparent activation energy for autodoping E'_{act} is -1.65 eV, resulting in a net value for E_{act} equal to -2.71 eV.

Phosphorus autodoping.—Whereas arsenic autodoping can be described at least qualitatively with the evapora-

tion-diffusion-reincorporation model without invoking chemical details, the case is more complicated for phosphorus. In particular, the increase of the autodoping maximum if the total pressure is reduced and of the enhancement of autodoping at higher temperature are remarkable.

The results of the equilibrium calculations, presented in Fig. 17, show that the gas phase is governed by the species PH₃, PH₂, and, for high phosphorus concentration, P₂. The presence of chlorine does not affect the equilibrium composition, owing to the poor stability of chlorine containing gaseous phosphorus compounds. Also, no phosphorus oxides are sufficiently stable to play a role of importance in the chemical balance.

The equilibrium composition is influenced, however, by the total pressure of the gas mixture (Fig. 18). The stability of monoatomic phosphorus is enhanced by reduction of the total pressure. The slope of $\log P_p$ vs. $\log P_{\text{tot}}$ changes from -1/2 if PH₃ is the prevailing phosphorus compound to zero if PH₂ is dominant. This phenomenon is reflected in the influence of the total pressure on the lateral autodoping maximum (Fig. 3). The empirical relationship between the autodoping and the total pressure is given as

$$\frac{\Delta(\log N_{p,\text{max}})}{\Delta(\log P_{\text{tot}})} = -0.22$$

Fig. 15. Equilibrium composition of the As-Si-H-Cl system as a function of the total pressure. Mass balance: 1% Cl; 10 ppb As. Temperature: 1350 K.

Fig. 16. Equilibrium composition of the As-Si-H-Cl system as a function of temperature. Mass balance: 1% Cl; 10 ppb As. Total pressure: 1 atm.

Thus, the thermodynamic data are consistent with the observations.

The temperature dependence of the chemical equilibrium shows that the relative amount of monoatomic P in the gas phase is enhanced at higher temperatures, with $E'_{\text{act}} = +2.84$ eV (cf. Fig. 19). If this is taken into account in a consideration of the temperature dependence of the autodoping process (Fig. 3), with $E'_{\text{act}} = +0.99$ eV, it can be shown that the actual activation energy for autodoping has a negative sign, viz., $E_{\text{act}} = -1.85$ eV.

Boron autodoping.—The observation that boron lateral autodoping is enhanced by reduction of the total pressure has made it difficult to solve the autodoping problems encountered with the employment of P⁺ substrates (13, 25, 26). Boron autodoping is also increased with increased pre-epitaxial bake time and temperature (cf. Fig. 3).

If chlorine is present in the gas phase, the reaction mixture is dominated by chlorine containing species such as dichloroborane, BHCl_2 (Fig. 20). The gaseous reaction preceding the incorporation of boron can be expressed as

The mass action law implies that reduction of the total pressure enhances the stability of monoatomic boron. This is shown in Fig. 21. The slope of $\log P_{\text{B}}$ vs. $\log P_{\text{tot}}$ is equal to $-1/2$. (It should be remarked that the same value is found if the predominant boron species are assumed to be BCl_3 , BH_2Cl , or BH_3). The autodoping maximum (cf. Fig. 3) is reduced by total pressure reduction according to

$$\frac{\Delta(\log N_{\text{B,max}})}{\Delta(\log P_{\text{tot}})} = -0.49$$

It appears that the reincorporation of boron is indeed governed by the thermodynamic characteristics of the chemical processes in the gas phase. This is further substantiated by the results of experiments in which epilayers were intentionally doped (Fig. 5). The boron doping level vs. the total pressure gave slopes with values of -0.43 and -0.52 for dichlorosilane and tetrachlorosilane, respectively (cf. Experimental section).

The influence of the presence of chlorine on the chemical equilibrium is depicted in Fig. 22. If the total partial pressure of chlorine is relatively small, the predominant species are BH_2 and BH_3 , or, if traces of oxygen or water are present, BOH . For larger chlorine partial pressures, the stabilities of BHCl_2 , BH_2Cl , and BCl_3 are enhanced. In the intermediate range the slope of $\log P_{\text{B}}$ vs. $\log X_{\text{Cl}}$ changes from 0 to -2 . For intentional boron doping, the experimentally found value for ξ was about -1 (cf. Experimental section, Eq. [3]). This indicates that chlorine containing boron compounds indeed play an important role in the gas phase. The observation that the addition of hydrogen chloride to the gas phase during epitaxy causes a decrease of the efficiency of the boron incorporation process has been reported by Bloem (27). A similar phenomenon occurs if water vapor is present in the gas mixture (27, 28). As for lateral autodoping, a significant reduction of the lateral autodoping was observed if a chlorine-rich silicon source was used (Fig. 4).

The influence of temperature on the equilibrium composition is shown in Fig. 23. The strong enhancement of the stability of monoatomic boron with an increase of temperature is clearly visible. The activation energy E'_{act} is $+6.14$ eV. An enhancement of the incorporation efficiency at higher temperatures was indeed observed in the intentional doping experiments (cf. Experimental sec-

Fig. 17. Equilibrium composition of the P-Si-H-Cl-O system as a function of the P atomic fraction. Mass balance: 1% Cl; 1 ppm O_2 . Total pressure: 1 atm. Temperature: 1350 K.

tion). The increase of the lateral autodoping peak with temperature (Fig. 3) is a remarkable feature of the boron autodoping phenomenon ($E'_{act} = +6.07$ eV). The thermodynamic analysis shows that this increase can be accounted for completely by the temperature dependence of the monoatomic boron stability. The corrected value for the activation energy for autodoping of boron is $E_{act} = -0.07$ eV.

Conclusion

Essentially, the lateral autodoping caused by anti-mony-, arsenic-, phosphorus-, and boron-implanted layers can be described by a mechanism which explains the process in terms of evaporation, gas phase diffusion, and reincorporation. In order to explain the influence of process conditions on autodoping phenomena, this model has to be extended with a description of chemical reactions in the gas phase in which the evaporated dopant is involved. The autodoping level in the epilayer is related to the partial pressure of monoatomic dopant in the gas mixture according to Henry's law, which is valid if surface limitations to the incorporation process are absent. This was shown to be the case for boron doping. Diffusion-controlled incorporation has also been reported for phosphorus (15) and arsenic (14) for low growth rates. On the other hand, evidence for kinetic control of arsenic

Fig. 18. Equilibrium composition of the P-Si-H-Cl-O system as a function of the total pressure. Mass balance: 1% Cl; 1 ppm O₂; 10 ppb P. Temperature: 1350 K.

Fig. 19. Equilibrium composition of the P-Si-H-Cl-O system as a function of temperature. Mass balance: 1% Cl; 1 ppm O₂; 10 ppb P. Total pressure: 1 atm.

doping has been published (20), which may explain deviations from the expected behavior.

In general, the partial pressure of a dopant D is governed by the presence of a stable gaseous compound $D_kH_lCl_m$ according to the chemical equilibrium

The mass action law gives the relationship between the monoatomic dopant gas and the experimental conditions and, consequently, between the autodoping level and the process conditions.

For intentional doping

$$\frac{d(\log P_{D,eq})}{d(\log X_D)} = \frac{1}{k} \tag{12}$$

where $P_{D,eq}$ is the equilibrium pressure of monoatomic dopant D and X_D is the total atomic fraction of D in the gas phase.

The influence of the total pressure on lateral autodoping is analogous to the effect of the total pressure on the monoatomic dopant partial pressure

$$\frac{d(\log P_{D,eq})}{d(\log P_{tot})} = \frac{2 - l - m}{2k} \tag{13}$$

It should be noted that for $k = 1$ and $l = m = 0$ the chemistry becomes trivial and the equations reduce to the forms which are in agreement with the implications of the "physical" evaporation-diffusion-reincorporation model.

The presence of chlorine in the reaction gas mixture, introduced via either a chlorine containing silicon source or addition of hydrogen chloride, may affect the autodoping level according to the expression

$$\frac{d(\log P_{D,eq})}{d(\log X_{Cl})} = -\frac{m}{k} \quad [14]$$

which implies that the possible presence of stable dopant chlorides reduces the efficiency of the autodoping process. Hence, if the prevailing dopant species are hydrogen and chlorine containing compounds, the stability of monoatomic dopant gas is enhanced at reduced pressure, resulting in increased autodoping.

If the experimentally observed autodoping behavior of antimony, arsenic, phosphorus, and boron is considered, it appears that arsenic and antimony display a behavior that is qualitatively in agreement with the "physical" model; *viz.*, the autodoping level is reduced by reduction of the total pressure, an extension of the pre-epitaxial bake time, and a rise of temperature. As a matter of fact, an analysis of the chemistry of these systems makes it clear that chemical reactions in the gas phase do not affect the autodoping mechanism qualitatively. In contrast, for phosphorus and boron a different pattern is observed: the autodoping level is enhanced by reduction of total pressure, extension of the pre-epitaxial bake time, and increase of temperature. The increased autodoping at low pressure can be explained by the statement, deduced from the thermodynamic analyses, that in the case of phosphorus and boron the stability of the monoatomic dopant gas is enhanced by reduction of the total pressure. Analogously, the stability of monoatomic phosphorus and boron is considerably enhanced at higher temperatures. The effect of the duration of the pre-epitaxial bake time on boron autodoping remains as yet unexplained. It may be assumed that either accumulation of evaporated impurities at the substrate surface during the pre-epitaxial

bake or departure from pure equilibrium conditions due to kinetic limitations are responsible for these observations. Finally, it has been shown that, in agreement with the considerations given above, the presence of chlorine causes a notable reduction of the autodoping maximum in the case of boron, whereas in the cases of arsenic and phosphorus no effect was observed. This is explained by the assumption that stable boron chlorides can be formed, whereas according to the thermodynamic analyses no stable chlorides of arsenic and phosphorus are present.

Dry Etching of Tapered Contact Holes Using Multilayer Resist

R. J. Saia* and B. Gorowitz*

General Electric Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

Optimum coverage of contact holes by sputtered metals typically requires sloping of the sidewalls. A number of different types of photoresists and dry etch techniques have been examined for this purpose. Two processes which will be discussed include (i) replication of a presloped single-layer AZ-type photoresist profile by anisotropically etching the resist and the silicon dioxide at comparable rates, and (ii) controlled lateral etching of a vertical-walled poly (methyl methacrylate) (PMMA) layer of a two-layer resist, while etching silicon dioxide in the vertical direction. The latter process preserves the inherent accurate resolution of the vertical PMMA profile, while providing an opportunity for tailored and reproducible sidewall angles. The results of mass and emission spectroscopy suggest that atomic oxygen plays an important role in the lateral etching of the PMMA resist.

With continuously decreasing microcircuit element dimensions, the ability to accurately etch small contact holes or vias in the 1.0-2.0 μm range with controlled sidewall angles provides an opportunity for improved coverage of the sidewalls by the deposited metallizations.

The most widely used method of producing sloped sidewalls is to replicate a presloped single-layer AZ-type photoresist profile by anisotropically etching the resist and silicon dioxide at approximately the same rate. This process is difficult to control and has a number of other disadvantages (to be discussed below) that make it particularly unreliable when used with holes in the 1 μm range.

A new technique for reliably producing tapered contact holes or vias in the 1 μm range will be described. This technique utilizes poly(methyl methacrylate) (PMMA), the lower remaining layer of a two-layer resist, to define holes with initially vertical walls in the mask. The plasma gas chemistry and the process conditions were selected so that the resist is etched laterally at a controlled rate relative to the vertical etch rate of the silicon dioxide. The process has been demonstrated in both a batch-loaded low pressure reactive ion etcher, and a high pressure single-wafer plasma system. The contact sidewall angles could be controlled and varied from 35° to 90°. This process makes use of the inherent accurate resolution and vertical wall profile of the multilayered resist, while providing the ability to taper contact holes or vias as small as 1 μm diam or any other dimension which can be resolved by lithographic techniques.

Experimental

Two types of plasma etchers were used in this study: a batch-loaded reactive ion etcher and a single-wafer high pressure plasma system. The former was an Anelva Model 503. This system is manually loaded, with a capability for etching eight 75 mm diam wafers per run or a lesser number of larger wafers. It is equipped with a cryopumped high vacuum system capable of reducing background pressures to the 10⁻⁶ torr range between runs. The gases are introduced into the chamber circumferentially, and their flows are maintained by electronic mass flow controllers. A roots blower backed by a mechanical pump is used to evacuate the etchant gases and volatile products.

RF power, at a frequency of 13.56 MHz, is provided to the lower of two parallel plate electrodes in a stainless

steel chamber having a volume of about 60 liter. The wafers being etched are placed in holes in a graphite disk which covers the 42 cm diam water-cooled cathode.

The high pressure plasma etcher (Tegal Model 703) was a single-wafer, cassette-to-cassette system. The reactant gases and the reaction products enter and exit, respectively, through arrays of holes in the upper electrode. The upper and lower electrodes are fabricated from aluminum and are separated by a gap of 6 mm. Both electrodes are water cooled. Excitation energy to the lower electrode, which holds the wafer, is provided by a 1000W solid-state RF generator operating at 13.56 MHz.

Analysis of the plasma was performed with an Inficon IQ200 quadrupole mass spectrometer, and a P.T. analytical PSS100 optical emission spectrometer. Both systems were attached to ports in the chamber of the batch reactive ion etching systems.

The silicon dioxide films that were etched were deposited on 75 mm diam silicon wafers by low pressure chemical vapor deposition (LPCVD) using dichlorosilane and nitrous oxide at 900°C. The wafers were then cleaned by standard techniques and coated with the photoresist systems described below.

Etch rates of photoresist and silicon dioxide were determined using a Sloan Dektak II profilometer and a Nanometrics Nanospec film thickness measuring system. Sidewall angles and the amount of lateral etching were measured using scanning electron microscopy.

Profile Control Using Preshaped Photoresist

One method of achieving sloped or tapered silicon dioxide contact hole sidewalls involves controlled photoresist erosion (1, 2). If the photoresist is preshaped to have a sloped profile before etching, the etch rate of photoresist with respect to silicon dioxide can be adjusted so that anisotropic etching of both will increase the photoresist hole diameter as the silicon dioxide is being etched in a vertical direction. This results in the formation of a slope in the oxide sidewall.

In this experiment, the LPCVD oxide films were masked with 10,000Å of Shipley AZ1470 positive photoresist. The photoresist profile was preshaped by reflow baking in a vacuum oven (100 mtorr) at 135°C for 30 min. Figure 1 shows the typical photoresist profile after standard projection lithography, after preshaping the photoresist, and after etching the silicon dioxide at 1:1 and 1.5:1 resist-to-oxide etch-rate ratios. Mixtures of NF₃

and Ar were used in the batch reactive ion etcher to vary the relative etch rates and, consequently, the incline angle of the contact hole sidewall. For example, as can be seen in Fig. 2, approximately equal etch rates of photoresist and silicon dioxide were obtained on planar topography using 20% NF_3 in Ar.

This process for forming sloped sidewalls can be employed reliably for contact holes in the 2 μm or larger range if precise control of the slope and bottom hole dimensions are not required. The photoresist profile depends on the initial lithographic exposure conditions, the surface topography of the wafer, and contact hole size. The resist reflow process is also sensitive to such factors as moisture, white light, temperature, and pressure, if reflowing is done in a vacuum oven. Figure 3 shows the effects of attempts to use the reflow method to produce tapered holes in the 1 μm range. A vacuum bake at 135°C for 15 min only round the top half of the resist profile, while longer oven exposures only decrease the hole diameter until finally it closes completely at the oxide interface. Under some conditions, it has been possible to avoid resist reflow by using the slope inherent to a particular lithographic tool or process. However, the range of conditions for successful use of the sloped resist profile to

make tapered oxide holes in the 1 μm range is obviously quite narrow, and precise control is difficult.

Tapered Contact Holes Using Multilayer Resist

To avoid the problem of variable photoresist profile and to avoid the need for a resist reflow process, it is desirable to use a high resolution photoresist patterning method that can produce vertical resist sidewalls which offer the best opportunity for precise control of contact hole dimensions. The production of sloped contact sidewalls without sloped photoresist, however, requires

Fig. 5. Contact sidewall angle and etch rate of silicon dioxide and PMMA vs. percentage O_2 in $\text{C}_2\text{F}_6/\text{He}/\text{O}_2$. Etching parameters: flow = 50 sccm, 20% C_2F_6 ; pressure = 2.0 torr; power = 400W.

that the photoresist mask be laterally etched as the silicon dioxide is vertically etched.

The basic steps in pattern formation, using one method of two-layer resist lithography are described in detail elsewhere (3-5). A thick (e.g., 1.5-2.5 μm) planarizing layer of PMMA (avg. Mw \sim 496,000) is applied to the wafer and baked at 200°C for 30 min in a nitrogen atmosphere. The PMMA is then coated with a 3000Å layer of AZ-type photoresist. After exposing and developing the top layer in a conventional manner, the lower PMMA layer is exposed with UV radiation (220-250 nm) using the upper layer as a mask. The PMMA is then developed and the AZ resist layer is removed. The resulting vertical-walled PMMA mask apertures must then be laterally etched at the same time as the silicon dioxide is being vertically etched. Theoretically, the tangent of the incline angle (shown in Fig. 4) produced by this method is equal to the quotient of the vertical etch rate of silicon dioxide and the lateral etch rate of PMMA.

The incline angle θ could be varied in the high pressure etcher from about 55° to 35° by adding oxygen to a $\text{C}_2\text{F}_6/\text{He}$ mixture (see Fig. 5). It can be seen from Fig. 5 that the vertical etch rates of PMMA are relatively high, but with typical interlevel dielectric thicknesses of 4000-5000Å, the loss of resist is not a problem. Figure 6 is a scanning electron microscopy (SEM) photo of a contact hole that was etched using this method. The remaining PMMA is still fairly vertical although the slope of the contact hole is about 60°.

The incline angle could also be controlled from 90° to 35° by adding oxygen to a mixture of CHF_3/Ar in the batch reactive ion etcher (see Fig. 7). To obtain a higher selectivity ratio of silicon dioxide to silicon, a two-step etch can be used in which oxygen is removed from the gas mixture in the second step.

Using an AZ- or Novolak-type resist, tapered contact holes could not be produced with the above conditions because this material did not etch laterally in the range of conditions investigated. What appears to be true lateral etching of photoresist has been observed by others using different etch conditions and gas compositions (6).

PMMA is known to have relatively poor plasma-etch resistance (7). In the case described here, this can be used to advantage. Novolak or AZ resists, conversely, tend to have a higher etch resistance, because they are condensation-type aromatic polymers. With condensation polymers, chain scissioning events during exposure to the plasma might not propagate sufficiently to produce large numbers of fragments that are small enough to be volatile. Acrylates such as PMMA, however, are addition-type polymers that can readily "unzip" via radical intermediates into low molecular weight volatile species.

Two of the species that are known to degrade and etch organic photoresist are atomic oxygen and fluorine.

Fig. 7. Contact hole sidewall angles and selectivity of PMMA to silicon dioxide vs. percentage of O_2 in $\text{CHF}_3/\text{Ar}/\text{O}_2$. Etching parameters: flow = 40 sccm, 38% CHF_3 in Ar; pressure = 30 mtorr; power = 225W.

Atoms or radicals are not affected by the sheath electric field of the plasma and therefore can etch in the lateral as well as the vertical directions if the sidewalls are not protected. Oxygen atoms influence the durability of PMMA (8, 9) since they are excellent radical initiators, and can therefore contribute to or enhance the lateral etch rate of PMMA.

Fluorine atoms that are generated in a plasma discharge can also abstract hydrogen from organic polymers providing unsaturated or radical sites. Compared to a normal saturated polymer chain, these sites are highly reactive

and easily combined with oxygen (10). The exothermic nature of hydrogen abstraction by fluorine can itself be enough to cleave carbon-carbon bonds (11).

Figure 8 shows the relative intensity of both F and O atom signals, using both emission and mass spectroscopy, as functions of oxygen addition to CHF_3/Ar . It can be seen that the population of atomic oxygen increases, while atomic fluorine is relatively constant as oxygen is added. This suggests that atomic O plays more of a role than does atomic F in the lateral etching of PMMA, because its presence correlates with the degree of slope produced.

While etching with a gas mixture that does not contain oxygen (for example, NF_3 and Ar), the incline angle could only be controlled from 60° to 73° (see Fig. 9). The corresponding percentages of NF_3 in Ar resulted in large differences in the amount of atomic fluorine present (see Fig. 10). The fact that the incline angles could only be controlled over a small range, in spite of a large difference in the amount of atomic F present, further demonstrates that atomic oxygen has a larger effect. Similar results were also observed for the etching of polyimide in CF_4/O_2 and SF_6/O_2 (12).

Summary

Tapered contact holes or vias were produced using a high resolution two-level resist, without preshaping the vertical-walled resist mask with a reflow method. Contact hole sidewalls were sloped by the controlled lateral etching of a PMMA mask while etching silicon dioxide in the vertical direction.

This process was demonstrated in both a high pressure plasma etcher and a low pressure reactive ion etcher. Mass and emission spectroscopy data suggest that atomic

Fig. 10. Relative intensity of F and O atom signals vs. percentage of NF_3 in Ar using mass spectroscopy.

oxygen plays a more important role in the lateral etching of PMMA than does atomic fluorine.

ABSTRACT

The incorporation of silicon in GaAs layers grown by metal-organic chemical vapor deposition has been studied using two different doping sources, silane and disilane. Epitaxial layers were grown on $\langle 100 \rangle$, $\langle 111 \rangle_A$, and $\langle 111 \rangle_B$ surfaces over a wide range of growth temperature and gas phase stoichiometry. When using silane, an influence of the substrate orientation on silicon incorporation was found. This behavior can be described by a qualitative model involving both the surface specific adsorption sites and possible surface chemical reactions. In the case of disilane, the incorporation process appears to be independent of substrate orientation and growth temperature. This temperature independence results in improved uniformity of the electron concentration over large substrate areas when disilane is used as the doping gas.

Silicon is commonly used as a dopant for the growth of n-type GaAs and $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers in metal-organic chemical vapor deposition (MOCVD) (1-3) and in molecular beam epitaxy (MBE) (4). The low volatility and low diffusion coefficient of silicon in GaAs are properties which make this dopant especially useful for the deposition of layers for device structures requiring abrupt dopant profiles (2). Perhaps a more important requirement for the fabrication of digital devices is the uniformity of the dopant concentration across large substrate areas. Doping with silicon in the MOCVD growth of GaAs and $\text{Al}_x\text{Ga}_{1-x}\text{As}$ is most commonly achieved by the addition of small amounts of silane (SiH_4) to the growth ambient. The silicon concentration exhibits a strong dependence on growth temperature when using silane (1-3). A strong temperature dependence of incorporation can lead to problems in obtaining uniform and reproducible doping levels over large substrate areas (3). We have recently shown that by using disilane (Si_2H_6) as the doping gas, the incorporation of silicon is made independent of growth temperature (5). Owing to this unique behavior of disilane, we expect an improvement in uniformity and reproducibility of the carrier concentration.

Only limited information is available in the literature on the incorporation process of silicon in GaAs MOCVD layers. Generally, the strong temperature dependence of silane as a doping source has been attributed to the stability of the SiH_4 molecule. It is assumed that the incorporation process is rate limited by the decomposition of the SiH_4 molecule (6). If this is the case, the growth temperature would be the major influence on silicon incorporation. The relative importance of the gas phase chemistry between the pyrolysis of SiH_4 and Si_2H_6 can in part be estimated by calculations based on the homogeneous decomposition kinetics of Si_2H_6 and SiH_4 using the available kinetic rate constants (7, 8). These calculations indicate that under our experimental conditions Si_2H_6 reaches gas phase equilibrium with its decomposition products (SiH_2 , SiH_3 , Si_2H_5 , Si_3H_{10} , etc.) on a time scale several orders of magnitude faster than SiH_4 (9), which indicates that SiH_4 is substantially more stable than Si_2H_6 in the gas phase. As a consequence, silicon doping by means of silane decomposition is expected to be more sensitive to reactions at the growing surface than to the gas phase chemistry present in the MOCVD growth ambient.

In the present study, we have investigated the influence of growth parameters, particularly the influence of adsorption sites at the surface, on silicon incorporation when using SiH_4 and Si_2H_6 as doping gases. Substrates of differing orientation were used to alter the number and nature of the adsorption sites present. Growth temperature and gas phase stoichiometry [$\text{AsH}_3:\text{Ga}(\text{CH}_3)_3$ ratio] were also varied over a wide range. To our knowledge, the effect of substrate orientation on the incorporation of Si has previously been studied only for layers grown by liquid phase epitaxy (LPE) (10). In the present study, the same saturation value of the electron concentration of $n \approx$

$5 \times 10^{18} \text{ cm}^{-3}$ is reached, for both SiH_4 and Si_2H_6 . This saturation value has also been reported for MBE (4) and other MOCVD layers (11). The amphoteric nature of silicon in GaAs which is well known for LPE material (12, 13) has been investigated here, particularly at high silicon concentrations. When SiH_4 is used as the dopant source the incorporation behavior of silicon appears similar to that of carbon (14). A correlation between the incorporation of silicon and carbon due to possible surface reactions between their adsorbed species is discussed below. The uniformity of dopant concentration across large substrate areas is compared for the two doping gases.

Growth and Characterization

The layers were grown in a horizontal MOCVD system at a reactor pressure of 77 torr on Cr-doped semi-insulating GaAs substrates. Starting materials were $\text{Ga}(\text{CH}_3)_3$ (TMG) and AsH_3 in a hydrogen carrier gas. SiH_4 and Si_2H_6 were used as doping gases, supplied in the form of dopant/ H_2 mixtures. Three different substrate orientations were used simultaneously during the runs for the study of the influence of adsorption sites on doping: $\langle 100 \rangle$, $\langle 111 \rangle_A$ ($\langle 111 \rangle_{\text{Ga}}$), and $\langle 111 \rangle_B$ ($\langle 111 \rangle_{\text{As}}$). The substrates were cleaned according to a standard procedure (14). The growth rate was held constant in all experiments at $0.05 \mu\text{m}/\text{min}$. The V:III [$\text{AsH}_3:\text{Ga}(\text{CH}_3)_3$] ratio was varied between 20 and 80, although most of the layers were deposited at a V:III ratio of 40. The linear gas velocity was approximately 30 cm/s in the 75 mm diam reactor. The substrates were placed on a RF-heated graphite susceptor during growth. Further experimental details are described in Ref. (15).

The silicon concentration in the layers was determined by secondary ion mass spectrometry (SIMS). The layers were characterized by electrical measurements using capacitance profiling and the van der Pauw-Hall method (16). Photoluminescence measurements were performed at room temperature. The luminescence was excited by the 4880 Å line of an argon laser and detected by a cooled S-1 photomultiplier tube.

In order to measure the uniformity of the carrier concentration across large substrate areas, growths of large area $\langle 100 \rangle$ substrates ($\sim 30 \text{ cm}^2$) were undertaken. Two growths under identical conditions were made. Silane was used as the doping source for one growth, and disilane was used in the second. The growths were carried out at a substrate temperature of 650°C. The carrier concentration was measured across the substrate surface by capacitance profiling, which has a measurement accuracy of approximately 5%.

Experimental Results

The influence of substrate orientation on silicon incorporation is shown in Fig. 1 and 2. Doping with SiH_4 was investigated over the range of the growth temperature 600°-900°C (Fig. 1). The well-known temperature dependence of the electron concentration determined by Hall measurements can be observed on all three surfaces. Over

Fig. 1. Influence of growth temperature on electron concentration for the $\langle 100 \rangle$, $\langle 111 \rangle$ A, and $\langle 111 \rangle$ B surfaces when using SiH_4 as doping gas.

the entire temperature range, the carrier concentration in layers grown on the $\langle 111 \rangle$ B surface is systematically the highest; on the $\langle 111 \rangle$ A it is the lowest. The slope of the curves are the same within the accuracy of measurement for the three surfaces which corresponds to an activation energy (ϵ) of 1.5 eV. This activation energy is in agreement with former studies for the $\langle 100 \rangle$ surface (1-3). The surface morphology of the layers grown on the $\langle 111 \rangle$ substrates exhibited hillocks that are characteristic for the particular surface, as described in Ref. (17). The $\langle 100 \rangle$ surfaces always gave a smooth specular surface morphology. Experiments were carried out in the range of 650°-800°C with Si_2H_6 as doping gas (Fig. 2). The accuracy of measurement was 5% for the $\langle 100 \rangle$ and 15% for the $\langle 111 \rangle$ samples. The latter is indicated by error bars in Fig. 2. A primary source of measurement uncertainty is attributed to fluctuations in the film thickness due to the rough morphology of the $\langle 111 \rangle$ surfaces. There is no influence of substrate orientation at the lower growth temperatures, while at higher temperatures above 760°C an influence can be recognized. A comparison of these figures shows that doping with Si_2H_6 is much more efficient than with SiH_4 , as discussed earlier (15). The electron concentration was inversely proportional to the growth rate for both silane and disilane doping. The mole

Fig. 2. Electron concentration as a function of growth temperature for the $\langle 100 \rangle$, $\langle 111 \rangle$ A, and $\langle 111 \rangle$ B surfaces when using Si_2H_6 as a doping gas.

fractions of the doping gas were therefore normalized with respect to the growth rate. Both sets of experiments in Fig. 1 and 2 were obtained at a V:III ratio of 40. The V:III ratio had only a weak influence on the electron concentration. For Si_2H_6 a slight increase and for SiH_4 a slight decrease of carrier concentration was observed as this ratio was increased from 20 to 80. The systematic change in carrier concentration was of ~15% in both cases.

The electron concentration in the layers increases linearly with the silicon concentration in the gas phase and saturates at a level of $n \approx 5 \times 10^{18} \text{ cm}^{-3}$. The SIMS measurements show that the silicon concentration equals the electron concentration for the $\langle 100 \rangle$ and $\langle 111 \rangle$ surfaces up to an electron concentration in the low 10^{18} range. At electron concentrations in the saturation region, silicon concentrations up to 10^{20} cm^{-3} were detected.

In the uniformity study previously described, the silane samples showed a fluctuation in carrier concentration of $\Delta n/n \sim \pm 0.15$ over each sample area; the lowest concentrations were obtained at the edges of the graphite susceptor. For the disilane samples we found $\Delta n/n \sim \pm 0.05$ for each sample, with the fluctuation occurring randomly over the substrate surface.

The Hall mobilities measured at room temperature for the silicon-doped samples are plotted as a function of electron concentration in Fig. 3. The solid line represents a fit to the experimental data from layers grown by different techniques [i.e., MBE, LPE, MOCVD, and inorganic vapor phase epitaxy (VPE)] under different experimental conditions (18, 19). In the range of $n = 10^{16}$ - 10^{18} cm^{-3} , the mobilities depend only on the carrier concentration. Both SiH_4 and Si_2H_6 yielded mobility values which are in agreement with this empirical curve.

The results of the photoluminescence measurements on the silicon-doped samples are shown in Fig. 4. The full width at half maximum (FWHM) of the band-edge luminescence is plotted vs. the electron concentration over the range of $n = 1 \times 10^{16}$ to $5 \times 10^{18} \text{ cm}^{-3}$. At low electron concentrations, the FWHM is almost independent of n , whereas above $n \approx 3 \times 10^{17} \text{ cm}^{-3}$ it exhibits a distinct increase with carrier concentration. The same spectra were obtained for both doping gases.

Discussion

Silicon doping during the growth of GaAs can be divided into the process of the physical incorporation of the Si and the electrical activation of the incorporated Si. The first process consists of the transport of the Si source molecule to the growth front, possible adsorption, its decomposition at or near the surface, and the removal of any reaction by-products. In order to become activated as a shallow electrically active impurity, the incorporated Si must reside on specific substitutional lattice sites in the GaAs. The electrical activation of the Si occurs subsequent to its incorporation. These two processes are not necessary correlated.

Fig. 3. Dependence of Hall mobilities 300 K on electron concentration. Doping gas: SiH_4 and Si_2H_6 . The solid line is the empirical curve from Ref. (19).

Fig. 4. Full width at half maximum (FWHM) of photoluminescence spectra at room temperature as a function of electron concentration.

The physical incorporation of Si is dependent on both the mass transport of the Si source specie and its subsequent reaction with the crystal surface and growth ambient. The growth conditions during LPE are close to thermal equilibrium, where both the incorporation and activation of the Si can be predicted from equilibrium thermodynamic considerations. In VPE and MOCVD growth of GaAs, the process of Si incorporation can be dominated by surface chemical reactions at the growth front.

The dopant activation, particularly in the case of an amphoteric dopant such as Si, is dependent on the stoichiometry of the crystal which is determined by the exact growth conditions (*e.g.*, temperature and As activity). The nature of the incorporated Si as either a donor or acceptor impurity will depend on the thermodynamic state specific to the growth technique and conditions. Calculations for the site selection predict an incorporation of silicon both on gallium and on arsenic sites under LPE growth conditions, whereas in VPE and MOCVD GaAs layers silicon should be incorporated only as a donor (13). This difference in electrical behavior is expected, because LPE is carried out under gallium-rich conditions, but MOCVD and VPE under arsenic-rich conditions. Photoluminescence data reported in the literature are in agreement with the theoretical thermodynamical site predictions mentioned above (13, 20), *i.e.*, silicon is a donor in layers grown by the MOCVD technique (20). A comparison of our SIMS data with our Hall data supports the conclusion that up to concentrations in the low 10^{18} region silicon is predominately incorporated on gallium sites.

At electron concentrations in the saturation region, the silicon incorporation continues with increasing silicon concentration in the gas phase. This difference between electron concentration and silicon concentration can be caused by compensation due to the amphoteric nature of silicon, by precipitations, or by complex formation. Data which are similar to our results were reported for diffusion of silicon into GaAs (21), where a maximum electron concentration of $5.6 \times 10^{18} \text{ cm}^{-3}$ and a maximum silicon concentration (SIMS) of $2 \times 10^{20} \text{ cm}^{-3}$ were achieved. In that study, the authors concluded that silicon is almost completely compensated due to its amphoteric character (21). Compensation at high doping levels is not unique to the potentially amphoteric Group IV dopants in GaAs. Behavior similar to that of silicon has also been observed in the case of sulfur doping of GaAs in the hydride system (22). In the case of sulfur, SIMS data indicated that beyond the saturation level of the electron concentration the sulfur incorporation still continues. Sulfur, as a Group VI element, is a substitutional impurity residing on arsenic sites and should act only as a donor. It was proposed that at high concentrations sulfur is incorporated as a complex, *e.g.*, a sulfur atom on an arsenic site com-

plexed with a vacancy. Alternatively, precipitations might appear at these high concentrations. When the silicon concentration is high, the incorporation behavior certainly is analogous, with most of the silicon no longer being a simple donor; *e.g.*, complexes between silicon on a gallium site and a vacancy or between silicon on a gallium site and silicon on an arsenic site may be formed. The Hall mobilities drop steeply in the saturation region of the electron concentration for silicon doping (Fig. 3) as well as with sulfur doping (22), indicating a strong compensation for both dopants. Studies of transmission electron microscopy and Rutherford backscattering channeling measurements on high dose silicon- and sulfur-implanted GaAs yield low precipitation (5 and 4%, respectively) and high substitutionality (70 and 85-90%, respectively) (23). The high substitutionality found for the dopants indicates that for both sulfur and silicon the formation of defect complexes at high doping levels is likely despite the substantial difference in the chemical nature of these two species.

Our results in Fig. 1 and our SIMS measurements indicate that for SiH_4 as the doping source more silicon is incorporated in layers grown on the $\langle 111 \rangle \text{B}$ surface than the $\langle 100 \rangle$ and $\langle 111 \rangle \text{A}$ surfaces. In LPE layers, the opposite behavior was found (10). However, the direct comparison between LPE and MOCVD layers is difficult, because of the difference in growth conditions as mentioned above. Our results show the importance of the adsorption site for silicon incorporation. The arsenic surface ($\langle 111 \rangle \text{B}$) seems to be the most active surface. This result is not unexpected, if one takes into account the nature of the ideal GaAs surfaces. The ideal gallium surface ($\langle 111 \rangle \text{A}$) has no free electron pair per surface atom, whereas the arsenic surface has one pair per atom, which would probably lead to enhanced adsorption of SiH_4 molecules on this surface. An analogous behavior was found for doping with sulfur in the hydride system, where the highest incorporation rate was obtained for the $\langle 111 \rangle \text{B}$ surface and the lowest for the $\langle 111 \rangle \text{A}$ surface (22).

There are instructive parallels between our observations of Si incorporation and the previous results on carbon incorporation in MOCVD GaAs (14). It was concluded that on the $\langle 111 \rangle \text{B}$ surface more hydrocarbons are adsorbed than on the $\langle 100 \rangle$ and $\langle 111 \rangle \text{A}$ surfaces. This leads to the highest carbon concentration in $\langle 111 \rangle \text{B}$ layers and the lowest in $\langle 111 \rangle \text{A}$. For decreasing growth temperature and increasing V:III ratio a decrease in carbon incorporation was found. The analogous behavior of silicon incorporation to carbon incorporation might be expected from the similar chemistry of the methane and the silane molecule. If we assume that the thermally stable SiH_4 molecule is adsorbed at the growth surface, it has to decompose by a specific surface reaction. The SiH_4 molecule is probably decomposed through a hydrogen transfer reaction. In such a reaction, the SiH_4 molecule is broken down by the transfer of hydrogen to either the GaAs surface or to other adsorbed species such as CH_3 . In the latter case, an increased density of adsorbed hydrocarbons at the surface might lead to an enhanced decomposition of SiH_4 molecules, thus explaining the increased silicon incorporation observed on $\langle 111 \rangle \text{B}$ layers. The exact nature of these surface chemical reactions is a subject of continuing research.

Using Si_2H_6 as the doping source, we do not expect this influence on substrate orientation, since Si_2H_6 is readily decomposed at the growth temperature (7, 24). If Si_2H_6 decomposes rapidly at or below the typical GaAs growth temperatures, the incorporation of silicon would be limited by the gas phase mass transport of Si_2H_6 to the growth front rather than by surface reaction kinetics. This would result in a weak or negligible temperature dependence to the silicon incorporation. Our experimental results follow these expected trends (Fig. 2). Assuming equal diffusivity of Si_2H_6 and $\text{Ga}(\text{CH}_3)_3$ in hydrogen, one might estimate a doping efficiency of 0.3 from Fig. 2. The interpretation of the numerical value is doubtful as the exact mole fractions of Si_2H_6 and $\text{Ga}(\text{CH}_3)_3$ at the sub-

strate surface cannot be determined without a direct *in situ* measurement. Additionally, since the actual species responsible for Si incorporation from Si_2H_6 is unknown, we cannot determine whether each Si_2H_6 molecule contributes one or two Si atoms to the crystal. The independence of temperature has important consequences for the uniformity of dopant incorporation across large substrate areas. The temperature distribution at the substrate holder will not always be completely uniform in a susceptor system. Due to the strong dependence of silicon incorporation on growth temperature for SiH_4 (Fig. 1), variations in the carrier concentrations are expected. A change in the substrate temperature (ΔT) of 1° at 650°C leads to a variation in carrier concentration ($\Delta n/n$) of 2% according to the following equation, where k is the Boltzmann constant

$$\frac{\Delta n}{n} = \frac{\epsilon \Delta T}{kT^2}$$

Another complicating factor in obtaining uniformity is the thermalization of the gas stream. In a typical MOCVD reactor, the substrate is the only directly heated area. Therefore, the doping gas heats up in the flow direction so that the molecules probably decompose more efficiently downstream than upstream. This effect leads to an increased silicon incorporation in the flow direction for SiH_4 . This effect has already been observed (3). The exact nature of the decomposition process of SiH_4 is yet unknown. Only *in situ* measurements which can distinguish the actual Si species present might clarify whether the rate-limiting processes take place in the gas phase or on the surface. In our silane samples, the decrease of carrier concentration at the edges of the substrate holder indicates a lower growth temperature in these regions, as expected for RF-heated graphite susceptors. In the disilane samples, the variation of the carrier concentration is not systematic across the substrate surface. This improvement of the uniformity across large substrate areas can be realized because of the absence of a temperature dependence of the incorporation process for disilane.

Our mobility data (Fig. 3) show that with Si_2H_6 the same high values can be reached as with other dopant materials at concentrations below the saturation of the electron concentration. It may be concluded that for both SiH_4 and Si_2H_6 the final electrical state of silicon in the crystal lattice appears to be the same. For Si_2H_6 , no additional compensation, for example due to additional carbon in the layers, could be detected. The results of our photoluminescence measurements support this conclusion (Fig. 4). Our data lie in the range of the curve reported for tellurium-doped melt-grown GaAs (25), which were obtained by cathodoluminescence. Additional broadening of the luminescence peaks, reflected in an increased peak width at half maximum, is expected for compensated material. This was not observed for our samples. However, our results disagree with data previously reported for silicon-doped MOCVD grown layers, where larger peak width values and an anomalous luminescence behavior were reported (11). Furthermore, our luminescence data demonstrate that the peak width depends strongly on the carrier concentration at levels higher than $3 \times 10^{17} \text{ cm}^{-3}$. Consequently, room temperature luminescence can be used in order to estimate the carrier concentration, as proposed in Ref. (25). This has the advantages of being a simple, fast, and nondestructive technique.

Summary

A study of silicon incorporation in MOCVD GaAs layers has been presented. Silane and disilane were used as doping sources. With both doping gases, electron concentrations up to a saturation value of $5 \times 10^{18} \text{ cm}^{-3}$ can be

reached. Below this saturation value, the silicon concentration in the layers equals the electron concentration, with silicon incorporated only as a donor. Above the electron concentration saturation value, silicon concentrations up to 10^{20} cm^{-3} have been measured. The incorporation of silicon using silane as the doping source depends on the substrate orientation. This orientational dependence is absent for disilane over the main growth temperature range. It appears that the decomposition of the stable silane molecules is determined by a surface reaction, possibly one with adsorbed hydrocarbons. The use of disilane instead of silane as the doping source leads to an improvement of the uniformity of carrier concentration across large substrate areas.

Transient-Enhanced Diffusion during Furnace and Rapid Thermal Annealing of Ion-Implanted Silicon

ABSTRACT

A transient-enhanced diffusion has been observed during the furnace or rapid thermal annealing of ion-implanted silicon. We have studied this transient in detail and show that, for doses of Group V dopants sufficient to amorphize the silicon, it arises from the trapping of interstitials by dopant atoms during implantation. These are retained during solid-phase-epitaxial (SPE) growth, but can be released by additional thermal processing to cause the observed transient and the formation of a band of extended defects. We have measured the enhanced diffusion coefficients and the duration of the transient for Sb-implanted Si by careful furnace annealing experiments. We obtain general expressions which predict the effects of the transient during any thermal processing based on SPE growth (furnace, CW laser, or rapid thermal annealing). We show that there is no analogous mechanism of vacancy trapping by Group III elements.

There have been many reports of transient-enhanced diffusion during furnace (1) or rapid thermal (2-5) annealing of ion-implanted silicon. The origin of these effects has, however, been the subject of considerable speculation. In this paper, we study the large transient diffusion which arises from the annealing of high concentrations of trapped point defects as they return to equilibrium concentrations. The transient will be large, since the activation energy corresponds to only the migration enthalpy of the point defects, but will only last until their concentration reduces to normal values. We distinguish between two possible origins of such nonequilibrium point-defect distributions. The first is ion-implantation damage resulting from the implantation of light atoms or low doses of heavy atoms. The silicon is damaged but not amorphized, and subsequent thermal processing to anneal the damage will cause transient-enhanced diffusion of the dopant. This mechanism is referred to as radiation-enhanced diffusion. A second mechanism, which is the principal subject of this paper, can occur when the silicon is turned amorphous before or during implantation. We show that large numbers of Si atoms are trapped by Group V dopant atoms in the amorphous material during implantation. These are retained during solid-phase-epitaxial (SPE) growth, but can be released later during thermal processing to give the transient-enhanced diffusion. We characterize the effect by careful study of Si-Sb alloys and their behavior during furnace annealing and arrive at a model which can predict the transient effects for any concentration of Sb or Bi dopants sufficient to amorphize the silicon, and any thermal processing technology which relies on SPE growth (furnace, CW laser, or rapid thermal annealing). Reasonable agreement is also obtained for the enhanced As diffusion seen during rapid thermal annealing. We show that there is no analogous effect for Group III elements. Finally, we discuss the various mechanisms for enhanced diffusion and their resulting dopant and defect distributions.

Experimental

To measure the enhanced diffusion coefficients during the transient, supersaturated alloys were produced by $^{121}\text{Sb}^+$ or $^{209}\text{Bi}^+$ ion implantation into {100} Si followed by SPE growth in a furnace under flowing dry N_2 gas, typically at 575°C for 40 min. Special implantation schemes were employed so as to produce a high concentration band of dopant well removed from the amorphous/crystalline interface, where radiation-enhanced diffusion would occur. Transient diffusion coefficients were then measured within the band of high, uniform concentration

by precipitating out a small fraction of the dopant and measuring the precipitate size distribution by transmission electron microscopy (TEM) (1). Figure 1 shows a Rutherford backscattering spectroscopy (RBS) analysis for one Si-Sb alloy. By scaling the implant doses, various concentrations could be achieved within the uniform band. Figure 2 shows the effect of additional furnace annealing. A band of precipitates formed within the region of uniform concentration, well removed from the damage layer marking the original amorphous/crystalline interface. The uniform dopant concentration allowed an accurate measure of diffusion coefficients as a function of concentration and temperature and ensured that no electric fields were present to affect the diffusion. Both float-zone and Czochralski silicon gave identical results. Transient diffusion coefficients were also measured in a Si-Bi alloy by the same technique.

To study possible point-defect trapping in Si-B alloys, float-zone silicon was first amorphized by $^{30}\text{Si}^+$ implantation (175 keV, $1.5 \times 10^{16} \text{ cm}^{-2}$) at liquid nitrogen temperature, followed by $^{11}\text{B}^+$ (35 keV, 1×10^{16} or $1.5 \times 10^{16} \text{ cm}^{-2}$) implantation. The low energy B implantation produced a broad profile with a large region of fairly uniform concentration. These samples were then SPE grown by furnace annealing at 575°C/1.5h, and diffusion coefficients were measured as before.

Some samples of the $^{121}\text{Sb}^+$ -implanted Si and of $^{75}\text{As}^+$ -implanted (100 keV , $1.0 \times 10^{16} \text{ cm}^{-2}$) Si were rapid thermally annealed using a graphite strip heater under flowing dry nitrogen gas, and the resulting precipitate and loop size distribution studied by TEM and RBS.

Determination of transient diffusion coefficients.—Transient diffusion coefficients D^* were determined for Si-Sb and Si-Bi alloys by furnace annealing for suitable times and temperatures so as to precipitate out a small amount of dopant. The precipitate size distribution observed by TEM allowed the measurement of D^* as a function of temperature and dopant concentration. Typical results are shown in Fig. 3. With high dopant concentrations, it was possible to precipitate some of the dopant with very few loops being generated (Fig. 3a). With continued annealing, loops nucleated at existing precipitates (Fig. 3b) and grew, finally achieving a constant size and number density. This marked the end of the transient; no further precipitation occurred at these low temperatures. Since only a small fraction of dopant had been precipitated, the concentration of dopant in solution was little changed, but the diffusion coefficients dropped by or-

Fig. 3. Results of furnace annealing of Si-Sb alloys of various concentrations. $9.3 \times 10^{20} \text{ cm}^{-3}$ at $700^\circ\text{C}/20 \text{ min}$ (a) and at $720^\circ\text{C}/20 \text{ min}$ (b). $5.0 \times 10^{20} \text{ cm}^{-3}$ at $740^\circ\text{C}/20 \text{ min}$ (c), $780^\circ\text{C}/20 \text{ min}$ (d), and $2.8 \times 10^{20} \text{ cm}^{-3}$ at $850^\circ\text{C}/20 \text{ min}$ (e). Shown are the underlying bands of loops in thick regions.

ders of magnitude. This transient cannot be explained by concentration-enhanced diffusion (6). It is clearly caused by trapped point defects which are released by the anneal, and result in transient-enhanced dopant diffusion before finally condensing into loops. The nature of the loops, therefore, indicates the nature of the trapped point defects. We have determined them to be interstitial in nature, in agreement with other workers (7) and to be faulted, lying on $\{111\}$ planes, and with Burger's vectors of $a/3 \langle 111 \rangle$ (1). This is a clear demonstration of the interstitialcy mechanism of diffusion, whereby substitutional dopant atoms are displaced from site to site by passing interstitials.

At lower dopant concentrations, higher temperatures were needed to cause Sb precipitation, and fewer measurements of diffusion coefficients could be obtained before the concentration of interstitials was significantly reduced by condensation into loops (Fig. 3c, 3d). At even lower concentrations, no loops at all were observed within the band of precipitates (Fig. 3e). Clearly, the interstitials are now being removed by other means, either to the surface, to the underlying damage band, or by recombination with thermally generated vacancies.

The diffusion coefficients determined before significant loop formation are shown on an Arrhenius plot in Fig. 4. They are greatly enhanced over tracer values (8) and show an activation energy of $1.8 \pm 0.2 \text{ eV}$. The low activation energy compared to the tracer value of 3.96 eV again rules out the possibility of concentration-enhanced diffusion effects (6), and corresponds simply to the migration enthalpy of the Sb by the interstitialcy mechanism. However, the enhancement is indeed a strong function of concentration. Figure 5 shows the Sb diffusion coefficient D^* measured or extrapolated to 680°C as a function of Sb concentration C_0 and ion-implantation conditions. It is clear that D^* is proportional to C_0 , although it is higher for room temperature implants than liquid nitrogen implants. This shows that the interstitials are trapped by Sb atoms, since then their concentration $C_i = \alpha C_0$, where α is the fraction of Sb atoms which trap an interstitial, and $D^* = C_i D^{\text{Sb}} = \alpha C_0 D^{\text{Sb}}$, where D^{Sb} is the diffusivity of Sb by the interstitialcy mechanism (9). In the case of the high concentration samples, the loop size and number density following the transient was proportional to C_0 , again showing that $C_i = \alpha C_0$ and allowing an estimate to be made of α . We found $\alpha \approx 0.02$ for room temperature implantation, and $\alpha \approx 0.01$ for liquid nitrogen implantation (10).

Also shown in Fig. 4 and 5 are points for a Sb sample which was recrystallized by ion-beam annealing using a high flux Si beam (11). Although the original Sb implantation was done at liquid nitrogen temperature, the diffusion coefficients are higher than expected for that con-

Fig. 5. Plot of transient diffusion coefficients at 680°C against dopant concentration.

centration. Possibly, annealing by Si ion irradiation allowed more Sb atoms to trap interstitials before the SPE growth took place, giving a larger enhancement. Alternatively, some of the damage induced by the continued irradiation of the recrystallized silicon was not removed, and the diffusion transient is due to the combined effects of point-defect trapping and radiation-enhanced diffusion.

Using the data of Fig. 4 and 5, we can arrive at a single, concentration-dependent, transient diffusion coefficient D^* , given by

$$D^* = 0.0083\alpha C_0 e^{-1.8/kT} (\text{cm}^2\text{-s}^{-1}) \quad [1]$$

where $\alpha = 0.01$ for LN_2 implants and $= 0.02$ for RT implants and $C_0 =$ atomic fraction of dopant. Although strictly determined for Sb, it is interesting to note that the Bi points in Fig. 4 are close to those for Sb, and the extrapolation to 680°C (Fig. 5) is even closer to the expected value for liquid nitrogen Sb implants (the activation energy for Bi was measured as 2.0 ± 0.2 eV) (12). This suggests that the trapping ratio α may be very similar for many Group V dopants, and limited only by the availabil-

ity of interstitials during implantation. We show later that this expression for D^* also gives fair agreement with the observed enhanced diffusion of As.

This very high transient diffusivity only lasts until the supply of interstitials is exhausted. We observe experimentally that for room temperature implantations, the end of the transient occurs roughly at $D^*t^* \approx 4 \times 10^{-12} \text{ cm}^2$ independent of dopant concentration, where t^* is the length of the transient in seconds, and at half this value for low temperature implantations. The fraction of dopant precipitated during the transient is approximately 7α , or 15% for room temperature implants. Although the loss of electrically active dopant is fairly small, in the high concentration samples significant effects may arise from the formation of the band of dislocation loops. Another serious effect of the transient-enhanced diffusion may be broadening of the dopant profile. Although not seen with the present Sb^+ or Bi^- implants, where the dopant simply precipitates out, profile broadening may occur with implantations below the solubility limit or perhaps with As^+ or P^+ implants. We will discuss the prediction of such effects in the next section.

We have also looked for transient-enhanced diffusion in $^{11}\text{B}^+$ -implanted silicon, which had been preamorphized by $^{30}\text{Si}^+$ implantation in order to exclude the effects of radiation-enhanced diffusion. Figure 6 shows TEM micrographs of the precipitates obtained. No extra spots were observed in the selected area diffraction patterns, and there was no evidence of coherency strains surrounding the precipitates. Either the precipitates had an identical crystal structure to the silicon or they were amorphous but of insufficient volume fraction to produce rings in the diffraction pattern. The density of boron in the precipitates was determined by completely precipitating out the boron in excess of the solubility limit and measuring the volume fraction of precipitates. Diffusion coefficients were then determined as before and are shown on an Arrhenius plot in Fig. 7. The points fall very close to the tracer values (8), are independent of B concentration, and show the usual activation energy. From these results, we conclude that there is no significant trapping mechanism for Group III elements.

Prediction of transient effects.—The transient diffusion coefficient together with the duration of the transient determined in the last section allow us to predict the transient effects for any processing technology based on the SPE growth of amorphous, ion-implanted layers. Taking the duration of the transient determined previously as $D^*t^* \approx 4 \times 10^{-12}$ or 2×10^{-12} for room or liquid nitrogen temperature implants, respectively, we obtain from Eq. [1]

$$t^* \sim \frac{2.5 \times 10^{-8}}{C_0} e^{1.8/kT} (\text{s}) \quad [2]$$

Fig. 7. Arrhenius plot of B diffusion coefficients in preamorphized, SPE-grown Si.

For process times $t < t^*$, we will see enhanced diffusion given by D^* (Eq. [1]). For process times $t > t^*$, we will observe the full transient effect D^*t^* and concomitant effects of precipitation and loop formation, and in addition may see the effects of normal diffusion for the remaining time, characterized by $D(t - t^*)$. The significance of this normal diffusion depends primarily on the temperature. At low temperatures D^* is many orders of magnitude greater than the normal diffusion coefficient D , and, therefore, t would need to exceed t^* by the same factor for the effects of normal diffusion to be observable. However, the situation changes at high temperature, since the tracer diffusion has a much larger activation energy. In fact, at a sufficiently high temperature T^* , D will exceed the transient diffusivity D^* , even for times less than t^* . The extrapolation of the tracer and transient diffusion coefficients in Fig. 4 cross at

$$T^* = 2.5 \times 10^{-5} [\ln(675/kC_0)]^{-1} \quad [3]$$

Here, the diffusion caused by thermally generated point defects equals the diffusion caused by the release of the fixed number of trapped interstitials. In Fig. 8, we summarize these predictions, plotting t^* against $1/kT$ for various dopant concentrations. The bold dotted line marks the temperature T^* above which normal diffusion exceeds the transient for all times. The duration of the transient is difficult to define precisely, and the values of t^* predicted by Fig. 8 are probably only accurate to within a factor of two. Figure 9 shows D^* as a function of $1/kT$ and C_0 , the bold line again marking the division between normal and enhanced diffusion.

To test the prediction of these transient effects we have taken the Sb-implanted Si ($C_0 = 9.31 \times 10^{20} \text{ cm}^{-3}$, implanted at liquid nitrogen temperature) and compared the effects of furnace and rapid thermal annealing (RTA). At typical RTA temperatures, the SPE growth process is completed in a few milliseconds, so that the annealing time can be taken as equal to the processing time. The sample for furnace annealing was first regrown at 575°C for 40 min and then annealed at 700°C for 90 min, at which temperature $t^* \sim 50$ min. The sample for RTA was annealed at 1050°C for a nominal time of 15s, where $t^* \approx 10$ s. Both treatments should therefore take the material to the end of the transient. From Fig. 10, we see that this is indeed the case. Figures 10a and 10b show that the precipitate size distribution is very similar, and the weak beam micrographs in Fig. 10b and 10c show that the loop size and number density are also very similar. These observa-

Fig. 8. Predicted duration of the transient as a function of dopant concentration and temperature.

Fig. 9. Predicted enhanced diffusion coefficient as a function of dopant concentration and temperature.

tions reflect the fact that the same numbers of interstitials have condensed with the two thermal processing treatments and have caused the same amount of dopant diffusion. The transient effects with Bi-implanted samples can also be predicted, simply by replacing the 1.8 eV activation energy in Eq. [1] and [2] with 2.0 eV. This increases t^* by a factor of 5 or 6 at typical temperatures of RTA, although we have not yet checked these predictions experimentally.

Transient effects with As-implanted samples have also been shown to have a 1.8 eV activation energy (3). If we assume the same trapping efficiency α for As as for Sb and Bi, the transient effects should again be predictable from Eq. [1] and [2]. Figure 11 shows the profile broadening after 1100°C/5s and 1150°C/10s annealing (nominal times) of As-implanted Si having a concentration of $1.2 \times 10^{21} \text{ cm}^{-3}$. From Fig. 7, we predict the duration of the transient to be ~ 4 s at 1100°C and only 2.5s at 1150°C. We can estimate the total expected profile broadening by combining the effect of the transient with the effect of steady-state concentration-enhanced diffusion (6) D^c to give $x \approx \sqrt{(2D^*t^* + 2D^c t)}$. Taking an average $D^c = 20D$, we predict the profile broadening at the lower temperature to be $\approx 350\text{\AA}$, very close to the observed 380Å, and at the higher temperature to be 470Å, somewhat lower than the measured 650Å. The broadening due to the transient dif-

Fig. 10. Comparison of Si-Sb alloy ($9.3 \times 10^{20} \text{ cm}^{-3}$) after furnace annealing at 700°C/90 min (a and c), and after rapid thermal annealing at 1050°C/15s (b and d).

Fig. 11. Profile broadening during rapid thermal annealing of As (100 keV, $1 \times 10^{16} \text{ cm}^{-2}$)-implanted Si.

fusion alone would be given by $x \approx 2D^*t^* = 280\text{\AA}$, and thermally activated diffusion is clearly significant at these high temperatures. The enhancement of the transient diffusion over tracer diffusion increases as the temperature is reduced. Kalish *et al.* (3) report enhancement by 170 times for 1010°C/10s RTA and 50 times for 1118°C/10s RTA. These times are both less than t^* , and we predict enhancements of 63 and 15 times, roughly three times lower than their results. Considering the probable errors in t^* and the experimental values for annealing time and temperature, the model predicts the observed effects very well. It should be noted that other mechanisms such as radiation-enhanced diffusion or pipe diffusion may well be contributing to the observed effects, since for the results shown in Fig. 11 the original amorphous/crystalline interface was at a depth of only $\sim 1400\text{\AA}$. We discuss these possibilities further in the next section.

No enhanced diffusion was reported by Hodgson *et al.* (13) during the RTA of As-implanted ($8 \times 10^{19} \text{ cm}^{-3}$) Si at 1200°C/1s. This is also predicted by the model, since from Fig. 7 we see that these experimental conditions lie very close to the point at which normal diffusion becomes dominant. We predict only a 20% enhancement, whereas they report a factor of two. In general, our model seems able to predict transient effects even in As-implanted Si to within a factor of two or three and explains why some experimental conditions result in no observed enhancement.

Discussion

Interstitial trapping mechanism.—We have clearly identified and characterized the mechanism of the transient-enhanced diffusion observed during thermal processing of Group V ion-implanted Si which has been amorphized. The transient is due to the release of interstitials trapped by the dopant atoms, and ends when they condense into loops or are otherwise removed. The concentration of trapped interstitials is dependent on ion-implantation conditions, but independent of subsequent thermal treatments which can only cause their release.

Fig. 12. Profile broadening during rapid thermal annealing of BF_2 (50 keV, $1 \times 10^{15} \text{ cm}^{-2}$)-implanted Si.

The trapping, therefore, occurs during implantation, most likely by the capture of mobile Si atoms by the dopant atoms in order to saturate their valence bands. Following recrystallization by SPE growth, these extra Si neighbors become trapped interstitials. They are not retained during recrystallization from the liquid phase by pulsed laser annealing (1).

There is no analogous effect with Group III dopants. This is not surprising since to reject the fifth Si neighbor from a Group V atom requires that a bond be broken, a process requiring considerable energy. Since SPE growth proceeds with an activation energy of 2.4 eV in the Sb case (14) while the Si-Sb bond energy is likely to be around 3 eV (the Sb-Sb bond energy), the chance of rejecting the fifth Si neighbor as the crystallization interface passes is roughly $e^{0.6/kT}$. Even at the high temperatures involved with RTA, there is less than a 1% chance of breaking the bond. This explains why the transient effects during RTA and furnace annealing are fundamentally similar. With Group III elements, even if many are only threefold coordinated in the amorphous state, to incorporate them substitutionally into the silicon lattice requires no bond breaking. Only an extra Si neighbor must be brought up to the dopant atom, a process probably requiring considerably less energy than the activation energy for SPE growth. It is not surprising, therefore, that no vacancy trapping occurs with Group III dopants during SPE growth, and no enhanced diffusion is observed.

Radiation-enhanced diffusion.—Transient-enhanced diffusion is also observed in silicon which has been damaged by implantation but not amorphized. Thermal processing which anneals the point defects comprising the damage will cause transient diffusion, which ends, as before, when they condense into loops. This mechanism will be effective for both Group III and Group V dopants. It is responsible for the enhanced diffusion reported during RTA of B-implanted Si (which does not amorphize the Si) (4). It may also be significant in situations where the Si is amorphized by the implantation to a depth not much greater than the projected range of the implanted ion. The amorphous/crystalline interface will intersect the dopant profile at a concentration near its peak, and

Fig. 13. Precipitates observed in Ga (100 keV , $1 \times 10^{15} \text{ cm}^{-2}$)-implanted Si after SPE growth followed by $720^\circ\text{C}/20 \text{ min}$ anneal (a), and $900^\circ\text{C}/20 \text{ min}$ anneal (b).

radiation-enhanced diffusion may then cause dopant redistribution or precipitation. We have investigated this possibility through the RTA of BF_2 (50 keV , $1 \times 10^{15} \text{ cm}^{-2}$)-implanted Si. The implantation produced an amorphous layer 550\AA thick, so that the damaged layer was located close to the peak in the B profile (15). After $1050^\circ\text{C}/10\text{s}$ RTA, the profile broadened by 400\AA corresponding to a diffusion coefficient of $\sim 8 \times 10^{-13} \text{ cm}^2\text{s}^{-1}$, which is close to the tracer value of $1.9 \times 10^{-12} \text{ cm}^2\text{s}^{-1}$. It would appear that radiation-enhanced diffusion gives much less enhancement over tracer diffusion, at typical temperatures of RTA, than the interstitial trapping mechanism. Increasing the dose may give more enhancement, although the damage layer will then move deeper into the silicon and be further from the peak in the concentration profile.

As with the interstitial trapping mechanism, radiation-enhanced diffusion will show increasing enhancement as the temperature is reduced, owing to the low activation energy involved. We have studied the effect of the transient in Ga (100 keV , $1 \times 10^{15} \text{ cm}^{-2}$)-implanted Si by fur-

Fig. 14. TEM micrograph of dislocation network formed in Sb (200 keV , $5 \times 10^{15} \text{ cm}^{-2}$)-implanted Si after SPE growth followed by $900^\circ\text{C}/30 \text{ min}$ anneal.

nance annealing. As with the BF_2 implant, a shallow amorphous layer was produced, only 1100\AA deep, close to the peak Ga concentration at 800\AA (14). The sample was SPE grown at $550^\circ\text{C}/40 \text{ min}$ and given furnace annealing treatments to precipitate out some of the Ga. The effects seen were similar to the Sb samples, in that precipitates and loops were observed (Fig. 13). The diffusion coefficient estimated from Fig. 13a is $D^* \approx 1 \times 10^{-14} \text{ cm}^2\text{s}^{-1}$; the tracer value is 5×10^{-18} . It is interesting to note that preliminary measurements again indicate an activation energy of 1.8 eV , suggesting that interstitials may be primarily responsible for the effect. The enhancement of 2000 times is less than the 6000 times seen with the same concentration of Sb from the interstitial trapping mechanism. More significantly, the high concentration of point defects only exists over a fairly narrow depth range in the crystal, whereas with the interstitial trapping mechanism, the concentration of interstitials follows the dopant profile. This may be the reason that radiation-enhanced diffusion appears to give less severe transient effects during RTA than the interstitial trapping mechanism.

Pipe diffusion.—Following either transient, the point defects involved usually condense into dislocation loops, and further annealing will cause these loops to grow and coalesce. Even at this stage, enhanced diffusion may still be observed due to fast pipe diffusion down dislocation cores, and this will not be of a transient nature. The effects of pipe diffusion will become greater than normal bulk diffusion when the dislocations are spaced closer than 1000\AA or so. With Sb, the loops generated as a result of the interstitial trapping mechanism do not produce serious dopant redistribution, since they occur primarily at the peak of the concentration profile and do not extend toward the junction. If of a sufficiently high density they may coalesce and form a planar dislocation network, as shown in Fig. 14. The effect of fast pipe diffusion is to allow precipitates lying on dislocations to grow at a much faster rate than those in the matrix. As the dislocation network anneals, segments are lost and large precipitates are left in the matrix.

The implantation damage around the original amorphous/crystalline interface will also condense into loops during annealing. With continued annealing, they also may grow and coalesce to produce a dislocation network. In the case of the Sb sample shown in Fig. 14, these two networks were clearly separated in depth, as can be seen in the cross-sectional TEM micrographs of Fig. 15. For the loops resulting from the interstitial trapping mechanism to coalesce into a network, they must have a high number density, which requires a high concentration of trapped interstitials and therefore a high dopant concentration. Experimentally, an Sb concentration C_0^* above $3 \times 10^{20} \text{ cm}^{-3}$ leads to a planar network, whereas the threshold for amorphization is only about $1 \times 10^{19} \text{ cm}^{-3}$. From the RBS profile in Fig. 16, we see that the Sb concentration reduces below C_0^* at a depth of 1200\AA , but does not reach 10^{19} cm^{-3} until a depth of 1800\AA . The two defect bands are, therefore, clearly separated, and there are no fast diffusion paths connecting the high concentration Sb region with the underlying crystal.

This is not the case for As^+ -implanted Si since the threshold for amorphization is roughly $2 \times 10^{20} \text{ cm}^{-3}$, which is very close to C_0^* . Therefore, the defect bands re-

Fig. 16. RBS analysis of Sb (200 keV , $5 \times 10^{15} \text{ cm}^{-2}$)-implanted Si SPE grown at $550^\circ\text{C}/30 \text{ min}$.

Fig. 17. Cross-sectional TEM micrograph of As (100 keV , $1 \times 10^{16} \text{ cm}^{-2}$)-implanted silicon after rapid thermal annealing at $1050^\circ\text{C}/10\text{s}$.

sulting from the interstitial trapping and the underlying damage are very close and will coalesce to produce a single band of defects, as can be seen in the cross-sectional TEM micrograph of Fig. 17. This band is situated just deeper than the peak As concentration, and the dislocation density is clearly high enough for pipe diffusion to be significant. Part of the profile broadening shown in Fig. 10 may, therefore, be due to this mechanism, since the dislocation band extends from 1100 to 1700\AA in depth, well within the broadened profile.

Conclusions

We have studied in detail the transient-enhanced diffusion observed during furnace and rapid thermal annealing of ion-implanted silicon, resulting from the trapping

of interstitials by dopant atoms during implantation. We have measured the transient diffusion coefficients D^* and duration of the transient t^* for Sb- and Bi-implanted silicon and arrive at a model which can predict the transient effects during any thermal processing based on SPE growth. We compare the predictions with experimental results, and we give a temperature T^* above which the transient effects will not be significant. We show that above a certain dopant concentration C_0^* the dislocation loops resulting from the transient will coalesce into a network. We show that radiation-enhanced diffusion and pipe diffusion may also be significant in some experimental circumstances.

Reactive Ion Etching of Silicon and Silicides in SF₆ or NF₃/CCl₄ or HCl Mixtures

T. P. Chow* and G. M. Fanelli

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Reactive ion etching of silicon (poly- and monocrystalline) and silicides (MoSi₂ and NbSi₂) in SF₆ or NF₃ and CCl₄ or HCl mixtures was investigated. Optical actinometry revealed that as the chlorine-based gas percentage increases, the fluorine atom density decreases most rapidly for SF₆/CCl₄ and most slowly for NF₃/HCl. Generally, both silicon and silicide etch rates exhibited a monotonic increase as the fluorine-based gas content increases. The dc self-bias increased with increasing HCl or NF₃ percentage but decreased with increasing CCl₄ or SF₆ percentage. Cross-sectional SEM of MoSi₂ polycide edge profiles showed, in SF₆/HCl mixtures, the most severe undercutting of the poly-Si layer occurred at 50% HCl.

Plasma etching of mono- and polycrystalline silicon (henceforth denoted by mono- and poly-Si) and various refractory metal silicides (such as MoSi₂ and WSi₂) in either fluorine- or chlorine-based gases have been extensively studied (1-10). Recently, a combination of these fluorine- and chlorine-based gases have been tried to achieve the optimum etching characteristics for silicon (11, 12) and refractory metal silicides (10). The main applications for these processes in silicon integrated circuit fabrication include formation of vertical silicon trenches for dielectric isolation and anisotropic etching of bilayer silicide/poly-Si stack (polycide) for MOS gate electrodes. Usually, both of these applications require highly selective and directional etching of silicon or silicide over photoresist and SiO₂. Basically, there are two ways of introducing two or more halide components into the etching reactions. The first is direct mixing of different halide gases at the inlet of the reaction chamber. Since the ratio of each component is controlled by the gas flow, it can be adjusted at will. The second is to use a molecule containing all of the halide components, such as fluorochloromethane (CF_{1-x}Cl_x). In this paper, a comparative study of reactive ion etching (RIE) of mono- and poly-Si and two metal silicides (MoSi₂ and NbSi₂) in SF₆ or NF₃/CCl₄ or HCl mixtures is reported.

Experimental Procedure

The RIE was performed in a commercial, parallel-plate-type reactor (Plasmatherm PK 1241) with an excitation frequency of 13.56 MHz. The conditions used for the RIE were total reactant gas flow rate of 20 sccm, substrate temperature of 30°C, RF power of 100 or 300W (0.20 and 0.59 W/cm², respectively), and electrode spacing of ~5 cm. The chamber pressure before plasma ignition was 45-50 mtorr with the difference attributed to the variations in pumping speed of various gases. During etching, the change in pressure as well as the dc self-bias on the substrate electrode was monitored and the plasma composition was probed through a quartz window with an automated optical spectrometer scanning between 200 and 800 nm. Also, there are always four 3 in. wafers, one oxide, two silicon, and one silicide, in the chamber. A few percent (2% usually) of argon was added to calibrate the emission intensity of atomic fluorine (13). Molybdenum and niobium silicide films were deposited by dc magnetron sputtering from cold-pressed alloy targets (both with a Si/metal ratio of ~2.3) onto oxidized silicon substrates in a batch system (Varian 3140). Poly-Si was deposited in an LPCVD system at 630°C and subsequently doped in POCl₃ at 1000°C for 15 min to yield a sheet resistance of 15 Ω/□ for a 1 μm thick film. Single-crystal, p-type silicon substrates, with (100) orientation and a resistivity of 1-10 Ω-cm, were used. Thermal oxide was grown in steam at 1000°C. Positive photoresist (Shipley 1470) was used to produce a step for etch-rate determination. The etch

*Electrochemical Society Active Member.

depth of all these films was measured with a stylus (Dektak).

Results and Discussion

Optical emission spectroscopy.—From optical emission spectra, actinometry was performed with argon to determine the fluorine atom density in these plasmas as the composition varies. In Fig. 1, the ratio between atomic fluorine intensity at 703.7 nm and argon intensity at 750.4 nm, normalized to its peak value, is plotted as a function of gas composition for SF₆ or NF₃/HCl or CCl₄ mixtures. (The intensity ratio reached a maximum at 100% SF₆ or NF₃ for all of the four plasmas mentioned here.) The fluorine intensity was found to drop off most rapidly for SF₆/CCl₄ and most slowly for NF₃/HCl. Specifically, the percentage of fluorine-based gas at which I_F/I_{Ar} fell to zero was 40% for NF₃/HCl and 80% for SF₆/CCl₄. Since the fluorine emission intensity can be directly related to the atomic fluorine density (13, 14), the latter follows the same trend. Besides fluorine, the change in chlorine concentration when the gas composition varies is also of interest. Unfortunately, argon actinometry on chlorine has

Fig. 1. The ratio between atomic fluorine emission intensity (at 703.7 nm) and argon intensity (at 750.4 nm), normalized to its peak value, as a function of gas composition for various SF₆ or NF₃/CCl₄ or HCl mixtures.

Fig. 2. Atomic chlorine emission intensity (at 725.6 nm), normalized to its own peak intensity, as a function of gas composition for various SF_6 or NF_3/CCl_4 or HCl mixtures.

been established only under certain sampling conditions (14, 15), and we did not try it here. Nevertheless, we monitored the variation in chlorine intensity at 725.6 nm. Its intensity, normalized to its own peak intensity, vs. gas composition is shown in Fig. 2. It can be noted that the composition at which the chlorine intensity reached a maximum was about the same as the one that the fluorine intensity vanished for all the four plasmas studied here.

Etching characteristics.—In general, the etch rate was highest for poly-Si and lowest for SiO_2 . Also, the silicon

etch rate increased monotonically with increasing fluorine content. In Fig. 3, the etch rates of poly- and mono-Si, SiO_2 , photoresist, $MoSi_2$, and $NbSi_2$ are shown as a function of gas composition at a RF power of 100W in NF_3/HCl mixtures. With pure NF_3 , both mono- and poly-Si were etched rapidly ($> 3000 \text{ \AA}/\text{min}$) and very selectively over oxide (30:1) and resist (5:1). As the HCl percentage increased, silicon etch rates as well as silicon-to-oxide and silicon-to-resist etch-rate ratios decreased. It can be seen that while the N+ poly-Si etch rate decreased monotonically with increasing HCl percentage, the mono-Si etch rate first increased slightly and then decreased. Apparently, even though there was an almost 50% decrease in atomic fluorine concentration when 25% HCl was added (Fig. 1), the increase in self-bias (shown later in Fig. 8) has apparently more than offset it, leading to a net gain in etch rate. Also, the etch rate of $MoSi_2$ followed the same trend as poly-Si, but that of $NbSi_2$ did not. For example, $NbSi_2$ was etched slower in 100% NF_3 than 75:25 $NF_3:HCl$. The reason for this could be the difference in vapor pressures among the chlorides and fluorides of molybdenum and niobium (10). MoF_6 is much more volatile than $MoCl_5$ and hence higher $MoSi_2$ etch rate can be obtained at higher fluorinated gas concentration. However, NbF_5 and $NbCl_5$ have about the same vapor pressure and the $NbSi_2$ etch rate decrease with increasing fluorine may be due to the lower dc self-bias. Since there may be other factors that contribute to this, more work is needed to understand this difference in sili- cide etch rate.

Increasing the RF power increases the silicon and sili- cide etch rate but also decreases the etch selectivity over oxide and resist. For example, the etch rate ratio between poly-Si and oxide at 50:50 $NF_3:HCl$ was 25 at 100W and decreased to only 10 at 300W (Fig. 4).

Similar etch rate dependence on fluorine/chlorine gas composition was observed for SF_6/HCl mixtures, as shown in Fig. 5. However, the poly- and mono-Si etch rates were lower. For example, the poly-Si was etched twice as fast at 50:50 $NF_3:HCl$ when compared to 50:50 $SF_6:HCl$. This can be explained by the higher atomic fluorine density in NF_3/HCl as shown in Fig. 1. At 50:50, a factor of 4 higher in fluorine concentration was seen from optical emission spectroscopy for NF_3/HCl vs. SF_6/HCl . This more efficient generation of fluorine from NF_3 is possibly because molecular nitrogen, created by

Fig. 3. Etch rates of poly-Si, mono-Si, $MoSi_2$, $NbSi_2$, SiO_2 , and positive photoresist (Shipley AZ 1470) in NF_3/HCl plasmas at 100W.

Fig. 4. Etch rates of poly-Si, mono-Si, $MoSi_2$, SiO_2 , and positive photoresist (Shipley AZ 1470) in NF_3/HCl plasmas at 300W.

Fig. 5. Etch rates of poly-Si, mono-Si, MoSi₂, NbSi₂, SiO₂, and positive photoresist (Shipley AZ 1470) in SF₆/HCl plasmas at 100W.

the dissociation of NF₃ molecules in such reactions as $2NF_3 \rightarrow N_2 + 2F$, does not react with fluorine atoms. However, sulfur and SF_x ($x < 6$), which are products in the dissociation of SF₆, apparently react with fluorine and hence the steady-state level of [F] will be lower in SF₆ plasmas than in NF₃. This hypothesis is plausible from optical emission spectra data in which significant peaks from N₂ bands were clearly visible, while no sulfur peaks were detectable. Similar observations on more efficient fluorine generation has been reported in an etching comparison between NF₃/Ar and CF₄/O₂ plasmas (20).

When CCl₄ was used instead of HCl, similar etch-rate dependence on gas composition was obtained as shown in Fig. 6 where an RF power of 300W was applied. Nevertheless, the etch rate of all the materials studied were

Fig. 6. Etch rates of poly-Si, mono-Si, MoSi₂, SiO₂, and positive photoresist (Shipley AZ 1470) in NF₃/CCl₄ plasmas at 300W.

Fig. 7. Mono- and poly-Si etch rates vs. gas composition in NF₃/CCl₄ at two different RF power levels (100 and 300W).

lower in the CCl₄ plasmas. The etch rate difference was most notable at 50:50 where, for example, the photoresist etch rate was halved and poly-Si was lower by over 30% (Fig. 4 vs. Fig. 6). When the applied RF power was lowered, the etch rate was also decreased as in the NF₃/HCl case mentioned earlier. In Fig. 7, a comparison of the poly- and mono-Si etch rates at two RF power levels, 100 and 300W, is shown. While the trend of increasing etch rate with increasing fluorine content is the same, the etch rates were significantly higher at the higher power level, particularly at low fluorine content. This is again consistent with the fact that ion bombardment enhances silicon etch rate more in chlorine-based plasmas (1, 5).

DC self-bias and pressure variations.—The degree of ion bombardment can be inferred from dc self-bias measurements and pressure variations. In Fig. 8, these two parameters are plotted vs. gas composition for NF₃/HCl and NF₃/CCl₄ plasmas. The self-bias of the cathode in HCl plasmas with NF₃ as additive decreased rapidly with increasing NF₃ percentage (from -120V for pure HCl to -30V for pure NF₃). However, when CCl₄ was used in place of HCl, the bias showed an opposite trend and increased from just over -10V for pure CCl₄ to -30V. Similar trends were also observed when SF₆ was substituted for NF₃, as shown in Fig. 9. In fact, even when inert gases like argon and nitrogen were used as additives, the same trends have been seen (8).

Since the pumping speed was held constant (with the throttle valve wide open) throughout the etching cycle, there was a pressure change when the plasma was ignited. Usually this pressure change was positive. It is worth noting that for pure NF₃, such a ΔP was 20 mtorr, and it decreased gradually as either HCl or CCl₄ was added. However, while in a pure CCl₄ plasma the pressure increase was 8 mtorr, in a HCl plasma there was a pressure decrease up to 7 mtorr (Fig. 8). Interestingly, quite different variations in pressure were measured for SF₆-based plasmas as evident from Fig. 9. The pressure change reached a maximum of 12 mtorr at 70:30 SF₆:HCl and 10 mtorr at 50:50 SF₆:CCl₄.

This change in self-bias and pressure may be related to the dissociation reactions of these molecules and apparently are distinct features of these plasmas. However, more work is needed to identify the basic reactions that lead to these variations.

Fig. 8. DC self-bias (V_{dc}) and change in pressure (ΔP) as a function of gas composition for NF_3/HCl and NF_3/CCl_4 plasmas.

Polycide edge profiles.—To study the effect of gas composition on polycide etching, a $MoSi_2$ /poly-Si stack, 3000 and 2000 Å thick, respectively, was etched in various percentages of SF_6/HCl plasmas. Figure 10 shows schematic drawings of the edge profiles before and after etching. The etch cycle is terminated just after the poly-Si layer has been etched so that no intentional overetching is performed. Since both the poly-Si and silicide etch rates decreased with decreasing SF_6 content, the total time needed to etch the polycide stack increased from 7 min

Fig. 9. DC self-bias (V_{dc}) and change in pressure (ΔP) as a function of gas composition for SF_6/HCl and SF_6/CCl_4 plasmas.

Fig. 10. Edge profiles of $MoSi_2$ /poly-Si stack in various compositions of SF_6/HCl plasmas at 100W.

for pure SF_6 to 32 min for 5:15 $SF_6:HCl$. Furthermore, the poly-Si/ $MoSi_2$ etch rate ratio increases with decreasing SF_6 content, from 4.6 with pure SF_6 to 10 with 5:15 $SF_6:HCl$ as calculated from Fig. 5. As is evident from these profiles, the maximum poly-Si undercut occurred at 10:10 $SF_6:HCl$ were $\sim 1 \mu m$ was observed. While it is difficult to explain the exact cause that results in these edge profiles, it is interesting to point out that chlorine emission peaked at the same composition (Fig. 2) while the fluorine concentration was essentially zero (Fig. 1). Hence, it is possible that the undercut is mainly caused by chlorine species. By contrast, in previous works (9, 16, 17), chlorine was reported to help passivate poly-Si sidewalls to enhance anisotropy. However, in those studies, fluorocarbons (such as C_2F_6) or fluorochlorocarbons (such as $CFCl_3$) were usually added and the etching was performed in relatively high pressure (0.3-0.4 torr) planar plasma reactors. Indeed, when only chlorine was used in conjunction with argon, undercutting of poly-Si was observed (9).

Etching of polycide using mixed fluorine/chlorine plasmas has been reported previously (18, 19). However, because of the difference in reactor configuration, reactants, and silicides used, it is not possible to compare those results with ours.

Summary

In summary, reactive ion etching of silicon and silicides in SF_6 or NF_3/HCl or CCl_4 mixtures is reported for the first time. It was found from optical argon actinometry that, as the percentage of chlorine component increases, the atomic fluorine density decreases most rapidly for SF_6/CCl_4 and most slowly for NF_3/HCl mixtures. The silicon and silicide etch rates generally showed a monotonic increase when more fluorinated gas is added. The self-bias increases with higher HCl or NF_3 percentage but decreases with higher CCl_4 or SF_6 percentage. Cross-sectional edge profiles of $MoSi_2$ /poly-Si stack etched in SF_6/HCl mixtures showed the most severe poly-Si undercut occurred at 50% HCl.

Epitaxial Growth of Silicon by CVD in a Hot-Wall Furnace

J. Bloem,* Y. S. Oei, H. H. C. de Moor, J. H. L. Hanssen, and L. J. Giling

Faculty of Science, R.I.M. Department of Solid State III, Catholic University, Toernooiveld, 6525 ED Nijmegen, The Netherlands

ABSTRACT

A theoretical and experimental study has been performed for the feasibility of epitaxial growth in a furnace. In this study, it is proven that growth in a hot-wall furnace in principle is possible — without deposition of silicon on the quartz ware of the cell — when the growth is carried out at near equilibrium conditions. For supersaturations larger than 10%, deposition also occurs on the quartz of the wafer boat or cell. A constant supersaturation, *i.e.*, a constant growth rate at all slices along the reactor tube can be achieved by imposing a temperature gradient over the cell. The best results are obtained for growth with SiHCl_3 , low Cl/H ratio, and high temperatures. Growth rates amount to 0.1-0.3 $\mu\text{m}/\text{min}$ for these conditions.

The epitaxial growth of silicon has become an inherent part of the silicon device technology since in 1960 the first transistor with epitaxial base was described (1). Recently, silicon solar cells with epitaxial layers on metallurgical-grade silicon substrates showed the feasibility of chemical vapor deposition in this rapidly growing technology (2). The growth of device quality epitaxial material is performed in cold-wall reactors operating at atmospheric pressure and at temperatures well above 1000°C. In this temperature range, the surface reactions leading to growth are relatively rapid and the growth rate is determined by the supply of reactant via gas phase diffusion. The concept of the stagnant boundary layer has been successfully applied to describe and to monitor the growth rate and the growth rate uniformity in production-type reactors (3).

A rather low packing density of substrates can be used in the epitaxial cold-wall reactors and the numbers produced per batch are restricted to, say, 20 slices of 4 in. diam. The epitaxial growth, therefore, is among the most expensive steps in the silicon device technology, and reactors with a high packing density of substrates in a resistance-heated hot-wall diffusion-type furnace should be very welcome.

The hot-wall reactor came into use when polycrystalline silicon had to be grown in thin layers on existing device structures acting as gate material in the self-aligned MOS technique. It appeared that poly-Si could be deposited on slices stacked in a diffusion furnace to give an extremely uniform polycrystalline silicon layer over the whole batch (4).

This method only works at the low temperatures where poly-Si is grown and where the efficiency of the growth

reaction is so low that depletion effects are of minor importance. Growth also occurs on the hot quartz walls and substrate holders. The method is therefore restricted to the deposition of thin polycrystalline layers at relatively low temperatures.

Studies to grow monocrystalline silicon in a hot-wall furnace have been performed since 1960. Deal (5), Lombos and Somogyi (6), and Nishizawa (7) showed the main problems to be the strong depletion and the rapid deposition on the quartz ware of the reactor. Ban (8) introduced a mechanically complex system in which a great number of slices can be processed simultaneously and rotating nozzles are used to direct the gas flow. Recently, Langlais *et al.* (9) gave an analysis of the thermodynamics of silicon deposition in a hot-wall reactor. Depletion effects were not studied specifically, but a growth at reduced pressure is recommended. Indeed, Ogirima and Takahashi (10) showed that SiH_2Cl_2 plus H_2 at a total pressure of 2 torr could give a reasonable growth rate distribution in a LPCVD reactor around 1000°C, with a special nozzle to introduce the reactant. A similar observation has been published by Duchemin *et al.* (11). In all the work cited above, high supersaturations were needed to come to an acceptable growth rate. Deposition of silicon on the hot tube wall and depletion in the direction of the gas stream does restrict the usefulness of the method. Another approach to the epitaxial growth of silicon has been pursued for a number of years in our laboratory (12). Details of the underlying concepts and of some results will be given in the following sections.

Equilibrium calculations.—Thermodynamic calculations of the Si-Cl-H system have been performed with increasing accuracy. Steinmaier (13) was the first to calculate the silicon growth rate as a function of the gas phase

*Electrochemical Society Active Member.

composition. Lever (14), Hunt and Sirtl (15, 16), van der Putte *et al.* (17), and Langlais *et al.* (9) showed the potentials of the computer calculations.

Experimental evidence has been obtained by Sedgwick (18), Ban (19), and Duchemin (20) showing that equilibrium between the gas phase and solid silicon is rapidly established at temperatures well above 1000°C, leading to gas-phase concentrations of SiCl_4 , SiH_2Cl_2 , and HCl close to the ones calculated from thermodynamic data.

In the present study, interest is focused on near-equilibrium situations in which only a small supersaturation is available; the equilibrium calculations, therefore, are even more interesting than in the cases discussed before where large supersaturations are involved.

Using literature data together with an iterative computer program based on minimalization of the Gibbs energy, the equilibrium composition of several Si-H-Cl gas mixtures in contact with solid silicon was calculated. This was performed for several Cl/H ratios, temperatures, and total pressures. Figure 1 gives an example of the equilibrium composition as a function of temperature of a gas mixture for Cl/H = 0.162 and $p_{\text{tot}} = 1$ bar. The total amount of silicon which is present in the gas phase can be deduced for each p , T , and H/Cl ratio by taking the sum total of all the partial pressures of gaseous compounds containing silicon. This total sum is equal to the solubility L of silicon in the gas phase for the given conditions of p , T , and H/Cl under the condition of complete equilibrium between solid and gas.

$$\sum p_{\text{Si}} = L = \sum_j x_j p_j (\text{Si}_x \text{H}_y \text{Cl}_z)_j \quad (x \neq 0) \quad [1]$$

The relative supersaturation percentage for an input pressure p_i follows from

$$\gamma = \frac{p_i - L}{L} 100 \quad [2]$$

The difference in chemical potential ($\Delta\mu$) between input and equilibrium mixtures is given by

$$\Delta\mu = kT \ln p_i/p_{\text{eq}} \quad [3]$$

Fig. 1. Calculated values of gas phase species in equilibrium with solid silicon as a function of temperature for Cl/H = 0.162 at 1 bar total pressure.

For small supersaturations and with $p_i = p_{\text{eq}} + \Delta p$, we can put

$$\ln \left(1 + \frac{\Delta p}{p_{\text{eq}}} \right) \cong \frac{\Delta p}{p_{\text{eq}}}$$

so that

$$\frac{\Delta\mu}{kT} = \ln \left(1 + \frac{\Delta p}{p_{\text{eq}}} \right) \cong \frac{\Delta p}{p_{\text{eq}}} \quad [4]$$

In this way, the relative supersaturation γ and $\Delta\mu/kT$ are equal for small supersaturations.

In cases where the chemical reactions in the gas phase give rise to volume changes (nonequal number of reactants and reaction products), it is advisable to use a relative solubility L_{rel} given by the ratio of the number of moles of silicon in the gas phase and the total number of reacting atoms

$$L_{\text{rel}} = \frac{n_{\text{Si}}}{n_{\text{tot}}} = \frac{\sum p_{\text{Si}}}{\sum p_{\text{Si}} + \sum p_{\text{Cl}} + \sum p_{\text{H}}} \quad [5]$$

where $\sum p_{\text{Cl}}$ and $\sum p_{\text{H}}$ are defined in the same way as $\sum p_{\text{Si}}$ in Eq. [1].

In Fig. 1, it is seen that at the lower temperatures SiCl_4 is the main gas phase component in equilibrium with solid silicon; at the higher temperatures the SiCl_4 content decreases, and SiCl_2 becomes the most important gaseous silicon compound. This situation leads to a minimum in the silicon solubility (L) as a function of temperature for a specific Cl/H ratio. Figures 2 and 3 give examples for different Cl/H ratios and total pressures. For lower values of Cl/H, the absolute value of L decreases and the minimum shifts to higher temperatures. For reduced pressures (or a replacement of H_2 by an inert gas), the minimum shifts to lower temperatures. For input partial pressures of SiCl_4 , SiHCl_3 , or SiH_2Cl_2 , the appropriate Cl/H curve can be selected and growth is expected for input values greater than the value of L , for $p_i < L$ etching of solid silicon will occur.

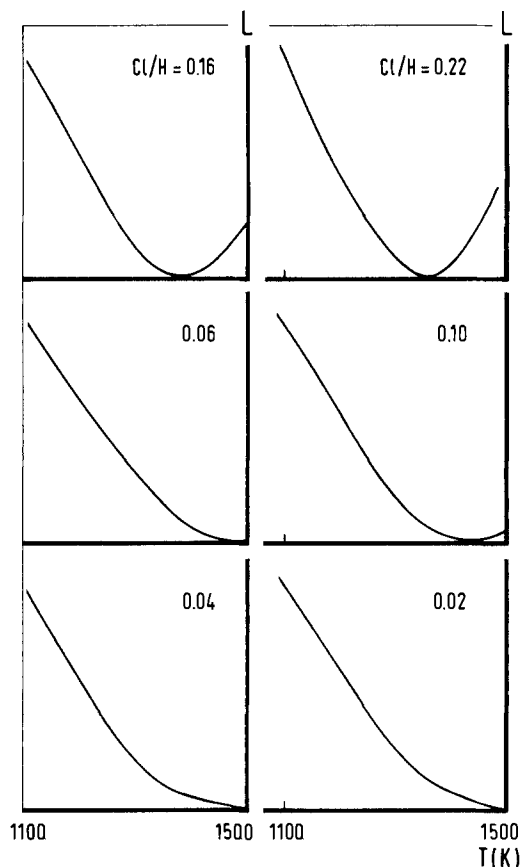

Fig. 2. The silicon solubility L , constructed from calculations as given in Fig. 1 for different values of Cl/H ratio at atmospheric total pressure. The minimum in L shifts to lower temperatures for increasing chlorine content. The preferred epitaxial temperature is around 1350 K.

Fig. 3. The silicon solubility L as a function of temperature at a constant Cl/H ratio at various total pressures in the Si-Cl-H system. Replacement of hydrogen by an inert gas as helium has the same thermodynamic consequences.

In Fig. 4, three experimental situations are depicted. Point A corresponds to an experiment where the input of $SiCl_4$, $SiHCl_3$ or SiH_2Cl_2 , and HCl in H_2 is such that for $T = 1000$ K the input mixture contains less silicon than the corresponding equilibrium value. So once this mixture comes into contact with the solid silicon crystals, the system will strive toward an equilibrium situation and the crystals will be etched. This applies for every situation where the combination of input concentration and temperature is lying below the solubility curves. Growth will occur when the input values exceed the solubility line. For mixture A, this is achieved at T larger than 1100 K. So for input concentration A below 1100 K, etching will take place; above 1100 K, the crystal will grow. Starting with an input composition at B directly will give growth be-

Fig. 4. The silicon solubility as a function of temperature in relation to various input conditions. Input mixtures with a Si/Cl ratio higher than the equilibrium value (L) give rise to growth at all temperatures (B). Lower input concentrations of silicon (A and C) lead to etching or growth dependent on temperature (see text).

cause the silicon content exceeds the solubility of silicon. To prevent deposition of silicon in colder parts of the reactor, conditions have to be chosen such that deposition does not start below a specified temperature (situation A). It has also to be realized that an input mixture of say $SiHCl_3$ in H_2 can have the required Si/Cl and Cl/H ratio; the gas phase species, however, still have to be adjusted to the equilibrium concentrations of $SiCl_4$, SiH_2Cl_2 , $SiCl_2$, etc. This process may take some time.

For a real growth experiment in a hot-wall reactor, a supersaturation has to be introduced in order to come to growth. The small supersaturations envisaged in the present experiments then will lead to a rapid reduction in growth rate in the direction of the gas stream. This depletion can be overcome in two ways. First, it is possible to introduce additional reactant via an inlet tube with carefully designed holes; in this way the Si/H or Cl/H ratio can be altered as a function of position in the reactor. Second, the temperature in the tube can be changed. In the latter case, we work in a temperature gradient and the solubility curve can be followed until the minimum in the solubility is reached. This idea is followed in the present study. All along the temperature gradient the gas phase is brought out of equilibrium and comes to equilibrium again by the deposition of silicon on the substrates.

The growth of silicon under a small supersaturation as can be realized by the gradual change of temperature described above has the additional advantage that growth of silicon on silicon is readily possible; growth of silicon on a foreign substrate, however, meets with nucleation difficulties and needs a higher supersaturation (21). This bears the possibility that growth on tube walls and quartz boats can be prevented and also gives the possibility of selective growth in windows of oxide layers present on a large number of silicon substrates in the reactor.

Growth rate.—For growth at a constant temperature, the growth rate (G) can be calculated for a constant flow rate V liter/min, an initial silicon partial pressure p_i bar, and a solubility L of silicon in the gas phase in bar at the temperature T from

$$G = \frac{(p_i - L)VM}{RTAp} 10^7 \mu\text{m/min} \quad [6]$$

where R is the gas constant ($82.06 \text{ cm}^3 \text{ bar/K-mol}$). M is

the molecular weight of silicon (28.086g), ρ is the density of silicon (2.3 g/cm³), and A is the silicon substrate surface area (cm²).

The flow V depends on temperature and total pressure (p_{tot}) present in the reactor cell

$$V = \frac{V_0 T p_0}{T_0 p_{\text{tot}}} \quad [7]$$

where V_0 is the gas flow at normal p and T ($p_0 = 1$ bar, $T_0 = 298$ K). For growth on a greater number of slices, each wafer has to be in contact with a gas phase with the same supersaturation. This can be realized as discussed before in a temperature gradient in which the gas phase is constantly brought out of equilibrium. In that case the equation for the growth rate becomes

$$G = \left(- \frac{dL}{dT} \right)_T \left(\frac{dT}{dx} \right)_x \frac{l V_0 M}{RT_0 A(x) \rho} \frac{p_0}{p_{\text{tot}}} 10^7 \mu\text{m/min} \quad [8]$$

where $(dL/dT)_T$ is the gradient of the solubility curve at temperature T for the Cl/H ratio and total pressure in question, $(dT/dx)_x$ the gradient of the temperature at position X , l the distance between two slices, and $A(x)$ the substrate surface area at position X . Growth has to be expected for a positive product $(-dL/dT)(dT/dx)$, i.e., at the low temperature side of the minimum of the solubility curve ($dL/dT < 0$) a positive temperature gradient must be applied, whereas a temperature drop in the direction of the flow ($dT/dx < 0$) is needed when one works at the high temperature side of this minimum, where (dL/dT) is positive (Fig. 2-4).

For constant growth rate all along the reactor tube, it is sufficient that the product $(dL/dT)(dT/dx) l$ is constant. In practice, a constant value of dT/dx combined with a constant wafer spacing is preferred. In this case, constant growth rate requires a linear change in the solubility curve. This optimal thermodynamic working point directly will follow from the solubility curves by calculating dL/dT for each T . No real constant value for dL/dT is present; however, a more or less flat region — where the deviations are smaller than 10% — is present around each inflection point in the L vs. T plot, allowing crystal growth in a temperature region with a width of about 100-200 K around 1200 K for each Cl/H ratio.

In principle, it is possible to work at the high temperature side of the minimum in L vs. T . A disadvantage will be that the gas mixture has to enter from the hottest side of the furnace. During the heating up from room temperature, the gas will pass a temperature region where, already, a state of supersaturation will be obtained and spontaneous nucleation in the gas phase may occur. This problem can be solved by following route C as indicated in Fig. 4, where in principle the gas mixture at high T is prepared *in situ* from an unsaturated silicon mixture in contact with a solid silicon source.

This disadvantage does not exist for growing in a positive temperature gradient, i.e., at the low temperature side of the solubility curve. Low temperatures are preferred in hot-wall reactors, especially when lower total pressures are of advantage, in order to prevent damage of the tube and attack of the quartz ware.

Equipment and procedures.—Basically, the system is a normal CVD system equipped with a furnace instead of a RF generator. A schematic presentation including the gas mixing system is depicted in Fig. 5.

The complete system is home-built and consists of a four-zone furnace with a total heated length of 135 cm. The inner diameter of the reactor tube was 45 mm, with a total length of 260 cm, including the necessary load-lock provision. With four independent controllers, any desired temperature profile can easily be adjusted.

Mass flow controllers and mass flowmeters controlled the flow of the hydrogen carrier gas, the dichlorosilane, or trichlorosilane and additional HCl. For the present experiments, the silicon samples [one side polished, low resistivity, Sb doped, (100) orientation, with a diameter of 5

Fig. 5. The apparatus used in the growth experiments consists of a four-zone furnace in which is a long quartz tube such that the load can be flushed at room temperature before introduction into the furnace. All gases can be directed to the vent when needed (not shown in the figure). The slices can be positioned parallel to or perpendicular to the gas stream, the experimental results being comparable.

cm], were cut into two parts and placed parallel to the long axis of the furnace. This has the advantage of giving a small disturbance on the flow characteristics; it has the disadvantage that because of the high heat conductivity of the silicon, the upstream part of the crystal is somewhat higher and the downstream part is somewhat lower in temperature than would correspond with its position in the furnace (for positive T -gradient in the flow direction).

In additional experiments, it has been shown that the slices can be placed parallel to or perpendicular to the main gas stream without significant differences in growth rate and crystallographic quality.

The moisture and oxygen content of the H_2 carrier gas was always below 1 ppm. The total flow (NTP) was always 3.5 liter/min, giving a gas velocity of about 15 cm/s at the growth temperature.

The sample holder loaded with up to 20 slices is introduced into the cold part of the quartz tube, purged with N_2 and H_2 , then slowly moved into the hot furnace. Just before the start of the growth experiments, an *in situ* HCl etch was performed with 0.5% HCl for 5 min. The etch rate of silicon by HCl is rather independent of temperature between 900° and 1200°C and amounts to 0.02 $\mu\text{m/min}$ (21) for the given HCl content.

Results

Experiments were performed with $SiHCl_3$ as well as with SiH_2Cl_2 as silicon sources. $SiHCl_3$ was taken to study (i) the effect of the input concentration on the growth rate (this gives indication about the practical usable concentration for growth and gives information indicating whether the equilibrium situation is achieved) and (ii) the influence of the temperature gradient on the growth rate.

With SiH_2Cl_2 it is possible to check whether a similar growth will be observed for a given Si/H and Cl/H ratio as obtained with $SiHCl_3$. This directly gives proof that equilibrium situations are attained in both situations.

$SiHCl_3/HCl/H_2$ mixtures.—In order to obtain homogeneous epitaxial layers with good crystalline qualities at reasonable growth rates, a number of initial requirements have to be fulfilled when growth is to be performed in an oven.

1. For optimal crystalline quality, the temperature range should be as high as possible (> 1200 K)
2. The adsorption of, e.g., chlorine should be as low as possible, which is favored by high temperatures and low chlorine content.
3. The solubility of silicon preferably should change linearly with T in order to achieve constant growth rates in the temperature gradient of the furnace.
4. The slope of the solubility curve should be as steep as possible to obtain high growth rates and high yields.
5. Deposition on furnace wall and quartz boats has to be prevented.

From the solubility curves as presented in Fig. 2 and 3, it can be seen that the requirements can best be met for Cl/H = 0.06 and $p = 1$ bar. For this ratio, a reasonable

value for dL/dT is obtained at high temperatures. In addition, the chlorine content of the gas mixture is relatively low, which favors a small coverage of the surface with chlorine. A temperature region around 1200 K should be preferred to guarantee constant growth rates. Since it can be expected that the crystalline perfection for $T < 1200$ K is not optimal, the temperature region above $T = 1220$ K was chosen, accepting beforehand that the growth rate theoretically should decrease at higher temperatures (smaller absolute values of dL/dT). For an equilibrium mixture ($\gamma = 0$) at the entrance of the furnace, it is expected that the growth rate starts at zero; as soon as the mixture comes out of equilibrium because of the temperature gradient, a constant growth rate should result. With the gradients used, every centimeter in the furnace gives a change in equilibrium concentration corresponding to $\gamma = 0.1\%$. Several growth experiments have been performed; some results are presented in Fig. 6 and 7. For $Cl/H = 0.0604$, various mixtures with a silicon content above and below the equilibrium value at the temperature at the entrance of the furnace (1220 K) were used. From the figures, it is apparent that etching occurs over the temperature range where the γ of the first wafer is negative (Fig. 6, $\gamma = -5.0$). Etching turns into growth almost at the point which theoretically was calculated. In this respect, the experiment is in agreement with theory. For low initial supersaturations, no growth is observed on the first slices, whereas the growth rate increases on the following slices. Above $x = 70$ cm, the growth rate drops drastically because of the decrease in $(dL/dT)_T$. In Fig. 6, every value of x represents a specific temperature, replotting Fig. 6 as $\log G$ vs. $1/T$ (Fig. 7, $\gamma = 10\%$, $dT/dx = 2$ K/cm) shows that only above 1000°C a constant plateau is reached. Even with a value of γ independent of x , the growth rate is limited by slow surface reactions at the lower temperatures. Higher initial supersaturations increase the growth rate at lower temperatures as long as the gas mixture is not yet in equilibrium. For $\gamma = 6.4$ and 4.8%, no silicon deposit was observed on the quartz ware of the reactor cell or on the wafer boat. For $\gamma \sim 10\%$, a slight deposit on the wafer boat in between the first four slices was observed. For higher initial supersaturations, the first part of the boat up to the fourth slice was covered with silicon; beyond this fourth slice, only the rim of the boat was slightly covered.

By comparing the equivalent experiments at different dT/dx , the highest growth rate is observed for the highest temperature gradient (Fig. 8). A general trend observed in all experiments is that for a given dT/dx all growth curves converge to the same growth rate 40-50 cm from the entrance. This may be an indication that equilibrium has been attained from that place.

The surface morphology of the grown layer strongly depends on the growth temperature and on the Cl/H ratio.

Fig. 6. The silicon growth rate as a function of position in the furnace for $Cl/H = 0.06$, a temperature gradient of 2 K/cm between 1220 and 1340 K in the $SiHCl_3-HCl-H_2$ system for different initial supersaturations.

Fig. 7. The silicon growth rate in the furnace system plotted as a function of reciprocal temperature for $Cl/H = 0.06$ in a mixture of $SiHCl_3-HCl$ and H_2 , a temperature gradient of 2 K/cm and an initial supersaturation of 10%. The curve shows the same character as in a cold-wall system at much lower chlorine content.

At low temperatures, the surface contains many growth hillocks; at temperatures between 1050° and 1080°C, the number of large growth pyramids is reduced, but many small bunches which have grown out almost isotropically are observed, whereas at high temperatures ($T > 1080^\circ C$), the surface is almost free of defects (Fig. 9). For the surface morphology, the temperature is more important than the degree of supersaturation. It must be remembered that, although the initial supersaturations may change, a constant Cl/H ratio is always present, so that most probably the same chlorine surface coverage is also present for experiments at the same temperature. For the highest growth rates (high temperature gradient, high γ initial) and low temperatures, locally polycrystalline growth could be observed on the first slices in the wafer boat. Except for these cases, all epilayers were monocrystalline. It has to be stressed that selective growth is nearly perfect for small supersaturations, below $\gamma = 10\%$. Growth on silicon is possible then without deposition on the quartz tube or boat.

SiH₂Cl₂-HCl-H₂ mixtures.—The experiments with SiH_2Cl_2 were performed to check the validity of the principle. For the same Cl/H ratio, temperature gradient, and initial supersaturation, one would expect the same growth curves as obtained in the equivalent $SiHCl_3$ experiment. Figure 10 gives the result for such a series of experiments, which have to be compared with those collected in Fig. 6. Apart from a higher growth rate, the

Fig. 8. The silicon growth rate as a function of the temperature gradient in the furnace, measured at 1300 K, for $Cl/H = 0.06$ in the $SiHCl_3-HCl-H_2$ system.

Fig. 9. Surface structures obtained at different temperatures for $Cl/H = 0.06$ and a layer thickness of about $20 \mu\text{m}$. At the higher temperatures, smooth surfaces are obtained, sometimes with characteristic "half-moon terraces" and full-size hillocks. Top, 1000°C ; middle, 1050°C ; bottom, 1080°C . The half-moon terraces are indicated with an arrow. Magnification $100\times$ before reproduction.

Fig. 10. Silicon growth rates as a function of position in the furnace for $Cl/H = 0.06$ and $dT/dx = 2 \text{ K/cm}$ in the $\text{SiH}_2\text{Cl}_2\text{-HCl-H}_2$ system at different initial supersaturations.

growth curves are very similar, including a complete absence of silicon growth on the boat. On the other hand, the surface morphology for SiH_2Cl_2 -grown layers is not as good as for SiHCl_3 -grown layers under identical conditions. The epilayer is monocrystalline, but many small hillocks are present at these temperatures and growth rates, where the SiHCl_3 grown layers are nearly defect free. This unexpected feature will be discussed below.

Experiments were also performed at higher Cl/H ratios, using mixtures of $\text{SiH}_2\text{Cl}_2\text{-HCl}$ and H_2 . Equilibrium concentrations were calculated for $Cl/H = 0.16$ and 0.35 . The latter case already represents a concentrated mixture of 17% SiH_2Cl_2 and 26% HCl in hydrogen. In all cases, the temperature gradient in the furnace gave rise to silicon growth as expected, indicating the quality of the thermodynamic data. The growth rates, in the order of $0.1\text{-}0.2 \mu\text{m/min}$, are plotted in Fig. 11; the relatively high growth rate at lower temperatures is obvious for the more concentrated systems. The quality of the grown layers was poor compared to growth at $Cl/H = 0.06$; even polycrystalline growth was observed at the lower temperature end of the furnace. Again, silicon deposit on quartz ware was observed for supersaturations exceeding 10%.

Discussion

It has been demonstrated, *e.g.*, by Sirtl *et al.* (22), Arizumi (23), and Claassen (24), and mathematically founded by Bollen *et al.* (25) that by using the mechanism of selective nucleation, growth of silicon is possible on surfaces with low nucleation barriers, *i.e.*, on silicon itself, whereas no growth will occur on foreign surfaces. The present work demonstrates that this principle can be extended to all SiO_2 surfaces within a furnace system; thus, epitaxial growth of silicon is made possible in a hot-wall reactor. Contamination of walls and boats can be prevented provided a low supersaturation can be maintained in the entire system. The experiments have to be guided by a thorough knowledge of the thermodynamics of the system. This point is illustrated in experiments with high Cl/H ratios, *e.g.*, $Cl/H = 0.16$ with 7.9% SiH_2Cl_2 and 14% HCl , and $Cl/H = 0.3482$ with 17.1% SiH_2Cl_2 and 26.4% HCl . Experiments with these mixtures demonstrate the reliability of the thermodynamic data on the Si-Cl-H system as selective growth sets in at $\gamma = 0$ and is restricted to a narrow range of initial supersaturations up to 10%. In the following, the etch and growth behavior and the crystallographic quality of the layers will be sketched in order to come to some conclusions on the feasibility of the system.

Etch and growth behavior.—As pointed out before, an equilibrium mixture entering the furnace will ideally

Fig. 11. The silicon growth rate as a function of reciprocal temperature in $\text{SiH}_2\text{Cl}_2\text{-HCl-H}_2$ system at $dT/dx = 2 \text{ K/cm}$ and three Cl/H ratios. The surface reactions appear to be much faster in the more concentrated mixtures (higher Cl/H ratio).

show no growth or etching. In the temperature gradient imposed on the system, a supersaturation is then building up of the order of 0.1% per degree. Figure 6 shows that with a gradient of 2 K/cm, about 40-50 cm are needed to bring the gas phase into equilibrium. This can be interpreted as a supersaturation of 10% being needed to come to continuous growth, this being improbably high; still, it is found that a steeper temperature gradient leads to a somewhat shorter pre-equilibrium zone.

Another possibility, however, points to the time needed to come to complete equilibrium. For the chosen gas velocity of about 15 cm/s, the results given in Fig. 6 point to a preliminary stage of about 3s. This view is further illustrated in the series of experiments with SiH_2Cl_2 in which the temperature gradient is kept constant; the Cl/H ratio, however, is changed from 0.06 to 0.16 and 0.35. Very clearly, the time needed to come to constant growth is much shorter at the higher Cl/H ratios.

This behavior can be explained from the known characteristics of the SiH_2Cl_2 , SiHCl_3 , and SiCl_4 systems (26, 27), in which two easy gas phase reactions are present

The SiCl_4 concentration, however, can only be brought to the required equilibrium level via a surface reaction

where Cl^* stands for an adsorbed chlorine atom on a reactive silicon site (*) given by

There is a slow reverse reaction

This reaction is the cause of surface controlled kinetics already at 1100°C for SiCl_4 as the initial reactant (27). In the SiH_2Cl_2 -HCl input mixture, therefore, SiCl_2 , SiHCl_3 , and SiH_2Cl_2 can be present in near equilibrium concentrations via the rapid gas phase reactions [10] and [11]. The formation of SiCl_4 , however, lags behind. As long as SiCl_4 is missing, an excess of HCl is present. It is known (21) that HCl etching proceeds at a constant rate rather independent of temperature down to about 900°C (dependent only on the purity, *i.e.*, oxygen content, of the gas). At 900°C, 1% HCl gives an etch rate of 0.1 $\mu\text{m}/\text{min}$; 1.5% HCl already 0.25 $\mu\text{m}/\text{min}$. In this way, the excess HCl can counteract the growth in situations where the complete equilibrium has not yet been established. Changes in SiCl_4 concentration occur via reactions [12] and [14]; a decrease in SiCl_4 content will take place slowly, rather independent of HCl content (27). The reverse reaction, formation of SiCl_4 , will be faster for higher HCl contents. From Eq. [12], the rate of formation of SiCl_4 and thus the rate of "equilibration" can be given as

$$\begin{aligned} R_{\text{SiCl}_4} &= K p_{\text{SiCl}_2} [\text{Cl}^*]^2 = K' p_{\text{SiCl}_2} p_{\text{HCl}^2/p_{\text{H}_2}} \\ &= K'' p_{\text{SiH}_2\text{Cl}_2} p_{\text{HCl}^2/p_{\text{H}_2}^2} \quad [15] \end{aligned}$$

When we now compare the situation for Cl/H 0.06, 0.16, and 0.35, the rate of SiCl_4 formation is calculated to increase from 1:16:105. This may explain the short introduction time as a kinetic factor needed to conform the mixture to a quasi-equilibrium one. The temperature dependence of the growth rate in the SiH_2Cl_2 /HCl system has been given in Fig. 11. The diffusion-limited region of crystal growth is extended to much lower temperatures, presumably because of the enhanced surface reaction rate discussed before. It has been postulated that for a diffusion-limited growth the surface quality will be superior to growth in a surface-limited region. This supposition is not confirmed here; this point will be discussed in the next section. It can be further mentioned that, in the region of constant growth, the growth rates found are not too far from, but always lower than, the calculated values and constant over the diameter of the substrates $\pm 40\%$.

According to Eq. [8], we expect a typical growth rate of 0.41 $\mu\text{m}/\text{min}$, to be compared with the measured rates of 0.1-0.3 $\mu\text{m}/\text{min}$. The calculated growth rate could apply to polycrystalline growth (9); for monocrystalline growth also, the density and velocity of atomic steps on the surface will play a part.

Crystallographic quality.—Growth and etching in the Si-Cl-H system leads to smooth and perfect surfaces only at higher temperatures and relatively low etch and growth rates. For the growth of silicon, Burmeister (28) and Revesz *et al.* (29) showed hillock formation and faceting to occur as a function of growth rate and temperature. A comparable change from monocrystalline to polycrystalline growth habit was observed by Bloem (30). Van der Putte *et al.* performed an extensive study on the silicon surface structure after etching with gaseous HCl (31).

Figure 12 combines these experimental results, indicating regions in which good quality epitaxial layers can be grown, as well as regions with bunched or even polycrystalline growth, all on good quality substrates in the Si-Cl-H system at atmospheric pressure. Trapping of impurities or growth units has to be considered as the main reason for the occurrence of growth defects. The experiments in the near-equilibrium growth in a furnace are reasonably in line with the data in Fig. 12; some additional influence of higher Cl ratios seems to be present. At Cl/H = 0.16 and 0.35, a diffusion-controlled growth regime appears to be present even at low temperatures. The layer quality, however, is by no means superior to layer growth at the same temperature and growth rate in the Cl/H = 0.06 system. This can be caused by the increased adsorption of chlorine containing species. Another point can be important too, *i.e.*, the quality of the HCl gas used in the experiments. The water content of the HCl may be adequate for normal CVD use; in the concentrated mixtures (26% HCl at Cl/H = 0.35) a small impurity content already counts heavily.

At 1000°C the formation of solid SiO_2 is possible for a water content exceeding 1 ppm. More than 4 ppm in the HCl cylinder thus already may be sufficient to deteriorate the crystalline quality because of blocking of moving steps on the growing surface.

Good quality epitaxial growth at still lower temperatures than given in Fig. 12 are possible under UHV condi-

Fig. 12. The experimental growth morphology in the Si-Cl-H system at atmospheric pressure as it depends on growth rate and growth temperature. Trapping of defects and impurities plays an important part in the determination of the resulting structure; low growth rates and high growth temperatures are favorable there.

Fig. 13. Example of selective growth of silicon inside a window etched into an oxide layer on top of a silicon wafer.

tions (molecular beam epitaxy), where disturbing effects of undesired impurities are minimized. In this respect, the conclusion comes forward that impurities have a stronger effect on the layer quality than the trapping of silicon containing growth units as such. At the lower temperatures the surface is heavily textured; going to higher growth temperatures, the (100) surface becomes smooth with isolated growth hillocks (Fig. 9). Each hillock has a dislocation in its center; often, hollow cores are observed. Sometimes, however, a typical flat top is present. Tsukamoto and van der Hoek (34) found the same type of defect, called half-moon terraces, on garnets and explained them as growth hillocks that have become inactive and obtained a flat top. On further growth they develop into the half-moon terraces.

The hillocks have a mean deviation of 2.56° from (100), with a variation from 0.5° to 3° . On the edges of growth regions facets form on prolonged growth (Fig. 13), mostly (111) faces are exposed, and some (113) and (115) facets are also found. A closer study of the faceting is underway. A further point in favor of the furnace system is the absence of steep temperature gradients that can be the origin of stress and slip in the substrates (35).

Feasibility of the system.—In CVD intended for growth of silicon on metallurgical silicon substrates for the production of solar cells the crystalline quality obtained in the present setup can be quite satisfactory when the specifications for surface planarity can be relaxed, an increased surface area could even have some advantage.

Another attractive feature is the batch-wise selective deposition of silicon in windows opened in SiO_2 layers on silicon substrates; in this application, thin layers are envisaged.

For other silicon device processes, the CVD in a furnace can be achieved satisfactorily only well above 1000°C . The furnace process will gain when the surface quality at the low temperature side can be improved. Working at lower oxygen impurity levels is one approach.

Introduction of SiCl_4 in the main gas stream reduces the amount of HCl needed and will help in bringing down the impurity content.

The growth rates obtained are in the order of $0.1\text{--}0.3 \mu\text{m}/\text{min}$; in order to obtain thick layers ($< 10 \mu\text{m}$), this rate is too low. Therefore the selective deposition of silicon in oxide windows appears to be the most attractive proposition for practical use of the near-equilibrium system in the furnace.

Conclusion

Chemical vapor deposition in a hot-wall reactor is possible without deposition of silicon on the quartz ware of the cell or the wafer boat. In terms of crystalline quality, the best results are obtained, for growth with SiHCl_3 , low Cl/H ratio, and high temperatures.

An important conclusion is the discovery of fast surface

reactions at high Cl/H ratios, such that a gas phase diffusion-controlled growth rate extends down to nearly 900°C in the furnace system. In order to profit in the sense of improved layer quality, the water content has to be reduced to very low levels.

In general, it can be stated that quite a number of questions are still present, but in principle a new and interesting method to produce epitaxial silicon has become available.

Acknowledgments

A Multiresponse Factorial Study of Reactor Parameters in Plasma-Enhanced CVD Growth of Amorphous Silicon Nitride

P. W. Bohn¹ and R. C. Manz

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A 2⁴ factorial design in the growth parameters has been implemented for plasma-enhanced CVD deposition of a-SiNH thin films. A variety of chemical and physical properties were used as responses to measure the strength of interactions between and among the factors studied. Statistically significant interactions of the primary factors (*i.e.*, reactant gas ratio, pressure, temperature, and RF power) were found for almost all responses measured. SiH₄/NH₃ ratio and RF power were found to have the most and largest effects on all responses. Changes in these variables resulted in changes in the film stoichiometry which have far reaching implications for the refractive index and buffered HF etch rate of these films. In each response, the trends observed support conclusions of previous single-variable experiments. The current experiments extend those studies by quantitating the various factor-factor interactions.

The formation of dielectric coatings for passivation and electrical insulation of GaAs has been a long-standing problem to those interested in high speed devices. Although silicon dioxide has been used almost exclusively in the development of silicon technology, its permeability to moisture and alkali ion diffusion eliminate it from consideration for use with GaAs. As an alternative, amorphous silicon nitride has been found to be useful, owing in part to its stability to etching reagents, mechanical robustness, and high resistivity (1). As an insulator it is attractive due to its reasonably large high frequency dielectric constant and breakdown potential (2) and compatibility with current processing techniques.

One method of growing silicon nitride thin films involves the chemical deposition of silane and ammonia at atmospheric pressure with temperatures between 700° and 900°C. However, when this material is used for passivation of GaAs, temperature limitations are imposed. To circumvent this problem with high temperatures, reactive plasmas have been employed to impart sufficient energy to the precursor species to generate the highly reactive intermediates needed for actual film growth (3, 4). This plasma-enhanced CVD process then permits growth of an amorphous hydrogenated silicon nitride (a-SiNH) at temperatures well below 400°C. At these lower temperatures, it is possible to deposit plasma-enhanced a-SiNH films directly on aluminum or gold metallizations on GaAs. Doing so then provides a barrier to chemical or mechanical damage and creates a film with the appropriate electrical characteristics for high quality electrical insulation. Interest also exists in using a-SiNH as a selective mask for further oxidations or doping procedures when deposited at low temperatures.

It is well known from a variety of experiments that, although values usually fall in specific ranges, the exact physical, chemical, and electrical properties of plasma-enhanced a-SiNH films depend strongly on the method and conditions of film growth (5-10). In the plasma-enhanced deposition process, many species are present which have sufficient energy to initiate bond cleavage processes. As a result, a panoply of reaction pathways is possible, and the most thermodynamically favorable products are not necessarily predominant. Thus stoichiometry and related properties can and do vary widely with changes in the deposition conditions. This aspect of the plasma-enhanced growth process is both an advantage and a disadvantage. The wide variation with reactor parameters means that considerable latitude exists to tailor the materials properties of the deposited film. However, very careful attention must be paid to the control of reaction conditions in order to produce films with reproducible properties.

Earlier experiments have addressed the dependence of film properties on plasma reaction conditions (2, 6). How-

ever, those studied have all taken the approach of varying one variable at a time and observing the effect as measured by one or more specific film properties. This approach can at best only examine two-dimensional projections of the *n*-dimensional response surface (11, 13). In addition, this approach is incapable of measuring the extent of interactions between the various growth parameters in determining the chemical and physical properties of a-SiNH. In a system as mechanistically complex as the plasma-enhanced CVD reactor, it is highly likely that several significant interactions will play a role in the growth chemistry. Thus, recognizing the complexity of the film growth process and wishing to understand interactions between system parameters in terms of each of several different responses, a 2⁴ factorial study with center point was planned and implemented. Of the many possible factors which could have been studied, some were eliminated for practical reasons (*e.g.*, changing the electrode spacing) and others were eliminated to leave only the four factors, which from one variable at a time studies, appeared to be most likely to have a statistically significant effect on one of the chosen responses. The experiment examined the effects and interactions of SiH₄/NH₃ molar flow ratio, total gas pressure [*i.e.*, $P(\text{SiH}_4) + P(\text{NH}_3) + P(\text{buffer})$], substrate (GaAs) temperature, and radio frequency power density on the Si/N ratio, refractive index, buffered HF etch rate, growth rate, concentrations of H bound to Si, and concentrations of H bound to N in the grown a-SiNH films.

Experimental

All samples were prepared in a Plasma-Therm radial flow, capacitatively coupled, 13.56 MHz reactor of the general Reinberg design (Fig. 1) (14). This reactor is equipped with automatic power sensing and tuning circuitry to maintain constant power levels during deposition. It also possesses a capacitance manometer-controlled throttle valve for maintenance of constant pressure and a set of temperature sensors which feed back to the pallet heaters to keep the substrate temperature constant. Calibrated mass flow controllers were used to obtain constant known gas flow rates into the reaction chamber. SiH₄ flow rate, NH₃ flow rate, total pressure, and temperature were all controlled to $\pm 1\%$ deviation. For these experiments, the electrode spacing was held constant at 1.9 cm.

The levels of the variables examined in this study are tabulated in Table I. SiH₄ was obtained as 2% SiH₄ in Ar, and NH₃ was obtained as 5% NH₃ in Ar. In each experiment, an auxiliary Ar flow was used to keep the total flow rate of all gases constant in addition to having the preset pressure constant. All gases were delivered from remote safety cabinets through precleaned 316 stainless steel tubing. The centerpoint or zero level of each factor was determined from previously established standard values for production growth of a-SiNH passivation layers in GaAs FET's.

Fig. 1. Cross-sectional diagram of the electrodes and gas flow pattern in the reactor used in these experiments.

Within the design, great care was taken to randomize possible sources of bias which would not be included in the design. Since two experimental runs, at most, could be made in any one day, the time order of the experimental growth runs was randomized. In addition, the positions of each of the test substrates in the reaction chamber were randomized. Each experimental run generated five separate samples for growth rate measurement, bonded hydrogen content, Si/N ratio and refractive index, etch rate measurement, and film stress.

Growth rate measurements were made by monitoring total thickness of material deposited on glass substrates with a pressure-sensitive stylus instrument for each of the 30 min growth runs. Growth rates varied from 76.9 to 210.8 Å/min. Film stress measurements were performed by examining the distortion of an elongated GaAs bar, before and after sample growth, with a laser deflection measuring instrument (Canon wafer flatness monitor). However, several samples had sufficiently low surface reflectivity after a-SiNH growth that reliable signals could not be obtained. Thus film stress was not included in the final response data. In general, however, values of the stress induced by film growth were in the 1×10^8 to 2×10^9 dyn/cm² range with both tensile and compressive values being observed. Measurements of the etch rate of GaAs supported samples were made in NH₄F buffered HF by measuring the difference in thickness between an etched region and a masked region after a standard etching time. Variation from 48 to 434 Å/min was observed.

Information about the total content of Si-H and N-H bonds was obtained by direct quantitative infrared absorption spectrometry of layers deposited on semi-insulating GaAs. Absorber concentrations were obtained by measuring the absorbances near 3350 (N-H) and 2150 cm⁻¹ (Si-H). The absorbances were then combined with bond cross sections calculated from a reanalysis of the nuclear reaction profiling data of Lanford and Rand (8). This new analysis took the physical nature of the system into account by constraining the linear data fit to pass through the origin and yielded cross-sectional values of 5.7×10^{-20} cm² for Si-H and 4.5×10^{-20} cm² for N-H.

Both refractive index and Si/N atomic ratios were obtained from the samples grown on silicon. Bulk Si and N

amounts were inferred from ESCA measurements in the near surface region. Ar⁺ sputtering was used to remove the surface contaminated layer prior to measurements. Tabulated sensitivity factors for the Si_{2p} and N_{1s} peaks were used to calculate the atomic ratios from relative peak areas (15). Refractive index measurements were obtained at 6328 Å with an automated ellipsometer using a He-Ne laser source.

Results and Discussion

The raw data from the experiment along with the design matrix are shown in Table II. In addition to the responses listed above, the total hydrogen content, being the sum of Si-H and N-H concentrations, is included in the last column. The bottom four rows of the table represent the center-point replicates run to establish an estimate of the true run-to-run variability inherent in the experiment. These raw data were reduced using the contrast coefficients algorithm (16) to yield the table of effects for each main factor and interaction. These are shown in Table III. The bottom two figures in each column are the standard error for the measurement of an effect and the size of the 95% confidence interval for the hypothesis that the effect in question is due only to statistical fluctuation and is not statistically significant. The results for each response will be discussed separately. In addition, the present results will be compared directly with the results of careful single-variable variation studies performed previously (17).

The refractive index data show a total of four significant effects. Since the interaction between reactant gas ratio and RF power is also significant, neither of these will be discussed as main effects. Increases in total pressure are found to cause a marginally significant decrease in the refractive index. This observation agrees with the single variable study, but over a much wider pressure range than investigated previously (17). Although both SiH₄/NH₃ ratio and RF power display significant effects alone, their two-way interaction is also significant. Both main effects agree in sign with the single variable results, and examination of the four-way contrast table (Table IVa) shows roughly equivalent averages except for the case of high SiH₄/NH₃ and low power. This combination yields a much higher value for refractive index. At either level of SiH₄/NH₃, decreasing the plasma power increases the index, while at either level of power, increasing the SiH₄/NH₃ ratio increases the observed index. The simplest view of the mechanism behind the statistically significant interaction must involve the separate steps of radical and ion generation, surface adsorption and incorporation into the growing film, and rearrangement of surface species. Generally, increases in the amount of Si incorporated have been associated with higher refractive index values. The differences in dissociation energies as measured by the bond energies of SiH₄ and NH₃ is small (~19 kcal/mol), so the ratio of active silicon containing species to active nitrogen containing species should remain fairly constant with changes in the electron temperature (18). Thus the origin of the interaction is probably not in the gas phase dissociation. However, it has been noted (6) that increases in the amount of incorporated Si can still lead to a decrease in the refractive index, if there exists a large proportion of Si-H vs. Si-Si bonds (*i.e.*, more Si terminations). Thus, the refractive index data must be interpreted in light of the Si/N ratios and [Si-H] concentrations.

The ESCA measurements of Si/N ratio show that the films are nitrogen deficient with respect to the stoichiometric compound, as expected. Also as expected, the SiH₄/NH₃ ratio has a significant effect on the Si/N ratio incorporated, such that increasing the relative proportion of SiH₄ increases the Si/N ratio. In addition, changes in RF power are significant, with decreases in the power leading to increases in the amount of silicon incorporated. These data are consistent with both the refractive index measurements just discussed and the Lorentz-Lorenz correlations observed in a-SiNH (19). The Lorentz-Lorenz

Table I. Levels of the four factors chosen for study. The - and + designations are arbitrary

Variable	Levels		
1 = SiH ₄ /NH ₃ flow ratio	0 = 1.70	- = 1.50	+ = 2.00
2 = Total pressure (torr)	0 = 1.50	- = 1.00	+ = 2.00
3 = Substrate temperature (°C)	0 = 275	- = 250	+ = 300
4 = RF power (W)	0 = 15	- = 10	+ = 20

Table II. Raw data for each of seven responses in the 2¹³ design matrix. Symbols on the left side of the table correspond to the level of the factor at the head of the column (labeled as in Table I) for that experimental run. Each experimental run is represented by a single row in the matrix. Levels for two-, three-, and four-way interactions are obtained by multiplying the signs for the main effects in that row [e.g., sign(12) = sign(1) × sign(2)]. The last four rows represent the center-point replicates, and the final column is derived from the first two data columns

correlation embodies the observation that for a particular film density the refractive index decreases with decreasing silicon content. Increasing the RF power is observed to decrease both the index and the Si/N ratio. In fact, the sign of the measured effect for all four main factors is the same for both the Si/N ratio and the refractive index, confirming a correlation between the two properties observed previously (17).

The buffered HF etch rate is also expected to be somewhat correlated with the Si/N ratio and refractive index of the films. An examination of the significant effects for the etch rate shows that SiH₄/NH₃ ratio, total pressure, the SiH₄/NH₃-RF power interaction, the pressure-temperature interaction, and the three-way interaction among the SiH₄/NH₃ ratio, pressure, and temperature are all statistically significant. The observation of a statistically significant three-way interaction precludes the discussion of more fundamental effects involving these factors. However, it is consistent with the previous observations that etch rate depends on several film properties including Si-N stoichiometry, H content, and density (6, 17). Because each of these is likely to be affected in a fundamental way by one of the factors studied, it is not surprising that the aggregate effect on etch rate includes a significant three-way interaction.

The growth rate is another response which includes significant three-way interactions, among pressure, temperature, and RF power and among SiH₄/NH₃ ratio, pressure, and RF power. Again, this observation is not surprising, based on the complex series of events (i.e., dissociation, adsorption, rearrangement) which determines the rate of incorporation of new moieties into the nascent epitaxial film. Increasing RF power or decreasing the pressure should act to increase the electron temperature and consequently the frequency of dissociative reactions of the active gases. An increase in the frequency of these dissociative reactions would naturally tend to increase the growth rate. The surface temperature is likely to play a role in the efficiency of adsorption and adatom rearrangement. Lower substrate temperatures would favor the sticking of highly reactive radical and ion species. However, a higher surface temperature would yield a higher surface mobility and enable newly adsorbed species to move to stable growth sites more quickly. Thus, a clear picture of the manner in which substrate temperature enters the growth rate picture is not forthcoming from the present data. This is especially true when it is considered that a sizable number of the species undergoing surface collisions are ionic rather than neutral. For the ions, the surface temperature would be expected to

Table III. Size of the effect for each main factor, two-, three-, and four-way interaction. Each column contains data for a specific response, while each row contains data for a specific effect or interaction. The effects and interaction values are obtained by combining the data in Table II according to the signs in the column for that effect or interaction. The S_i value at the bottom of each column is an estimate of the standard error for that response. The number just below it is the size of the 95% confidence level for the hypothesis that the effect is due to random fluctuation only. Effects which are statistically significant at the 95% level are italicized

(a)		(b)		(c)	

play only a minor role in comparison to other factors such as the surface dc bias arising from differences in ion and electron mobilities. Thus, the most important conclusion from the growth rate data comes from the presence of three-way interactions, which are indicative of a highly complex overall mechanism in which changes in any of the machine parameters can have different implications for various processes in the overall mechanism.

The remaining responses are all measures of the hydrogen content of the film. Examining first the [Si-H] measurements, it is seen that nearly all of the factors affect the amount of hydrogen bonded to silicon. There are two interesting observations. First there is a statistically significant interaction among all four factors studied. This points to an extremely complex mechanism for passivation of Si open valencies by hydrogen. The second concerns the magnitude of the various effects. Far and away the largest effect is that of RF power, which, in the absence of higher order interactions, would suggest that increasing the RF power decreases the concentration of Si-H linkages, presumably by increasing the concentration of Si-Si and Si-N bonds. Concentrations of these latter species could not be measured quantitatively due to overlap of the Si-N stretching band with broad Si-H and N-H bending modes in the mid-IR. The next largest effect is the main effect due to SiH₄/NH₃ ratio. As expected, increasing the SiH₄/NH₃ ratio tends to increase the [Si-H] concentration in the solid.

The [N-H] concentration response shows far fewer statistically significant effects. Increasing the SiH₄/NH₃ ratio decreases the [N-H], while increasing the RF power and pressure together increases the [N-H]. An examination of the four-way contrast table (Table IVb) for the RF power-pressure interaction effect on [N-H] shows that both factors are working in the same direction. Decreasing the pressure at constant RF power acts to decrease [N-H], while decreasing the RF power at constant pressure does the same. Combining observations, the total hydrogen content (i.e., [H]_{total} = [Si-H] + [N-H]) shows a significant SiH₄/NH₃-RF power interaction which can be attributed primarily to the influence of the RF power. Again constructing the table of contrasts (Table IVc) shows that decreasing the RF power while keeping the SiH₄/NH₃ ratio constant increases the total hydrogen content, while the SiH₄/NH₃ ratio has no clear impact from the table.

Note that these results for hydrogen content are consistent with the picture emerging from the refractive index and Si/N data. The main effect of RF power on the refractive index (a decrease in *n* with increasing power) correlates with a decrease in Si/N, a decrease in [Si-H], an increase in [N-H], and a decrease in total hydrogen content. Thus it appears that changing the plasma conditions, by changing its energy, drastically affects film properties through alterations in the stoichiometry. Increasing the power results in relatively less Si and more N incorporation, a loss of bound hydrogen, and an increase

in the amount of hydrogen bound to N atoms. These changes result in a lower refractive index and a higher growth rate but have relatively little effect on the buffered HF etch rate.

Examining only the number of significant main effects summed over all responses shows RF power and SiH₄/NH₃ flow ratio are the most important factors, being statistically significant for six of the seven responses studied. Pressure is somewhat less important, and substrate temperature by itself is relatively unimportant for the specific set of responses measured. In addition, a surprisingly large number of interactions were found to be statistically significant. As would be expected from the main effect observations, these were primarily those which involved RF power and/or the SiH₄/NH₃ ratio.

In summary, a multivariate factorial design experiment has been implemented to examine the hypergeometric response surface for reactor parameters on a-SiNH film properties. This study was performed primarily to examine the interactions of various reactor parameters on film properties, information which could not be gleaned from previous single-variable experiments. The results of the design have led to three major conclusions. First, there are statistically significant interactions of the primary factors for nearly all responses. The large number of these preclude quick conclusions about the effect of changing the level of one of the machine parameters while keeping all others constant. Second, the RF power level and SiH₄/NH₃ ratio are the most important factors for the set of responses studied here. Third, changes in power, reactant gas ratio, or pressure are amplified through changes in the film stoichiometry. Changes in the refractive index, for example, are symptomatic of changes in the Si/N ratio and the amount and placement of bound hydrogen. In each response, the general trends tend to support the directions observed in previous single-variable experiments and extend those conclusions by actually measuring the strength of factor-factor interactions.

ABSTRACT

The photovoltage spectra of heteroepitaxial silicon on sapphire (SOS) exhibit an oscillatory pattern (thin film interference effects). The amplitudes of the oscillations increase with decreasing film thickness. We attribute this amplitude increase to anomalous optical behavior of the silicon-sapphire interface region, and we propose the use of "interference photovoltage spectroscopy" as a practical means for probing the silicon-sapphire interface.

The optical properties of silicon-on-sapphire in the ultraviolet and in the visible spectral range are known to be dependent on the crystalline quality of the film (1). This dependence is commonly believed to originate from crystallographic disorder (large density of {221} twins and associated defects) which is especially severe in the silicon near the interface between the silicon film and the sapphire substrate. Practical methods have been formulated for the assessment of SOS film quality by visual inspection of the films [haze determination (2)] and by quantitative UV-reflectivity measurements (3). Recently, we proposed using the reflectivity in the near infrared and visible spectral range for an optical probing of the quality of the silicon near the silicon-sapphire interface (4). This approach was based on measurements of reflectivity spectra, and especially on the analysis of the amplitude of reflectivity oscillation vs. photon energy. The method appears to be sufficiently sensitive to distinguish between as-grown SOS films of different crystalline quality. Furthermore, it makes it possible to observe changes induced by the film processing steps (such as thermal annealing or hydrogenation) which are not in all cases resolvable in the UV-reflectivity method and in the haze evaluation.

In this paper, we discuss a simplified version of the method based on photovoltage measurements (5, 6) in which the film itself is a detector of the optical phenomena involved.

SOS films utilized in this study were intentionally thinned by plasma etching from an original thickness of about 6000Å to the desired thickness ranging from 1000 to 3000Å. No significant increase in epilayer roughness was observed after etching, as measured by an α -step and an interference contrast microscopy. Photovoltage spectra of thinned films are shown in Fig. 1. (The spectra are as measured, i.e., they are not normalized to a constant photon flux.) The photovoltage was generated by monochromatic chopped light and detected using lock-in detection previously described (5). Measurements were carried out using a metal-semiconductor (M-S) configuration (5). Semitransparent Au-electrodes were simultaneously evaporated on all films under study. Prior to evaporation, the film surfaces were cleaned by 15s etching in buffered HF.

The photovoltage spectra in Fig. 1. exhibit a characteristic interference pattern, i.e., series of maxima and minima, which are due to interference of the light reflected from the front silicon-Au interface and from the Si-sapphire interface. For the analysis of the magnitude of the oscillations, it is convenient to introduce the parameter Δ defined as

$$\Delta = (V_{\max}/V_{\min})^{1/p} - 1 \quad [1]$$

where V_{\max} and V_{\min} are defined in Fig. 1a, and p is the

parameter describing the power dependence of the photovoltage, V , on the illumination intensity, I , i.e., $V \sim I^p$. The effects of nonlinearity ($p \neq 1$) are significant at low temperature, where trapping effects become more significant. For example, at 220 K [this temperature corresponds to the maximum magnitude of photovoltage (5)] the amplitude of photovoltage oscillations V_{\max}/V_{\min} is smaller by a factor of two than at room temperature; this effect is associated with a reduction of the p value from $p = 1$ at

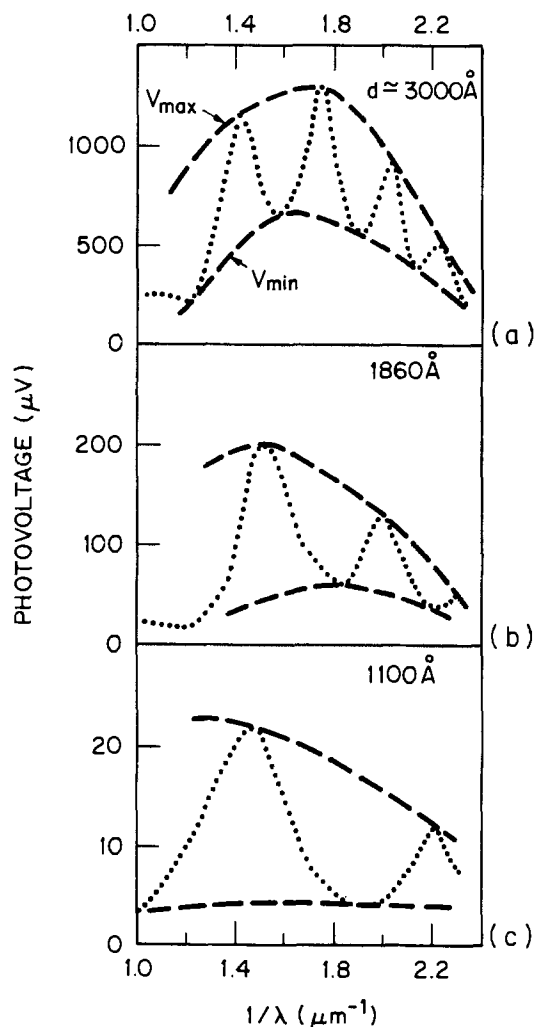

Fig. 1. Photovoltage spectra of "A" category (density of {221} twins less than 4%) SOS film measured at 300 K. (a), (b), and (c) correspond to film thicknesses of about 3000, 1860, and 1100Å, respectively.

*Electrochemical Society Active Member.

Fig. 2. Interfacial disorder parameter, Δ (see text), measured vs. film thickness for films of "A" and "F" categories. Density of {221} twins less than 4% and about 14%, respectively; Δ is obtained with about 10% error.

room temperature to $p = 0.7$ at 220 K. The results of Fig. 1 illustrate two tendencies: (i) separation of minima-maxima on the energy scale increases with decreasing film thickness, and (ii) in the region of negligible absorption of SOS films (when $\alpha d < 1$), the amplitude of oscillations increases with decreasing film thickness.¹ The first result is an obvious consequence of decreasing the optical path, dn (where d is the film thickness and n is the refractive index). The observation that V_{\max}/V_{\min} increases

with decreasing film thickness is of primary importance, since it demonstrates that V_{\max}/V_{\min} is affected by the Si-sapphire interface region.

The dependence of Δ (measured at $1/\lambda = 1.4 \mu\text{m}^{-1}$, i.e., in a region of negligible optical absorption of the film) on film thickness is shown in Fig. 2 for two films: "A" category film of good crystalline quality (density of {221} twins less than 4%) and "F" category film of the inferior quality ({221} twin density about 14%). The results show that not only does Δ increase with decreasing film thickness, but also the difference between the two films becomes more pronounced for smaller film thickness. The shaded area between the two curves defines a range of values of the parameter expected in SOS films of different thicknesses and crystalline quality. The optical phenomena responsible for the observed differences are not well understood at present. The empirical relation, however, seems to be strong enough to be used as a practical means for probing, on a relative basis, the interface quality. The results in Fig. 2 can be used to compare different films using relatively simple interference photovoltage spectroscopy measurements.

Manuscript submitted Dec. 10, 1984; revised manuscript received March 20, 1985.

RCA Laboratories assisted in meeting the publication costs of this article.

¹The observed reduction in the magnitude of the photovoltage at the short wavelengths is related to the reduction of light intensity (the photovoltage is not normalized to the light level). The observed reduction in the amplitude of oscillations (difference between V_{\max} and V_{\min}) at the short wavelengths is caused by light absorption at the film surface away from sapphire interface.

Argon Entrapment and Evolution in Sputtered TaSi₂ Films

R. A. Levy* and P. K. Gallagher

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The use of tantalum disilicide over doped polycrystalline silicon (poly-Si) for gate and interconnect metallization is becoming an integral part of the design and processing of VLSI devices. Under certain sputtering and/or processing conditions, the silicide surface has been seen to exhibit sporadically blisters and voids during high temperature processing. In this study, we shall demonstrate that the occurrence of these defects in TaSi₂ is related to the entrapment of argon during deposition and the evolution of that gas during subsequent processing. This conclusion will be deduced by ascertaining, through a series of controlled experiments, the contributory effect of a wide range of processing parameters, by proposing a phenomenological model to explain the governing mechanism of blister and void formation, and by providing analytical evidence to verify this model.

The use of tantalum disilicide over doped polycrystalline silicon (poly-Si) for gate and interconnect metallization has been implemented in devices designed and processed in accordance with the 2.5 μm Twin-Tub CMOS technology (1). This polycide structure has the advantage of preserving the MOS interfacial stability of poly-Si while reducing, due to the lower resistivity of the silicide

*Electrochemical Society Active Member.

($\sim 50 \mu\Omega\text{-cm}$), IR drops and RC delay times in the circuit (2-4). Although several techniques are available for formation of the disilicide, cosputtering from separate Si and Ta targets in an inert ambient is generally preferred because it produces smoother surfaces and affords better control on the desired stoichiometry of the films (5, 6). Following deposition, the amorphous silicide films typically undergo several high temperature processing steps.

Generally, these include sintering to crystallize the structure and minimize the sheet resistance, passivation to restore the gate oxide thickness uniformity eroded during reactive ion etching, and flow as well as reflow to smooth the phosphosilicate glass (PSG) topography and drive in the junctions (7). Under certain sputtering and/or processing conditions, the silicide surface has been seen to sporadically exhibit blisters and voids after flow. In this study, we shall demonstrate that the occurrence of blisters and voids in TaSi_2 is related to the entrapment of argon during deposition and the evolution of that gas during subsequent high temperature processing. We shall proceed to accomplish this task by ascertaining through a series of controlled experiments, the contributory effect of a wide range of processing parameters, by proposing a phenomenological model to explain the governing mechanism of blister and void formation, and by providing analytical evidence to verify this model. We shall then conclude this investigation by offering recommendations which should prove successful in eliminating the occurrence of these potentially fatal defects.

Processing Variables

If not otherwise specified, the silicide films investigated in this study were deposited at a rate of $\sim 100\text{\AA}/\text{min}$ in a magnetron unit with capabilities for cosputtering from a tantalum target and two boron-doped silicon ($\sim 0.14\ \Omega\text{-cm}$) targets. All wafers were held at ground potential and rotated in a planetary station to enhance deposition uniformity. The sputtering chamber was evacuated to $< 1 \times 10^{-6}$ torr, with the combined aid of a roughing and an oil diffusion pump, and was backfilled with pure Ar (99.995%) at a pressure of 2×10^{-3} torr. Following silicide deposition, device wafers were patterned, reactive sputter etched, sintered, passivated, and implanted (P, B). LPCVD films of undoped oxide ($\sim 1000\text{\AA}$) and PSG ($\sim 16\ \text{k}\text{\AA}$) were then deposited and the wafers subjected, during flow, to the highest thermal treatment of the process. In the case where experiments were conducted on monitor wafers, several steps of the process were purposely deleted to exclude extraneous effects.

The characteristic morphology of blisters and voids, associated with the high temperature processing of cosputtered TaSi_2 , is illustrated in Fig. 1 with SEM micrographs taken both on monitor and device wafers. Blisters in these $\sim 2500\text{\AA}$ thick films are generally seen to be uniform in shape (dome-like) and vary extensively in size, with some stretching in large areas as much as $50\ \mu\text{m}$ across. The distribution of blisters on the silicide surface appears random with some being close enough for PSG to form a partially resolved envelope over the agglomerated units. In some cases, the damage produced by these defects is so severe that parts of the PSG film are literally blown out. Voids, on the other hand, appear to be irregular in size and shape but still randomly distributed across the silicide surface.

One of our initial considerations as the cause of this blistering problem included the possibility that it was instrument-related. Thus, experiments were initially conducted to evaluate possible effect of instrumental variation and then to ascertain effects of other processing variables.

Effect of instrumental variation.—Starting with a group of oxidized ($\sim 610\text{\AA}$) n-type silicon ($1.5\text{-}3\ \Omega\text{-cm}$) substrates, LPCVD polysilicon ($\sim 4000\text{\AA}$) was deposited and doped in a PBr_3/O_2 (1000°C) ambient. Following an oxide clean, TaSi_2 ($\sim 2500\text{\AA}$) was cosputtered at a rate of $\sim 95\ \text{\AA}/\text{min}$ in a sputtering unit using a symmetric two-gun arrangement. The sputtering chamber was pumped to $< 5 \times 10^{-7}$ torr with the combined use of a Vac-Ion and turbomolecular pump prior to backfilling with Ar (99.9%) at a pressure of 4×10^{-3} torr. All wafers were then sintered at 950°C for 30 min in Ar. A wafer selected from this group was introduced, with no additional processing, into a furnace at 1100°C for 20 min in a 99% N_2 -1% O_2 ambient. In Fig. 2a, an optical micrograph of that sample prominently exhibits the presence of blisters confirming, despite character-

Fig. 1. SEM micrographs illustrating the characteristic morphology of blisters and voids on both monitor and device wafers.

istic differences in the geometries of the sputtering units, the occurrence of the effect. Another result, worthwhile noting at this point, is the fact that blisters and voids are seen here despite the absence of an implant step or the use of an overlaying PSG film.

Effect of PSG deposition and flow.—Another wafer selected from the above group received sequentially $\sim 1000\text{\AA}$ LPCVD undoped oxide and $\sim 16\ \text{k}\text{\AA}$ PSG. Optical examination of the wafer at that stage (Fig. 2b) indicated a surface devoid of relevant morphological structures. How-

Fig. 2. Optical micrographs of TaSi_2 subjected to various process treatments.

ever, after an 1100°C/20 min/99% N₂-1% O₂ flow, the emergence of large blisters (Fig. 2c) was evident at 400× throughout the surface of the wafer. A comparison of Fig. 2a and c emphasizes the magnification effect produced by the added presence of PSG. Presumably, as the TaSi₂ swells at high temperatures due to an internal gas pressure buildup, evolution of some of this gas from burst bubbles coupled with the high temperature softening characteristic of PSG has a "ballooning" effect on the glass surface. At high enough pressures, the glass itself cracks allowing for the gas to escape.

Effect of thermal flow cycle.—Two of the wafers also withdrawn from the above group with combined ~1000Å LPCVD undoped oxide and 16 kÅ PSG were subjected to a flow cycle of 1000°C/90 min/N₂. Microscopic examination of both wafers after that step revealed, as shown in Fig. 2d, the localized presence of small blisters (~2 μm) and occasional areas devoid of PSG. Consistent with the kinetic theory of gases, there appears to be, here, less of a pressure buildup, which in conjunction with the higher rigidity of PSG at this lower flow temperature further masks the effect. However, reflowing one of the wafers at 1100°C/20 min/99% N₂-1% O₂ readily triggers blistering, as shown in Fig. 2e. Thus flow temperature appears to be a major contributing factor to blister formation.

Effect of oxide passivation.—In an attempt to investigate the effect of oxide passivation on blister formation, a set of n-type silicon monitors was precleaned prior to deposition of ~2500Å TaSi₂. All wafers were then sintered at 900°C for 30 min in Ar and passivated at 900°C for 80 min in dry O₂. One of the wafers from this group, identified as (I), was split into halves (IA, IB). A half of that wafer (IA) had its passivating oxide stripped off, while the other half (IB) was kept untreated for control purposes. Each of these halves was then split forming now four quadrants (IA1, IA2, IB1, IB2) which all received ~1000Å LPCVD oxide for purposes of magnifying the blistering effect. Quadrants IA1 and IB1 were subjected to a 1000°C/90 min/N₂ flow, while quadrants IA2 and IB2 received a 1100°C/20 min/99% N₂-1% O₂ flow treatment. The four quadrants were pieced together to reconstruct the original wafer layout and examined with an optical microscope. Figures 3a and b offer a comparative look at samples IA1 vs. IA2 and IB1 vs. IB2, respectively. It is evident from these photographs that no blistering was apparent, in this case, on both quadrants flowed at 1000°C for 90 min in N₂ regardless of the presence or absence of the passivating oxide, while the 1100°C/20 min/99% N₂-1% O₂ flow treatment triggered blistering in both quadrants. Controlled experiments run in parallel with 1 kÅ PSG and no glass yielded similar results thus ruling out the effect of oxide passivation on blister formation.

The effect of passivation time was also examined with TaSi₂ (~2500Å) deposited directly, after a preclean, onto five p-type Si monitors. The wafers were all sintered at 900°C/30 min/Ar then each passivated at 900°C in O₂ for periods of 1.33, 2, 4, 8, and 16h, respectively. Microscopic examination revealed a brownish silicide surface on the two wafers passivated for 8 and 16h pointing to the presence of an oxide. X-ray fluorescence analysis of the silicide films indicated the presence of a significant amount of entrapped Ar which was observed to gradually de-

crease by a factor of ~3 after 16h of oxidation time. Thus, it appears from this data that SiO₂ formation on the surface, as a result of Si transport from the underlying substrate through the silicide grain boundary, has the effect of also sweeping forward the Ar gas. Following deposition of ~1000Å of LPCVD oxide and flow at 1100°C/20 min/99% N₂-1% O₂, all wafers passivated up to 4h exhibited progressively increasing signs of blisters and voids for shorter oxidation times. Furthermore, the absence of these defects observed in samples passivated for 8 and 16h is believed here to be directly related to the measured decrease in the concentration of entrapped Ar.

Effect of sintering cycle.—The effect of sintering ambient was investigated using a group of wafers with TaSi₂/N⁺ poly Si/SiO₂/Si structure. The polysilicon (~3000Å) was first deposited on oxidized (~600Å) monitors and then doped in a PBr₃/O₂ ambient (1000°C). Following a surface oxide strip and a preclean, the silicide was co-sputtered (~2500Å) and the wafers subsequently submitted for Auger analysis to determine their stoichiometry. A wafer selected with a characteristic composition of TaSi_{2.4} was split into halves with one half sintered at 900°C/30 min/H₂, while the control half received a 900°C/30 min/Ar treatment. Both sections were coated with a ~1000Å LPCVD undoped oxide and subjected to an 1100°C/20 min/99% N₂-1% O₂ flow treatment. Microscopic examination of both sections revealed a similar blistering formation across the surface. However, an interesting observation, noted in the context of this particular investigation, was that the positioning of wafers on the LPCVD sled had the effect of masking parts of the surface from deposition. Microscopic examination of blistering across the bordering areas clearly revealed (Fig. 4) the magnification resulting from the presence of the overlying oxide. That is, again, consistent with previously stated conclusions that blistering does indeed occur in the absence of an overlying oxide and that the visual effect is simply enhanced by the "ballooning" action of the softened glass at high temperatures.

To evaluate the effect of sintering time on blister formation, monitor wafers similar in structure (TaSi₂/N⁺ poly Si/SiO₂/Si) to those described in the previous paragraph were sintered at 900°C in Ar for periods of 0.5, 2, 4, 8, or 16h. X-ray fluorescence analysis of all sintered samples indicated the presence of Ar which was seen to be persistently retained in all cases. The addition of ~1000Å LPCVD oxide on these samples followed by the 1100°C/20 min/99% N₂-1% O₂ flow exhibited, with no exceptions, blisters. Altering the sintering temperature to 1000°C on samples from the same group yielded a significant roughening of the silicide surface and a tendency toward random formation of small blisters (≥1 μm) at that heat-treating stage, *i.e.*, even prior to flow.

Effect of film stress.—In view of the possibility that blister formation could be the result of intrinsic and/or thermal stresses generated during deposition and/or high temperature treatments, a systematic investigation of

Fig. 3. Comparative optical micrographs of samples (a) IA1 vs. IA2 and (b) IB1 vs. IB2.

Fig. 4. Optical micrograph revealing the magnification effect resulting from the presence of the overlying oxide.

these stresses at relevant processing steps was undertaken. Starting with five oxidized ($\sim 600\text{\AA}$) n-type silicon monitors (10–20 $\Omega\text{-cm}$), LPCVD polysilicon ($\sim 3000\text{\AA}$) was deposited and doped in a PBr_3/O_2 ambient (1000°C). After stripping the surface oxide, the curvature of all five wafers was measured using a laser leverage technique. Following deposition of $\sim 2500\text{\AA}$ TaSi_2 , the radius of curvature on each of the wafers was remeasured, and the stress due to silicide deposition calculated. Results of those measurements yielded average values of $-1.8 (\pm 2.3) \times 10^9$ dyn/cm², thus revealing at this step a trend toward a compressive state of stress. Two wafers from this group (S1 and S25) were sintered at $900^\circ\text{C}/30$ min/Ar, two others (S5 and S15) at $1000^\circ\text{C}/30$ min/Ar, while the fifth wafer (S20) received a $900^\circ\text{C}/30$ min/Ar sinter followed by a $900^\circ\text{C}/80$ min/ O_2 passivation. Measurement of the radius of curvature, after these steps, registered a change on all five wafers, from a compressive trend to a definite tensile stress with a recorded average value of $1.7(\pm 0.3) \times 10^{10}$ dyn/cm². Following LPCVD deposition of $\sim 1000\text{\AA}$ undoped oxide (wafers placed back to back in the reactor) and ~ 14 kÅ PSG on both sides of each of the wafers, stress measurements revealed little change from the previously recorded average value. Wafers S1 and S5 were then selected for an $1100^\circ\text{C}/20$ min/99% N_2 -1% O_2 flow, while S15, S20, and S25 were subjected to a $1000^\circ\text{C}/90$ min/ N_2 flow. Stress measurement taken, after that stage, yielded insignificant changes, regardless of the type of flow, from the average values observed after the silicide sintering step. There is the possibility that during the high temperature flow cycle the stress becomes compressive. Extrapolation of the stress-temperature data of Retajczyk and Sinha (8), however, does not indicate the onset of compressive stress in TaSi_2 until $\sim 1200^\circ\text{C}$. In view of those results, the characteristic tensile stress of the sintered silicide film as well as that of the composite film structure cannot be reconciled with the high temperature generation of blisters since a compressive, rather than the measured tensile stress, would be expected to generate these defects.

Effect of compositional variation.—In an effort to examine possible trends between compositional variations in the silicide and blister formation, wafers with Si/Ta ratios close to 2.2, 2.4, and 2.7, as determined by Auger analysis, were deposited directly on precleaned p-type Si substrates. Following a $900^\circ\text{C}/30$ min/Ar sinter, the sheet resistance measured across each of the wafers yielded average values of 2.1, 2.2, and 2.4 Ω/\square for $\text{TaSi}_{2.2}$, $\text{TaSi}_{2.4}$, and $\text{TaSi}_{2.7}$, respectively. X-ray fluorescence analysis of the Ar concentration in the silicide showed negligible differences among those three investigated compositions. Addition of $\sim 1000\text{\AA}$ LPCVD oxide followed by flow at 1100°C for 20 min in 99% N_2 -1% O_2 revealed, under microscopic examination, blister formation regardless of the degree of deviation from the stoichiometric composition. An important point to note with regard to this particular experiment is that, just as described above in the section on Effect of oxide passivation; blistering was observed in silicide deposited directly on p-type Si. In view of the total absence of phosphorus in the underlying substrate as well as the overlying oxide there is certainly no plausible argument here for support of any essential role of phosphorus in blister formation.

Effect of poly-Si substrate doping.—In the course of investigating the mechanism of blister formation, the possible role of the phosphorus dopant in the underlying polysilicon was considered. To resolve this question, several experiments were conducted on device wafers (with TaSi_2). Following LPCVD poly-Si deposition ($\sim 3000\text{\AA}$), groups of these device wafers were doped in a PBr_3/O_2 ambient at temperatures of 900° , 950° , and 1000°C yielding variable values for sheet resistance of ~ 112 , 27, and 21 Ω/\square , respectively. Further variations in the doping of poly-Si was achieved by using an LPCVD *in situ* phosphorus doping technique ($R_s \approx 408 \Omega/\square$ for a thickness of $\sim 3200\text{\AA}$ at $\sim 700^\circ\text{C}$ deposition) and an As implant (50 keV, $1\text{E}16 \text{ cm}^{-2}$). Regardless of the doping technique used,

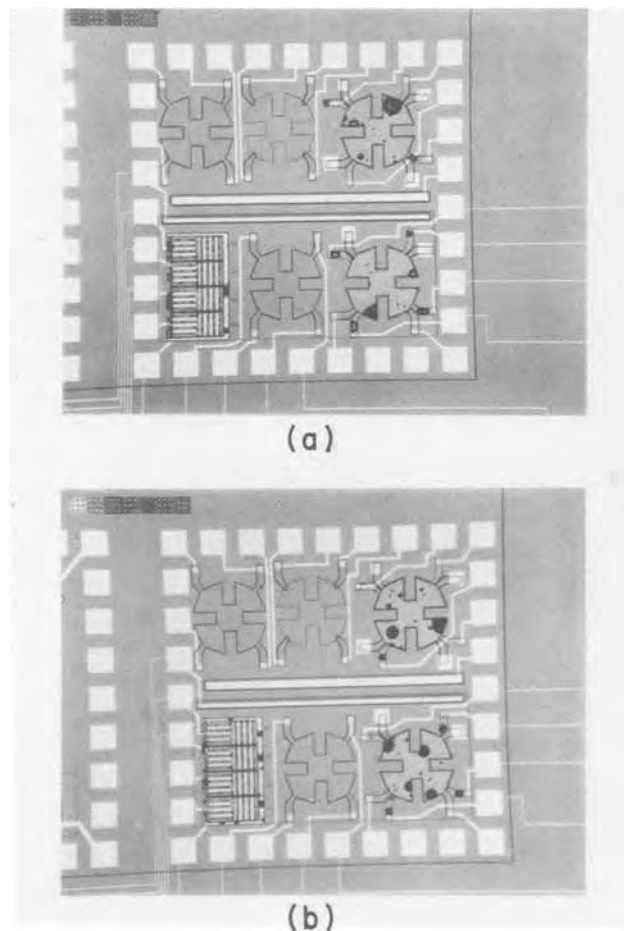

Fig. 5. Optical micrographs of van der Pauw patterns with (a) poly-Si doped at 950°C in PBr_3/O_2 and (b) poly-Si implanted with As (50 keV, $1\text{E}16 \text{ cm}^{-2}$).

processing of all device wafers proceeded with TaSi_2 deposition, sintering ($900^\circ\text{C}/30$ min/Ar), patterning, source/drain implants, PSG deposition and flow ($1100^\circ\text{C}/20$ min/99% N_2 -1% O_2). Microscopic examination after the latter step revealed the presence of blisters of various sizes randomly distributed across wafers from each of these groups. Typical photographs of device wafers with poly-Si doped at 950°C and As implanted are shown, respectively, in Fig. 5a and b. The fact that lowering the phosphorus concentration in the poly-Si or replacing it by arsenic showed no improvement reaffirms our contention, stated in the section on Effect of compositional variation, that blistering can occur even in $\text{TaSi}_2/\text{p-type Si}$, after capping with LPCVD undoped oxide and flowing at 1100°C , despite the total absence of phosphorus. It is important to point out that both the N^+ ($1\text{E}15 \text{ cm}^{-2}$ B, $4\text{E}15 \text{ cm}^{-2}$ P) and P^+ ($1\text{E}15 \text{ cm}^{-2}$ B) van der Pauw patterns of Fig. 5a and b have exhibited blistering after the $1100^\circ\text{C}/20$ min/99% N_2 -1% O_2 flow. That is indeed significant in view of the fact that P^+ van der Pauw patterns have shown, as shall be discussed in the next section, a significant tendency to be less prone to blister formation with a lower temperature flow cycle ($1000^\circ\text{C}/90$ min/ N_2).

Effect of P and B implants.—Following silicide deposition, sintering, and passivation, areas exposed during source/drain definition to double implants of P (100 keV, $4\text{E}15 \text{ cm}^{-2}$) and B (30 keV, $1\text{E}15 \text{ cm}^{-2}$) have reproducibly shown a tendency toward blister formation as opposed to areas implanted solely with B (30 keV, $1\text{E}15 \text{ cm}^{-2}$). A comparative examination of N^+ and P^+ van der Pauw patterns, shown in Fig. 6, clearly illustrates the harmful effect of that double implant. Wafers with the standard TaSi_2/N^+ poly-Si/ SiO_2/Si structure subjected to double P implants (100 keV, $4\text{E}15 \text{ cm}^{-2}$) were observed to blister

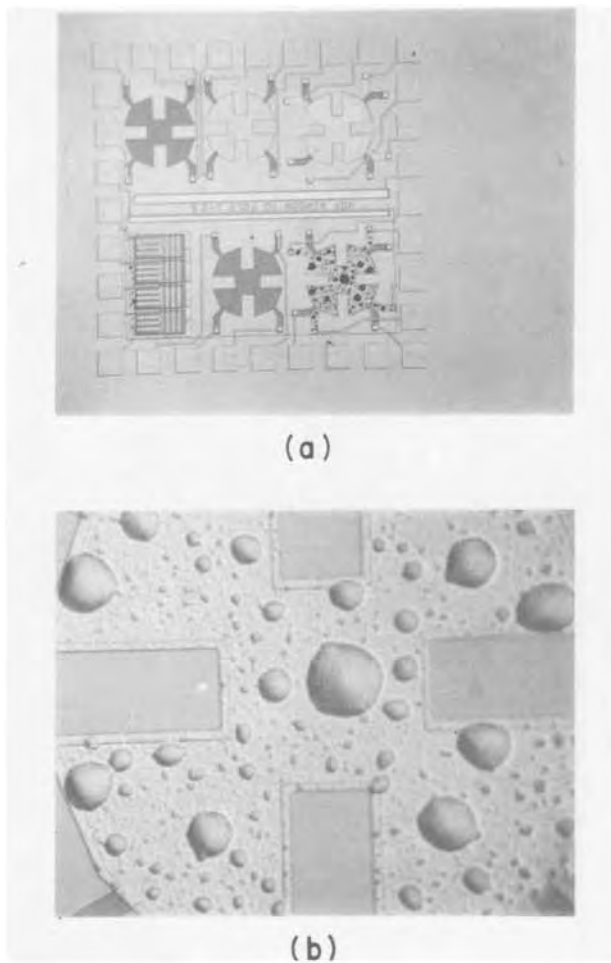

Fig. 6. (a) Comparative examination of N⁺ and P⁺ van der Pauw patterns; (b) magnified portion of N⁺ van der Pauw pattern.

reproducibly after PSG flow (1000°C/90 min/N₂), compared to the marginal situation encountered with single implants. In view of these results, it appears evident that the damage associated with high energy high dose implants and not necessarily the implant species plays a contributory role in the mechanism of blister formation.

Effect of gas ambient during sputtering.—The effect of Ar pressure during deposition on blister and void formation was investigated using a group of monitor wafers with the standard TaSi₂/N⁺ poly-Si/SiO₂/Si structure. The LPCVD polysilicon (~3000Å) was first deposited on oxidized Si (~600Å) then doped in PBr₃/O₂ ambient (1000°C). Following oxide removal, TaSi₂ was cosputtered at varying Ar pressures of 2, 3, 4, 6, or 8 μm (Hg) on these wafers which were subsequently all sintered at 900°C/30 min/Ar. X-ray fluorescence and Rutherford backscattering (RBS) measurements were then conducted on various samples to evaluate the concentration of argon entrapped in the silicide films. The results, shown in Fig. 7 and 8, indicate a monotonic decrease in the entrapped argon concentration as a function of higher Ar pressures. Sections of these wafers, with no additional processing (*i.e.*, no overlaying LPCVD oxide), were subjected to a flow treatment of 1100°C/20 min/99% N₂-1% O₂. Figure 9 illustrates the surface morphology of the silicide after that treatment as a function of Ar pressure. Blistering was observed at this magnification (660×) to emerge in films deposited at Ar pressures of 2, 3, and 4 μm. At higher pressures, no blistering was detected but silicide delamination from the underlying polysilicon was evident. Examination of these photographs also reveals a gradual smoothing of the surface with higher Ar sputter pressures reflecting a dramatic decrease in void density. Sections of these wafers flowed at 1000°C/90 min/N₂ indicated a similar behavior as shown in the SEM photographs of Fig. 10. The high

Fig. 7. X-ray fluorescence (XRF) measurements of the argon concentration in TaSi₂ films sintered at 900°C/30 min/Ar as a function of sputtering Ar pressure.

density of voids observed on the sample sputtered at 2 μm gradually gives way to the pore-free surface of the silicide cosputtered at 8 μm. We believe both these observations to be consistent with an Ar entrapment and release

Fig. 8. Rutherford backscattering (RBS) measurements of the argon concentration in TaSi₂ films sintered at 900°C/30 min/Ar as a function of sputtering Ar pressure.

mechanism which shall be described in the next section. It is worth noting at this point that the choice of an optimum Ar sputtering pressure should take into consideration not only the minimization of the Ar content in the film but also that of O₂ which often increases at the higher sputtering pressures and is possibly the source of the observed delamination problem.

The idea of sputtering with Xe at a 2 μm pressure rather than Ar has also been considered during the course of this investigation. Split lot experiments have reproducibly shown no evidence of blistering on the Xe-sputtered silicide, after flow at 1000°C/90 min/N₂, despite widespread occurrence of the problem on control wafers. Furthermore, comparative examination of gate interconnects, after P-glass removal, clearly indicate, as shown in

Fig. 10. SEM micrographs of the surface morphology of TaSi₂ films sputtered at an Ar pressure of (a) 2 μm, (b) 4 μm, (c) 6 μm, and (d) 8 μm after a flow treatment (with no PSG) of 1000°C/90 min/N₂.

Fig. 11. Comparative examination of TaSi₂ gate interconnects sputtered in Xe (top) and Ar (bottom).

Fig. 11, a decrease both in void density and void depths at the surface of the silicides sputtered in Xe. These results point to the fact that the nature of the gas used for sputtering affects its entrapped concentration, thereby influencing blister and void formation. Based on the above results, we shall now propose a phenomenological model to explain the high temperature blister and void formation mechanism in co-sputtered TaSi₂.

Phenomenological Model

Results from the present investigation as well as other reported studies have shown the formation of blisters and voids in TaSi₂ to be primarily dependent on the concentration of entrapped Ar, the processing temperature, and the extent of implant damage. Quantitative determination of the Ar content, by combined vacuum fusion and mass spectrometric analysis,¹ have indicated the presence of 1.8 a/o of the gas in TaSi₂ films sputtered at a pressure of 2 μm. Generally, the fraction (f), of Ar trapped during sputtering in a film is given by (9)

$$f = \frac{\alpha N}{\alpha N + R}$$

where N is the number of Ar atoms bombarding a unit area of film per unit time during deposition, α is the effective sticking coefficient of the Ar during deposition, and R is the deposition rate of the TaSi₂ film. Clearly, there are three possible ways of reducing f ; these include increasing the deposition rate which is rather difficult to achieve in sputtering, and decreasing N and/or α . Decreasing N may be accomplished by operating in a getter sputtering mode or by depositing at high sputtering pressures provided that does not of itself lead to the incorporation of other contaminants (*i.e.*, H₂O, O₂, ...). Decreasing α may be achieved by operating in a bias or ac sputtering mode, or by increasing the substrate temperature.

For TaSi₂ films sputtered at a pressure of 2 μm, differential thermal analysis measurements have determined, as shown in Fig. 12, the onset of crystallization to be at ~330°C. At that transition temperature, evolved gas analysis has indicated, as seen in Fig. 13, release of most of the entrapped gases including H₂, N₂, O₂, and H₂O but only a small fraction of the Ar. We postulate that this remnant Ar is the source of both blisters and voids formed during high temperature processing of TaSi₂. Upon deposition, the films, as shown in the TEM micrograph of Fig. 14a, are amorphous with the Ar presumed to be distributed randomly throughout the silicide. During the sintering process, the Ar is believed to be swept along by grain boundary formation and occasionally trapped, in its diffu-

sion path, at random defect sites (*i.e.*, dislocations stacking faults, . . .). The TEM micrograph of Fig. 14b provides evidence that bubbles, typically 60Å in diameter, are indeed present at grain boundaries as well as at random intragranular sites in the sintered silicide (900°C/30 min/Ar). During the diffusion of He in Cu, Barnes and Mazey (10) have reported the velocity of He bubbles to be inversely proportional to the bubble radius. Furthermore, the faster migration of small bubbles at 800°C was observed, by hot stage transmission electron microscopy, to result in coalescence with the larger but slower bubbles. A similar situation appears to have occurred in TaSi₂ during the 1000°C flow cycle. Small bubbles merged, as shown in Fig. 14c, into larger bubbles (~150Å) which seem now to be pinned at triple points of grain boundaries. Thus, due to this thermal migration and coalescence, the density of bubbles has decreased but the volume occupied by individual bubbles has increased causing lo-

cal silicide swelling. In a thermodynamic equilibrium, the gas pressure within a bubble is balanced by the surface tension force between gas atoms and lattice. For a bubble of radius r , the surface tension force is $2\gamma/r$ where γ is the surface energy and is generally of the order of 10^3 erg/cm² (11). Assuming ideal gas behavior, one obtains for a bubble of radius r

$$\left(\frac{2\gamma}{r}\right) \left(\frac{4}{3} m^3\right) = mkT$$

OR

$$\frac{8}{3} \pi \gamma r^2 = mkT$$

where m is the number of atoms in the bubble, k is Boltzmann's constant, and T the absolute temperature. At a temperature of 1000°C where a bubble diameter is typically 150Å, the calculated value of m amounts to 2.68×10^4 atoms and the corresponding pressure within such a bubble is estimated to be 2.67×10^3 atm. However, these high pressures appear to be still within the order of magnitude of typical values reported for fracture strength of thin

Fig. 15. Superposed x-ray fluorescence spectra of TaSi_2 as deposited (solid line) and after a flow treatment (with no PSG) of $1100^\circ\text{C}/90 \text{ min}/99\% \text{ N}_2\text{-}1\% \text{ O}_2$.

films (12). A quick check on the validity of the above calculations is provided by considering the fact that the observed density of bubbles n , as determined from examination of Fig. 14c, is of the order of $6 \times 10^{15} \text{ cm}^{-3}$ for 2500\AA thick TaSi_2 films. From the product nm , the total number of solute atoms per cubic centimeter is estimated at $\sim 1.6 \times 10^{20}$. Since the density of TaSi_2 (atomic weight $\sim 240\text{g}$) is 9 g/cm^3 , the total number of solvent atoms per cubic centimeters is $\sim 6.7 \times 10^{22}$. Thus, the calculated fraction of Ar atoms in the film is within the order of magnitude of the measured concentration.

For large enough bubbles and high enough temperatures ($\geq 1000^\circ\text{C}$), an equilibrium breakdown resulting from loss of surface tension under such conditions triggers explosions of these bubbles. Such outbursts close to the free surface contribute to formation of the observed surface voids. Gases emerging close to the bottom surface could possibly get trapped at the silicide polysilicon interface, contributing to potential loss of film adherence. Gases bursting from within the silicide cause catastrophic damage to the film integrity. In the presence of a PSG film, the Ar gas evolving from the silicide in turn pressurizes that coating. At adequate flow temperatures where the glass can be plastically deformed, various size blisters readily form reflecting the wide range in pressure outbursts. In extreme pressure conditions, the PSG film itself cracks releasing the gas trapped at the glass-silicide interface.

Because of the considerable vacancy production during high energy high dose implants, and because the strain energy associated with trapped atom-vacancy clusters is expected to be less than that for Ar atoms trapped at defect sites, one can predict, in such cases, significant enhancement of the migration and coalescence process leading to aggravated blistering. That is, indeed, consistent with our reported observations. Analytical evidence to support this proposed model will now be presented.

Analytical Evidence

Several analytical methods have been used to confirm the entrapment of argon in sputtered TaSi_2 and the subsequent evolution of the gas during high temperature processing. These techniques have included x-ray fluorescence (XRF), energy and wavelength dispersive spectroscopy (EDS and WDS), evolved gas analysis (EGA), and transmission electron microscopy (TEM).

The fluorescence data were gathered in an x-ray Milliprobe unit interfaced to a Li-drifted Si detector and a PGT-3 analyzing system. A Cr target operating at 50 kV and 9 mA provided the source of radiation. The sample was placed in a chamber flushed with N_2 to eliminate

Fig. 16. (a) Superposed energy dispersive spectra (EDS) of a blistered area (white dots) and an undisturbed region (dark background) on the sample; (b) EDS data shown on an expanded scale over a range of 1.28-3.84 keV.

peaks resulting from Ar absorption in air. This is normally done using He, but N_2 is preferred in this case because it suppresses the large Si peak which would otherwise overload the x-ray counting system. A 0.75 mm aperture and 4.8 mm beam stop were used for enhancing count rate efficiency. In cases where extraneous diffraction peaks were observed, the sample was reoriented to lessen their interference effect. Figure 15 exhibits superposed x-ray fluorescence spectra of TaSi_2 as deposited (solid line) and after a 1100°C flow cycle with no glass on (dotted line). The $\sim 2500\text{\AA}$ thick silicide was cosputtered, in this case, at an Ar pressure of $2 \mu\text{m}$ onto a $\sim 3000\text{\AA}$ thick PBr_3 -doped (1000°C) polysilicon substrate. The as-deposited silicide appeared under microscopic examination to be specular while the heat-treated silicide revealed an abundant formation of fine blisters throughout the sample. From a comparison of the spectra of Fig. 15, it is evident that entrapped Ar is indeed present in the as-deposited TaSi_2 film and not in the heat-treated sample confirming total evolution of the gas after the 1100°C thermal cycle. Furthermore, the insignificant change in the magnitude and shape of the overlapped Ta/Si peaks between both spectra reflect, here, the lack of stoichiometric variation in the film after heat-treatment. It is worthwhile noting, at this point, that, although the x-ray fluorescence technique is not quantitative due to the absence of proper standards, it is quite practical and has been extensively used within the context of this investigation in monitoring changes in the Ar content as a function of processing variables.

The x-ray microanalysis data were gathered in conjunction with an SEM by focusing the 20 kV electron beam on the blistered regions of the sample surface or on the flat undisturbed TaSi_2 areas of a device wafer flowed at 1000°C for 90 min in N_2 . Special precautions, in this case, were taken to etch back the P-glass down to the 1000\AA undoped SiO_2 layer to insure minimum absorption of the

Fig. 17. Wavelength dispersive spectra (WDS) of a blistered area (upper curve) and a undisturbed region (lower curve) on the sample.

Fig. 18. (a) SEM secondary electron image of a leaf of a van der Pauw pattern; (b) multiple scan Ar x-ray images exposed for 5 min, and (c) 15 min.

electron beam with no disturbance of the underlying trapped gas. Both energy dispersive (EDS) and wavelength dispersive (WDS) x-ray systems were used.

Full EDS spectra of both these regions are shown in Fig. 16a in an overlay fashion. Outlined in white dots is the elemental spectrum from the surface of a blister while the dark background represents an elemental spectrum of a spot in the undisturbed region of the sample. It is evident from examination of this photograph that both spectra exhibit identical intensities for the Si, Ta, and Fe peaks, but only the spectrum of the blistered area shows the presence of an Ar $K\alpha$ peak at 2.96 keV. This may be seen more clearly in Fig. 16b, where the 1.28-3.84 keV range is shown on an expanded scale. This result unequivocally associates the presence of Ar with the blistered areas.

The gathering of the WDS data required an adjusted beam current of ~ 50 mA. Because of the absence of available Ar standards, sample positioning was optimized using the $L\alpha 1$ peak (4.154\AA) of a silver standard. Representative WDS spectra are shown in Fig. 17, where the upper curve denotes the results of the analysis of a blister and the lower curve from the same undisturbed area where the EDS measurements were taken. Both spectra show a weak third order Ta $L\alpha$ line (4.559\AA) but only the upper curve shows the presence of an Ar $K\alpha$ line at 4.193\AA . That again reconfirms the correlation between local presence of blisters and local presence of argon. The WDS Ar $K\alpha$ peak was used in turn to generate x-ray area

maps shown in Fig. 18. Figure 18a is a secondary electron image of one leaf of a van der Pauw pattern. Figures 18b and c are multiple scan Ar x-ray images exposed for 5 and 15 min, respectively. Although the image clarity is partially obscured by background signals over the whole area due to the relatively low Ar peak to noise ratio, one can obviously see a direct correspondence between local Ar agglomeration and the formation of blisters across the sample. Although a single pass WDS spectrum (Fig. 17, lower curve) indicates that the concentration of Ar is below the detection limit, an improved peak to noise ratio at longer exposure time (Fig. 18c) shows that a very low concentration of Ar is present over the whole cloverleaf area. A similar x-ray map of P showed only a uniform distribution of noise, thus ruling out, as previously noted, the role of P in the blistering formation mechanism. X-ray mapping of Si in the same general area is shown in Fig. 19 where a uniform distribution is now seen both within the $TaSi_2$ van der Pauw pattern and the delineated oxide area with signal intensities simply reflecting the difference in the Si concentration. Similarly, an x-ray map for Ta (Fig. 20) shows as expected, a uniform distribution of that element only over the $TaSi_2$ van der Pauw pattern.

The evolved gas analysis (EGA) measurements were gathered from an assembled apparatus comprised primarily of a small Mo furnace with provisions for temperature monitoring and control, a quadrupole mass spectrometer and a turbomolecular pump capable of achieving pressures down to $\leq 1 \times 10^{-8}$ torr. The output of the spec-

Fig. 20. X-ray mapping of Ta on a leaf of a van der Pauw pattern.

trometer was fed into a data acquisition unit in turn interfaced to a Fluke 1720 microcomputer used for processing and plotting of the data. The temperature was typically stepped up at a rate of $10^{\circ}\text{C min}^{-1}$ up to $\sim 1150^{\circ}\text{C}$. The TaSi_2 samples, under present consideration, were deposited at an Ar pressure of $2 \mu\text{m}$ on Teflon substrates in order to flake off the film and eliminate substrate contributions. It is evident from examination of Fig. 13 that significant evolution of the Ar gas occurs over the temperature range of $900^{\circ}\text{--}1100^{\circ}\text{C}$ in coincidence with the temperature range where blister formation is most evident. EGA measurements of other gases such as H_2 , N_2 , O_2 , and H_2O on similar samples indicated, as shown in Fig. 13, gas evolution only at the $\sim 330^{\circ}\text{C}$ crystallization temperature of TaSi_2 .

A representative vertical TEM micrograph taken on sample with a $\text{Si/SiO}_2/\text{N}^+$ poly-Si/ TaSi_2 structure annealed at 1000°C is shown in Fig. 21. It appears that voids reflecting the gas presence are located at various levels throughout the TaSi_2 film with the voids at the bottom interface presumably accounting for potential poor adherence, those at the center for potential local delamination, and those on top for the surface porosity.

Fig. 21. TEM vertical cross section illustrating presence of voids at various levels of TaSi_2 film.

Concluding Remarks

It is apparent from the present investigation that both blister and void formation result from argon entrapment during sputter deposition and subsequent evolution of that gas during high temperature processing of TaSi_2 . Although other argon-free deposition techniques (evaporation, LPCVD, . . .) may be tried to circumvent the problem, it is evident that with sputter deposition the process must be tailor-fit to minimize the argon concentration in the film. Our results have shown that good quality TaSi_2 films could, indeed, be achieved by optimizing the Ar sputtering pressure, minimizing the implant damage, and reducing the high temperature flow cycle.

ABSTRACT

Process of forming graded steps on a GaAs substrate, which are as deep as 7-8 μm and have an arbitrarily small slope angle down to 13° has been developed by using the rounded edge profile of photoresist layer as a protective mask for Ar ion-beam etching of the substrate. Mask preparation and ion-beam etching have been optimized in terms of both controlling the slope angle and achieving smooth etched surface. The use of a large ion incident angle near 70° has been found to be most advantageous for smoothing an etched surface. Graded steps thus formed have been found to be significantly useful for improving the reproducibility and yield of delineating fine geometries on the substrate by contact lithography, primarily owing to the allowance of using a thin photoresist layer. By using this process, a new optoelectronic integrated circuit (OEIC) fabrication technique has been proposed and applied to the fabrication of AlGaAs/GaAs monolithic photoreceiver circuits, namely, an integrated PIN photodiode/field effect transistor (FET) front end as well as an integrated PIN/amplifier. It has been demonstrated that this technique eliminates previous problems of photolithography and interconnection processes in OEIC fabrication and improved the overall process stability. The circuits fabricated in this study exhibited subnanosecond responses, confirming that the parasitic capacitances have been successfully reduced in the present integrated structure.

Applications of fiber-optic transmission and data processing systems have been widely spread in this decade with the association of a marked improvement in performance and reliability of optoelectronic devices such as lasers and photodetectors. The system's needs for higher bit rate or greater information capacity is the motivation for further improvement in device characteristics. These needs include high performance, high reliability, compactness, ease of interface to electrical circuits, and lower cost. The optoelectronic integrated circuit (OEIC) is a monolithic circuit in which optoelectronic devices and electronic circuits are integrated together on a single semiconductor substrate. This new class of device is regarded as most capable of meeting most of the above-mentioned requirements (1-4). In particular, monolithic integrations of a laser with its driver circuit (5-11) and of a photodetector with an amplifier (12-16) and other electronic signal processing circuits have a capability of increasing the speed and noise performances due to the reduction of parasitic reactances which have been responsible for the performance degradation experienced in previous equipment composed of discrete elements. Development of such OEIC's has been energetically carried out for these several years on both AlGaAs-GaAs (1) and InGaAs(P)-InP (2) systems aimed at wavelength ranges near 0.8 μm and 1.3-1.5 μm , respectively. The high electron mobility in these crystals facilitates high speed electronic circuits. The fabrication technologies of both discrete optoelectronic and electronic devices have been greatly advanced in recent years.

In integrating these elements, however, considerable difficulty in processing has been introduced primarily because of the structural difference between the constituent elements. The optoelectronic devices usually possess multilayer epitaxial structure with a thickness of more than several microns, where the electronic devices such as the field effect transistors (FET's) and bipolar transistors have active layers as thin as 1 μm . Such a structural difference causes, almost inevitably, the appearance of steep mesa steps on the OEIC substrate. These steps degrade the reproducibility of every photolithographic process involved in the series of OEIC fabrication steps, and the overall fabrication yield can be significantly lowered. In order to minimize such effects of steps, a few remedies have been examined so far. A method to etch a well in the substrate before growing the epitaxial heterostructure for the optoelectronic devices has been employed in most of previous studies. It was found to be very effective for ad-

justing the surface level between the optoelectronic and electronic regions so that the fine pattern definition can be carried out in both regions. Kolbas and his co-workers have proposed a method to polish and etch the epitaxial AlGaAs/GaAs structure overgrown in the GaAs substrate region outside the wells, so that the substrate can be planarized (12). Liao and his co-workers have used selective epitaxy to fill a well in the InP substrate by growing InGaAs layer with the aid of silicon nitride mask and then etching the overgrown ridge of InGaAs at the mask periphery (17). Shibata and his co-workers have introduced the use of PIQ to refill and planarize an isolation well generated between the laser and the bipolar transistor areas in their laser/driver structure (8). Although these proposed methods have appreciably improved photolithographic reproducibility, the success of these processes requires a high controllability of the etch and refill procedure and the uniformity of the wafer, which are not easy to achieve primarily because of the complicated cross-sectional structure of the refilled epitaxial layer particularly at the well periphery.

The purpose of this paper is to describe a new OEIC fabrication technique, in which the mesa steps are degraded in a well-controlled fashion and the reproducibility of fine pattern lithography is significantly improved (18). The present technique uses Ar ion-beam etching to produce graded steps so that good control of the etch depth and therefore of the step slope, and also a high uniformity of these parameters over the wafer, can be facilitated. A small slope angle achieved by this technique prevents complicated overgrowth, such as ridges at the substrate well periphery, and simplifies the subsequent photolithographic steps. The use of Ar ion-beam etching to control the slope angle is essentially based on our previous success of fabricating InP microspherical lenses on InGaAsP/InP double heterostructure light emitting diode wafers (19, 20). This method has been now extended to OEIC fabrication in AlGaAs/GaAs system (18). Optimization of two fundamental procedures to form graded steps on the OEIC substrate, namely, the preparation of photoresist mask and the Ar ion-beam etching, has been performed in this study and applied to fabricate AlGaAs/GaAs monolithic photoreceivers.

In the next section, we report the method of obtaining graded steps on a GaAs substrate. The effect of grading on photolithography will be discussed in the third section. The Application section describes the application of the present technique to fabricate OEIC's, in which a

monolithic AlGaAs/GaAs PIN/FET and also a PIN/amplifier are demonstrated.

Graded-Step Process

The essential procedure for forming graded steps on a substrate is shown in Fig. 1. Photoresist masks for ion-beam etching are first prepared on the GaAs substrate surface Fig. 1a. A commercially available positive acting photoresist, Shipley AZ-4620, has been used in our study. The photoresist patterns with the width appropriate to the device design are delineated by conventional photolithographic technique. They are subsequently baked at a temperature higher than the glass-transition point of photoresist so that rounded contours are generated by the effect of surface tension on the photoresist surface (20). Then the substrate is subjected to Ar ion-beam etching Fig. 1b using, in this experiment, Veeco Microetch system in which Ar⁺ ions are generated by a Kaufman ion gun, neutralized, and then fed to bombard a rotating target. During the etching, the rounded mask contour is transferred to the substrate surface. The shape of the step is dependent on the initial photoresist thickness and the photoresist to substrate ion-beam etch rate ratio which is a function of etching parameters such as the ion incident angle ϕ . The morphology of the etched surface is of the

greatest importance in device applications, and it has to be optimized by choosing suitable etching conditions, as will be described later. By terminating the ion-beam etching when the substrate is etched down to appropriate depth, a graded step can be obtained (Fig. 1c).

In order to obtain a sufficient controllability of the step geometry, it is important to know the deformation behavior of photoresist baked at an elevated temperature. Figure 2 shows the height (h) of the photoresist stripe pattern measured at the center of the stripe width (W) as a function of the baking temperature. The initial resist thickness used was approximately 6.5 μm . The baking was carried out under nitrogen gas flow for 10 min. When the temperature was below 100°C, a concave resist cross section appeared to exhibit a height smaller than the initial value. As the temperature increases, a convex cross section is achieved, as is shown in Fig. 2. The convex shape has been confirmed from stylus measurement to be precisely a part of a cylinder, which is consistent with the fact that the surface tension dominates, stabilizing the resist geometry (20). The temperature for cylindrical deformation is observed to increase with the increase of the pattern width. It is also found that the height variation with the temperature becomes weaker as the pattern width increases. Strong height decreases observed near 200°C, particularly for narrow patterns, would suggest the occurrence of resist decomposition and/or evaporation. It is shown from the present result that the resist geometry can be readily controlled within the accuracy of a few tenths of a micron by using the width of 80-100 μm baking near 200°C. When it is necessary to protect an area of the substrate wider than the stripe, one can use an additional resist layer overlying partly the stripe pattern.

Another important parameter for controlling the step geometry is the ion-beam etch rate ratio between the resist and the substrate. We measured the etch rates of AZ-4620 resist and GaAs as a function of the ion incident angle. The result is shown in Fig. 3 together with their ratio. The ion energy and the current density were kept constant at 500 eV and 0.57 mA/cm², respectively, in this experiment. The etch rate ratio is found to vary monotonically in a wide range from 0.22 to 0.7 by increasing the incident angle from 0° to 70°.

In principle, by combining the resist deformation characteristic and the etch rate ratio variation with the incident angle, one can produce steps with arbitrary geometries on the GaAs substrate. However, the etched surface morphology is known to be affected by the ion-beam etching conditions, particularly by the ion incident angle. This effect has been actually found in our previous study of InP etching (19-21), but no data are available for GaAs,

Fig. 2. Photoresist height measured at pattern center as a function of baking temperature for a variety of pattern widths. The initial pattern height is 6.4 μm in this case.

Fig. 3. Ar ion-beam etching rates of GaAs and photoresist and their ratio vs. ion incident angle.

Fig. 4. Scanning electron micrographs showing ion-beam etched surfaces of GaAs. The ion incident angles used are 50° (a, b), 60° (c, d), and 70° (e, f). The ion energy and the current density are 500 eV and 0.57 mA/cm^2 , respectively. The etched depth is approximately $7\text{ }\mu\text{m}$ throughout. The bars in a, c, and e indicate $2\text{ }\mu\text{m}$ scale and in b, d, and f $0.2\text{ }\mu\text{m}$ scale. Note that the etched surface becomes defect free at the incident angle of 70° .

particularly for large etching depth, as would be required in OEIC applications. We attempted to correlate the etched surface morphology with the ion incident angle for a fixed etching depth of $7\text{ }\mu\text{m}$ using the ion energy of 500 eV and the current density of 0.57 mA/cm^2 . In this measurement, we used a substrate holder, as shown in the inset of Fig. 5, which lifts up the substrate to prevent it from being exposed to foreign material atoms sputtered during etching (20, 22). Figure 4 gives a set of scanning electron micrographs showing the GaAs surfaces etched at the ion incident angle of 50° (Fig. 4a, 4b), 60° (Fig. 4c, 4d), and 70° (Fig. 4e, 4f). At the incident angle of 50° , numerous low bumps with the diameter around a few microns are found on the etched surface, some of which form cones, as seen in Fig. 4b. The generation of bumps and cones is presumed to be attributed to the local masking effect (23) brought about by either the residual contamination existing on the surface prior to etching or foreign materials such as sputtered materials redepositing on the surface being etched (20). Column III atoms, Ga in

Fig. 5. Density of surface defects observed under microscope plotted vs. ion incident angle. The etching parameters used are same as in Fig. 4. The inset shows schematically the substrate holder used which can lift up the substrate surface for preventing the redeposition effect.

this case, accumulate at the etched surface of III-V semiconductors (27) to eventually form Ga droplets on the surface during prolonged etching. These may contribute to generate a strong masking effect to form bumps and cones as observed here. However, surface defects observed here have very small heights, differing from the feature found for high energy (40 keV) Ar ion bombardment at normal incidence (25). The nature of defect formation during ion-beam etching seems quite complicated, and further studies are required for fully understanding mechanisms of their formation. In practical view, however, glancing ion-beam incidence as has been used here is presumed to be significantly effective for smoothing the surface bumps. The mechanism of surface smoothing during ion bombardment has been discussed previously (25). The surface for the incident angle of 60° exhibits smoother morphology. Although some bumps are observed to remain, their contours are much rounded, as shown in Fig. 4d. By further increasing the incident angle to 70° , the surface smoothness is significantly improved. The number of such surface defects counted under microscope is plotted as a function of the ion incident angle in Fig. 5. The defect density is reduced down to 5000 cm^{-2} at 70° . This is close to the etch pit density of standard boat-grown GaAs crystals, and no additional effect of these ion-beam-generated defects on the device processing is anticipated. Moreover, these residual defects can be removed by carrying out solution etching of the substrate after ion-beam etching. Taking these into account, we have used in the following experiments the ion incident angle of 70° - 75° and short-time etching by $\text{H}_2\text{SO}_4 \cdot \text{H}_2\text{O}_2 \cdot \text{H}_2\text{O}$ system after the ion bombardment. The depth of surface damage production by ion-beam bombardment is expected to be less than 200 nm for GaAs at the ion energy of 500 eV (26). It has also been shown on III-V semiconductors ion-beam etched that the surface composition is modulated by the occurrence of column V atom dissociation and column III atom accumulation (20, 21, 27, 28). The solution etching employed after the ion-beam etching is effective for both smoothing the surface and removing damages.

Effect of Grading Steps in Photolithography

When photoresist technique is applied to the substrate having steps on its surface, the thickness of the photoresist varies at these steps and this causes the degradation of pattern defined by conventional contact lithographic apparatus. Photomicrographs showing such thickness variation at the step are given in Fig. 6. The step shown in Fig. 6a was formed by etching with a solution of $8\text{H}_2\text{O}_2 + 1\text{H}_2\text{SO}_4 + 1\text{H}_2\text{O}$, and the step in Fig. 6b was by the present graded-step process. The step height (d_s) is $7\text{ }\mu\text{m}$ for each, and the slope angles (θ) generated are approximately 45° and 13° for Fig. 6a and 6b, respectively. The photoresist (Microposit 1300-31) spin coated has a thickness of $2\text{ }\mu\text{m}$ when measured on the planar surface. The resist depletion at the top and the resist accumulation at the bottom of the slope are shown in Fig. 6a, and these effects are markedly reduced in Fig. 6b. The resist thicknesses, d_1 at the upper and d_2 at the lower surface, measured as a function of θ are plotted in Fig. 7 for two different values of the resist thickness on the planar surface. When a thicker ($d_0 = 3.4\text{ }\mu\text{m}$) resist is used, the step coverage is realized, but the resist thickness difference between above and below the step is more than $3\text{ }\mu\text{m}$ for every θ value examined. However, the thinner ($d_0 = 2\text{ }\mu\text{m}$) resist cannot cover the step edge for θ larger than 40° . However, the resist thickness difference $d_2 - d_1$ of only $1.4\text{ }\mu\text{m}$ is obtained by decreasing θ to 13° . In previous OEIC structures often having steep and high mesa steps on the substrate, it has been inevitable to thicken the resist layer for complete coverage. It has been shown from the present result that the use of a thin resist is allowed and the thickness variation at steps is reduced by grading steps.

Figure 8 shows scanning electron micrographs showing resist patterns delineated across steps with a height of $7\text{ }\mu\text{m}$ formed by solution etching (Fig. 8a) and the present

Fig. 6. Photomicrographs showing photoresist thicknesses on substrate steps having slope angle of 45° (a) and approximately 13° (b). It is clearly shown that the thickness uniformity is significantly improved by grading steps.

Fig. 7. Dependence of photoresist thicknesses at slope top (d_1) and bottom (d_2) on slope angle θ for two different levels of thickness measured in planar region (d_0). The difference, $d_2 - d_1$, is observed to be greatly reduced by using a graded step and a thin resist layer.

Fig. 8. Scanning electron micrographs showing resist patterns defined across substrate steps having slope angle of 45° (a) and 13° (b), respectively. A resist residue at the slope bottom in a indicates the difficulty of patterning process. The graded step in b is free from this problem.

graded-step process (Fig. 8b), respectively, corresponding to Fig. 6a and 6b. The resist thicknesses used are 3.4 and 2 μm , respectively. It is seen in Fig. 8a that resist residue exists at the slope bottom. Prolonged exposure has been observed to remove the resist residue but simultaneously cause a severe pattern widening at the slope top. The pattern defined across the graded step (Fig. 8b) shows no such problems. Figure 9 summarizes the result of pattern size deviations with respect to the mask pattern width, ΔW_0 on the planar part of the substrate, ΔW_1 at the slope top, and ΔW_2 at the slope bottom, measured as a function of the slope angle for two different resist thickness (d_0) values. In this measurement, the exposure time was adjusted for pattern improvement with the development time kept nearly constant. As shown in Fig. 9, the pattern width difference between the top and the bottom of the slope is in excess of 3.5 μm at θ larger than 40°, and it is reduced well below 0.5 μm by using the resist thickness of 2 μm and the value of θ of 13°. Thus the results shown in Fig. 8 and 9 demonstrate the superiority of graded steps for fine pattern lithography.

The quality of photoresist pattern when defined by contact lithography is sensitive to both the resist thickness and the mask to resist surface separation primarily

Fig. 9. Relation of deviations of resist pattern widths at slope top (ΔW_1) and slope bottom (ΔW_2) with respect to mask width as a function of slope angle for two different resist thicknesses. The effect of grading steps in improving the width fidelity is obvious. d_0 is defined to be the photoresist thickness measured in the planar region.

Fig. 10. Relation of exposure time with photoresist thickness at fixed development time. Closed circles show minimum exposure for pattern delineation, and open circles indicate overexposure which exhibit deviations of pattern widths with respect to the mask width as indicated by ΔW . The graded-step process examined here enables the use of exposure time at 8s, whereas the conventional 45° step needs the exposure time near 30s.

due to light diffraction. In view of the results of resist pattern definition described above, we attempted to correlate the pattern size difference observed at the top and the bottom of the step with the resist processing conditions. Figure 10 shows the exposure time required for pattern definition as a function of the thickness of the resist coated on a planar substrate for a constant resist development time of 30s. The minimum exposure time increases sharply as the resist thickness increases, reflecting an exponential decrease of light intensity along the resist depth. Additional plots and lines shown in the figure represent how large deviation (ΔW) of pattern width is produced by overexposure. It is only when the resist thickness of below $2 \mu\text{m}$ is used with minimum exposure time that no pattern width deviation is detected. At the resist thickness of $4 \mu\text{m}$, for example, even the minimum exposure for 20s produces width deviation of $1 \mu\text{m}$. We can estimate by using this characteristic together with Fig. 7 the pattern width deviation to be generated for a variety of slope angles. For the solution-etched step with $\theta = 45^\circ$, the resist layer of thickness $3.4 \mu\text{m}$ in the planar region is needed for obtaining usable step coverage. This causes a resist accumulation of $5 \mu\text{m}$ at the bottom and a thickness reduction to $1 \mu\text{m}$ at the top of the mesa slope, as shown in Fig. 7. The thickness of $5 \mu\text{m}$ is found from Fig. 10 to require the minimum exposure time of approximately 30s. However, this causes a significant overexposure to produce a pattern width deviation from the mask size at the top of the mesa slope. The amount of this is expected to be more than $2 \mu\text{m}$ as indicated in Fig. 10. However, actual pattern width deviation observed between the top and bottom surfaces is much more than $4 \mu\text{m}$, as shown in Fig. 9. For the graded step with $\theta = 13^\circ$, the same proce-

dures for a $2 \mu\text{m}$ thick resist gives the minimum exposure time of 8s and the pattern width deviation becomes smaller than $0.5 \mu\text{m}$, which agrees fairly well with the result shown in Fig. 9. Thus when the step is well graded so that the resist thickness is minimized, the pattern size deviation is reduced and its value can be expected directly from the exposure conditions. On the contrary, when the step becomes steep and the resist is thickened, the deviation becomes significantly more than expected from the thickness effect. This is presumed to be attributed to the second-order effects such as the light diffraction enhancement due to the mask to resist gap increase at the slope bottom and the overdevelopment effect at the slope top. The discussion made above confirms the usefulness of graded steps in fine pattern definition; they reduce the pattern width deviation less than $0.5 \mu\text{m}$ for the step height of $7 \mu\text{m}$.

Application to OEIC Fabrication

The graded-step process enables the use of thin photoresist layers for a series of photolithographic processes involved in OEIC fabrication so that sufficiently fine device geometries can be produced for both optical and electronic elements. This is particularly significant in OEIC's such that mesa step formation for epitaxial structure isolation is carried out in early stages of the fabrication procedure. This advantage of the present process has been used in fabricating monolithic PIN/FET and PIN/amplifier circuits on GaAs substrates. In the present fabrication, a horizontally integrated structure has been adopted, in which the photodiode and the FET's are all prepared on the semi-insulating (SI) GaAs substrate surface. This structure is advantageous in eliminating parasitic reactances which degrade the circuit performances such as the response time, as has been often experienced in assembling discrete elements.

Figure 11 illustrates the sequence of fabrication procedure. A channel was formed on a (100) orientated surface of SI-GaAs substrate using the graded-step process. The step height produced is typically $7\text{--}8 \mu\text{m}$. Then the growth of the photodiode structure consisting of a $2.5 \mu\text{m}$ thick n^+ -GaAs contact layer (Se-doped, $n = 10^{18} \text{cm}^{-3}$), a $2.5 \mu\text{m}$ thick n^- -GaAs photoabsorption layer (undoped, $n \leq 10^{15} \text{cm}^{-3}$) and a $0.5 \mu\text{m}$ thick high resistivity (HR) $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ window layer was performed over the whole surface of the substrate by metal-organic chemical vapor deposition (MO-CVD) as in our previous studies (29). The PIN photodiode mesa structure was delineated within the channel by removing the unwanted parts of the epitaxial structure using the graded-step process. Then the FET layers consisting of a $0.7 \mu\text{m}$ thick undoped-GaAs buffer layer and a $0.35 \mu\text{m}$ thick n -GaAs (Se-doped, $n = 1 \times 10^{17} \text{cm}^{-3}$) channel layer were prepared by MOCVD. The channel mesas were delineated again by the graded-step process. Subsequently, the PIN photodiode and the

Fig. 11. Fabrication sequence of PIN/FET and PIN/amplifier circuits. The graded-step process is used in every step (except b).

Fig. 12. Schematic cross section of AlGaAs/GaAs monolithic photoreceiver. The graded-step process has been extensively used in constructing this structure. The PIN photodiode and the FET are both formed horizontally and directly on a Si-GaAs substrate, and this configuration eliminates parasitic capacitances.

FET's were processed and the interconnections between the PIN photodiode and the front-end FET as well as among FET's were formed.

The detailed cross section of the monolithic photoreceiver is shown Fig. 12. The p-type region was formed by diffusing Zn into the HR AlGaAs layer to reach the AlGaAs-GaAs interface. Lifting off and subsequent alloying of Au/AuGe and Au/Zn/Au composite films were carried out for forming n- and p-type ohmic contacts, and the Schottky barriers were made by lifting off Al films. The FET's formed in this circuit had recessed-gate structures with the recess depth of approximately $0.15 \mu\text{m}$. The interconnections between the photodiode and the FET and within the amplifier were all formed by lifting off Au/Ti. Silicon nitride films were used for both forming antireflection coating of the photodiode and passivating FET channels. Figure 13 shows scanning electron micrograph of the processed PIN/FET chip. The PIN photodiode has the photosensitive area of $100 \mu\text{m}$ diam, and the FET channel width is $80 \mu\text{m}$. It is demonstrated in this figure that the PIN-FET interconnection and the FET gate contact are successfully formed over the mesa steps, respectively, having widths of 8 and $2 \mu\text{m}$. Figure 13b shows the interconnection exhibiting no pattern size degradation.

The performance of the fabricated PIN/FET was analyzed with the circuit shown in Fig. 14 under dc bias application of $V_1 = 10\text{V}$ and $V_2 = 4\text{V}$. The dark current of the PIN photodiode was less than 10 nA , and a high quantum efficiency of approximately 70% was observed. The pinch-off voltage was -2.5V , and the transconductance of 80 mS/mm were achieved in the present FET owing to the application of the recessed-gate structure. The current amplification characteristic was measured and the current amplification ratio of 1.4 was determined, which is consistent with the PIN load resistance of 200Ω multiplied by the FET transconductance of 6.5 mS . The pulse response measurement was carried out using a $0.85 \mu\text{m}$ wavelength AlGaAs/GaAs laser diode. The upper trace in Fig. 15 shows the driving current of the laser, and the lower one the FET drain current. The rise and fall time

Fig. 13. Scanning electron micrographs showing PIN/FET chip fabricated by the present technique. The PIN-FET interconnection has been successfully formed across $8 \mu\text{m}$ deep steps. Also a $2 \mu\text{m}$ long FET gate has been facilitated.

Fig. 14. Diagram of measurement circuit for monolithic PIN/FET. The dotted line indicates the part of monolithic integration.

can be determined to be as small as 0.6 ns from the lower trace. These compare well with the calculation, 0.57 ns , which was made by the sum of the capacitances of the photodiode (1.0 pF) and the FET gate (0.3 pF) and the load resistance.

We previously integrated similar PIN/FET in a form of vertical structure in which the FET layers are positioned above the PIN epitaxial structure with an intermediate high resistivity layer to isolate them (29). The response time of such vertical PIN/FET was observed to be degraded appreciably when the isolation layer becomes thinner than $5 \mu\text{m}$, due to the parasitic capacitance induced between the upper FET layer and the lower conductive (n^+) layer in the PIN structure. No such parasitic capacitance is expected in the present horizontal structure, and the result described above is considered to have demonstrated this advantage of the horizontal structure.

Figure 16 shows the photomicrograph and the circuit diagram of the PIN/amplifier photoreceiver chip. The chip size is $1.6 \times 1.0 \text{ mm}$. In this circuit design, a feedback amplifier including a monolithic resistor and an output buffer to ECL has been adopted. The circuit response analyzed under the application of laser light revealed the rise and fall time to be approximately 1.0 ns , which is consistent with the expectation made by the total capacitance of the PIN photodiode and FET gate (1.35 pF) and the feedback resistor ($1.3 \text{ k}\Omega$). This has again confirmed the elimination of parasitic capacitances in the present integrated structure. The details of the performance analysis are reported in a separate paper (30).

Summary

A new OEIC fabrication technique incorporating a graded-step process has been developed. This process has enabled the formation of steps on the semiconductor sub-

Fig. 15. Oscilloscope traces of current for source laser (upper trace) and output current of PIN/FET (lower trace), indicating fast rise and fall time of 0.6 ns of the present PIN/FET.

strate with their slopes much graded, down to the slope angle of 13° , which has not been possible by conventional solution etching. The mask formation and the subsequent Ar ion-beam etching procedures have been optimized for the application to OEIC fabrication. Significant effects of grading substrate steps have been demonstrated in defining fine patterns on the substrate using contact lithography. The graded steps have enabled one to use a thin resist layer, and therefore the pattern size deviation has been markedly reduced. The application of this process to fabricating AlGaAs/GaAs PIN/FET and PIN/amplifier circuits has confirmed a successful and reproducible operation of this process to generate fine device geometries such as $8\ \mu\text{m}$ interconnections and $2\ \mu\text{m}$ gate contacts, regardless of the existence of PIN photodiode mesa as high as $8\ \mu\text{m}$.

The present result has demonstrated the usefulness of this process in OEIC fabrication. When the mesa steps are formed at early stage in the fabrication process sequence, as in most cases of OEIC fabrication, the improvement of photolithographic reproducibility by the present process can contribute enormously to increase in overall fabrication reproducibility and yield. Such an advantage of the present process could play an increasingly important role in extending the integration scale of OEIC's.

Reports on the Energy Research Summer Fellowship Awards

Cathryn Goodman

Gary A. Reitz

Holly-Dee Rubin

Hal Van Ryswyk

For the summer of 1984, the following students were awarded Energy Research Summer Fellowships. Each award carried with it a grant of \$2000.

Ms. Cathryn Goodman, of Northwestern University, Evanston, Illinois.

Mr. G. A. Reitz, of the University of Texas, Austin, Texas.

Ms. Holly-Dee Rubin, of Princeton University, Princeton, New Jersey.

Mr. Hal Van Ryswyk, of the University of Wisconsin, Madison, Wisconsin.

The Energy Research Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need. They are made to graduate students pursuing work between the degrees of B.S. and Ph.D., in a college or university in the United States or Canada." The recipients' projects are in fields relating to energy research or of interest to The Electrochemical Society. The Awards are sponsored by the Department of Energy and made by the Summer Fellowship Committee of The Electrochemical Society.

Cathryn Goodman received her B.S. degree in Ceramic Engineering from the University of Illinois, Champaign-Urbana in 1981. Following graduation, she worked as a process engineer in the hybrid circuit development laboratory of Motorola, Incorporated, in Franklin Park, Illinois. She is currently a Ph.D. candidate at Northwestern University in Evanston, Illinois. Her thesis topic concerns the characterization of surface states at the semiconductor/electrolyte interface.

Ms. Goodman's report is given below.

Characterization of Surface States at the InP/Liquid Interface

Photoelectrochemical (PEC) cells offer one of the most promising methods for converting solar energy into useful chemical fuels. The primary components of a PEC cell are a semiconductor photoelectrode, an electrolytic solution, and a metal counterelectrode. The energy difference between the redox potential of the redox couples in the electrolyte and the Fermi level in the semiconductor produces a depletion region in the semiconductor at the electrode/electrolyte interface. The depletion region separates charge carriers that are photogenerated near the semiconductor surface before they can recombine. Minority carriers are swept to the interface, where they can take part in a redox reaction. Conversely, majority carriers are swept to the counterelectrode through the external circuit, where they can take part in a different reaction. The net result is the conversion of light energy to chemical free energy. Because of their potential for practical applications, many studies have been conducted to optimize the efficiency of PEC cells (1-7). One particularly promising system involves the production of hydrogen using a p-InP photocathode.

Several properties of p-InP make it a good choice for use as a photocathode in PEC cells. First, the bandgap of the semiconductor used as a photocathode must be small enough to allow for a significant portion of the solar spectrum to generate electron-hole pairs and yet be large enough to straddle the appropriate redox energy levels (H^+/H_2 and O_2/H_2O for photohydrolysis). The efficiency of the cell is optimized when the bandgap of the semiconductor is 1.3 eV (8). Therefore, the bandgap of InP, 1.35 eV, makes it an ideal choice for this purpose. Second, the stability of the electrode is an important factor in determining cell performance. The use of a p-type material is advantageous because the electrons that are swept to the surface of the electrode cathodically protect it against oxidation. Since the products of reductive corrosion reactions are thermodynamically less stable than oxidation products (5), photoelectrodes made of p-type materials are inherently less subject to corrosion than n-type photoelectrodes.

Indeed, several PEC cells with p-InP photoelectrodes have been developed with efficiencies as high as 16% (3, 4, 6, 7). The key factor in obtaining these high efficiencies was the development of surface treatments for the semiconductor electrode. The surface treatment of the semiconductor photoelectrode is important to cell efficiency because of the role that surface states perform in PEC cell operation. The presence of surface states associated, for example, with native defects or adsorbed species can act as charge carrier traps, recombination centers, or intermediate states for charge transfer.

It was previously concluded that the InP surface treatments increased the efficiency of the PEC cells by altering the surface states (5). This suggests that the efficiency of a PEC cell can be maximized only if these surface states are understood and controlled. In order to develop an accurate model for recombination and charge transfer via surface states, quantitative data of surface-state energy levels, den-

sities, and capture cross sections are required. This study utilizes steady-state photocapacitance spectroscopy (9, 10) to characterize the semiconductor electrode/electrolyte interface states, to determine the effect of various surface modifications on these states, and to correlate these results to cell performance.

Steady-state photocapacitance (Phcap) spectroscopy of liquid junction cells involves the measurement of the capacitance of a reverse biased semiconductor electrode as a function of the wavelength of incident sub-bandgap light. For a p-type semiconductor in the dark, the positive charge in the Helmholtz layer is compensated by the fixed negative charge associated with ionized acceptors in the semiconductor. The space-charge layer in the semiconductor has a capacitance that can be described by the equation for a parallel plate capacitor

$$C = Ak \epsilon_r / W$$

where A is the area of the plates, k is the dielectric constant, ϵ_r is the permittivity of free space, and W is the distance between plates. A change in the concentration of fixed charge in the depletion layer will change the depletion layer width, W , and will be detected as a change in the capacitance. In photocapacitance experiments, the fixed charge is altered when defect levels are optically populated or depopulated. When the incident monochromatic light is of the energy required for a particular transition, a normally occupied (unoccupied) state can be depopulated (populated). The change in the trap occupation will alter the space-charge layer width and will be detected as a discontinuity in the measured capacitance. The energy level of the transition can therefore be determined from the threshold energy of a capacitance discontinuity. The density of the states can be calculated from the magnitude of the capacitance change.

The photocapacitance technique also allows for the discrimination between surface and bulk states by two methods. First, if the bias applied a p-type semiconductor photoelectrode is made more cathodic, the depletion width will increase, thereby increasing the number of bulk traps contributing to the Phcap signal. An increase in the magnitude of signals due to bulk traps will then be observed. If only bulk states contribute to the measured capacitance of the electrode when it is exposed to incident light of a particular energy, the capacitance is related to applied voltage by the Mott-Schottky equation (11)

$$\frac{1}{C^2} = \frac{2}{q\epsilon\epsilon_0 N} (V - V_{FB})$$

where q is the electronic charge, ϵ is the dielectric constant of the photoelectrode, N is the total density of fixed charge, V is the applied voltage, and V_{FB} is the flatband voltage. Therefore, if a plot of $1/C^2$ vs. V is linear when C is the capacitance measured with incident light of sufficient energy to promote a particular transition, it can be concluded that the transition is related to a bulk defect state. The second method for distinguishing surface and bulk states is to change the electrolyte. A change in the composition of the solution would be expected to affect only surface-related features.

The work in this laboratory to date has involved the investigation of p-InP photoelectrodes subjected to surface treatments that have been shown to increase PEC cell efficiency. Single-crystal liquid-encapsulated Czochralski InP substrates with net acceptor concentrations of $1-5 \times 10^{16}$ per cubic centimeter were used as the photocathodes. The crystals had a (100) or (111) orientation and were chemically-mechanically polished prior to use. The electrodes were illuminated with monochromatic light from a Zeiss MM12 double prism monochromator equipped with a 250W quartz-halogen lamp. Photocapacitance measurements were performed over the spectral range of 0.5-1.5 eV with a Boonton 72B capacitance meter. The photocapacitance experiments were conducted with a 6M KOH (pH = 14), a 1M KCl + 0.05M CH₃COOH + 0.05M CH₃COONa (pH = 4.8), or a 1M KCl + 0.01M HCl (pH = 2.1) electrolyte. Pt served as the counterelectrode, and a standard calomel electrode served as the reference electrode. The applied bias was controlled with a BAS CV-1B cyclic voltammetry unit. The surface modifications included a 10s concentrated HCl etch and a Co/Pt treatment (7).

A previous study has shown that the Co and Pt treatment has a dramatic effect on the Phcap spectra of an InP electrode (10). The spectra for a sample subjected to an HCl etch exhibited only a single photocapacitance threshold, which occurred at 1.25 eV. The capacitance decrease at 1.25 eV was attributed to the promotion of electrons in a defect state 1.25 eV below the conduction band to the conduction band. After the Co and Pt treatment, the transition at 1.25 eV diminished and an increase in capacitance appeared at 1.20 eV. It was concluded that the Co and Pt treatment introduced a surface state 1.20 eV above the valence band into which electrons were promoted.

The reason for the enhanced efficiency following a Co and Pt treatment appears to be twofold (10). First, the efficiency increased due to a reduction in the number of recombination states near the valence band. Second, the introduction of a state at $E_v + 1.20$ eV presumably allowed for more efficient charge transfer from the semiconductor to the redox couple via the surface state.

These results indicate that photocapacitance spectroscopy is sensitive to semiconductor surface modifications. This information, along with a knowledge of cell efficiencies, allowed a model to be developed for the role of surface states in PEC cell operation. It is desirable, however, to obtain direct quantitative evidence that will allow for the discrimination between surface- and bulk-related states and permit the calculation of defect-state concentrations.

The time period covered by this Fellowship was devoted to studying PEC cell photocapacitance response as a function of bias and electrolyte composition in order to characterize surface and bulk states. The equations developed by Haak and Tench (9) were employed to calculate surface-state densities.

Figure 1 gives a typical Phcap scan for an as-received p-InP photocathode in KOH with no external bias. The spectrum indicates that a transition occurred to a state 1.17 eV above the valence band and that another transition occurred from a state 1.27 eV below the conduction band to the conduction band. Defect states at approximately $E_v + 1.2$ eV and $E_c - 1.3$ eV were consistently observed in a number of electrodes. An analysis of the photocapacitance signals indicates concentrations of $1.1 \times 10^{11}/\text{cm}^2$ and $1.7 \times 10^{11}/\text{cm}^2$ for the $E_v + 1.2$ eV and $E_c - 1.3$ eV transitions, respectively. It should be noted that these measurements were made with a light intensity which may not have been sufficient to saturate the defect states. Therefore, the actual concentrations may have been higher.

To determine if the transitions involved surface or bulk traps, a series of spectra as a function of reverse bias were obtained. The results are shown in Fig. 2. The contribution to the photocapacitance signal due to the $E_v + 1.2$ eV transition can be seen to increase with reverse bias. However, in this case, a plot of $1/C^2$ as a function of applied potential for the capacitance values measured when the electrode was subjected to 1.2 eV light did not reveal the nature of the 1.2 eV transition. The scatter in the data was too great to allow for a conclusion to be made as to whether or not the trap obeyed the Mott-Schottky equation. More precise measure-

Figure 1

Figure 2

ments are needed to determine if the 1.2 eV transition is bulk related. In contrast, the $E_c - 1.3$ eV Phcap signal decreased as the cathodic bias increased. This indicates that the transition is surface related.

To verify the surface sensitivity of the Phcap measurements, experiments were conducted using several other electrolyte solutions. The photocapacitance response for an as-received sample in solutions with pH = 2 and pH = 5 are shown in Fig. 3. Curve (a), pH = 5, shows the same capacitance transitions that were observed in Fig. 1 (pH = 14). Curve (b), pH = 2, however, differs significantly, owing to a large capacitance increase at approximately 1.25 eV. In ad-

Figure 4

Figure 3

dition, the decrease in capacitance at 1.3 eV is not present in this spectrum. Figure 4 shows the photocapacitance spectra in the three solutions for an electrode subjected to an HCl etch. Again, a transition at 1.25 eV appears, and the 1.3 eV transition disappears in the spectra corresponding to acidic solutions. The dependence of the Phcap spectra on the composition of the electrolyte solution confirms that photocapacitance is sensitive to interface states at the semiconductor/electrolyte interface.

It is interesting to note the similarity between the photocapacitance spectra from the Co- and Pt-treated sample (10) and the as-received and etched samples in an acidic electrolyte (Fig. 3 and 4). The reason for the similarity is not understood, but the capacitance discontinuities may be associated with the same defect states. Work will continue to determine the mechanisms responsible for the photocapacitance results.

In summary, the work to date has shown that steady-state photocapacitance spectroscopy is a powerful tool for obtaining valuable information about the semiconductor/electrolyte interface in a photoelectrochemical cell. The technique allows for the detection and characterization of both bulk and interface charge-carrier traps. Additional information concerning the nature of these states can be obtained by varying the applied bias and the electrolyte. In particular, the work with InP looks promising for detailed kinetic studies, and work will continue to correlate the observed surface states and efficiencies.

The author would like to thank The Electrochemical Society for its support through the Summer Fellowship and Professor B. W. Wessels for helpful consultations. The author is grateful for the continued support of the Gas Research Institute and Eltron Research Incorporated. Optical measurements were performed in the facilities of the Materials Research Center at Northwestern University supported in part by the National Science Foundation.

Currently, Mr. Reitz is pursuing his Ph.D. degree at the University of Texas at Austin.

Mr. Reitz's report is given below.

Electrochemical Reduction of Olefins Catalyzed by Nickel Complexes

A recent significant development in catalysis is the discovery of redox transformations mediated by altered oxidation levels of metal complexes or organometallic reagents. We report here our investigation of the catalytic reduction of olefins mediated by controlled reduction of nickel complexes of varying structure and reduction potential.

The physical properties of nickel complexes with bipyridine and related dinitrogen-containing ligands have been extensively studied, both in aqueous and nonaqueous solution, by spectrophotometry (1-4), electrochemical techniques (5-8), ESR (5), and circular dichroism (9), yielding information about their magnetic moments and conductivities (10-12), stability constants (13-15), and heats (16) and kinetics (17) of formation. These nickel complexes have been reported to catalyze a variety of homogeneous reactions, including *cis* addition of deuterium cyanide to olefins (18), insertion of CO into nickel-ligand bonds to yield ketones and tertiary alcohols (19), Michael additions (20), and polymerization of olefins (21-24). Nickel complexes have also been electrochemically generated *in situ* to catalyze the formation of substituted olefins (25).

Both nickel complexes NiL_mX_n and their parent compounds NiX_n form complexes with vinyl monomers such as acrylonitrile (21-24). Under certain conditions, Ni complexation with the vinyl monomer initiates polymerization of the monomer. Kern (21) has noted that anhydrous $NiCl_2$ is unreactive toward acrylonitrile in the absence of Zn metal. Barton *et al.* (22) have determined that free radical polymerization of several vinyl monomers was initiated by the $NiCl_2$ -N,N-dimethylaniline complex. Several aryl (bipyridine) nickel halide complexes, which themselves exhibit no catalytic activity for the polymerization of vinyl monomers, have been prepared by Uchino and co-workers (23). However, in combination with Lewis acids, these nickel complexes catalyzed the polymerization of several vinyl monomers.

The purpose of the work reported herein was to examine whether electrochemical generation of radical ions of several nickel dinitrogen containing complexes would initiate polymerization of the vinyl monomer acrylonitrile. The complexes examined were NiL_2Cl_2 complexes, where L = bipyridine, 1, and substituted bipyridines, phenanthroline, 2, and substituted phenanthrolines, and biquinoline, 3, and substituted biquinolines. One NiL complex was also examined, where L = hexa-aza-macrocycle, 4.

Experimental

Materials.—Anhydrous nickel (II) chloride was obtained by the method of Pray (26). Green $NiCl_2 \cdot 6H_2O$ (MCB, reagent grade) was refluxed with freshly distilled thionyl chloride ($SOCl_2$) (MCB, reagent grade) for 2.5h in a reflux apparatus equipped with a drying tube. Excess $SOCl_2$ was removed by distillation. The flask containing orange anhydrous $NiCl_2$ was then transferred to a vacuum desiccator containing NaOH and allowed to stand for several days to remove any remaining traces of $SOCl_2$.

N,N-dimethylformamide (DMF) (MCB, glass-distilled) was purified by predrying over anhydrous magnesium sulfate (Fisher, Certified grade) or anhydrous barium oxide (Fisher, technical grade) followed by vacuum distillation (bp:78°C at 39 torr). Chloroform (MCB, reagent grade) and methanol (VWR Scientific, reagent grade) was used as received. Tetrahydrofuran (THF) (MCB, reagent grade) was refluxed over calcium hydride and distilled prior to use. Acrylonitrile (MCB, reagent grade) was purified by washing with successive portions of dilute H_2SO_4 , dilute Na_2CO_3 , and water, and drying over molecular sieves (MCB, 4A), followed by simple distillation. This afforded acrylonitrile (bp:77°C), greater than 95% purity by NMR. Anhydrous tetrabutylammonium perchlorate (TBAP) (Southwestern Analytical Chemicals, electrometric grade) was recrystallized from Skelly B: ethyl acetate and dried at 50°C *in vacuo* for 4-6h. Ferrocene (Aldrich) was purified by sublimation prior to use.

Ligands obtained from Aldrich (2,2'-bipyridine, 1,10-phenanthroline [gold label], 4,7-diphenyl-1,10-phenanthroline) and Alfa (4,4'-dimethyl-2,2'-bipyridine, 2,9-dimethyl-1,10-phenanthroline, 2,2'-biquinoline, 4,4'-dicarboxy-2,2'-biquinoline) were all reagent grade unless specified and were used without further purification. All other ligands (2-chloro-1,10-phenanthroline, 2,9-dichloro-1,10-phenanthroline, 2,9-diamino-1,10-phenanthroline, and hexa-aza-macrocycle) were synthesized (27, 28).

The $Ni(bpy)_2Cl_2$ complex was prepared by dissolving anhydrous $NiCl_2$ in methanol, adding excess bipyridine, stripping off the solvent under vacuum, and subliming the excess bipyridine out of the solid mixture. All other nickel complexes were prepared by a variation of the method of Inskeep (1). Stoichiometric amounts of anhydrous $NiCl_2$ and the ligand were dissolved in methanol, warmed to effect complete solution, and the solvent then removed under vacuum. Because of limited solubility in methanol, stoichiometric amounts of both of the biquinoline complexes, the 2,9-dichlorophenanthroline complex, and the hexa-aza-macrocycle complex were refluxed with anhydrous $NiCl_2$ in THF for 6h. The THF was then removed under vacuum.

Instrumentation and equipment.—Cyclic voltammetry was performed using a Bioanalytical Systems BAS-100 Electrochemical Analyzer and a Houston Instruments Hiplot DMP-40 digital plotter. The cell used was a one-compartment cell equipped with a 3 mm² platinum disk working electrode, a platinum wire counterelectrode, and a silver/0.1M silver nitrate in acetonitrile reference electrode. Tetra-n-butyl ammonium perchlorate (TBAP) was used as the supporting electrolyte (0.1M in DMF). All solutions were deaerated with argon for at least 10 min prior to obtaining the voltammograms. Positive IR compensation for

solution resistance was utilized in all experiments. The scan rate in all experiments was 100 mV/s.

Preparative electrolyses were performed using a Princeton Applied Research (PAR) Model 173 potentiostat, a Model 179 digital coulometer, and a Model 175 universal programmer. The cell used was a two-compartment cell with a fine glass frit separating the working and counterelectrode compartments. Solutions of 0.2M TBAP in DMF were used as the electrolyte. A platinum wire coil electrode and a platinum gauze electrode were used as the working and counterelectrodes, respectively, while Ag/AgNO₃ was used as the reference electrode. Typically, 75-100 mg of acrylonitrile and a few milligrams of anhydrous Ni(bpy)₃Cl₂ were dissolved in 5 ml of the electrolyte solution, placed in the working electrode compartment, and deaerated with argon prior to electrolysis. Controlled-potential electrolyses were performed at -2.2V.

All potentials reported herein are referenced to the Ag/AgNO₃ reference electrode. The ferrocene/ferrocenium couple displays a one-electron reversible wave centered at +0.02V vs. Ag/AgNO₃, as compared with +0.307V vs. an aqueous saturated calomel electrode (SCE) (29).

Low resolution mass spectra were obtained on a du Pont 21-491 mass spectrometer with INCOS data system. Proton nuclear magnetic resonance spectra were obtained on a Varian EM-390 spectrometer.

Results and Discussion

The electrochemical reduction of olefins using nickel complexes as catalysts was studied, and acrylonitrile was chosen as a model substrate. Acrylonitrile displayed no electrochemical activity over the DMF solvent window +0.50 to -2.50V vs. Ag/AgNO₃. Addition of acrylonitrile, however, to solutions of the nickel complex caused, in all cases, disappearance of reversibility of the voltammetric waves associated with reduction of the nickel complex and concomitant formation of other waves attributed to association of acrylonitrile with the nickel complex. Peak potentials obtained by cyclic voltammetry of the NiL₃Cl₂ and NiL complexes in DMF are tabulated in Table I. Also included in Table I are the peak potentials seen upon addition of a small amount of acrylonitrile to the NiL_nX₂ solutions.

Cyclic voltammograms of the nickel (tris)bipyridine complex prior to and following addition of acrylonitrile are shown in Fig. 1. The Ni(bpy)₃Cl₂ complex itself displays a nearly reversible wave centered at -1.57V vs. Ag/AgNO₃ and a second irreversible reduction wave at E_{p,c} = -2.40V. These waves are replaced, on addition of acrylonitrile, by a quasireversible wave centered at -2.07V and two other irreversible reduction waves at -1.57 and -1.71V. Since acrylonitrile itself does not undergo cathodic reduction at potentials less negative than -2.50V, the appearance of new waves for the Ni(bpy)₃Cl₂-acrylonitrile complex indicates that electrocatalytic reduction of acrylonitrile by the Ni(bpy)₃Cl₂ complex is occurring. Preliminary examination by mass spectrometry of the products obtained by

Fig. 1. Cyclic voltammograms of 5×10^{-3} M Ni(bpy)₃Cl₂ in 0.1M TBAP/DMF (a) prior to addition of acrylonitrile and (b) after addition of acrylonitrile. Platinum working electrode area: 3 mm². Scan rate: 100 mV/s. Reference electrode: silver/silver nitrate (0.1M) in acetonitrile.

constant-potential coulometry of a solution of acrylonitrile and Ni(bpy)₃Cl₂ in 0.2M TBAP/DMF reveals the major product of the electrolysis to be a polymer of acrylonitrile. Ni(bpy)₃Cl₂, then, acts as a catalyst for the cathodic polymerization of acrylonitrile.

Similar catalytic behavior is observed for most of the related nickel complexes, as shown in Table I. The parent NiCl₂-acrylonitrile complex is reduced at a potential substantially less negative than that of the Ni(bpy)₃Cl₂ analog; however, the nonreversibility of the NiCl₂-acrylonitrile system makes NiCl₂ a poor choice for a catalyst. Except for the Ni(2-Cl(phen))₃Cl₂-acrylonitrile complex, the largest cathodic peak in all of the NiL_mCl₂-acrylonitrile voltammograms is the most negative of the observed peaks. Focusing on the largest cathodic peak, all of the complexes show catalytic activity toward reduction of acrylonitrile, though with varying reduction potentials depending on the structure of the ligand.

Within each series of related ligands, substituent effects on the reduction potential of the NiL_mCl₂-acrylonitrile complex are observed for the largest cathodic peaks in the voltammograms. For the 2,2'-bipyridine series, substituting the slightly electron-donating methyl groups on the 4,4' positions results in a small negative shift in reduction potential, as would be expected. The parent complex of the phenanthroline series, Ni(phen)₃Cl₂-acrylonitrile complex, shows a quasireversible wave centered at -2.07V. The 4,7-diphenyl substituted phenanthroline complex is much easier to reduce (-1.95V) than the unsubstituted complex. As anticipated, the electron donating methyl and amino groups both shift the reduction potential of the acrylonitrile complex to more negative potentials (-2.16 and -2.33V, re-

Table I. Cyclic voltammetric data for nickel complexes and their interaction with acrylonitrile

^d AN = acrylonitrile.

^e (q) = Quasireversible.

spectively). Anomalous results are obtained from the Ni(2,9-diCl(phen))₃Cl₂-acrylonitrile complex, though. With two electron withdrawing groups on the ring, the reduction potential would be predicted to be shifted anodically. However, a cathodic shift of 90 mV is obtained for this complex, compared to the parent Ni(phen)₃Cl₂-acrylonitrile complex. The biquinoline series behaves as expected, though. The parent Ni(biqn)₃Cl₂-acrylonitrile complex possesses a reduction potential of -1.67V, while the 4,4'-dicarboxy analog reduces at -1.43V, which exhibits the predicted substantial negative anodic shift.

Between the series of complexes, especially the bipyridine and biquinoline series, there is a large difference in reduction potential between the NiL_mCl₂-acrylonitrile complexes ($\Delta E_p = 0.19V$ for the parent complexes). This difference in reduction potential is probably because the more conjugated biquinoline ring system is easier to reduce than the less conjugated bipyridine ring system, and that difference parallels the change in reduction potential from biquinoline itself to bipyridine (about 0.50V) (30).

It has been demonstrated that nickel complexes with various ligands can catalyze the cathodic reduction of acrylonitrile. Electrochemical stability of the catalyst is also necessary for any practical system. Toward this end, only the Ni(bpy)₃Cl₂, Ni(4,4'-diMe(bpy))₃Cl₂, Ni(phen)₃Cl₂, and Ni(4,7-diPh(phen))₃Cl₂ complexes have demonstrated sufficient reversibility to be potentially useful on a large scale.

Acknowledgments

Synthesis of several ligands (2-chlorophenanthroline, 2,9-dichlorophenanthroline, 2,9-diaminophenanthroline, and hexa-aza-macrocyclic) by Martin Johnson is greatly appreciated. G. A. R. is grateful for support as an Electrochemical Society Energy Research Summer Fellow. A special thanks goes to Professor Marye Anne Fox for her guidance and support. This work was supported by the U. S. Department of Energy, Fundamental Interactions Branch.

Ms. Rubin's report is given below.

Cation and Wavelength Effects on the CdSe/Fe(CN)₆⁴⁻ Photoelectrochemical Solar Cell

The major obstacles in the utilization of semiconductor liquid junction cells for solar energy conversion have been photocorrosion of the semiconductor material and the rather low energy conversion efficiencies of these devices. As previously reported (1), the photodecomposition of n-CdS in a Fe(CN)₆^{4-/3-} electrolyte is dramatically decreased in the presence of a mixture of K⁺ and Cs⁺ ions. Not only is stability improved, but monochromatic (488 nm) conversion efficiencies in excess of 20% have been observed. Gerischer (2) had previously demonstrated that addition of a K₄Fe(CN)₆/K₃Fe(CN)₆ mixture to the aqueous CdS photocell slightly decreased the photo-oxidation reaction

The slower decomposition has been attributed to a competition between oxidation of solution Fe(CN)₆⁴⁻ and the oxidation of the electrode surface (3). However, we have shown (1) through diffuse reflectance FTIR spectroscopy that there is actually a layer of K_xCs_y[Cd^{II}Fe^{II}(CN)₆] on the surface of the electrode under the conditions employed. This layer is produced when photochemically generated Cd²⁺ ions react with solution Fe(CN)₆⁴⁻. Layers of this type have already been shown to enhance charge transfer and inhibit corrosion at metal electrodes (4). For the case of the semiconductor, we believe that the enhanced stability and efficiency are associated with good orbital overlap between the semiconductor bandedges and the redox active surface layer orbitals. Once reduced, the surface material is then capable of facile charge transfer to solution Fe(CN)₆⁴⁻.

Because of the smaller bandgap of CdSe, and owing to reports (5) of stabilized photocurrents of n-CdSe in aqueous alkaline Fe(CN)₆^{3-/4-}, this system was found to be of interest. The results of this investigation are reported below. Experiments were conducted using both single-crystal and polycrystalline n-CdSe electrodes. Samples were irradiated using either an argon ion or helium-neon laser. The electrolyte was composed of 0.2M K₄Fe(CN)₆ and 0.01M K₃Fe(CN)₆ with 0.1M KOH as supporting electrolyte. A standard potentiostated three-electrode configuration was employed using a platinum counterelectrode and a SCE reference electrode. Analogously to n-CdS, bandgap irradiation leads to the formation of an insoluble K_x[Cd^{II}Fe(CN)₆] surface layer. The n-CdSe/Fe(CN)₆^{4-/3-}/KOH system is stable for periods in excess of several hours when irradiated with 488 nm light (current density ~ 1 mA/cm²). Addition of Cs⁺ leads immediately to a precipitous decay in photocurrent ($t^{1/2} \sim 30$ min), in contrast to the stability effects of Cs⁺ on the n-CdS system.

These results can be explained using the model previously described (1). The incorporation of Cs⁺ cations into the surface layer is expected to cause the redox potential of the surface species to become more positive (6). In the case of the n-CdS, this shift could lead to increased overlap between the semiconductor valence band states and the oxidizable cadmium ferrocyanide surface layer. n-CdSe, though, is expected to have a valence bandedge which is already at a more negative potential than that of n-CdS by ~

700 mV (5a). Therefore, any positive shift in the redox potential of the surface layer may shift these levels significantly positive of the valence band edge, actually decreasing the degree of overlap, and thus slowing interfacial charge-transfer kinetics and enhancing electrode decomposition processes.

A most unusual result was discovered in the course of these studies. The n-CdSe cell photocurrent stability was found to be dependent on the wavelength of incident irradiation. When irradiated with 488 nm light, stable photocurrent output was achieved in excess of several hours. However, when excitation is at 633 nm, the photocurrent decays rapidly ($t^{1/2} \sim 30$ min). Furthermore, preirradiation at 488 nm induces photostability upon subsequent irradiation at 633 nm. To our knowledge, such a wavelength dependent photoelectrochemical decomposition reaction has never before been reported. As will be discussed in a forthcoming communication (7), we attribute the wavelength dependence to the photochemical properties of the surface species, *i.e.*, the surface species undergoes a purely photoinduced reaction, possibly CN^- loss, which modifies the surface layer in such a way so as to enhance charge-transfer rates at the semiconductor electrolyte interface.

Mr. Van Ryswyk's report is given below.

Luminescent Properties of a Surface-Modified Cadmium Selenide Electrode

We have used photoluminescence (PL) and electroluminescence (EL) to characterize electric fields in a variety of semiconductor electrodes. Samples of n-CdSe have been the focus of several such studies (1-4) and reflect the importance of this small bandgap material in the design of efficient photoelectrochemical cells (PEC's).

Modified semiconductor surfaces are now being intensely investigated with regard to device applications. A novel system recently reported by Bocarsly *et al.* is based on the modification of n-CdS and n-CdSe electrodes using a ferri/ferrocyanide electrolyte; for n-CdS, the modified electrode leads, for specific cations, to an appreciable increase in optical-to-electrical energy conversion efficiency obtainable in a PEC (5).

In this report, we examine PL and EL properties of a ferri/ferrocyanide-modified n-CdSe electrode. We show that PL intensity from the modified electrode is in good accord with a dead-layer model found applicable to naked, homogeneous electrodes (4, 7, 8), and that EL properties of

Fig. 1. Auger spectrum of the surface layer of a ferri/ferrocyanide-modified CdSe electrode as a function of sputter time. Conditions are listed in the experimental section. Relative peak-to-peak sensitivities are: K, 0.80; Cd, 1.0; Fe, 0.21; C, 0.20; N, 0.33; Se, 0.06; O, 0.50.

the modified CdSe electrode are comparable to those of the naked electrode.

Experimental

Samples of n-CdSe c-plates were purchased from Cleveland Crystals, Incorporated. The crystals were mounted with the (0001) (Cd-rich) face outwards, then etched in Br₂-methanol (1:10 v/v), rinsed with water, and dipped in conc HCl for 10s. The electrodes were irradiated at open circuit with 50 mW cm⁻² of 488 nm light from an Ar⁺ laser in an electrolyte of 0.2M K₄Fe(CN)₆/0.01M K₃Fe(CN)₆/1M KOH for 25 min before being brought into circuit in the same electrolyte at +0.1V vs. SCE for 10 min. The stability of this modified electrode was tested by operation in a PEC employing fresh ferri/ferrocyanide electrolyte and 633 nm excitation (HeNe laser), a wavelength which did not promote film growth. Only those electrodes showing a steady photocurrent with time were used in succeeding experiments. Unless otherwise noted, the cation used in all electrolytes was K⁺, which was found to stabilize the surface layer on CdSe (6).

The experimental setups for the dead-layer measurements and EL efficiencies are described elsewhere (1, 7). EL experiments were performed using a 0.5M OH⁻/0.1M S₂O₈²⁻ electrolyte with either K⁺ or Na⁺ counterions. Peroxydisulfate concentrations were determined by iodometric titration.

Auger electron spectroscopy (AES) was performed on a modified electrode using a Physical Electronics Model 548 instrument operating with a 3 keV, 25 μA primary electron beam approximately of 200 μm diam. Sputter etching was conducted using a 2 mm diam beam of 5 keV, 25 mA Ar ions with the chamber backfilled to 5 × 10⁻³ torr of Ar.

Results and Discussion

Modification of the shiny CdSe electrode as described above yields a dull black matte surface. An Auger spectrum of the surface layer shows it to consist of K, Cd, Fe, C, N, and O in a ratio of 1.0:1.0:1.0:6.1:6.0:0.70. A sputter etching experiment, illustrated in Fig. 1, shows the surface layer composition to be relatively independent of depth, eventually giving way to the CdSe substrate. Species with related compositions, such as K₂CdFe(CN)₆ and KCdFe(CN)₆, have zeolite-like channels (9). If the modified electrode has a similar structure, the presence of oxygen may signify trapped water.

When the modified electrode is used as a photoanode in a PEC, its PL intensity can be quenched by applied potential. Figure 2 presents photocurrent-μ PL intensity-voltage data (iLV curves); the potential-independent spectral distribution permits PL to be monitored at 720 nm. Quenching of PL in PEC's has been described using a dead-layer model originally applied to semiconductor-metal, Schottky barrier systems: e⁻-h⁺ pairs formed within a distance on the order of the depletion width do not contribute to PL; this model thus relates PL intensity to the thickness of the electric field in the electrode. The quantitative form of the model is given by Eq. [1]

$$\phi_r/\phi_{rFB} = \exp(-\alpha'D) \quad [1]$$

where ϕ_r and ϕ_{rFB} are radiative efficiencies in circuit and at flatband potential (assumed to be open circuit), respectively; D is the dead-layer thickness; and $\alpha' = \alpha + \beta$, with α and β the solid's absorptivities for the exciting and emitted light. For the Fig. 2 data, D is calculated to be approximately 3000 Å at short circuit, which is roughly equal to the depletion width for this sample with N_D of $\sim 1 \times 10^{16}$ cm⁻³. When the experimental curves are compared to curves calculated by assuming that all of the applied potential appears in the semiconductor (7), good accord is found, indicating that applied potential appears predominantly in the semiconductor, and not in the Helmholtz layer or the surface layer.

An additional probe of the surface layer is to use the modified electrode to generate EL in basic S₂O₈²⁻ electrolyte. This can be done with an efficiency equal to that of the naked electrode in the same electrolyte; lower-limit, integrated efficiencies of $\sim 6 \times 10^{-4}$ are reproducibly obtained when pulsing to -1.2V vs. SCE. The spectral distribution of

Fig. 2 Relative photocurrent (top panel) and PL intensity (bottom panel) for a modified CdSe electrode with excitation at 514.5 nm (solid line) and 620 nm (dashed line). Values for α' of 1.5×10^5 and 8.4×10^4 cm⁻¹ were used in the dead-layer analysis at 514.5 and 620 nm, respectively (10). The iLV curves for each excitation wavelength were swept simultaneously at 20 mV/s. The electrolyte redox potential is +0.17V vs. SCE.

the EL is also identical with that of the naked electrode. Subsequent stable operation as a PEC with 633 nm irradiation in the ferri/ferrocyanide electrolyte indicates that no drastic change in the surface layer has occurred.

The EL efficiency may be varied by changing the cation present in solution; the use of NaOH/Na₂S₂O₈ electrolyte brought about a two-fold drop in EL efficiency, which could be recovered upon allowing the electrode to stand for 20 min in the original KOH/K₂S₂O₈ electrolyte.

Peroxydisulfate will spontaneously oxidize ferrocyanide, so we attempted to generate EL by dipping the derivatized electrode in a concentrated S₂O₈²⁻ solution to oxidize the surface layer, rinsing with water, then pulsing to -1.2V vs. SCE in a concentrated KCl electrolyte. Although large reduction currents flowed, no EL was detected. This experiment argues against a charge hopping mechanism whereby holes are injected by the electrolyte into the surface layer for transfer to the semiconductor. Nonetheless, the cation specificity of the EL suggests that the surface layer plays some role in the injection process. The mechanism of charge injection is under investigation at this time.

Conclusion

Photoluminescence and electroluminescence from a ferri/ferrocyanide-modified CdSe electrode has been studied. Potential applied to the modified electrode appears primarily in the semiconductor and not in the surface layer, based on an analysis of PL quenching using the dead-layer model. EL can be generated in basic S₂O₈²⁻ electrolyte with an efficiency and spectral distribution which match those of the naked electrode; EL efficiency can be modestly varied by choice of sodium or potassium cation.

Alkaline Water Electrolysis Anode Materials

D. E. Hall*

American Cyanamid Company, Chemical Research Laboratories, Stamford, Connecticut 06904

ABSTRACT

In recent years, considerable progress has been made in developing alkaline water electrolysis anodes. Several laboratories have reported oxygen evolution overpotential reductions of 100-150 mV or more, relative to uncatalyzed nickel. Some candidate anode materials have shown stable operation for thousands of hours under typical commercial electrolysis conditions. Preferred electrocatalysts have been the mixed metal oxides, especially the AB_2O_4 spinels and ABO_3 perovskites. Other metal oxides, alloys, and high surface-area forms of nickel have also been studied. This review summarizes recent work in developing practical alkaline water electrolysis anodes.

Anode overpotential is a major source of inefficiency in alkaline water electrolysis. In commercial electrolysis, the commonly used unactivated nickel anode has an oxygen evolution overpotential, η_{O_2} , of about 400 mV, representing ~20% of the total cell voltage. As a result, higher anode efficiency is an important goal in current electrolyzer development programs.

There are three practical approaches to improving anode efficiency. First, the electrolysis temperature can be increased. In the context of this review, higher temperatures introduce the possibility of increased anode corrosion. Second, the conventional nickel anode can be made more efficient, primarily by increasing its electrochemically active surface area. Third, new anode electrocatalysts, particularly those based on mixed metal oxides, show great promise.

This review summarizes recent progress in improving alkaline water electrolysis anodes. Experimental results from typical commercial electrolysis conditions and advances in practical anode development are emphasized. Other recent reviews (1-3), which also cover subjects outside the scope of this paper, should be consulted for further information.

Practical Considerations

Four main factors must be considered in developing a commercially practical anode for alkaline water electrolysis: electrochemical efficiency, stability, scale-up, and cost.

Efficiency is the initial screening criterion in any anode development program. As shown later in this review, the best electrocatalysts to date provide oxygen evolution overpotentials more than 150 mV lower than η_{O_2} on uncatalyzed nickel. This represents a voltage savings of about 8-9% in modern, high-efficiency electrolysis equipment. Coupled with the need for high electrocatalytic activity is the requirement of low internal anode resistance. This resistance depends on both the anode materials and structure.

Once high efficiency has been demonstrated, the anode must be tested for stability. As a rough goal, physical and chemical degradation should be minimal during several, even as many as ten or more (4), years of operation. The anode must not only be stable at oxygen evolving potentials, but must resist open-circuit corrosion as well. With the recent advent of highly efficient cathode catalysts, the anode corrosion products, however limited, must not foul the cathode surface. In addition to chemical and physical stability, the anode should provide a constant

*Electrochemical Society Active Member.

potential after an initial break-in period, rather than the time-dependent potential increase which occurs at nickel anodes (5-7).

Manufacturing scale-up is a necessary but difficult part of commercial anode development, involving a move from the laboratory to a pilot processing facility. A way must be found to manufacture anodes on the order of 1 m² in area. The process must be under sufficient control to assure constant anode quality. Because of cost constraints, an automated or semiautomated manufacturing process is necessary.

The maximum practical anode cost depends on the capital cost constraints for the entire electrolysis system. This, in turn, depends not only on competing electrolysis systems, but on nonelectrolytic hydrogen production alternatives as well. The permissible cost of any anode improvement will be based on the power savings realized from it and the anticipated anode lifetime.

Nickel Anode Structures

Nickel has traditionally been used as the anode material in alkaline water electrolysis. It is relatively inexpensive and highly corrosion-resistant at positive potentials in alkaline electrolytes. The oxygen evolution efficiency of nickel is among the highest for elemental metals (8). As a result, the nickel anode is the benchmark against which improved anodes are compared. Table I gives some current *vs.* potential data reported for various conventional nickel anodes.

Nickel anode efficiency has been improved by developing high surface-area anode structures. For example, porous, high surface-area anodes have been made by sintering fine nickel powders prepared by nickel tetracarbonyl decomposition. These anodes, although generally less porous, are essentially similar to the positive plaques used in nickel-cadmium batteries. In high-pressure (30 atm) electrolysis at 200°C, the oxygen evolution overpotential, η_{O_2} , on sintered, porous nickel anodes was about 100 mV lower than on smooth nickel anodes, at current densities of 500-1500 mA/cm² in 35% KOH electrolyte (9). However, sintered, porous nickel anodes were only marginally more efficient than nickel cloth anodes in atmospheric pressure electrolysis, over the temperature range 25°-90°C (10). This was attributed to poor inner surface utilization in the porous anode at atmospheric pressure, presumably due to gas blockage. Similar results were obtained in 5N KOH at 25°C, *i.e.*, 100 mesh nickel screen and sintered, porous nickel anodes produced approximately equal current densities when compared potentiostatically at 1.64 V/DHE (11). However, because

Table I. Conventional Ni anodes

Anode	Test conditions	i , mA/cm ²	Potential	Ref.
Solid Ni	30% KOH, 70-80°C	200	$\eta_{O_2} = 415$ mV	(9)
Ni-plated steel	28% KOH, 70°C, initial	75	$\eta_{O_2} = \sim 320$ mV	(6)
Ni-plated steel	28% KOH, 70°C, 160 days	75	$\eta_{O_2} = \sim 400$ mV	(6)
Smooth Ni	29% KOH, 70°C, after 2h	1000	$E_{an} = 0.66$ V/NHE	(56)
Sandblasted Ni	29% KOH, 70°C, after 2h	1000	$E_{an} = 0.64$ V/NHE	(56)
Nickel plated steel	29% KOH, 70°C, after 2h	1000	$E_{an} = 0.64$ V/NHE	(56)
Nickel screen, 100 mesh	5N KOH, 60°C	500	$E_{an} = 1.66$ DHE	(32)
Smooth Ni	34% KOH, 90°C	100	$E_{an} = 1.45$ HE	(10)
Polished Ni	50% KOH 80°C	100	$E_{an} = 1.67$ DHE	(62)
Polished Ni	50% KOH 150°C	100	$E_{an} = 1.55$ DHE	(62)
Polished Ni	50% KOH 208°C	100	$E_{an} = 1.37$ DHE	(62)
Polished Ni	50% KOH 264°C	100	$E_{an} = 1.24$ DHE	(62)
Sandblasted Ni	50% KOH 30°C	100	$E_{an} = 0.70$ V/Hg/HgO	(24)
Sandblasted Ni	50% KOH 70°C	100	$E_{an} = 0.60$ V/Hg/HgO	(24)
Sandblasted Ni	50% KOH 110°C	100	$E_{an} = 0.53$ V/Hg/HgO	(24)
Sandblasted Ni	50% KOH 130°C	100	$E_{an} = 0.50$ V/Hg/HgO	(24)

the sintered, porous anodes degraded less with time, they were superior after about 60h of electrolysis. In contrast, another study (12) showed that 50% and 80% porous nickel anodes were initially superior to massive nickel anode forms in 30% KOH at 80°C, but showed greater overpotential increases with time.

Anodes with thin, sintered, porous nickel coatings were made by applying nickel powders, in polysilicate-based slurries, to nickel and steel substrates (13). The coatings were sintered under a reducing atmosphere. The nickel coating morphology depended on the sintering temperature and, to a lesser extent, the sintering time. Decreasing the sintering temperature through the range 980°-760°C and the sintering time through the range 30-5 min progressively preserved more of the fine structure in the coatings. A corresponding η_{O_2} decrease of about 70 mV was observed in electrolysis at 200 mA/cm² in 30% KOH electrolyte at 80°C. Although the interior coating surfaces participated in the oxygen evolution reaction to some extent, the η_{O_2} reduction obtained by increasing the coating thickness was small. In a subsequent study (14), the porous nickel-coated mild steel anodes were operated for 1200h at 100 mA/cm² in 30% KOH at 80°C. After an initial rise, the anode potential was essentially constant. Nickel-iron alloy formation in the steel surface region, during the high temperature sintering treatment used to bond the coating to the substrate, greatly increased its corrosion resistance.

Nickel coatings made by slurry coating and sintering nickel powder have also been applied to foamed nickel anode supports (15). The resulting anodes were operated at 500 mA/cm² in 40% KOH electrolyte at 90°C. The voltages of cells with porous nickel/foamed nickel anodes and cathodes were about 50-100 mV lower than those of cells with uncoated foamed nickel electrodes. Cells equipped with the coated electrodes maintained a stable 1.68V operating voltage at 200 mA/cm² in 100h electrolyses at 118°C.

The results cited above show that coatings made by sintering fine nickel powder prepared by Ni carbonyl decomposition reduce oxygen overpotential. Avoiding the high temperatures used for nickel sintering, which produce a concomitant loss in surface area, would appear to offer the advantage of maximized anode surface area. However, Balajka found that TFE-bonded nickel powder applied to 100 mesh nickel screen was ineffective (16). Such anodes were actually about 60 mV less efficient than similar screens with electroplated nickel coatings, at a current density of 370 mA/cm² in 30% KOH electrolyte at 80°C. This poor performance was ascribed to possible oxidation of the metal surface during electrode preparation.

Nickel whisker anodes (17, 18) were made from polycrystalline nickel whiskers grown by chemical vapor deposition of Ni(CO)₄ gas in an electromagnetic field. Whiskers, with diameters from 0.1 to 50 μ m and lengths from

one-tenth to several centimeters, were sintered at 800°-1000°C into continuous, fibrous networks on 200 mesh nickel screen. The resulting anodes were up to 90% porous, with specific surface areas of up to 5×10^3 cm²/g. The anodes were tested in 30% KOH electrolyte, at current densities from 100 to 1000 mA/cm², based on apparent anode surface area. Oxygen evolution overpotentials were about 100 mV lower on whisker anodes than on multilayer, 200 mesh nickel screens. There was no loss of structural integrity during 48h of electrolysis at 1000 mA/cm².

Raney Alloy Anodes

Raney nickel is made by alloying nickel with metals such as aluminum or zinc. When the Raney alloy is leached in alkaline electrolyte, a high surface-area structure with high electrochemical activity is produced. Several approaches to making Raney nickel anodes for alkaline water electrolysis have been reported.

Raney Ni-Zn alloy was prepared by electrodeposition from chloride electrolyte (19). The electrodeposition conditions affected both the composition and structure of the alloy. A maximum BET specific surface area, greater than 25 m²/g, for the leached anodes was obtained at a deposition potential of 1.07 V/SCE. Correspondingly, electrolysis cells containing Raney nickel anodes and cathodes had minimum voltages using alloy electroplated at -1.07 V/SCE. Analysis of the experimental data indicated that the improved performance of Raney nickel-coated anodes was due solely to greater anode surface area (20). An electrolysis cell containing Raney nickel-activated iron anodes and cathodes was stable for 3000h at a current density of 200 mA/cm² and a temperature of 110°C.

Electrodeposition of Ni-Zn alloy onto nickel or stainless mesh has also been used to make Raney-type porous electrodes by plating for as much as 24h (21). These electrodes differed from the usual sintered powder porous anodes in their pore structure, which was channel-like and full of very fine hairline cracks. Porosities ranged from 65% to 75%, average pore sizes from 1 to 3 μ m. Electrochemical measurements in 6N KOH showed that the electrodeposited porous anodes were generally inferior to sintered ones.

A plasma-sprayed Ni-Al anode coating produced an initial overpotential reduction of 200 mV in electrolyses at 160° and 200°C (22). After 100h, the η_{O_2} improvement was still 180 mV at 160°C, whereas at 200°C, the improvement decreased to 150 mV after 350h. In contrast, Raney nickel prepared by plasma spraying Ni-Al alloy particles was found to be a poor oxygen evolution catalyst in another study (23). This was attributed to rapid oxidation of the anode surface. The Raney nickel structure was found, however, to be useful as a support for other catalysts, as discussed later in this review.

Raney nickel deposited on foamed nickel anode supports behaved similarly to sintered, porous nickel coat-

ings on foamed nickel, i.e., cell voltages were 50-100 mV lower when Raney nickel-coated anodes, and cathodes were used instead of uncoated foamed nickel electrodes (15). In 40% KOH electrolyte at 118°C, Raney nickel was initially superior to sintered, porous nickel, but the advantage declined to only 20 mV within 100h.

Various Raney alloy anodes tested at 90°C were about 60 mV more efficient than conventional, low surface-area nickel anodes (24). At a current density of 100 mA/cm², η_{O_2} was 240 mV for Raney nickel, 240 mV for Raney nickel-cobalt (30 atom percent (a/o) Co), and 230-240 mV for Raney cobalt. These values compared with 300 mV for steel-blasted nickel and 280 mV for electrodeposited nickel.

Several methods of doping Raney nickel anodes with lithium were studied by Martin *et al.* (25). In almost all cases, anode activity declined greatly during 24h of electrolysis at 80°C, at a current density of 1000 mA/cm². Best results were obtained by preoxidizing the anodes in H₂O₂ + LiOH or thermally in air. In the same study, better results were obtained when Raney nickel anodes were impregnated with cobalt oxide. Overpotential reductions of more than 130 mV were measured after 24h of electrolysis at 80°C, at a current density of 1000 mA/cm². Impregnating Raney nickel with mixed cobalt-nickel oxides was no more effective than using cobalt alone.

Ion-Implanted Nickel Anodes

In an unusual approach to nickel anode activation, the unique characteristics of ion implantation were investigated (26). Ion implantation offers the advantage of controlled additions of dopants to only the near surface region, an important factor when expensive dopants are used. In addition, the maximum surface concentrations of the implanted materials are not limited by solid solubilities.

Various doses of 50 keV Ag⁺, Li⁺, He⁺, and Kr⁺ ions were implanted. Electrochemical measurements in 30% KOH electrolyte at 80°C showed that implantation of 0.3-4.0 × 10¹⁶/cm² Ag⁺ ions reduced η_{O_2} by 20%-40%, with best results in the range 0.3-1.3 × 10¹⁶/cm². After 24h of electrolysis, the Ag⁺ implanted anodes showed a well-defined open-circuit discharge plateau. The discharge corresponded to about two electrons per implanted Ag atom, suggesting formation, during electrolysis, of an intermediate complex containing one oxygen per implanted Ag atom. Unimplanted Ni anodes showed no well-defined discharge plateau.

Inert gas (He⁺ and Kr⁺) implants produced no η_{O_2} reductions, indicating that the improvement caused by Ag⁺ was not due to radiation damage effects. Li⁺ ions were implanted to increase the electronic conductivity of the nickel oxide anode surface layer. As discussed elsewhere in this review, lithium additions by other techniques have increased the oxide film conductivity and produced a corresponding η_{O_2} decrease. Unexpectedly, no η_{O_2} reduction was produced by Li⁺ implants.

High-Temperature Degradation of Nickel Anodes

Nickel anode degradation during high temperature service has been investigated, primarily in conjunction with the French high-temperature electrolysis programs. Giles (27) analyzed the physical and electrical characteristics of roll-compacted, sintered, porous nickel anodes before and after pilot plant operation at CEM. Electrolysis was carried out at 1000 mA/cm², in 35% KOH at 200°C, under 30 atm pressure. During 250h of electrolysis, anode porosity decreased from about 45% to about 20% as corrosion products accumulated within the anode. As the finely porous corrosion products filled the larger anode pores, the mean pore diameter fell from 1.9 to 0.3 μ m after 23h and to 0.1 μ m after 83h. X-ray diffraction showed both Ni(OH)₂ and NiO, but no +3 nickel species, in the corrosion product. Anode tensile strength dropped from 50 to 20 N/mm² after 83h of electrolysis. The electrical resistivity increased from about 27 × 10⁻⁶ Ω -cm to about 46 × 10⁻⁶ Ω -cm during the same period. Despite the slowing of

the nickel corrosion rate with time because of the partly protective nature of the corrosion layer, Giles concluded that using sintered, porous nickel anodes in high-pressure, high-temperature service was questionable.

A joint GDF/EDF study (28) addressed nickel corrosion in the temperature range 130°-180°C. While positive potentials were not imposed on the nickel specimens, the corrosion tests were carried out in an oxygenated environment in 40% KOH. Specimens of Ni 200 and Ni 201 industrial castings, a powder metallurgy compact (Ni 270), and high-purity, zone-refined nickel were studied. In the oxygenated electrolyte, the porous corrosion products were NiO and Ni(OH)₂ at 130°C, while only NiO was observed at 180°C. Corrosion rates at 180°C were 10-15 μ m/yr for high-purity nickel, and 30-45 μ m/yr for Ni 200, 201, and 270. Restricting the sulfur content of the nickel was found to retard corrosion.

Ni(OH)₂-Catalyzed Nickel Anodes

Perhaps the most straightforward approach to catalyzing the nickel anode is to add Ni(OH)₂ to its surface. Under anodic polarization, the Ni²⁺ species can be converted to Ni³⁺. Electrochemical and ellipsometric studies (7) demonstrated that trivalent nickel was the desired species for efficient oxygen evolution. Thus, Ni(OH)₂ may be regarded as the electrocatalyst precursor.

Attempts to catalyze nickel anodes with Ni(OH)₂ have benefited from the extensive work on nickel electrodes for alkaline storage batteries (29). Sintered, porous nickel anodes impregnated with Ni(OH)₂, essentially nickel battery positives, were considerably more efficient for oxygen evolution than similar unimpregnated anodes (10). Electrolysis was carried out at 90°C in 34% KOH electrolyte. At a current density of 400 mA/cm², η_{O_2} was only about 100 mV on the impregnated anodes, while the unimpregnated anodes were, as discussed earlier, no more efficient than nickel cloth anodes. This enhanced activity was attributed to higher superficial surface area rather than improved utilization of the inner anode surfaces. Anodes impregnated with 1.91g of Ni(OH)₂ per cm³ of void volume, a characteristic nickel battery positive loading, showed rapid disintegration under continuous charging at 80°C. This was presumably due to high internal stresses. Anodes with a lower Ni(OH)₂ loading of 1.15 g/cm³ of void volume were dimensionally and structurally stable during more than 100 days of operation at 400 mA/cm².

In a study of nickel battery positive plates, the oxygen evolution reaction was observed at an earlier stage of charging when the plates were impregnated electrochemically rather than chemically (30). Water electrolysis anodes in sheet and woven screen form, with sintered, porous nickel coatings, were electrochemically impregnated with Ni(OH)₂ (31). In a one-step impregnation process, the amount of Ni(OH)₂ precipitated varied linearly with the charge passed. This allowed the catalyst loading to be controlled accurately. On Ni(OH)₂-impregnated anodes, η_{O_2} at 200 mA/cm² was 45-60 mV lower than on similar uncatalyzed anodes, in 30% KOH electrolyte at 80°C. Optimum Ni(OH)₂ loadings were about 1-4 mg/cm² of apparent anode surface area. At higher loadings, overpotentials rose as the outer pores of the nickel coatings became plugged with Ni(OH)₂, resulting in a loss of effective anode surface area.

Lithiated NiO electrocatalyst was prepared by vacuum decomposition of a mixed slurry of Ni(OH)₂ and LiOH (32). Lithium, present at 1 a/o in the finished catalyst, greatly reduced the electronic resistivity from the undoped value (>10⁸ Ω -cm) to 100 Ω -cm. The BET specific surface area of the catalyst was 100 m²/g. Anodes were made by mixing the catalyst with TFE binder and sintering onto 100 mesh nickel screen. In 5N KOH electrolyte at 60°C, the catalyzed anodes were about 55 mV more efficient than uncatalyzed nickel screens and were comparable to NiCo₂O₄-catalyzed anodes, which are discussed in the following section.

NiCo₂O₄

The oxygen evolution characteristics of the mixed oxide spinel, NiCo₂O₄, have been reported extensively, most notably by Tseung and co-workers (11, 32-36). In strongly alkaline electrolytes at high positive potentials, *i.e.*, conditions typical of commercial electrolysis, oxygen evolution proceeds by decomposition of species with tetravalent cations (35, 37).

NiCo₂O₄ has been made in several ways. Freeze-drying mixed Ni and Co nitrates, followed by vacuum decomposition at 250°C and a final heat-treatment for 10h at 400°C in air, is preferred. The resulting catalyst has a high specific surface area (70 m²/g by BET) and a moderate electrical resistivity (10 Ω-cm) (32). Anodes made with freeze-dried NiCo₂O₄ were more efficient than similar anodes catalyzed with NiCo₂O₄ made by mixed nitrate coprecipitation (34). It was proposed that the freeze-dried product was more homogeneous, *i.e.*, there was less separation of Ni and Co oxides. NiCo₂O₄ has also been made by direct thermal decomposition of the mixed nitrate salts on anode substrates (32). However, the anodes were less efficient than those made with freeze-dried NiCo₂O₄.

Highest anode efficiencies have been obtained with the freeze-dried NiCo₂O₄ incorporated into a TFE-bonded coating (32). Optimum efficiency was obtained using 15%-30% TFE binder. For example, at 60°C in 5N KOH, a catalyst loading of 13 mg/cm² produced a current density of 1000 mA/cm² at 1.6 V/DHE. However, oxygen bubbles were observed to cling to the hydrophobic anode surface. Applying a thin, hydrophilic nickel cobalt oxide layer to the anode surface improved bubble release. This reduced the anode potential by about 20 mV at 1000 mA/cm² in 5N KOH at 25°C. In another study (16), TFE-bonded NiCo₂O₄ anodes were about 150 mV more efficient than nickel-plated nickel screen when operated at a current density of 370 mA/cm² in 30% KOH electrolyte at 80°C.

Doping NiCo₂O₄ with varying amounts of Sr and La was effective in reducing η_{O_2} (25). Best results were obtained when 0.5 atoms of (2/3 Sr + 1/3 La) per atom of cobalt were added. The resulting material, with nominal composition NiCo₂Sr_{0.66}La_{0.33}O_{5.17}, produced a 300 mV overpotential at a current density of 1000 mA/cm².

NiCo₂O₄-catalyzed anodes have shown high oxygen evolution efficiency in several laboratories. Long-term anode stability, however, is open to some question. At a current density of 330 mA/cm², an overpotential decrease of 150 mV relative to nickel anodes was reported (5). However, poor stability was noted at temperatures above 100°C and current densities greater than 200 mA/cm². In contrast, thermally decomposed NiCo₂O₄ anodes were stable for 2000h of electrolysis at 1000 mA/cm² at a temperature of 120°C. In another study, NiCo₂O₄ anodes were stable for over 1000h of electrolysis at 1000 mA/cm², at temperatures from 120°C to 200°C (38). However, the catalyst was very sensitive to corrosion at open circuit.

In tests of about 150 days duration at low current density (75 mA/cm²) and temperature (70°C) in 28% KOH, a TFE-bonded, freeze-dried NiCo₂O₄ anode was initially about 60 mV more efficient than a nickel-plated steel anode (6). After 150 days, due to a lower η_{O_2} increase with time, the NiCo₂O₄ anode advantage was over 100 mV. Similarly, in 18 days of electrolysis at 330 mA/cm², η_{O_2} was about 100 mV lower on NiCo₂O₄ anodes than on uncatalyzed Ni screen in 30% KOH at 90°C (39).

Co₃O₄

The spinel Co₃O₄ has shown promising efficiency and long-term performance. Thermally decomposed Co₃O₄ was deposited on electroformed nickel plates with conic holes (40) and was tested in atmospheric pressure electrolysis at 120°C. After 6000h of electrolysis at 1000 mA/cm² in 40% NaOH electrolyte, the anode potential was about 0.59V *vs.* Hg/HgO reference (containing the bulk electrolyte composition). After an initial break-in period, the rate of η_{O_2} rise with time was only 4 mV/1000h.

Co₃O₄ anodes containing 0, 4, 7, and 10 a/o Li dopant were prepared by freeze drying and vacuum decompos-

ing the mixed Li and Co nitrates (33, 37). This was followed by heat-treatment at 600°C for 10h to produce the Li-doped spinels. The electrical resistivities of the catalyst powders varied greatly with the extent of Li doping, from 10⁴ Ω-cm at 0% Li to 10 Ω-cm at 4% Li, and 1 Ω-cm at both 7% and 10% Li. TFE-bonded anodes were made using 10/3 weight ratios of the catalyst powders to TFE. These anodes were operated at 1000 mA/cm² in 5M KOH at 70°C. The anode potential dropped markedly with increasing Li doping, *i.e.*, 1.69V with no Li dopant, and 1.56, 1.535, and 1.52V, respectively, at 4, 7, and 10 a/o doping. The enhanced O₂ evolution activity with increased Li doping was attributed to the increased fraction of Co³⁺ ions which could form if all the Li entered tetrahedral lattice sites (37).

An electrolysis cell equipped with a TFE-bonded, 10% Li-doped Co₃O₄ anode was operated for about 6000h at 1000 mA/cm² (33). The cell contained 45% KOH electrolyte at 85°C. An anode half-cell measurement after approximately 5600h indicated an η_{O_2} increase of about 50 mV during operation. The Li content of the anode was unchanged. A TFE-bonded, Li-doped Co₃O₄ coating was applied to a porous nickel anode substrate (9). In 30% KOH electrolyte at 70°C, at a current density of 1000 mA/cm², η_{O_2} was 300 mV at the beginning of electrolysis and 290 mV after 1000h of operation.

Other AB₂O₄ Mixed Oxides

A variety of AB₂O₄ spinel compounds (B = Al, Cr, Mn, Fe, or Co) were used to prepare TFE-bonded anodes (15). The anodes were tested in 30% KOH at 80°C. At a current density of 1000 mA/cm², the spinel anode overvoltages were 30-70 mV lower than the overvoltage of uncatalyzed nickel.

The mixed oxides NiLa₂O₄, NiPr₂O₄, and NiNd₂O₄ were prepared by thermal decomposition on platinum supports (41). In potentiostatic experiments conducted in 30% KOH at 50°C, the three catalysts showed similar current *vs.* potential characteristics. A low Tafel slope (approximately 40 mV/decade) was observed at current densities of up to 100 mA/cm². At higher current densities, the Tafel slope was about 120 mV/decade. The anode potentials were approximately 1.6 V/RHE at 1000 mA/cm². The oxygen evolution overpotentials on the mixed oxide anodes were observed to be essentially stable for several hundred hours, at current densities as high as 1000 mA/cm².

The NiLa₂O₄ anode electrocatalyst has been doped with Li, Mg, and Fe, replacing some of the Ni, and with partial substitution of sulfur for oxygen (12). The surface properties of the Li-doped materials were claimed to be slightly superior to undoped NiLa₂O₄. However, Li doping produced an increase in bulk catalyst resistivity as x in Ni_{1-x}Li_xLa₂O₄ was increased from 0 to 0.24, in contrast to the lower resistivity produced by doping Co₃O₄ with Li, as discussed in the preceding section. The net effect on η_{O_2} was negligible. Mg doping also increased the electrical resistivity of the catalyst. Similarly, high levels of Fe doping, *e.g.*, $x = 0.06$ in Ni_{1-x}Fe_{2x/3}La₂O₄, increased electrical resistivity. Lower Fe doping (*e.g.*, $x = 0.03$) produced a resistivity decrease, but failed to improve η_{O_2} for the NiLa₂O₄ anode. Cobalt substitution, while effective in reducing η_{O_2} , produced a nonstoichiometric oxide of nominal formula Ni_{1.8}Co_{0.2}LaO₃. Its anodic polarization was about 25 mV lower than that of NiLa₂O₄ in 30% KOH electrolyte at 85°C, over the current-density range 100-1000 mA/cm². At the current density of 500 mA/cm², the Co containing anode also showed superior time behavior during 300h of electrolysis, producing a ~100 mV lower anode potential during the last 150h. However, raising the electrolysis temperature to 110°C produced a significant deterioration in performance, so that the Co containing anode became inferior to NiLa₂O₄. Treatment of NiLa₂O₄ with H₂S to incorporate sulfur into the catalyst worsened the anode polarization behavior. This was attributed to the higher resistance of the sulfur containing anodes.

La-Sr-Co-Oxides and Variants

Perovskite anode catalysts of the La_{1-x}Sr_xCoO₃ type, and substitutional variants, have been studied more extensively than any other mixed oxides, with the possible exception of NiCo₂O₄. Their high activities for oxygen evolution are similar to that of NiCo₂O₄, with the relative superiority of the two types of catalyst still open to question. For example, in 30% KOH electrolyte at 145°C, La_{0.5}Sr_{0.5}CoO₃ was about 120 mV superior to NiCo₂O₄ at 1000 mA/cm² (38). However, under similar conditions (120°C, 1000 mA/cm²), cells with La_{0.5}Sr_{0.5}CoO₃ anodes showed 0.1V higher voltages than similar cells with NiCo₂O₄ anodes (42). A mixed La-Sr-Co oxide of unspecified composition, deposited on a Raney nickel substrate, was 180 mV more efficient than an unactivated nickel mesh anode at a current density of 1000 mA/cm² in 40% KOH electrolyte at 160°C (23). The anode was stable for more than 1000h.

It is generally agreed that the La-Sr-Co perovskite composition has a significant effect on oxygen evolution overpotential. The relationship between η_{O_2} and x in the formula La_{1-x}Sr_xCoO₃ is not completely clear, but an overall trend toward higher catalytic activity in the compositional midrange has been determined. When 5-10 mg/cm² La_{1-x}Sr_xCoO₃ coatings were applied by spray pyrolysis, a broad η_{O_2} minimum, centered at about $x = 0.5$, was observed at a current density of 10 mA/cm² (43). At a current density of 500 mA/cm², optimum overpotentials of about 330 mV were measured over the approximate range $0.5 < x < 1.0$. These results were obtained in 6N KOH electrolyte at 80°C. In a later study with more data points reported, the variation in η_{O_2} with x was refined (25). At current densities of 100, 500, and 1000 mA/cm², an overpotential minimum was found at about $x = 0.75$, while $x \approx 0.15$ produced an overpotential maximum. At low current densities in 45% KOH at 25°C, La_{0.5}Sr_{0.5}CoO₃ and La_{0.8}Sr_{0.2}CoO₃ had approximately equal potentials, while both were superior to LaCoO₃ (44).

The variation in electrical resistivity, ρ , vs. x for several perovskite families Ln_{1-x}Sr_xCoO₃ is roughly similar to that described above for η_{O_2} vs. x (45). This suggests that electrical resistivity is an important factor in the efficiency of perovskite anode catalysts. For most of the lanthanides studied, ρ was 0.1-10 Ω -cm at $x = 0$, decreasing to about $10^{-3.5}$ Ω -cm at $x = 0.5$. The minimum ρ composition interval for La containing perovskites was quite broad, from about $x = 0.2$ through $x = 0.6$, the highest value investigated. The ρ decrease as Sr was substituted for La has been attributed to more Co⁺³/Co⁺⁴ couples in the doped perovskite (44).

La_{0.5}Sr_{0.5}CoO₃ coatings have been prepared by a number of methods. Spray pyrolysis was used to deposit 7 mg/cm² coatings in a study of the effects of final calcination temperature (22). Best results were obtained by calcining the coatings at 600°-700°C. In 8N KOH at 80°C, η_{O_2} was about 380 mV at 1000 mA/cm². Raising the coating loading to about 15 mg/cm² further reduced η_{O_2} to about 340 mV at 1000 mA/cm². Thermally decomposed coatings, containing 1.2 mg/cm² La_{0.5}Sr_{0.5}CoO₃, were also studied (24). At 90°C, these coatings gave η_{O_2} approximately 250 mV at 100 mA/cm² and 330 mV at 1000 mA/cm². From η_{O_2} at 90°C and the rate of overpotential change with temperature, $d\eta_{O_2}/dT$, an overpotential of 220 mV was estimated for 1000 mA/cm² electrolysis at 160°C. TFE-bonded anodes (36% TFE, 14 mg/cm² loading) were nearly as active as anodes without TFE at low current densities, in 6N KOH at 80°C (43). However, η_{O_2} increased rapidly at current densities above 10 mA/cm² due to resistance losses between catalyst particles in the coating. Changes in TFE content and preparation method did not overcome this problem.

The effects of electrolysis temperature on the activity of La_{1-x}Sr_xCoO₃ are unclear. It is generally agreed that, at temperatures up to 160°C, an increase in electrolysis temperature produces an increase in catalyst activity. Because $d\eta_{O_2}/dT$ for the perovskite catalysts is greater than for other anodes (e.g., Raney nickel, unactivated nickel)

their relative improvement is greater with increasing temperature (24). Continuous improvement up to 200°C was reported for electrolysis in 36% KOH at 22 atm pressure (43). The η_{O_2} improvement at 1000 mA/cm² relative to unactivated nickel anodes was 260 mV at 160°C and 280 mV at 200°C. However, a subsequent publication from the same laboratories (22) reported a decrease in activity between 160° and 200°C, at 1000 mA/cm² in 8N KOH. The experimental evidence indicated that this was an intrinsic property of the catalyst.

The stability of La-Sr-Co oxides under anodic polarization has been good. In 36% KOH at 160°C, La_{0.5}Sr_{0.5}CoO₃ was stable during 500h of electrolysis at 1000 mA/cm², producing a 150 mV η_{O_2} reduction (22). A series of La_{1-x}Sr_xCoO₃ compounds, prepared by freeze drying, were corrosion resistant at 220°C in 75% KOH electrolyte (44). No activity loss was observed during 1000h of continuous operation, and 2600h of operation with periodic interruption, at 1000 mA/cm² in the temperature range 120°-200°C (38). However, La-Sr-Co oxides were reported to be very sensitive to passive corrosion.

Several anode electrocatalysts have been made by substituting nickel or iron for some or all of the cobalt in La_{1-x}Sr_xCoO₃. The oxygen evolution activity in the family of compounds La_{1-x}Sr_xFe_{1-y}Co_yO₃ increased with increasing x and y (46). SrCoO₃ itself could not be synthesized as a perovskite. As a result, the most efficient anode catalyst prepared was La_{0.2}Sr_{0.8}Fe_{0.2}Co_{0.8}O₃. In 1M KOH electrolyte at 25°C, that catalyst produced a steady potential of 0.90V vs. Hg/HgO at 100 mA/cm², after an initial potential rise during the first 40h of electrolysis.

Nickel substitution for cobalt, in the series of compounds La_{0.5}Sr_{0.5}Ni_{1-y}Co_yO₃, has also been investigated (22). Coatings with 10 mg/cm² of the perovskites were prepared by spray pyrolysis and tested in 8N KOH at 80°C. At a current density of 1000 mA/cm², a minimum η_{O_2} of about 310 mV was obtained at about $y = 0.6$. The compound LaNi_{0.2}Co_{0.8}O₃ was plasma sprayed to produce 8 mg/cm² coatings (24). At 90°C, η_{O_2} was 270 mV at 100 mA/cm² and 330 mV at 1000 mA/cm². The 90°C data and $d\eta_{O_2}/dT$ were used to estimate an overpotential of 240 mV at 160°C, at a current density of 1000 mA/cm². An anode catalyzed with La_{0.2}Sr_{0.3}Ni_{0.4}Co_{0.6}O₃ produced an initial 140 mV overpotential reduction at 200°C, but lost activity after 1h of electrolysis (25). Surface analysis showed an increase in the Sr/La ratio.

The perovskite electrocatalyst LaNiO₃ was prepared by coprecipitation of La and Ni nitrates, followed by an oxidizing heat-treatment at 800°C (47). Anodes were made by pressing the LaNiO₃ powder into pellets and sintering at 750°C. In approximately 1M hydroxide electrolytes at 25°C, the rate of O₂ evolution on LaNiO₃ was about 10⁵ times faster than on Pt and about 10² times faster than on NiCo₂O₄. At a current density of 100 mA/cm², η_{O_2} was about 310 mV. The Tafel slope was 40 mV/decade. The LaNiO₃ surface was nonstoichiometric, with almost all the nickel in the +2 state. It was proposed that the high activity of LaNiO₃ was due to its high surface carrier density (approximately 10²⁰/cm²).

Recently, Bockris and co-workers suggested a course for future perovskite electrocatalyst development (48). Their XPS examinations indicated a nonstoichiometric surface, in which charge is mainly compensated by oxygen vacancies. Because of the strong affinity of oxygen-deficient surfaces toward oxygen in the form of OH, an increase in electrocatalytic activity would be expected with increasing M²⁺-OH bond strength, where M²⁺ is a surface transition metal ion. As a result, it was proposed that perovskite electrocatalyst research should focus on finding a bonding sequence which produces low intermediate radical coverage. In an experimental study covering 18 perovskite compositions, carried out by the same group, the electrochemical desorption of OH was found to be rate determining in every case (49). Very recently, the study of perovskite electrocatalysis was extended (50). It was shown that reaction rates increase with decreases of magnetic moment, stability of the perovskite lattice, and

enthalpy of transition metal hydroxide formation, and with increased number of d-electrons in the transition metal ion. The latter correlation is consistent with the earlier proposal that rate-determining steps involve OH desorption.

ABO₂ Metal Oxides

Thin films of ABO₂ metal oxides were prepared by RF-sputtering the parent alloys under various O₂ partial pressures, followed by annealing in air (51). Metal A was Pt or Pd, and B was Co, Rh, or Cr. The oxides exhibited the delafossite structure, *i.e.*, for PtCoO₂, alternating layers of Pt linearly coordinated with two oxygen atoms and Co octahedrally coordinated with oxygen. Oxygen evolution activity depended strongly on the transition metal, in the order Co > Rh > Cr, but was nearly independent of the noble metal. It was suggested that this was due to coverage of the noble metal with a poorly conducting oxide. The Co containing oxides produced oxygen evolution potentials more than 100 mV lower than a Pt anode in 1M NaOH at 23°C.

In electrolysis at 120°C, NiCoO₂ anodes prepared by thermal decomposition showed oxygen evolution potentials similar to those of NiCo₂O₄ and La_{0.5}Sr_{0.5}CoO₃ anodes at a current density of 1000 mA/cm² (42, 43). At lower current densities (100-200 mA/cm²), NiCoO₂ was superior to the other anode materials.

Base Metal Alloys, Intermetallics and Non-Oxide Catalysts

It has been known for some time that nickel-iron alloys show relatively low oxygen evolution overpotentials (52, 53). However, the variation of η_{O_2} with alloy composition was not clearly defined, because results vary depending on alloy history and pretreatment.

Recently, Ni-Fe alloy anodes have been re-examined. Gras and Pernet (54) studied the anodic behavior of alloys containing 9, 28, and 50 w/o nickel, in comparison to two forms of nickel. They found that the 9% Ni alloy was unstable, in agreement with earlier results (53), while the catalytic activity of the 28% nickel alloy was lower than that of pure nickel. The corrosion-resistant 50% nickel alloy was about 70 mV more efficient than nickel after 100-200h of electrolysis, in the current-density range 100-1000 mA/cm². Anode composition *vs.* depth profiling, by secondary ion mass spectrometry, showed that the surface was enriched with potassium and oxygen after electrolysis. It was proposed that *in situ* formation of a Ni_xFe_yO_zK_w complex oxide increased the catalytic activity of the anode.

In another study (55), high surface-area nickel-iron alloy anodes were prepared with a 37% nickel powder prepared by codecomposition of nickel and iron carbonyl. The powder was applied to anode substrates as a sintered, porous coating. In 30% KOH electrolyte at current densities up to 400 mA/cm², the alloy anodes evolved oxygen as efficiently as similar anodes prepared with pure nickel powder.

Non-noble metal catalysts were made by plasma spraying coatings of >90 w/o Ni and/or Co plus <10 w/o stainless steel onto preheated iron or nickel-coated iron substrates (56). Anode overpotentials were 60-80 mV lower than on smooth nickel, at 1000 mA/cm², in 29% KOH at 70°C. At current densities <500 mA/cm², there was no variation of anode potential *vs.* time for 1000h of operation. At 1000 mA/cm², the anode potential increased from 1.54 to 1.60 V/NHE during the first 300h of electrolysis, then remained constant up to 1000h.

Ni-W alloys and the intermetallic compounds Ni₃Ti, NiTi, and NiTi₂ were investigated by Lu and Srinivasan (57). Titanium was alloyed with nickel to increase the number of d-band vacancies and, thus, electrocatalytic activity (58). However, as discussed in the following section, such a correlation was not found at the oxide-covered electrodes. Best results were obtained with Ni₃Ti, for which η_{O_2} was 20 mV lower than on nickel, in 30% KOH electrolyte at 80°C.

While the last-cited study found no correlation of oxygen evolution activity to electronic properties, Osaka *et al.* (59) did find a correlation to magnetic properties, which strongly connected, in turn, to electronic properties, for cobalt borides and composite cobalt borides. For cobalt borides, the O₂ evolution activity depended significantly on the Co/B ratio, as well as the sintering temperature used to make the catalyst. Optimum preparations produced higher electrocatalytic activity than nickel or cobalt. These best conditions included a 3:1 ratio of cobalt to boron, and a sintering temperature of 400°-500°C, at which the saturation magnetization showed a maximum. Among the composite cobalt borides, cobalt iron boride (Co:Fe:B = 1:2:1) sintered at 450°C had the greatest catalytic activity. At 100 mA/cm² in 6M KOH at 25°C, cobalt iron boride produced a potential of about 0.65V *vs.* Hg/HgO. It was found that those catalysts which formed thicker and more-stable oxide films in higher oxidation states had higher activities for oxygen evolution.

Precious Metal Catalysis

Available experimental evidence strongly indicates that individual precious metals and their oxides have little or no superiority to nickel in their electrocatalytic activity (10, 11, 15, 60). The exception is ruthenium oxide, which is a highly efficient oxygen evolution electrocatalyst (24) but is unstable in alkaline electrolyte.

Oxygen evolution on smooth platinum and iridium electrodes was examined by Appleby *et al.* (10) and compared to O₂ evolution on nickel. In 25% KOH electrolyte, Ir was markedly superior to Pt in the temperature range 25°-90°C. In 34% KOH, the relative superiority of Ir was somewhat less. Tafel slopes were about 2RT/3F, with evidence of a change to a higher slope at current densities above 10 mA/cm². However, neither Ir nor Pt was as effective an electrocatalyst as pure nickel. Another study (11), in which Ni and Pt screen anodes were compared, produced the same result.

Pt, Pd, Rh, and Ni coatings were electrodeposited onto foamed Ni anode supports and tested at a current density of 200 mA/cm², in 30% KOH electrolyte at 90°C (15). The rhodium coating performed best, providing a cell voltage of 1.72V, followed by Pd (1.74V), Ni (1.75V), and Pt (1.80V).

Ir and Ru alloys with 25, 50, and 75 a/o nickel were investigated as oxygen evolution anodes in 30% KOH electrolyte at 80°C (57). The Ni-Ru alloys with 50 and 75 a/o Ru dissolved anodically. The maximum overpotential reduction was produced by the 50Ni-50Ir alloy, which was 40 mV more efficient than pure nickel at a current density of 20 mA/cm². The electrokinetic parameters for the alloys were similar to those for nickel. Correspondingly, cyclic voltammetry showed that the surface of the alloy anodes was predominantly composed of nickel oxide species. Because of coverage by oxide films, there was no dependence of electrocatalytic activity on alloy electronic structure.

Outstanding oxygen evolution activity was obtained at pyrochlore structure oxide anodes (61). The catalysts are described by the general formula A₂[B_{2-x}A_x]O_{7-y}, where A = Pb or Bi, B = Ru or Ir, 0 < x < 1, and 0 < y < 0.5. In 3M KOH at 75°C, a typical Pb₂[Ru_{2-x}Pb_x]⁴⁺O_{6.5} catalyst evolved oxygen at an overpotential of about 120 mV at a current density of 100 mA/cm². In comparative potential sweep experiments, pyrochlore anodes were >100 mV more efficient than Pt black, RuO₂, or NiCo₂O₄. A supported Pb₂[Ru_{1.49}Pb_{0.51}]⁴⁺O_{6.5} anode was life-tested at a current density of 200 mA/cm² for more than 1000h, in 3M KOH at 75°C. After the first 200h, the rise in anode potential *vs.* time slowed noticeably, reaching a potential of about 1.5 V/RHE, about 50 mV higher than the potential measured at the beginning of the test. X-ray diffraction of the used anode did not reveal chemical degradation. Attempts to maximize anode efficiency using high (62 mg/cm²) catalyst loading TFE-bonded structures produced stability problems as the catalyst layer separated from the support during 504h of operation.

Summary

A number of approaches have been taken to improve the oxygen evolution anode. To date, results using metal oxide electrocatalysis have generally shown more promise than those obtained with modifications of the nickel electrode structure. Catalysts such as NiCo₂O₄, Li-doped Co₃O₄, and the La-Sr-Co oxides have been tested extensively. Work on these systems makes up a large share of the recent literature. It is encouraging that this work has been extended to address the question of what material and surface properties are responsible for electrocatalytic activity. Further research of this type may lead to important catalyst modifications or the development of entirely new catalyst systems.

Less-studied metal oxide catalysts, such as LaNiO₃ and the pyrochlore oxides, have also produced excellent results. More research is needed, however, to determine the full potential of these catalysts.

With the exception of the relatively inexpensive ruthenium, as used in the pyrochlore oxides, it is unlikely that practical oxygen evolution anodes will be based on precious metals. Overpotential reductions obtained with Pt, Ir, or Pd, for example, have been modest. In addition, the promising results obtained with far cheaper materials mitigates on economic grounds against the use of precious metals.

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1984, the following students received grants of \$2000.00 for use in electrochemical research, as part of the three Summer Fellowship Awards of The Electrochemical Society, Inc.

Mr. Paul M. Kovach, Indiana University, Bloomington, Indiana, received the Edward G. Weston Fellowship.

Ms. E. Tracy Turner Jones, University of Illinois, Urbana, Illinois, was the winner of the Colin Garfield Fink Fellowship.

Mr. Neal T. Sleszynski, State University of New York, Buffalo, New York, was awarded the Joseph W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." They are intended to cover a period during which the recipient has no financial support for the continuance of his or her work.

The Edward G. Weston Summer Fellowship Report

Voltammetry of Some Metal Complexes at Electrochemically Treated Electrodes

Paul M. Kovach

Many types of carbon electrodes are widely used in electroanalytical chemistry. The attractive properties of carbon electrodes are their large potential ranges in aqueous solution and low residual current. However, few molecules display diffusion-controlled electrochemical behavior in aqueous solutions because of the various factors that control charge-transfer processes at these electrodes. In addition to the inherent electron-transfer rates of the species being considered, it is also necessary to recognize that the surface of carbon has a rich chemistry that may well affect the observed electrochemistry (1-5). Graphitic carbon has a heterogeneous surface which contains many carbon-oxygen functionalities, such as carbonyls, carboxylates, and phenolic hydroxyls (6), which are located on the edge plane. Attempts have been made to characterize and modify the nature of these functional groups on the carbon surface to influence the observed electrochemistry (7-14).

Many treatments have been developed to improve the electrochemical properties of carbon electrodes (15-25). These treatments are important since many compounds, such as ascorbic acid, display poor electrochemistry at carbon electrodes. This can lead to complicated and often uninterpretable voltammograms, due to the overlap of voltammetric waves. Therefore, it would be desirable to know what types of carbon surfaces contain which types of functionalities, how they affect the electrochemistry, and how to modify the functionalities on the surface to obtain an electrode with predictable electrochemical properties.

Carbon fibers allow the fabrication of electrodes of very small dimensions (26, 27), and their small size gives them several unique electrochemical properties (28). As with other carbon electrodes, carbon fiber electrodes frequently are treated to improve their electrochemical reversibility (29-31). One electrode treatment, which we are examining in detail, involves the electrochemical oxidation of the surface of a single carbon fiber (29). Voltammograms obtained with this electrode exhibit a large shift in half-wave potential for many species relative to untreated electrodes; in particular, the overpotential for the oxidation of ascorbic acid is greatly reduced. This allows the voltammetric resolution of ascorbate from the catecholamine neurotransmitters and their metabolites

(32, 33). However, further investigation has revealed significant changes in the voltammetry of many species at this electrode and severe adsorption of several classes of compounds (34).

In this communication, we report the voltammetry of a series of highly charged metal complexes at an electrochemically treated cylindrical carbon fiber electrode. The voltammetric behavior is explained in part by the interaction of solution species with surface functional groups formed during the oxidative electrochemical treatment of the carbon fiber electrode.

Experimental

Reagents.—The inorganic compounds $\text{Ru}(\text{NH}_3)_6\text{Cl}_3$, $\text{Co}(\text{NH}_3)_6\text{Cl}_3$, and $\text{K}_3\text{Fe}(\text{CN})_6$ were used as received. $\text{K}_4\text{Mo}(\text{CN})_8 \cdot 2\text{H}_2\text{O}$ was synthesized as reported in the literature (35). All other chemicals were reagent grade and used as received. All species were studied in phosphate buffer solution (0.1M total phosphate) adjusted to the proper pH with phosphoric acid. Solutions (1.0 mM) were prepared with doubly distilled water and purged thoroughly with nitrogen before use.

Electrodes.—Cylindrical electrodes were constructed from carbon fibers (Thornel VSB-32, Union Carbide). Individual fibers (radius = $5\mu\text{m}$) were aspirated into glass capillaries which were then pulled to a fine taper with a pipette puller (David Kopf Instruments, Model 700C). The fiber was sealed in the pulled glass capillary by carefully placing a drop of epoxy (EPON 828, Miller-Stephenson) at the end of the glass with another pulled capillary so that the epoxy enters the capillary without coating the carbon fiber that extends beyond the glass. The electrodes were trimmed with a scalpel so that approximately $500\mu\text{m}$ of carbon fiber extended beyond the end of the capillary. The exact length of the protruding fiber was measured with an optical microscope. Electrical contact to the fiber was made by filling the capillary with mercury and inserting a short wire into the capillary.

Apparatus.—Potentiostatic control for cyclic voltammetry (CV) was maintained with a polarographic analyzer (Princeton Applied Research Corporation, Princeton, New Jersey, Model 174A). Potential waveforms for electrochemical treatment of the carbon fiber electrodes were applied through the polarographic analyzer by a function generator (Krohn-Hite, Avon, Massachusetts, Model 1200A). A 25 ml vial served as the electrochemical cell. Potentials are reported *vs.* a saturated calomel electrode.

Electrochemical treatment.—The electrochemical treatment of the cylindrical carbon fiber electrodes was a two-step process (29). The electrochemical treatment was applied to the electrode in phosphate buffer (pH 7.4) and consisted of a triangular wave (70 Hz, 0 to +3.0V *vs.* SCE

reference) for 20s, followed by a constant potential of +1.5V for 20s. The current-potential curves for the triangular wave treatment were monitored with an X-Y oscilloscope. The electrode was then potentiostated at -0.2V vs. SCE for a period of 40-60 min in buffer solution. Previous work in this laboratory has shown that the electrode undergoes some type of equilibration process after electrochemical treatment. The equilibration period allows for a more stable response. Background voltammograms were then obtained.

Results and Discussion

Properties of electrochemically treated electrodes.—Background scans obtained in pH 7.4 solution at 100 mV·s⁻¹ every 60s with an untreated electrode exhibit little background current. In contrast, voltammograms obtained in the same manner after electrochemical treatment show a significant increase in background current, and this current does not change significantly with time. An estimate of the capacitance (*C*) of the carbon fiber surface can be obtained as $C = i/v$, where *i* is the observed current at a particular potential and *v* is the scan rate, from voltammograms recorded in buffer solution. The capacitance of an untreated electrode at pH 7.4 is approximately 30 μF/cm², and that of an electrochemically treated electrode is approximately 270 μF/cm². This appears to indicate a change in the surface roughness of the electrode. This is apparent from observations of the fiber with electron microscopy. The appearance of the fiber after electrochemical treatment is similar to that observed after air oxidation at 680°C (36). The increase in surface roughness of the fiber is caused by the oxidation of the carbon fiber and is known to increase the amount of carbon-oxygen functionalities on the surface (11). The change in capacitance correlates with the change in surface roughness, but may also result in part from a change in carbon-oxygen surface functionality. Indeed, a severe oxidation process at carbon fibers has been shown to double the O:C ratio relative to the control specimen and produce a surface that contains carbon-oxygen functionalities in the ratio 54% carboxyl, 22% carbonyl, and 24% hydroxyl, as determined by x-ray photoelectron spectroscopy (XPS) (12).

Voltammetry of metal complexes.—A series of electroactive metal complexes was used to probe the chemical nature of these functional groups at the oxidized surface. Voltammetry of metal complexes at untreated cylindrical carbon fiber electrodes is generally characterized by poor electrochemical reversibility, due to the character of the carbon fiber surface. The voltammograms of Ru(NH₃)₆³⁺ at untreated electrodes appear to be the most reversible of the compounds examined. Therefore, the electrochemically active area of an untreated carbon fiber electrode was determined from voltammograms of Ru(NH₃)₆³⁺. The length of the fiber was then calculated from the observed current from the equation for the current at a cylindrical electrode

$$i = 4\pi nFDCl / \ln(4Dt/r^2)$$

where *l* is the length of the electrode, *r* is the radius of the fiber, *D* is the diffusion coefficient, and *t* was taken as the time required to reach the limiting current in the voltammogram where steady-state behavior is approximated (37). The length calculated in this manner is typically 60% of the length measured by optical microscopy. The calculated length was used to quantitate changes in voltammetric behavior after electrochemical treatment.

At electrochemically treated carbon fiber electrodes, voltammograms of highly charged inorganic anions are roughly sigmoidal with small amounts of peak-shaped character (Fig. 1). The magnitude of the peak voltammetric current obtained for Fe(CN)₆³⁻ and Mo(CN)₆⁴⁻ at these electrodes at pH 7.4 is less than would be predicted (Table I). When the electrodes were removed from solution containing the electroactive species, washed with distilled water, and transferred to buffer solution, no

^c Obtained from voltammogram which was not first scan.

voltammetric waves were observed which would indicate the adsorption of these species to the electrode.

Voltammograms of highly charged inorganic cations exhibit significant changes in behavior (Fig. 2). The current that is observed in initial voltammograms of Ru(NH₃)₆³⁺ or Co(NH₃)₆³⁺ is significantly larger than expected for diffusion control. The observed current densities for Ru(NH₃)₆³⁺ and Co(NH₃)₆³⁺ at an electrochemically treated electrode are 11.8 and 1.4 times greater, respectively, than those calculated for an untreated electrode (Table I). The increase in current is observed for the reductive scan only. The adsorption of highly charged

cationic species at the electrochemically treated electrode is responsible for the increased current density. The initial voltammetric scan in a solution of $\text{Ru}(\text{NH}_3)_6^{3+}$ exhibits a very large current, much greater than predicted for diffusion-controlled conditions. Voltammetry in buffer solution, after voltammetry in solution containing $\text{Ru}(\text{NH}_3)_6^{3+}$ and rinse, shows a voltammetric wave presumably due to adsorbed $\text{Ru}(\text{NH}_3)_6^{3+}$. The magnitude of this wave decreases with successive voltammetric scans in buffer solution.

The reduction of $\text{Co}(\text{NH}_3)_6^{3+}$ has a shift in peak potential from -0.65V (*vs.* SCE) at untreated electrodes to -0.38V at treated electrodes. The shift in wave position is indicative of a surface which increases the rate of ligand substitution for the complex or the rate of electrochemical kinetics. It is known that the $\text{Co}(\text{II})$ complex is labile and decomposes in aqueous media without the presence of free ligand (38, 39).

The $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ redox couple exhibits a reverse wave at other types of carbon electrodes. However, no reverse wave is observed on the scale at which the voltammogram is recorded due to the large magnitude of the cathodic current. Voltammograms recorded at more sensitive scales on the first scan do indicate the presence of a reverse wave. Successive scans in a solution of $\text{Ru}(\text{NH}_3)_6^{3+}$ show an exponentially decaying current magnitude that approaches a constant value. The current magnitude, observed when steady-state conditions are reached, is dependent on the length of time between scans (*e.g.*, 30, 60, or 90s). A longer period between scans results in a larger peak current for the voltammogram. If the electrode is allowed then to rest for a long time in solution containing $\text{Ru}(\text{NH}_3)_6^{3+}$ and a voltammogram is then taken, a very large peak current is again observed.

When reduced, the adsorbed ruthenium complex appears to be labile to substitution, and may substitute in a manner similar to that for $\text{Co}(\text{NH}_3)_6^{2+}$. The substituted ruthenium-ammine complex is nonelectroactive and may be adsorbed to the electrode. In this manner, it hinders adsorption of more $\text{Ru}(\text{NH}_3)_6^{3+}$ from solution. The desorption of the substituted ammine appears to occur on a long time scale; therefore, increasing the period between scans results in greater observed current.

Electrochemically treated cylindrical carbon fiber electrodes display significant changes in the observed electrochemical characteristics. Most notable is the improved electrochemical reversibility of a wide number of compounds at these electrodes. Other features, however, such as the susceptibility to adsorption, complicate the use of these electrodes for voltammetric analysis. The primary reason for the change in voltammetric behavior with electrochemical treatment appears to be a change in the nature of the carbon fiber surface due to electrochemical oxidation. The results of the investigations reported here are consistent with the voltammetric behavior expected at a surface containing many carbon-oxygen functionalities. These functionalities appear to be anionic in nature at pH 7.4 and suggest the presence of carboxyl groups. A more detailed account of the characterization of the electrochemically treated carbon fiber electrode will appear in the literature.

Mediated Oxidation at a Polymer-Modified Electrode. Savéant-Andrieux Treatment of the Kinetics

E. Tracy Turner Jones

In electrocatalysis at a modified electrode, an immobilized reversible redox center acts as a fast electron-

transfer mediator for a solution species that is oxidized or reduced slowly or not at all at the bare electrode. The primary aim is to diminish the overpotential required for direct oxidation or reduction of the substrate. A secondary, related aim is to achieve good catalytic efficiency. While a monolayer of catalyst can indeed reduce the overpotential, the catalytic efficiency will often be poor. If catalyst is instead distributed throughout a polymer film, the catalytic efficiency can, under the right conditions, increase in proportion to the number of equivalent monolayers of catalyst present (1). Such a polymer-modified electrode takes advantage of the three-dimensional distribution of catalyst found in homogeneous electrocatalysis. In addition, the arrangement facilitates separation of product and catalyst and conserves the often expensive catalyst while providing for its high local concentration (2).

In a series of papers published in 1982 (3-5) Andrieux and co-workers presented a kinetic model for the following system

where P and Q make up a mediator redox couple immobilized in a polymer film, and A and B are the reduced and oxidized forms of the substrate. Mediated oxidation is given here; transposition to reduction is straightforward. The model, which was developed for stationary voltammetric techniques such as rotating disk electrode voltammetry, encompasses four factors that determine the magnitude of the mediated current: diffusion of substrate from the bulk solution to the film-solution interface, further diffusion of substrate through the film toward the electrode surface, electron "diffusion" within the film (the sum of the electron propagation processes by mediator self-exchange or physical diffusion), and the rate of the electron cross-exchange reaction between mediator and substrate.

Four redox situations of practical interest were identified and treated under three different case designations: A, B, C (5). In case A, the equilibrium constant for the cross-exchange reaction ($K = k_1/k_2$) may take any value, and the $A \rightleftharpoons B$ electrode reaction is irreversible. Where K is greater than or equal to unity, case A has catalytic possibilities. Case B has limited utility. While not catalytic itself, case C is useful for modeling catalytic systems. The cross-exchange reaction equilibrium constant in case C is greater than or equal to unity, and the $A \rightleftharpoons B$ electrode reaction is fast enough that it occurs at more negative potentials than does oxidation of P. When K is large, two distinct plateau currents may be obtained at a polymer-modified rotating disk electrode. The separation of direct oxidation of substrate from mediated oxidation of substrate facilitates diagnosis of the parameters that limit the currents.

The kinetic behavior of each case above is thoroughly defined by a set of differential equations derived from Fick's laws of linear diffusion and by a set of boundary conditions. Simple closed-form equations defining a few types of characteristic limiting behavior are used in the analysis of experimental data. Andrieux and Savéant (5) have presented these closed-form equations in terms of K and four component currents: i_A , i_S , i_E , i_k . Each current is related to one of the four rate-limiting factors described above. The component current i_A is simply the limiting current that would be observed at the bare electrode rotating in the substrate solution. It is a measure of the maximum deliverance of substrate by diffusion to the film-solution interface of the modified electrode. The magnitude of i_S depends upon the diffusion coefficient of substrate in the film. The diffusion-like transport of electrons among the mediating centers of the film determines i_E . And i_k is the largest current that could be deliv-

ered by the cross-exchange reaction. These currents are described in more detail elsewhere (4).

The closed-form equations for case C in the limit of large K are given in Fig. 1. The type of limiting behavior for each pair of plateau current expressions is given by an ESR designation. In these limiting situations, one or two of the rate-limiting factors predominate over the others. The ESR designation is a general guide to the nature of the limiting processes; the first two letters point to the electron (E) and substrate (S) diffusion processes within the film, and R indicates the influence of the cross-exchange reaction rate. A cycle of concentration profiles taken for a potential at which P is oxidized at the mass-transfer-limited rate is a useful tool for understanding the transitions among limiting behaviors (Fig. 2).

The strategy for analyzing a given polymer-mediator-substrate system involves evaluating i_A , i_S , and i_E , and constructing Koutecky-Levich plots [i^{-1} vs. (rotation rate) $^{-1/2}$] from the sum of the oxidation plateau currents. Much of the experimental validation of the theory to date has been provided by Anson's group in association with Savéant (6, 7).

We have investigated the use of poly(styrene sulfonate) (PSS) as a matrix for the mediated oxidation of ferrocene-1,1'-disulfonate [$Fe(CpS)_2^{2-}$] in CH_3CN by electrostatically bound tris(2,2'-bipyridine)osmium(III) [$Os(bpy)_3^{3+}$], a case C system.

Experimental

Poly(styrene sulfonate, sodium salt) (Polysciences, Incorporated, $M_w = 6 \times 10^6$) was purified through dialysis and filtration. A 1.00% (w/v) PSS, 0.038% (w/v) Zonyl FSN (du Pont) spin coating solution was prepared in 3:2 methanol:water. The FSN, a fluorosurfactant, made it possible to spin coat films of uniform thickness on Teflon-shrouded glassy carbon electrodes. The osmium salt, $Os(bpy)_3(ClO_4)_2$, was synthesized according to a method outlined by Burstall *et al.* (8). The solution used to load films had the following composition: 0.50 mM $Os(bpy)_3^{2+}$, 10 mM dicyclohexyl-18-crown-6 (Aldrich), 0.020M tetra-n-butylammonium tetrafluoroborate (TBABF₄), and 4.0% (v/v) water in distilled-in-glass acetonitrile (Burdick and Jackson). The crown ether was included to force dissociation of the sodium sulfonate moieties (9). The volume of water added was judged to promote swelling of the polymer film without causing its dissolution. Both components were important for achieving rapid exchange of $Os(bpy)_3^{2+}$ into the PSS films. Another loading solution as prepared in the same manner but for the substitution of $Ru(bpy)_3^{2+}$ for $Os(bpy)_3^{2+}$. The perchlorate salt of the ruthenium complex was prepared as described by Glass and Faulkner (10). The acid form of $Fe(CpS)_2^{2-}$ was synthesized according to a method by Knox and Pauson (11) and then titrated with an aqueous

solution of tetra-*n*-butylammonium hydroxide (Aldrich). Tetra-*n*-butylammonium ferrocene-1,1'-disulfonate was recovered in a rotary evaporator and recrystallized twice from ethanol/diethylether. The electrolyte, TBABF₄, was part of a batch for which the preparation has been described (9).

An AFMSR Rotator System fitted with a glassy carbon rotating disk electrode (RDE) (Pine Instrument Company) was used in conjunction with a Z-80 microprocessor based cybernetic-potentiostat (12) to obtain all electrochemical data. Two Teflon-shrouded (12 mm od) 6 mm diam glassy carbon disks were polished with 0.25 μm grit diamond compound then 0.05 μm grit alumina slurry (Buehler Limited). In order to improve the adsorption of PSS films on the glassy carbon, the polished electrodes were treated with 25% ClSO₃H in CH₂Cl₂ (v/v) for several minutes. Apparently, sulfonation of aromatic rings in the glassy carbon structure made the electrode surfaces more polar. Spin coating was accomplished by locking the RDE's onto a shaft driven by a controlled speed motor (Electro-craft Corporation). A special cell was built for the rotation experiments (Fig. 3). The design minimizes convective turbulence and uncompensated resistance. It features a removable platinum auxiliary electrode separated from the spherical working electrode chamber by a glass frit. The Ag/Ag⁺ reference electrode (0.01M, CH₃CN) is sequestered in an adjustable side arm that draws into a Luggin capillary.

Results and Discussion

Spin coating at 4000 rpm consistently produced films that gave an even blue interference color. Loading was accomplished in approximately 12 min by cycling freshly

Fig. 3. Diagram of the electrochemical cell built for rotation experiments.

spin-coated electrodes between -0.2 and $+0.8\text{V}$ in the 0.5 mM Os(bpy)₃²⁺ solution (Fig. 4). A dry-loaded film gave a yellow interference color.

Once a film was loaded, the electrode surface was rinsed with CH₃CN and the electrode was transferred to a solution of 0.020M TBABF₄ and 0.50% (v/v) H₂O in CH₃CN. The electrode was cycled in this solution (Fig. 5) until the Os(bpy)₃^{2+/3+} sites within the film reached stable configurations. This process, which took approximately 30 min, was marked by a 200 mV negative shift of the formal redox potential of the PSS-Os(bpy)₃^{2+/3+} couple. Similar behavior was observed by Majda and Faulkner for the PSS-Ru(bpy)₃^{2+/3+} system (9). The Os(bpy)₃^{2+/3+} sites had converted from "weakly bound" configurations, in which the individual osmium center may have interacted with two sulfonate groups, to "strongly bound" configurations, in which each osmium center may have interacted with three sulfonate groups. The formation of

Fig. 4. Growth of voltammetric signal for Os(bpy)₃^{2+/3+} exchanging into a PSS film. Initial and final potentials were -0.2V .

Fig. 5. Conversion of redox polymer film of Fig. 4 to a dehydrated strongly-bound state. Initial and final potentials were $-0.2V$.

tight strongly bound centers and the loss of film fluidity that accompanies dehydration could combine to produce electroinactive domains of mediator sites. This film lockup, as well as leaching, could account for the smaller peak amplitudes of the dehydrated film (Fig. 5).

In order to obtain an effective loading value for a dehydrated $\text{Os}(\text{bpy})_3^{2+/3+}$ -exchanged film, the electrode was poised at $-0.2V$ for 5 min prior to a single cycle between -0.2 and $+0.775V$. The area under the oxidation peak was integrated to determine the effective loading value in microcoulombs. An average of $370 \pm 16 \mu\text{C}$ was calculated for the ten films that form the basis of this study. Ideally, once the loading value for a film was measured, a series of experiments would have been conducted to determine i_E , i_S , and the mediated substrate oxidation current. In practice, the loaded films were not robust enough to survive such a regimen. So the work done with each film was limited, and every effort was made to generate reproducible film systems.

One of the most appealing features of the kinetic model developed by Andrieux and co-workers is that knowledge of the *in situ* film thickness is not required for determining i_E . In addition to a film's loading value in coulombs, all that is necessary is the Anson slope from a chronocoulometric experiment

$$i_E = \frac{\pi}{4} \frac{(\text{slope})^2}{\text{loading value}}$$

In general, potential steps were made from -0.1 to $+0.85V$ for pulse widths ranging from 100 to 1000 ms. The component current i_E was determined to be $250 \pm 20 \mu\text{A}$. Given the high local concentration of the osmium com-

Fig. 6. Current-potential curves for oxidation of $0.10 \text{ mM Fe}(\text{CpS})_2^{2-}$ at a rotating glassy carbon electrode coated with PSS- $\text{Os}(\text{bpy})_3^{2+/3+}$. Order in which rotation rates were selected is given on right. Scan rate = $5 \text{ mV}\cdot\text{s}^{-1}$.

plex in the films (estimated to be $0.3\text{--}0.5M$) relative to the concentration of supporting electrolyte, migration effect were probably present.

Three substrate solutions were used in the mediation experiments: 0.10 , 0.25 , and $0.40 \text{ mM Fe}(\text{CpS})_2^{2-}$ in 0.50% (v/v) H_2O , $0.020M$ TBABF₄ acetonitrile solutions. Rotation rates ranged from 100 to 1225 rpm. Attempts to use higher concentrations or rotation rates failed, apparently because of the accelerated fouling that accompanied the increased substrate flux. Three loaded films were run at each substrate concentration. Two of the nine trials were eventually discounted because the film loading values were too low. Rotation rates were selected in a different order with each trial so that intruding effects could be identified without putting the short-lived films through repeat runs. The suspected fouling process had no discernible impact upon the magnitude of the combined plateau current ($i_1 + i_2$) as long as there was not a total film failure. The fouling did, however, affect the shape and location of the superimposed $\text{Os}(\text{bpy})_3^{2+}$ oxidation peak. In a successful trial shown in Fig. 6, the shrinking peak flattened and shifted to more positive potentials as the film became fouled, reflecting the increasing difficulty with which the mediator sites were oxidized.

The Koutecky-Levich plots for $i_1 + i_2$ are linear and intercept the origin (Fig. 7). The slopes are inversely proportional to substrate concentration. It is not clear from any of the voltammograms whether the shoulder that precedes each mediator peak is an artifact or is actually the first plateau current and a measure of i_S . In any event, another means of measuring i_S was chosen.

The formal redox potential of the polymer-bound $\text{Ru}(\text{bpy})_3^{2+/3+}$ couple is approximately $+0.85V$, well removed from the onset of $\text{Fe}(\text{CpS})_2^{2-}$ oxidation. For i_S

Fig. 7. Koutecky-Levich plots of $(i_1 + i_2)^{-1}$ vs. $(\text{rpm})^{-1/2}$ for the PSS-Os(bpy) $_3^{2+/3+}$ film in Fe(CpS) $_2^{2-}$ solutions.

determinations, then, the ruthenium complex is a natural choice as a surrogate for the closely related osmium bipyridine complex. Freshly spin-coated electrodes were loaded with the ruthenium complex to the level of the osmium complex and then dehydrated using the standard procedure. Care was taken to avoid oxidation of water in the films. Voltammetric data were obtained for three substrate concentrations (Fig. 8). Table I contains the i_s component currents determined from the intercepts of the Koutecky-Levich plots of the plateau currents. The i_s values are roughly proportional to substrate concentration, as expected. They are also very small, less than $1 \mu\text{A}$, indicating slow substrate diffusion through the film.

The Levich constant for oxidation of Fe(CpS) $_2^{2-}$ at a bare electrode had been determined in earlier experiments that employed a wide range of substrate concentrations and rotation rates. Table II gives the i_A values calculated from the Levich constant for the rotation rates and substrate concentrations ultimately used in the mediation experiments.

All the evidence points to SR characteristic limiting behavior (see Fig. 1 and 2). There are two current plateaus, and the i_E/i_S ratio is very large so the R, R + E, ER, ER + S, S, and S + E characteristic behaviors are ruled out. The i_E component current is also larger than the i_A values; the E characteristic behavior is out. Koutecky-Levich plots of $i_1 + i_2$ are linear, which narrows the field to R + S and SR. And finally, the cross-exchange reaction between Os(bpy) $_3^{3+}$ and Fe(CpS) $_2^{2-}$ is likely to be very fast so that i_E/i_S will be large. The SR characteristic limiting behavior becomes the best candidate.

In the SR situation, a rapid cross-exchange reaction and slow substrate diffusion through the film unite to confine the substrate within the film to a thin reaction layer

Fig. 8. Current potential curves for direct oxidation of Fe(CpS) $_2^{2-}$ at a rotating glassy carbon electrode coated with PSS-Ru(bpy) $_3^{2+/3+}$. Scan rate = $5 \text{ mV}\cdot\text{s}^{-1}$.

Fig. 9. Cross section of PSS-Os(bpy) $_3^{2+/3+}$ film in Fe(CpS) $_2^{2-}$ solution illustrating proposed concentration profiles of mediator and substrate.

adjacent to the film-solution interface. The mediator concentration profile is generally flat and at the maximum value. We believe that our system represents an extreme of the SR case. The zero intercept of the Koutecky-Levich plots of Fig. 7 means that the modified electrode was able to oxidize the entire Levich flux. Therefore, the concentration of the substrate in the solution was drawn down to zero at the film-solution interface. Substrate did not penetrate the film; the cross-exchange reaction occurred at the interface. And since i_E can be no more than three times as large as i_A , the mediator concentration profile would have sloped down toward the film solution interface to some degree. These features are shown in Fig. 9.

Work is underway to explore the extent to which the parameters that govern the kinetics of the polymer-mediator-substrate system can be tuned. The goal is to use the mediator more efficiently. That is, the entire volume of the film should be involved in the cross-exchange reaction. Toward that end, the water content of the substrate solutions will be increased to further swell the film and the mediator concentration within the film will be lowered.

Acknowledgments

The author is grateful to the Electrochemical Society for the Colin Garfield Fink Summer Fellowship Award and to Professor L. R. Faulkner for his steady support.

The Joseph W. Richards Summer Fellowship Report Analysis of Square Wave Voltammetric Results at a Tin Oxide Semiconductor Microelectrode

Neal T. Sleszynski

Microelectrodes have been used by biochemists and neurophysiologists for several decades to study cell biochemistry and nerve cell communications (1, 2). Although usually used in potentiometry, in a small number of cases these microelectrodes have been used as voltammetric sensors (usually in the amperometric mode) to identify electroactive species such as neurotransmitters (3, 4). Only recently have electrochemists recognized the potential of microelectrodes for classical electrochemical problems. Wightman has published a useful review of microelectrode applications in analytical chemistry as well as biochemistry (5).

The major attraction of microelectrodes for the analytical chemist is the improved signal-to-noise ratio, which arises from the increase in current density associated with nonplanar diffusion. When overall small dimensions are not required, the use of arrays of microelectrodes can be advantageous. Microelectrode arrays offer higher, more easily measurable currents while retaining the desirable features of the individual microelectrodes in the array. Although arrays have been constructed manually (22, 23), certain types of microelectrode arrays may be constructed using semiconductor fabrication technology (6, 7, 24-26) if appropriate materials for the electrode and insulating layer are successfully identified.

In conjunction with the National Research and Resource Facility for Submicron Structure at Cornell University, we have constructed a number of microelectrode arrays from SnO₂, a commonly used semiconductor in the electronics industry, with the goal of testing the recently developed theory of square wave voltammetry at microelectrodes for reversible processes (8). Electrodes constructed of SnO₂ have been examined by a number of experimenters (9-18). Initial work in the area focused on the use of these electrodes in spectroelectrochemistry (10-12). The area of optically transparent electrodes has been reviewed by Kuwana and Winograd (19), and a summary of the uses of SnO₂ for this purpose is given there. A paper by Osa and Kuwana (12) reviews the use of tin oxide and other optically transparent electrodes in non-aqueous solutions.

A number of other studies examined the problem of electron transfer kinetics on these electrodes. Kuwana's review notes that the reversibility of ferrocyanide at these electrodes depends on pH and chloride ion concentration. In a paper with Strojek (11), Kuwana shows cyclic voltammograms which indicate that the maximum reversibility for ferrocyanide on tin oxide electrodes is seen at pH = 1.5, although from their figure it appears that even at this pH the electron transfer is only quasi reversible. Laitinen and co-workers (13) have also noted an effect of chloride ion, which appears to be specifically adsorbed. The peak shape for a cyclic voltammogram indicates ei-

ther a charging process or an exhaustive surface electrolysis. Experiments showed that an electrode removed from a chloride containing electrolyte and placed in a chloride-free environment retained adsorbed chloride for several hours. Access to cathode potentials was found to be limited by reduction of tin oxide to metallic tin. Further studies by this group on the surface properties of these electrodes have included the study of bromide (15) and iodide (16).

Armstrong and co-workers (18) have conducted extensive surface studies of SnO₂ and In₂O₃ semiconductor electrodes using ESCA and Auger spectroscopy. Although a comparison of surface properties with capacitance behavior and accessible potential range was made, no information was provided which would shed light on either the strong adsorption of halides or variations in electrode kinetics.

Albertson and co-workers (17) have determined the electron-transfer rate constant for the reduction of ferrocyanide at SnO₂ using both electrochemical and spectrophotometric means. Unfortunately, the experimental conditions were such that the electron-transfer rate was determined under conditions which other workers had already noted as yielding quasi-reversible behavior (pH 7). The electron-transfer rates determined by the two methods agreed closely, with an average of $4.3 (\pm 0.2) \times 10^{-4}$ cm/s. No measurements were made at lower pH values, where the couple is known to exhibit more reversible behavior.

Laitinen's group has used almost exclusively electrodes constructed in their own lab. They have examined the electrical and electrochemical properties of SnO₂ films with varying amounts of antimony as a dopant (14). Their studies showed the sensitivity of the electrode kinetics to semiconductor composition, in particular the dopant level. In the same study, they measured electron-transfer rates at the best of these electrodes for a number of compounds. They found that for compounds with quasi-reversible electron-transfer rates electron transfer rates are uniformly faster at Pt electrodes. Reversible behavior was seen under certain conditions for Fe(o-phen)₃²⁺ and Fe(CN)₆⁴⁻. Work has also been done on modifying the electrode surface with submonolayers of adsorbed Pt (20). This modified electrode surface showed greater activity for the reduction of oxygen than a bulk Pt electrode.

In order to test the square wave at microelectrode theory, it is necessary to identify a species which is reversible on the commercial SnO₂ material, Nesla Glass, which was used to construct the electrode. For convenience, cyclic voltammetry was used to initially screen compounds, using the peak-to-peak separation criteria of Nicholson and Shain (21). Species examined included ferrocyanide, ferrous oxalate, Ru(bpy)₂²⁺ in aqueous media, and Ru(bpy)₃²⁺ and ferrocene in acetonitrile. All were found to exhibit quasi-reversible behavior under the conditions used, at scan rates as slow as 100 mV/s. These results indicate that commercially available SnO₂ may be an unreliable material for applications in which reversible electron-transfer behavior is necessary. It is apparent from the results reported by Laitinen and co-workers (14), however, that carefully fabricated semiconductor surfaces, or electrode surfaces which have been modified with adsorbed Pt (20), are capable of yielding the desired behavior.

The most reversible of the species tested, ferrocyanide, was used for square wave experiments which compared experimental behavior with that predicted by theory. Figure 1 shows the comparison of the experimental results and the theoretical fit, as calculated using simplex optimization techniques, for an array of 100 disks each 30 μm in radius. The effect of the slow electron transfer can be seen in the quality of the fit, especially at higher overpotentials. Despite this problem, the calculated fit yields a radius of 28 μm, in good agreement with the radius of 30 μm measured using a microscope.

In conclusion, it can be said that the recently developed theory of square wave voltammetry at microelectrodes is

Fig. 1. Square wave voltammogram of 0.5 mM ferrocyanide on a SnO_2 microelectrode array (100 disks of radius $30 \mu\text{m}$). Square wave frequency: 10 Hz. 50 mV step amplitude.

capable of describing the experimental behavior seen at these arrays, even in the absence of a completely reversible electron transfer.

Acknowledgment

In addition to acknowledging The Electrochemical Society for a generous summer fellowship, the author would like to thank Richard Tiberio at Cornell University for electrode construction and the Office of Naval Research for project support.

Chlorine-Caustic Soda

Production and capacity.—Domestic.—Major U.S. chlor-alkali producers are listed in Table I (1). The major end-use markets for chlorine and caustic are summarized in Table II (2).

As Table III shows, the production of chlorine and caustic rebounded from 1983 levels. The average operating rate for 1983 was 68.7% of capacity; in 1984, it was 75.6% of capacity. (3-9).

Returns on caustic soda and chlorine generally increased throughout the year as the general economy recovered. Prices for caustic soda range from \$195 to \$265/ton, 50% caustic, location dependent. Chlorine tabs have gone from \$150 to \$170/ton levels to \$195-200/ton (56-61).

Occidental and PPG have taken an optimistic view of the future, as evidenced by their modernization plans. Occidental is installing a \$30 million, 400 ton/day chlorine, 440 ton/day caustic soda plant at its Taft, Louisiana, facility. The new plant will be Eltech's membrane cell technology. This is reportedly the largest plant in the U.S. The new plant is expected to be on stream in early 1986. PPG is replacing its graphite electrode technology at its Natrium, West Virginia, plant with monopore diaphragm equipment. The trend is to make the plant more energy efficient. The new equipment, at a cost of \$105-\$110 million, is expected to be on line the first quarter of 1985 (10).

By April, Occidental Chemical boosted its chlor-alkali capacity at Taft, Louisiana, to more than 1000 ton/day. This was the result of starting up a 230 ton/day chlor-alkali plant idled more than a year ago at the facility (11, 12).

SRI International has released a report which indicates the problem of excess chlor-alkali production is likely to continue. Year to year fluctuations in demand have been 2% greater since 1975, as compared with the period from 1965 to 1974. Overcapacity generally exists around the world, so the industry cannot expect much help from exports. Western Europe ran at 75% in 1982, and Japan at 76% in 1982. Growth is predicted at 2%/yr in 1982. Growth is predicted at 2% in Western Europe, and 1.1% in Japan. New chlor-alkali capacity is coming on stream in the Middle East and Asia (13).

Pennwalt Corporation announced plans to convert the Tacoma, Washington, 250 ton/day plant to the ICI FM 21 membrane technology, which will be the largest such facility in North America. This will be the second facility to employ coated cathodes. Start-up of the plant is expected in the second half of 1985 (14, 15).

ICI's FM 21 technology is said to be energy efficient due to coated anodes and cathodes and the use of Du Pont's Nafion membrane. The technology was proven in

* Electrochemical Society Active Member.

¹This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. It represents a summary of the published information on production, plant capacities, consumption, markets and trends, prices, raw materials, new developments, and health and environmental aspects in the electrolytic and related industries.

The material presented herein has been obtained from many sources, as noted in the list of references, and does not necessarily represent the opinions of the authors.

The Industrial Electrolytic Division is grateful for the support received from the Vittorio de Nora-Diamond Shamrock Fund, which assisted in meeting the publication costs of this article.

three European plants and six other installations will be commissioned in 1984 (15-18).

PPG Industries has received an award from Research and Development magazine (IR-100 award) for its "Bizec" membrane chlor-alkali electrolyzer technology. The cell technology reduces energy by more than 25% as compared to diaphragm cell technology. A demonstration-scale plant is operating at the Lake Charles, Louisiana, complex. This is PPG's first cell technology to use permionic membrane technology (19, 20).

In a bid for further integration, Occidental Chemical Corporation will reopen the 500 million lb ethylene facility at Lake Charles, Louisiana, formerly owned by Cities Service. This move will further integrate the company's chlorine and natural gas liquids (21).

Eltech Systems Corporation, Occidental Chemical Corporation and its subsidiary, Anode Products Incorporated, have settled pending litigation related to Eltech's patents for chlor-alkali diaphragm cells (22).

Japan.—Kashima Chlorine and Alkali Company has converted from mercury cell chlor-alkali technology to ion-exchange membrane technology at its Kashima works. Mercury cells must be replaced in Japan by June of 1986 (23).

Three Japanese companies—Asahi Chemical, Asahi Glass, and Tokugama Soda—are perfecting the ion-exchange membrane processes (24).

Table I. Major U.S. chlor-alkali producers (thousands of tons)

consumers other than the aluminum producers. Since 1979, prices for producing a pound of aluminum have gone from \$0.024 to \$0.18 (108).

The Tennessee Valley Authority service area has increased rates from 24.8 mill in 1979 to 37 mill this year. Several producers in the TVA area have closed or markedly reduced capacity. The TVA area has become the "swing" area for primary aluminum production. These energy policies will likely send primary aluminum production off shore and to areas with incentive energy policies for smelters (108).

Alcoa announced that it will phase out some of its high cost domestic capacity and will be buying more primary aluminum ingot on the open market (109, 110).

The Bonneville Power Administration made an agreement with six Northwest aluminum producer plants. Eleven Direct Service Industries (DSI's) have agreed to buy 2,640 MW of BPA power at 22.7 mill/kWh. BPA disclosed that over a 6 month period the agency will gain \$1.48 billion in total revenues (111).

Alcoa and Reynolds adjusted their output with respect to BPA's incentive power (112-114).

Kaiser announced that two additional potlines will be closed on September 9 at its Mead, Washington, facility. The domestic aluminum smelting rate will drop a full percentage point with the closing (115-118).

Reynolds Metals Company shutdown its 23,000 ton/year potline at Jones Mill, Arkansas primary smelter. Alcoa announced that it will restart its 25,000 ton/year potline at Alcoa, Tennessee, as the Tennessee Valley Authority decided to provide additional "limited interruptible power." Alcoa shutdown a 34,000 ton/year potline at Rockdale, Texas, a net shutdown of 9,000 ton/year. Martin Marietta Aluminum, Incorporated, announced it would close its 82,000 ton/yr smelter at The Dalles, Oregon, if no buyers were found by December 1. Martin Marietta has decided to divest of all aluminum operations (119-121).

Alcan reached agreement with Arco to acquire Arco's interest and a primary aluminum smelter in Sebree, Kentucky, and rolling mills in Indiana and Kentucky and Arco's alumina interests in Ireland (122-125).

Reynolds Metals Company announced it will temporarily idle its 25,000 ton/yr production lines at its Troutdale, Oregon, facility (126-127).

Vertical integration in the aluminum industry seems to have paid off, with companies integrating smelting of primary aluminum capacity with sources of alumina and bauxite (128, 129).

Martin Marietta, in its withdrawal from the world aluminum production arena, will sell four of its six operating facilities to Comalco Limited, of Melbourne, Australia (130-134).

Alcoa reportedly scrapped plans for a 200,000 metric ton/yr smelter in Manitoba, Canada (135, 136).

Reynolds Metals announced that it revised its primary aluminum capacity downward from 1,150,000 to 1,036,000 ton as a result of the permanent closure of its San Patricio, Texas, aluminum reduction plant near Corpus Christi, Texas (137).

Aluminum consumption is projected to reach new record for the second consecutive year. Total aluminum consumption is projected to exceed 16 billion lb for the first time (138).

Alumax, Incorporated, announced a 40,000 ton cutback as the aluminum market weakened. The Intalco plant at Ferndale, Washington, was cut 3,000 tons, and further reductions were likely when the six month Bonneville Power Administration's power rate reductions expire (139).

Aluminum took one step closer to becoming a commodity as trading in futures contracts began on the New York Commodity Exchange. Fears that volatility of primary aluminum prices would increase seem to have been mollified, and North American producers have been more supportive of COMEX than originally expected (105).

Canada.—Canadian aluminum capacity is tabulated in Table XVIII.

Table XVIII (106). Canadian aluminum ingot capacity

Company/Location	Jan. 1, 1984 Annual capacity (short tons)	Operating rate (short tons)
Alcan Aluminum Limited		
Arvida, Quebec	426,000	411,200
Beauharnois, Quebec	51,800	51,800
Grand Baie, Quebec	188,500	188,500
Isle Maligne, Quebec	80,500	80,500
Kitimat, British Columbia	295,400	295,400
Shawinigan Falls, Quebec	92,600	92,600
Total	1,185,000	1,120,000
Canadian Reynolds Metals Company		
Baie Comeau, Quebec	175,000	175,000
Total Canadian	1,360,000	1,295,000
Percent operating		95.2

Alcan Smelters and Chemical Limited, the main operating unit of Alcan, will begin construction of an \$85 million anode baking facility at its Arvida works in Jonquiere, Quebec. The facility will have an annual capacity of 92,000 metric tons and will replace an older plant at the site (140).

Alcan and ICI have filed suit against the state of California's unitary tax law. Alcan and ICI contend that they should be taxed only on their U.S. earnings, and not on their worldwide earnings. Both Alcan and ICI have interests in California (141).

Alcan Aluminum Limited announced that it was withdrawing its benchmark price for aluminum, the standard which had been in effect for more than 20 years. Aluminum is now traded on the London Metals Exchange (LME) and was the reason cited for the withdrawal (142).

Alcan will build a \$770 million smelter in the Laterriere region near Chicoutimi, Quebec. The first phase of the smelter will have a capacity of 80,000 metric ton/yr and a final production capacity of 250,000 metric ton/yr by the end of 1991. Once completed, this smelter will replace the works at Alcan's Arvida complex (143-149).

Pechiney Corporation, Alumax, and Societe Generale de Financement will construct a new smelter at Becancour, Quebec. Aluminerie de Becancour, Incorporated, (ABI) will be responsible for the construction and operation. The ABI will use Pechiney Aluminum's smelting technology (150-159).

Alcan, citing poor market conditions and uncertain exports, postponed its plans to construct two primary aluminum smelters and a hydroelectric generating facility in British Columbia (160-164).

Alcan reduced its output of aluminum ingot by 37,500 metric tons at its Arvida, Quebec, smelter (165).

Japan.—Japan's aluminum supply and demand and imports are summarized in Tables XIX and XX.

The Ministry of International Trade and Industry (MITI) is restructuring the Japanese aluminum smelting and semifabricating industry. The plan will reduce primary aluminum capacity to 300,000 ton from the present 710,000 ton, although current production is only 350,000 ton. Predicted primary aluminum demand will increase about 3%/yr to 2.1 million metric ton/yr by 1988, compared to 1.8 million metric ton/yr now. The difference will be made up of imports, primarily from Japanese invested smelters overseas (167-169).

Kobe Steel Limited, will supply two Japanese aluminum smelters with 100,000 ton of alumina/yr for four years. The alumina will be supplied from the Worsley alumina project in Western Australia. Nippon Light Metal Company, Limited will receive 20,000 ton and Sumitomo Aluminum Smelting Company, Limited will receive 80,000 ton; all to be processed into primary aluminum for Kobe (170, 171).

New Zealand.—The proposed Aramoana aluminum smelter is still under consideration despite earlier indications that the consortium (Pechiney, CSR Limited, and Fletcher Challenge) had abandoned the project because of increased power costs. New Zealand's energy minister says the government wishes to expand aluminum smelting on the South Island, but that to do so would involve major changes in current power planning including

Table XX (166). Imports of primary aluminum and alloy to Japan (metric tons)

Country	1984 (first half)	1983 (first half)	Percentage change
Canada	40,502	50,213	-19.3
U.S.	87,947	145,524	-39.6
Australia	79,452	46,292	+71.6
New Zealand	66,122	77,903	-15.1
U.S.S.R.	3,674	6,373	-42.4
South Africa	6,600	11,187	-41.0
Norway	42	2,013	-97.9
France	—	—	—
Britain	—	—	—
Federal Republic of Germany	—	501	—
Austria	227	1,347	-83.2
Total	284,566	341,353	-16.6

speeding up some hydropower projects to meet the 1988 "first potline" for Aramoana (172).

Australia.—A confirmed site for the much delayed aluminum smelter in Western Australia was announced in December. The site, at Kemerton, 60 miles south of Perth, was the one originally chosen. The consortium project, comprised of South Korean Kukji-ICC Group (50%), the U.S. Reynolds Group (25%), and the Australian Girffiths Group (25%) is expected to make a development announcement during the first quarter of 1985 (173, 174).

Alcan Australia Limited announced that it is postponing a new third potline at its Kurri Kurri aluminum smelter in New South Wales because of low prices for primary aluminum ingot (175, 176).

Alcoa of Australia Limited's Wagerup alumina refining started up in April. The 500,000 metric ton/yr facility is near Perth and was completed in June 1982, but was mothballed due to low world alumina demand (177, 178).

Australia is emerging as a significant world producer of primary aluminum in contrast to its traditional role as a supplier of bauxite and alumina. Australia has abundant coal resources to supply large quantities of competitively priced electricity. Worldwide decline in capacity was traceable to the oil price rise in the 1970's. By the end of 1986, the total annual rated capacity of all Australian smelters will exceed 1 million metric tons. The Portland smelter, being built by Alcoa of Australia Limited will cost \$1.15 billion and produce 300,000 metric ton/yr by November 1986, all to be exported (179-183).

The Tomago aluminum smelter near Newcastle has been operating the first two 115,000 metric ton/yr potlines at full capacity. The plant is scheduled to reach full capacity of 230,000 metric ton/yr in September 1984. The plant uses 180,000 Ampere technology developed by Pechiney Aluminum (184-186).

Europe.—The European aluminum industry predicts marginal growth for aluminum, only in the transportation sector. The North American market is projecting growth in the transportation, building and construction, and foil and beverage can markets (187).

England.—The Commodities Research Unit in London published a study indicating the importance of the six major producers will decline and that there will be a strengthening trend toward free-market pricing. Cheap energy will continue to be the major influencing factor in plant location selection (188, 189).

Deeside Aluminum Limited is operating a secondary aluminum plant in Wrexham, North Wales, which will toll convert scrap ingot into high quality extrusion ingot. It is said to be the only plant of this type in the world (190).

Italy.—Elfim, the Italian state holding group, has announced plans to shut down two aluminum plants in the next two years. Citing losses of \$105 million in 1980, and \$189 million in 1983, Elfim has asked for \$342 million in aid over the next two years from the Italian government (191).

Table XIX (166). Japan's primary aluminum supply and demand

	1984 (metric tons)
Demand	1,889
Supply from overseas projects	600
From long-term contracts	457
From others (domestic production and spot imports)	835
Total	1,892
Stocks	607

Egypt.—Egypt is to export 110,000 tons of primary metal in 1984. The Aluminum Company of Egypt expanded its capacity from 133,000 tons per year to 166,000 tons per year with Soviet aid (243).

Greece.—The Hellenic Industrial Development Bank (ETVA) has selected Kaiser Engineers and Constructors of Oakland, California, as technical consultants for the planning phase of a 600,000 metric ton/yr alumina refinery to be built in Greece with Russian technology and equipment. Construction is scheduled to begin in 1985 at an estimated cost of \$450 million. The U.S.S.R. would purchase 380,000 metric ton/yr of sandy alumina for 10 years; Bulgaria may buy another 200,000 metric ton/yr, but no agreement has been signed yet (192, 193).

Hungary.—Alumina production was 425,000 ton, while bauxite was 1.47 million metric ton, a 1.7 and 3.1% increase, respectively (194, 195).

Norway.—Ardal Og Sunndal Verk (ASV), Norway's largest aluminum producer, may be taken over by Norsk Hydro AS, currently the third largest Norwegian producer, by year's end (196).

A 50,000 metric ton capacity expansion is being studied by Norsk Hydro for its Karmoe aluminum smelter (197).

Brazil.—Hanna Mining Company plans to sell its minority interest in Alcoa Aluminco SA to Alcoa for \$55 million, if Alcoa negotiates an investment by Grupo Camargo Correa, Brazil's largest construction company. Alcoa and Hanna are joint owners of Alcoa Aluminco, which operates a bauxite mine, an alumina refinery, and a 90,000 metric ton/yr smelter in Southern Brazil (198).

Construction has been completed on 40% of the first 80,000 metric ton/yr potline at Albras, Brazil, the 360,000 metric ton/yr. Japanese-Brazilian aluminum project. Because work was suspended on the 800,000 metric ton/yr Alunorte project, Albras will have to buy alumina from outside sources. The second half of the Albras' phase-one project is due for start-up in June 1986 (199).

The Companhia Vale do Rio Doce (CVRD) has discovered another bauxite deposit in the northern state of Maranhao. The new reserves are estimated at 50 million metric tons, with a mineral content of 66.6%. 90% of the world's bauxite reserves with this mineral content are in Brazil (200).

The \$1.4 billion Alumar alumina-aluminum project was scheduled to start up in February. Alcoa and Shell are partners. Eventually the smelter will produce 300,000 ton/yr of primary aluminum and 500,000 metric ton/yr of alumina (201-203).

Venezuela.—Venezuela's Aluminio del Caroni SA (Alcasa) expects to earn an estimated \$29 million profit in 1984 due to abundant hydroelectricity and extensive alumina supplies from the 1 million ton/yr Interalumina plant (204).

Jamaica.—Bauxite shipments for the first nine months of 1984 amounted to 7,084,999 metric tons, including 3,952,725 tons of crude bauxite and 3,132,274 tons of refined bauxite (alumina). The totals included a GSA shipment of 879,316 tons of bauxite. The final bauxite shipment of Reynolds Metals Company of 1,031,699 tons was also included. Reynolds closed its Jamaican bauxite operations this year. The alumina exports declined mainly because of lack of electric power and labor disputes (205-207).

The Jamaican and Columbian governments have entered into an agreement to build an aluminum smelter in Columbia which will provide another outlet for Jamaican bauxite. The smelter will use abundant Columbian coal. No private or foreign investors are involved (208-210).

Indonesia.—The Aschar aluminum smelter in Indonesia has been completed bringing the rated capacity to 225,000 metric ton/yr of primary aluminum. The smelter is the largest in Asia and the largest source of supply for Japan (211).

Taiwan.—A collapse of negotiations between Taiwan Aluminum Corporation and Aluminum Company of America will cancel a Taiwanese smelter project. The \$50 million project was canceled because the Taiwanese government could not meet Alcoa's terms, for what Alcoa felt was necessary to meet minimum profitability and investment requirements (212).

Advancements in Technology.—The aluminum industry could be threatened in the aerospace market by composites. Sikorsky Aircraft's all composite-airframe helicopter, which made its maiden flight in August, will be turned over to the Army for further testing and evaluation in early 1985. The helicopter is made primarily from graphite and du Pont's Kevlar with small amounts of fiberglass (213). However, since aerospace and aircraft industries account for only about 6% of the total aluminum consumption, the impact will not be that great (214). Aircraft building is expected to increase in 1985 by 25% in the private sector and about 10% in the military (215).

Ford Motor Company announced that it expects 90-95% of the radiators it uses to be made of aluminum, rather than copper and brass, by 1988. About 20% of Ford's radiators are presently made of aluminum (216).

Engineers expect the superplastic forming of aluminum to make rapid inroads into the production of aircraft parts in the U.S. in the next 3-4 years (217).

Bethlehem Steel Corporation introduced a primarily aluminum coal hopper car prototype. The prototype will be tested by Southern Companies Services, Incorporated (218).

Trail King Industries, using a new line of bottom dump trailers, has realized a payload saving which will lead to increased use of aluminum in the future. A weight savings of 43% is realized by using aluminum to replace steel (219).

Carbochlorination for aluminum recovery from Italian leucitites has been studied. Much research work appears necessary for industrial use of chlorination in extractive polymetallic oxide material such as aluminous ores (220).

Alcoa announced that it is selling its ring-furnace technology for producing prebaked carbon anodes. Furnaces using this technology have been operating for up to 15 yr at the company's smelters in Rockdale, Texas, and Warrick, Indiana (221).

Alcoa entered into an agreement with DWA Composites to acquire special metal matrix technology for the development of high strength metal matrix composites using wrought aluminum powder technology aluminum alloys (222).

Toth Aluminum has recently opened an \$8.5 million plant in Vacherie, Louisiana, for producing aluminum, silicon, and titanium chlorides from kaolin clay (223, 224).

Aluminum-lithium alloys, in development for some years, will shortly become a commercial reality, as plans are announced for production by three of the world's major aluminum producers. Alcan, Alcoa, and Pechiney all announced plans to produce the alloy. Alcoa will market under the trade name Alithalite, Alcan will market Lital, and Reynolds Metals Company, which is still doing substantial research to develop its own line, will market under the tradenames Reyalite and Reyalith (225-235). Lithium decreases the density of aluminum-lithium alloys by 3% for every 1% lithium. Alcoa shows 10% more stiffness of the alloy for weight in these alloys (236).

Novamet Aluminum, a unit of Inco U.S. Incorporated, is taking orders for aluminum lithium billet. Novamet is the first company in the U.S. to market the new alloy commercially (237).

Comalco has developed a new aluminum alloy that can withstand 200°C. The key to the unique properties of the alloy seems to be small amounts of strontium and silicon (238).

An aluminum alloy which decomposes in water was marketed by Tafa, a firm in Bow, New Hampshire (239, 240).

Environmental.—Primary aluminum was excluded from Superfund taxing, although aluminum compounds, copper, and zinc were not (241).

Potlinings containing carbon, metal salts, and cyanide compounds are disposal problems to the aluminum industry. Alternatives for waste disposal are being developed by the Aluminum Association, the EPA, and the Bonneville Power Administration. One method uses controlled temperatures of 1500°F, which burns carbon and destroys cyanide, but only partially destroys the fluorides by the addition of limestone to produce calcium fluoride. The second method, pyrosulfolysis, was developed by Martin Marietta Aluminum, Incorporated, and uses direct injection of steam and sulfur dioxide into the combustor which combines with the salts to form sulfates, releasing the fluoride for recycle to the smelter (242).

Beryllium.—Production and price.—Beryllium production and consumption statistics for 1984 are given in Tables XXI and XXII (244).

The sole producer of metallic beryllium in the western world is Brush Wellman, Incorporated (245). Beryllium hydroxide concentrate is produced in Delta, Utah, from both local bertrandite ore and imported beryl ore.

Brush Wellman attributed record second quarter sales and earnings to continuing strong demand for beryllium products in the electronics industry (246). Sales of beryllium and specialty materials increased over 43% to \$68.3 million during the quarter. Chairman Henry Piper noted that the sales upsurge which began in the third quarter of 1983 continued through the first half of 1984 and showed no signs of slackening.

In June, Brush Wellman announced a \$57 million expansion of beryllium copper strip capacity at Elmora, Ohio, and Reading, Pennsylvania (247, 248). The investment will roughly double the company's strip capacity by late 1985, alleviating recent long production lead times. Cabot Corporation's Wrought Products Division invested \$16 million in wide strip rolling mill equipment, which went into operation in June in Elkhart, Indiana.

The General Services Administration awarded a \$13,467,000 contract to Brush Wellman for delivery of 60,000 pounds of beryllium metal (249). The beryllium will be delivered to GSA during the 12 months of calendar year 1985. The purchase is the second in a series un-

der an agreement that provides for future deliveries at prices to be negotiated.

In July, beryllium oxide powder sold for \$25.50/lb, while beryllium containing alloys were selling for \$130-\$140/lb beryllium content (250). The alloy price rose slightly, to \$140-\$144/lb by the close of the year (251). Beryllium 5 in. rod listed for \$241.39 in May (252). At the end of the year, 5 in. beryllium rod was listed at \$313/lb, delivered (253).

There are few notable sources of beryllium minerals. The U.S. Bureau of Mines assesses total world reserves of beryl and bertrandite at about 419,000 tons of contained beryllium (254).

Significant beryllium was found during drilling at Highwood Resources Limited's Thor Lake property, in the Canadian Northwest Territories (255). Two bulk samples assayed 0.93 and 1.6% of BeO. A later report (251) claimed that 2.33% BeO had been assayed. Plans exist for a feasibility study at the find.

Bearcat Explorations Limited and Colt Exploration Limited have acquired mineral claims to a beryllium prospect near Kimberley, British Columbia (256). A surface exploration program indicated that the prospect contained 500,000 tons of ore averaging 0.1% beryllium oxide. The prospect could be developed by open-pit mining. Evaluation work was scheduled to start in the spring of 1984.

Highwood Resources is optimistic about the beryllium prospect it has been exploring near Thor Lake in the Northwest Territories (257). Total reserves have been estimated at 1.61 million tons of ore with an average grade of 0.75% BeO. Development of a commercial operation will require three years of work if results of feasibility studies are positive.

Demand and market.—Beryllium oxide has excellent properties as a heat conductive, dielectric material (258). It is used in sintered form as a heat sink. Its primary uses are in high technology industries such as electronics, aerospace, and national defense (259). Applications have been made in optical components for large spaceborne telescopes in the space shuttle navigation system, and in stereophonic cartridge stylus cantilevers (254).

Brush Wellman, Incorporated, has developed a new alloy for the electrical and electronics industries (245). The new alloy, Brush Alloy 174, contains 0.15-0.50% beryllium and will cost only about half as much as Brush Wellman's beryllium copper, which contains up to 2% beryllium. It has about four times the electrical conductivity of phosphor bronzes, with comparable yield strength, and will be sold primarily to manufacturers of connectors, relays, and switches.

The future of beryllium in the electronics industry appears secure (247). Beryllium copper strip now accounts for 12-15% of the alloy strip market. Double digit growth in use is expected to continue through the decade. Imports are not a major concern; the sole Japanese beryllium copper producer is mainly concerned with internal consumption.

Chromium.—U.S. Chromium production and consumption statistics are given in Table XXIII (260). World mine production and reserve base on chromite are given in Table XXIV (261).

Chromium ore was imported (1980-1983) as chromium contained in chromite and ferrochrome as follows: from Republic of South Africa, 55%; from Zimbabwe, 8%; from U.S.S.R., 7%; from Philippines, 6%; and from other sources, 24% (260).

World resources total about 36 billion tons of shipping-grade chromite, sufficient to meet conceivable demand for centuries (261).

Major South African ferrochrome producers operated at capacity for most of the year without building inventories, while U.S. production of 50-55% charge chrome was reduced to one company, Macalloy, which is in Chapter 11 bankruptcy. Ferrochrome imports into the U.S. totaled 332,537 tons according to the Bureau of Mines. South Af-

World total (rounded)	8,921	9,210	7,540,000

rican producers accounted for 205,579 tons of the import figure (262, 263).

A new stainless steel, Type 409, a 12% chrome content steel for primary use in automobile catalytic converters and tubular manifolds could amount to 150,000 ton/yr of stainless steel—about 10% of total stainless production (264).

NASA licensed its iron-chromium battery technology to Sohio. Sohio estimated that 15 lb of each metal will be required per kilowatt hour of power generated. Sohio is investigating the technology for large batteries (265).

A new copper-chrome alloy was marketed by Battelle Memorial Institute's Columbus Laboratories. By using rapid solidification or solid state microblending normally immiscible materials can be combined. The copper-chrome alloy is not a solid solution, but a microcomposite material with excellent electrical conductivity (266).

Ferrochrome refining using plasma technology was announced by SKF Steel, Bofors, Sweden (267).

A membrane system to remove chromium from wastewater was announced by Bethlehem Steel, Consep Membranes, and Bend Research (268).

Turkey announced a new chrome chemicals complex. After exporting chromite for 136 years, they will produce 22,000 ton/yr sodium dichromate, 8,500 ton/yr of sodium sulfate, and 3,200 ton/yr of chromium sulfate. Turkey plans to export 75% of the production (269). American Chrome an Chemical announced a chromic acid plant in Corpus Christi, Texas (270). The plant uses proprietary technology (271). Ferrochrome capacity will be doubled at Outokumpu Oy's Tornio works to 120,000 metric ton/yr using process lump concentrate from Outokumpu's Kemi mine (272).

The GSA awarded an upgrading contract to Macalloy Corporation for converting 141,601 tons of chromite into high carbon ferrochrome during 1985. Macalloy contracted to convert 121,753 tons of chrome ore during 1984 (273). Meanwhile, the FEMA (Federal Emergency Management Agency) and GSA evaluated the ferrochrome and chromium metal stockpile for National Defense. High purity chrome (99.5%) was recommended to be purchased (274). The GSA issued a tender for 1,000 tons of electrolytic chrome metal for stockpile which now contains 3763

tons with a goal of 20,000 tons. The GSA apparently designed its specifications around Elkem Metal's specifications, the major U.S. producer of chrome metal (275).

The Bureau of Mines reported that chemical usage of chromium from January to October was 351,649 tons. Consumption for all of 1983 was 188,580 tons (276). Production and consumption in the U.S. are tabulated in Table XXIII. Table XXIV shows world production and reserves of chromium.

A Chromium Association was formed for interested miners, alloy producers, consumers, and traders (278). Chromium mine and plant expansions are summarized in Table XXV.

Copper.—Production.—Copper production and consumption statistics for 1984 are given in Tables XXVI and XXVII (279).

Domestic.—Early in the year, skidding copper prices led to production cutbacks at U.S. mines (280). Kennecott announced a 13% production cut at its Utah Copper Division plant in Bingham Canyon on January 18. Also affected were the division's 200,000 short ton/yr smelter and refinery. At Amoco Minerals' Cyprus Bagdad mine in Arizona, with a capacity of 81,000 short ton/yr, production was reduced by 25% on January 16. All mining and milling activities were later halted (281). Amoco's Cyprus Pima mine, with a capacity of 52,000 short ton/yr, was mothballed on January 1.

Faced with continuing depressed copper prices, Kennecott notified unions representing its copper workers that it wished to reopen all labor agreements as soon as possible (282). A Kennecott spokesman said that the agreements reached in 1983 were based on expectations that the U.S. economic upturn would also benefit the copper industry.

The United Steel Workers of America, the copper industry's principal labor organization, turned down an industry appeal for labor contract concessions (283). The

appeal was made by Kennecott, Inspiration Consolidated, and two divisions of Newmont Mining. A union spokesman said that the union believes that industry guarantees, especially in the area of job security, would be needed before any concessions could be made.

Asarco Incorporated will close one of its three smelting facilities within a year because they cannot meet environmental regulations (284). The closing of the Tacoma, Washington, plant will cost \$38 million. During 1983, the plant accounted for about 30% of Asarco's 213,400 ton output of blister copper. The closing was to be scheduled depending on extension of a federal pollution variance effective until the end of 1984.

Asarco also announced that it would suspend open-pit mining operations at its Silver Bell copper mine on August 15 (285). A leaching operation was to continue producing copper at about one quarter of the mine's normal 21,000 ton/yr rate. Asarco was to reconsider opening the mine at the end of the year. The Silver Bell mine had been closed earlier in 1981, and was reopened in September 1983. An Asarco executive said that Silver Bell was "one of those mines . . . hanging on a thread between continued operations and shutdown at the prices we have seen so far in 1984" (286).

According to the president of Asarco, Richard Osborne, the present plight of the domestic copper industry has resulted in the loss of 18,000 jobs by copper workers, as well as shutdown or curtailment of 40% of U.S. copper production capacity (287). Osborne claimed that, if competitive pressure could be eased, some U.S. operations could be reopened and upgraded (286).

Phelps Dodge closed its 40,000 ton/yr mine and concentrator at Ajo indefinitely in mid-August (289). Previously, the facility had been operating at full capacity. The Ajo smelter will continue to operate, handling material from PD's other mines at Morenci, Arizona, and Tyrone, New Mexico.

Copper refining operations at Copper Range Company's White Pine, Michigan, complex were halted until the price of copper improved or until the facility could be sold (290). The decision to halt operations was based in part on an inability to reduce costs further.

Asarco, Incorporated announced suspension of operations at its Haywood, Arizona, copper smelter for 8-11 weeks beginning November 26 (291). The shutdown was scheduled to allow rebricking of the flash smelting furnace due to recent premature failures in the year-old facility. The furnace has been building to its full capacity of 175,000 short tons, and had supplied about one-third of Asarco's domestic copper output.

Material swapping within the copper industry has increased, as producers and merchants attempt to cut freight and inventory costs to the lowest levels possible (292). Most swapping takes place at the cathode level, where brands are indistinguishable, a factor important to some brand-conscious producers.

Import relief for domestic producers.—Eleven U.S. copper producers, representing 85% of the domestic industry, asked the International Trade Commission for import relief, in the form of a quota limiting foreign imports to 350,000 tons in each of the next five years (293, 294). The domestic industry, in return, pledged to continue modernization programs to insure its economic viability. The January petition, filed by producers including Asarco, Anaconda, and Phelps Dodge, asserted that total imports of refined and blister copper increased 140% since 1979, and about 54% between 1982 and 1983, resulting in the loss of 18,000 jobs (295, 296).

However, opinion was divided on the merits of temporary protection for the copper producers. Representative S. Boehlert, whose district includes copper manufacturing companies, claimed that such relief would harm the employment of nearly 200,000 people in downstream copper manufacturing. Protectionist sentiments were criticized by domestic as well as foreign sources (297). During a Copper Roundtable at the National Association of Recycling Industries, it was claimed that American brass mills would be hurt unless protection was extended to semifabricated and finished goods manufacturers as well as to primary producers.

A joint lobbying effort in Washington was launched by the Copper and Brass Fabricators Council and the National Electrical Manufacturers' Association, against quotas or tariffs on copper imports (298). NEMA claimed that an import quota of 415,000 ton/yr would reduce employment by domestic fabricators by 5,712 jobs, while creating a temporary gain of only 2,594 jobs in mining, smelting, and refining. A \$0.05 tariff would cost 2,117 jobs in the fabricating industry, according to NEMA.

At an International Trade Commission hearing in May, foreign copper producers testified that the domestic copper industry's troubles are due to technologies that have decreased their copper needs by substitution and miniaturization (295). According to a spokesman from Peru's Minpeco mining company, U.S. copper consumption fell 15% relative to other market economies between 1974 and 1983. The foreign producers also faulted U.S. producers for a nonaggressive marketing approach. U.S. producers and legislators testified that Chilean imports of refined and blister copper are the most serious problems, having increased 240% since 1979 and accounting for about 55% of 1983 imports.

Citing a need to address "the issue of fair competition," Representative J. F. McNulty, Jr. urged a national copper policy (299). McNulty criticized multilateral development banks for assisting less developed nations in increasing copper production when the worldwide copper surplus was estimated at 750,000 tons. In February, McNulty and 23 other legislators urged Treasury Secretary Donald Regan to register U.S. opposition to a \$70 million loan application from Zambia to the World Bank. McNulty also continued efforts to pass an environmental equalization tariff to account for the estimated \$0.10-\$0.15/lb that domestic producers spend to comply with environmental laws (300).

Import protection for the copper industry would cost consumers \$602 million, according to the Federal Trade Commission (301). The FTC also told the International Trade Commission that adjustments or tariffs would be more cost-effective methods of relief for the copper industry than import quotas.

Exxon Minerals Company joined the National Electrical Manufacturers Association in opposition to the petition (302). Foreign opposition was nearly universal, with Canadian, Australian, Mexican, Chilean, and Zambian producers, and the Philippine government, all against the U.S. producers' petition. Responding to the U.S. producers' import quota request, a spokesman for the Intergovernmental Council of Copper Exporting Countries (CIPEC) claimed that such a move would damage all copper producers by depressing international copper markets (303).

The International Trade Commission noted, in a formal report sent to the White House in July, that declining domestic ore grades were a major factor affecting U.S. market supplies of copper (304). Ore grades have declined from 2% in the 1920's to about 0.65% and projections suggest 0.45% ore in 2000. Because U.S. copper ore is 35% less rich, on average, than in foreign countries, milling costs are 55% above the foreign average. The commission did note, however, that productivity increases could offset higher wages and lower ore quality enough to hold domestic mining cost increases in line with those in foreign countries.

The report also cited outdated smelting facilities as a problem troubling the domestic industry. Each major copper producer was asked what specific steps it would take to become more competitive if import relief was granted. Asarco outlined plans to invest in mining and milling operations, including technological improvements. Magma Copper, Phelps Dodge, Duval, and Inspiration Consolidated Copper also revealed investment plans predicated on import relief.

On June 14, the ITC voted unanimously that the domestic copper industry had suffered substantial injury from imports of refined and blister copper from nations such as Chile, Zambia, and Zaire (305). ITC Chairman Alfred Eckes stated that "the issues are clearly defined and the evidence is compelling." In addition to the overall quota of about 350,000 ton/yr, the domestic producers requested a 114,000 metric ton/yr quota for Chile, less than half of the 282,000 tons imported in 1983 (306). A 97,000 metric ton/yr limit was recommended for Canada.

However, while recognizing the damage caused by imports, the ITC was split over how to apply remedies (307, 308). While two commissioners recommended that the President impose a 425,000 short ton/yr quota, two others recommended boosting the import duty by \$0.05/lb. One commissioner said that neither would be sufficient to solve the industry's problem (309). Supporting the latter view, Interior Secretary William Clark called for negotiating orderly marketing agreements with foreign producers (310, 311). According to Clark, only a recovery of world copper prices could bring relief, as domestic producers must now sell at a loss.

In September, the President rejected proposals to impose either import quotas or tariffs on foreign copper (312, 313). U.S. Trade Representative William Brock stated that "the argument against quotas and tariffs was abundantly clear, in that they would have raised the cost to our fabricators, placing at risk four jobs for every one saved."

Canada.—In Canada, a government report painted a bleak picture for the future of the copper industry (314). The industry was called more vulnerable than at any time in history. Among the disadvantages of the Canadian industry, the report noted high labor, materials, and handling costs. Also cited was the use of more modern technology at many foreign smelters. William Rompkey, Minister of Mines, also pointed out marketing and financial difficulties (315). The study estimated that plant modernization and pollution abatement measures over the short term would require about C\$1.1 billion.

Harold Fargey, president of the Mining Association of Canada, cited government-imposed costs which erode the ability of Canada's mining industry to compete (316). Because 80% of Canada's mineral output is exported, the industry must be able to compete worldwide or lose much of the \$13 billion/yr in export income and put many of Canada's 650,000 mining jobs in jeopardy.

According to M. N. Anderson, chairman of Cominco, Canada is losing its position as a great mineral producer because of high costs (317). While Canadian copper production costs are about \$0.90/lb, the figure for Peru and Chile is about \$0.50/lb. While Alfred Powis, chairman of Noranda Mines, cited the role of third world governments, a member of the Canadian parliament laid some of the blame on the Canadian government. Michael Wilson

cited regulatory and tax measures enacted in the 1970's when international competition was becoming severe.

The Quebec government reported that it will order Noranda to reduce SO₂ emissions from its Rouyn smelter by 40% (318). The smelter was claimed to be responsible for about one-half of total Quebec SO₂ emissions. Quebec indicated willingness to help Noranda pay the estimated \$100 million cleanup cost. Noranda's Horne copper smelter would have to cut SO₂ emissions by 50%, while a 65% cut would be required at the Gaspé smelter (319).

The Quebec government granted Falconbridge Copper Corporation C\$25 million to encourage development of the Ansil copper deposit near Noranda, Quebec (320). The company had suspended work on the project because of low copper prices. The latest phase of development is expected to be completed by early 1987.

Expecting a stronger copper market, Sherritt Gordon Mines authorized continued operations and development at its Ruttan mine in Manitoba (321). The May decision was a reversal of earlier plans to terminate operations at Ruttan by June 15.

Noranda Mines announced that it would lay off up to 400 workers at its Horne smelter and its Montreal refinery (322). The layoffs were needed because of the continuing copper market slump.

Kidd Creek Mines announced that it would spend C\$54 million to increase the annual capacity of its copper operation from the current level of 59,000 to 90,000 metric tons by 1988 (323). The expansion is expected to reduce the unit cost of copper production.

Brenda Mines of Peachland, British Columbia, indefinitely suspended operations at its copper mine on December 14 (324). Reopening was said to require copper prices of \$0.75-\$0.80/lb. The mine can produce up to 30 million pounds of copper/yr.

Foreign.—In February, Chile's Codelco declined to curtail copper output (326). Copper exports account for 36 percent of the dollar value of all Chilean exports. Severe mid-year storms, which battered Chile with 140 mph winds and avalanches, forced Codelco to close its El Teniente Division (319). The storm damaged water, energy, and ore transport systems at the 350,000 metric ton/yr facility. Also closed was the 100,000 metric ton/yr Andina Division.

At Codelco's Chuquicamata Mine in Chile, the world's largest open-pit copper mine, ore grades were reported to be declining from the present 1.68%, with 1% copper expected by the end of the century (325). A similar level was predicted for El Teniente, the second largest mine, with the 1% level maintainable for 100 years. To counter declining ore grades, Codelco has installed an electrowinning and leaching plant to recover copper from tailings, at a cost of \$0.42/lb. Overall, Chilean production costs were pegged at \$0.50/lb by Hans Feddersen, of Codelco's El Teniente Division. Included was a \$0.05/lb increase due to earlier pollution abatement measures.

A three-year plan issued by Chile's Economic Ministry anticipated a 4% annual increase in copper production and a \$2.5 billion investment in the nation's mining industry (326). The plan calls for copper output to rise from 1,257,000 tons in 1983 to 1,410,000 tons in 1986. Export earnings in 1986 would total \$28.5 million at an average copper price of \$0.70/lb.

Because of a critical shortage of foreign exchange for machinery and parts, Zambia Consolidated Copper Mines experienced operational difficulties (327). World and African Bank loans of \$120 million were expected to be used, in part, to rehabilitate the mines and boost copper output by up to 50,000 metric ton/yr.

Pasar, the Philippine copper concern, lifted force majeure and began supplying customers with 50% of their contracted tonnage on August 1 (328). Following an accident-related shutdown on May 13, its smelter was back at full capacity. The \$122 million smelter is 34.3% owned by the state-controlled National Development Company.

Peru's copper production will rise by 60,000 metric ton/yr to 400,000 metric ton/yr in 1985, with the opening of new mines at Tintaya (329). Peru exported 292,000 of the 322,000 ton of copper it produced in 1983.

Price.—Despite increased demand early in the year, copper prices fell (330). The price decline, as much as \$0.05/lb in only a few days, was blamed on technical factors triggered by the Commodities Exchange, as well as falling precious metal prices. Inspiration Consolidated Copper Company of Phoenix lowered its price for copper cathode to \$0.64/lb on January 9 (331). This was the lowest domestic price quote since October 1982.

Citing increased competition in the marketplace, both Inco and Noranda, announced on January 1, reduced premiums over the Commodities Exchange copper price (332). A wider range of purchasing options was also introduced.

In the second quarter, a healthy demand resulted in a drop in copper stockpiles (333). This was particularly true of the London Metal Exchange, where stocks declined from 436,000 metric tons at the end of 1983 to 252,000 metric tons by mid-May. A short-lived rally pushed U.S. producer prices to \$0.70-\$0.705/lb (334). However, copper prices slid in a market governed by financial factors (333). Rising interest rates in the second quarter, coupled with a strong dollar, were cited as the Comex price dropped from over \$0.70/lb at the beginning of April to \$0.623/lb by mid-May.

Despite the downturn in copper prices, Morton Schultz of Harold Sacks and Company predicted that copper prices would move higher as long as overall business continued to improve (335). Good first quarter earnings and a move away from a situation of copper oversupply were cited as positive factors.

In little more than three weeks in July, the low end of the domestic producer copper price sagged three times to new 26 month lows (336). Kennecott dropped its price by \$0.03 to \$0.62/lb. At the same time, Comex prices rose by more than half a cent, to \$0.5815/lb. and then to \$0.5955/lb. Meanwhile, Merrill Lynch analyst, David Moison, characterized the supply-demand balance as good, primarily due to production losses in Chile, Peru, Brazil, and among domestic producers such as Kennecott, which pared production at its Utah division by two-thirds on July 1.

Codelco purchased 30,000 metric tons of copper on the London Metal exchange in July (319). The purchase was made partly to compensate for storm-related production losses, but also because Codelco considered the price of around \$0.60/lb to be unrealistic (337). Codelco's market actions, according to a company spokesman, were short term and not aimed at supporting prices over a long period. As prices recovered somewhat, Codelco halted copper purchases on the London Metal Exchange in August (338). Company sources, however, acknowledged that Codelco will periodically enter the market in the future to act as a buffer when prices fall, or to add momentum when prices rise. A second factor in Codelco's move was slackened Far East demand, making it unnecessary to buy copper off the LME to supply European customers as copper production was diverted to Japan.

Demand.—A shortage of higher grade copper cathode developed early in the year (339), as Chilean refined copper was diverted from the U.S. East Coast to Japan, where copper producers earlier cut output by 10-15%. Supply problems were also reported in the European market.

Early in the year, commodity specialists were bullish on copper futures despite the depressed markets (340). The building industry, which accounts for 30 percent of U.S. consumption, experienced a 15% jump in housing starts as the year began. Futures traders were hoping for a repeat of 1982, when copper prices leaped by more than \$0.25/lb on the spot market.

During the first half, copper demand improved and inventories declined (341). It was estimated that total nonsocialist world inventories would shrink by 100,000-200,000 short tons in 1984, followed by a larger reduction

of about 400,000 short tons in 1985. Part of the inventory draw down was attributed to demand from European fabricators who had cut stocks to very low levels.

An English study predicted that world copper consumption would grow at 1.5%/yr throughout the 1980's, resulting in a 1985 usage equaling or exceeding the previous 10 million metric ton record of 1979 (342). The relative importance of copper as a pure metal was seen to decline, owing to slackening use in communications wire, while use of copper engineering alloys was expected to grow. Despite the overall growth of copper demand, it was predicted that further North American mine closings would occur as production became more concentrated in mines under government control. The report also predicted that copper prices would continue to be subject to wide fluctuations.

A British report predicted that there would be no substantial short-term copper demand increase in Europe (343). Imports of refined copper by the United Kingdom, according to official import statistics, were lower in 1983 than at any other time in the postwar period.

The Senate approved an amendment to increase national defense stockpile funds by \$250 million in fiscal 1985, with indications that a significant portion would be used to purchase copper (344). The copper inventory goal is 1 million short tons, while only 29,048 short tons are now stockpiled. In addition to taking advantage of favorable copper prices, the measure was seen as a way of aiding the ailing domestic copper industry.

Markets.—The International Copper Research and Development Association (INCRA) proposed strategies for defending current copper markets and developing new applications at its annual meeting in June (345). The focus will be on three areas: improving copper-brass radiators, defining agricultural benefits of copper as a micronutrient in plant growth, and promoting copper-nickel sheathing of off-shore oil rigs and ship hulls.

Two copper executives called for increased research and promotional efforts to expand copper markets (346). Although certain copper markets, such as power transmission lines and automobile radiators, are determined by large companies according to long-term economic analyses, other uses such as plumbing and heating can be increased.

Lithium.—Domestic lithium production and consumption are given in Table XXVIII (347). World mine production and reserve base statistics are given in Table XXIX (348).

Lithium chemical and metal consumption increased by 11% to the equivalent of 60 million pounds of lithium carbonate in the western world (349).

Footo Mineral and the Government of Chile began a joint venture (Sociedad de Litho) production facility, rated at 14 MM lb/yr, in the Salar de Atacama Basin. The lithium content of the salt brine ranges from 1400 to 1500 ppm. The large magnesium ratio extended Footo's research to the better part of a decade. The project reportedly cost \$48 MM (350, 352, 355).

The indicated reserves in the Atacama Basin represent 40% of the world's lithium supply (350).

World total (excluding U.S.)	2,100	2,700	9,100,000

^a Withheld to avoid disclosing company proprietary data.
Identified lithium resources total 8.06 million tons (348).

The Bolivian government signed an agreement with the United Nations to carry out a geothermal feasibility study for eventual recovery of the lithium salts of the Salar de Uyuni (356, 357).

Amax, Corfo, and Molibdeno began a development program for a mine plant rated at 12 MM lb/yr of lithium carbonate. Estimated costs are \$210 MM; targeted production is 1988 (358).

A majority of the lithium carbonate from Chile will go to the aluminum industry (355).

The lithium industry overcapacity will be largely dependent upon the aluminum industry. A 10-12% increase in demand is projected. The 2-3% lithium content for aluminum alloys continues to create interest in the aircraft industry. Lithium decreases the density of Al-Li alloys by 3% for every 1% Li content (351). The alloy and lithium batteries will be the major growth areas (352-354).

Several companies are working on lithium metal sulfide batteries for electric vehicles among other applications. This battery system is also promising for utility load leveling (359).

At year's end, lithium carbonate was priced at \$1.54/lb and lithium hydroxide was \$1.93/lb. The lithium metal price was about \$22.70/lb (347).

The EPA notified the Department of Defense that lithium-sulfur dioxide batteries exhibit a characteristic of "radioactivity" and are thus subjected to Resource Conservation and Recovery Act rules when they are discarded (360).

Magnesium.—Magnesium continued the rebound begun in 1983. Early in the year, prices were hiked, and projections for growth in new and existing markets were good.

Production and price.—Western world magnesium production totaled 173,000 metric tons in 1975, and increased each year to a peak of 236,000 tons in 1980 (362). During the recession, production plunged to 156,000 tons in 1982 before rebounding sharply in 1983 and 1984. Production and consumption figures are given in Tables XXX and XXXI (362).

Magnesium price hikes were posted by major producers at the beginning of the year (363). Dow Chemical Company increased the base price for 99.3% Mg ingots and grinding slab by \$0.05, to \$1.43/lb. Die-cast alloys AZ91B and AZ91XD were offered at \$1.28/lb. The price increase for ingot and grinding slab followed a similar price increase posted by Amax, Incorporated.

Dow and Amax increased their prices for die casting magnesium in early April (364). Dow's price for AZ91XD was \$1.30, while the Amax price for AZ91HP was \$1.26/lb.

The lower Amax quote was viewed as part of a plan to be the leading supplier to the Detroit market.

Increased magnesium earnings were a major factor in the return of Amax to profitability in the first quarter, after eight consecutive quarterly losses (365, 366). Due to both higher margins and shipments, the magnesium business was in the black after losses in 1983.

Under a restructuring of its metals groups, Amax announced that magnesium production at Salt Lake City, Utah, would become part of the new specialty product unit (367, 368). Integrating management and reducing administrative costs were expected to produce cost savings in a continuing austerity program.

According to a Dow spokesman, the company was studying an increase in operating rate at its Freeport, Texas, plant (363). In the third quarter of 1983, the plant output had been raised from about 50% to about 70% of capacity.

Dow Chemical announced that a new, high purity, corrosion-resistant magnesium sand casting alloy had been developed at its Freeport, Texas, facility (369). The new alloy, designated AZ91C/HP, is intended for use in military aircraft exposed to highly corrosive salt water environments. The new alloy contains reduced levels of iron, nickel, and copper contaminants, making the alloy less susceptible to corrosion. The new alloy was initially marketed at \$1.43/lb, the same price as the standard AZ91C alloy it replaced.

Demand and Markets.—Overall magnesium use is expected to increase 5-7% in 1985 (362), as the industry rebounds from the recession. As the lightest structural metal, and with its corrosion resistance properties, magnesium is being used increasingly in the hand tool and military market. Greater use of magnesium sand castings is expected in the aerospace industry, especially for helicopter parts. It is also being used to desulfurize iron during steel production, and to produce titanium and zirconium.

The outlook for magnesium die castings is brighter than it has been for some time (370). New applications are expanding opportunities for magnesium in key areas such as the automotive and electronics industries, high purity alloys, and improved die casting technology. The magnesium die casting market may have increased as much as 75% over 1983 levels. While magnesium's light

weight has always been recognized, its other properties, such as high strength and stiffness, excellent heat dissipation, and improved corrosion resistance, are now being used to advantage.

These properties and others, plus the need to boost fuel economy by building lightweight vehicles, have improved the prospects for magnesium use in new car designs. A survey of producers and die casters indicated that magnesium continued to penetrate the automotive markets held by aluminum (362). Projected growth from 1984 to 1985 was as much as 10-15% in the automotive market. According to a Dow spokesman, growth will result not only from an increase in the number of vehicles built, but also because of increased usage per unit. With one-third of the weight of aluminum, and comparable strength and fracture resistance, magnesium is a serious contender to reduce auto body weight and fuel consumption. Magnesium is about twice the price of secondary aluminum ingot. However, magnesium parts are often easier and more economical to produce than aluminum parts.

There is now about 1 lb of Mg used per domestic auto produced, and as much as a tenfold increase may occur by 1990. Ford's Ranger and Bronco II trucks have magnesium brake and clutch pedal support brackets and clutch housings. The clutch housings are directly exposed to road splash, but do not require special protective coatings. At a weight of 6 lb, the housings have met Ford's weight reduction goal without increased cost. The clutch and brake pedal support was traditionally made from stamped steel, and more recently, from lighter aluminum die castings. The magnesium bracket, with a 20% thinner wall, weighs less than 1.5 lb, vs. 3 lb for the aluminum bracket. Ford is also planning to use magnesium clutch housings in new compact-sized Aerostar vans (370).

General Motors has used magnesium in several new applications, including headlamp assemblies and grill covers on the Pontiac Fiero. In the headlamp assembly, with very thin walls, magnesium outperformed aluminum in wind pressure tests for distortion and cracking. The grill cover, directly above the engine, requires dimensional stability, heat dissipation, and surface finish properties. Magnesium engine valve covers may be used on the Calisto, a new luxury car planned for introduction by Cadillac in the 1987 model year (371). In addition to light weight and rigidity, magnesium offers good sound damping characteristics in the valve covers. GM is also considering new applications for magnesium in engines, transmissions, and interiors. Chevrolet has produced a 3 lb magnesium bracket that may be used on two million cars (362).

Amax Specialty Metals held three seminars in the Detroit area to spur automotive use (371). Major U.S. automakers and their suppliers of cast magnesium components were invited.

Die casters predict a 15-25% increase in magnesium use for computer parts (362). Valuable properties for computer applications are lightness, sound deadening, and tolerances which can be closer than when aluminum is used. The magnesium die casting process is about 40-50% faster than aluminum die casting.

A portable computer by Grid Systems Incorporated, uses several Mg die castings (362). Other computer manufacturers use magnesium in internal parts such as heat sinks and disk drive actuator arms.

Manganese.—Domestic manganese production and consumption statistics are given in Table XXXII (372). World production and reserve base data are given in Table XXXIII (373).

The U.S.S.R. and Republic of South Africa account for more than 80% of the world's identified manganese resources (373).

On a 1983 base, U.S. demand for manganese is expected to follow raw steel production trends and increase at an average annual rate of about 3% through 1990. It is estimated that 1985 U.S. mine production will be zero, based

Table XXXII. U.S. manganese production and consumption

	1983	1984 (est.) (thousands of short tons)
Production	None	None
Imports for consumption

World total (rounded)	24,700	24,900	12,000,000

on 35% manganese content ore, and U.S. apparent consumption of manganese will be 750,000 tons, content basis (373).

Tennessee Eastman Company announced that in 1986 it will end a process which requires manganese ore for the production of hydroquinone, owing to cost and efficiency. This change could reduce U.S. capacity considerably for the production of manganese sulfate, a by-product of Tennessee Eastman's process. Manganese sulfate is an important intermediate in other manganese chemicals, synthetic manganese dioxide, fertilizers, and animal feed (375-378). Meanwhile, Sedema, SA increased its capacity because of uncertainty of manganese sulfate supplies (379).

The ITC terminated its countervailing duty investigation of ferroalloys from Spain. The Ferroalloys Association notified the ITC that it wished to cancel its countervailing duty imposition request (380).

The GSA announced that Elkem Metals was awarded a \$17.8 MM contract for upgrading 80,000 tons of manganese ore into high carbon ferromanganese during 1985. Elkem will do the conversion at the Marietta, Ohio, facility (381-383).

During the year, an oversupply situation cut prices and tonnages of the South African producers, with Gabon being the one country which raised production at its Moanda operation, exporting to the U.S.S.R., Japan, Norway, and the U.S. Ghana will make further investment in its manganese mine at Nsuta. The U.S. Fuller Company constructed a calcining kiln to process fine manganese carbonate to manganese oxide at Nsuta. The \$25 MM plant has yet to perform, but is expected to be in full production in 1986 (384, 385).

A Norwegian ferroalloy producer, Elkem AS, will increase production of medium carbon ferromanganese by 40,000 metric ton/yr to 115,000 metric ton/yr (386).

Broken Hill Proprietary, Limited, announced a 3 yr capacity expansion in its manganese alloy operations at Bell Bay, Tasmania, from 135,000 to 190,000 metric ton/yr primarily for the export market (387, 388).

The takeover of Union Carbide's silicon and manganese operations in Quebec by Elkem Metals was completed (389, 390).

Large-scale field tests to remove manganese and silver from ore were successful. Haber, Incorporated, and Houston Mining and Resources have completed tests of Haber's alpha process to extract silver and manganese economically. The process recovers 95% of the manganese and virtually all of the silver (392).

The Exclusive Economic Zone (EEZ) off U.S. and Territorial coasts contain extensive deposits of ferromanganese, says the U.S. Geological Survey. Manganese nodules are most promising off the Hawaiian and Pacific Island Territories EEZ. Recent findings show high concentrations of cobalt in a ferromanganese crust (395).

Imports of manganese dioxide in 1984 surpassed all of 1983 in the first nine months (380).

Foote Mineral announced that it is spending \$17.4 MM to convert part of its electrolytic manganese metal plant to electrolytic manganese dioxide. Electrolytic manganese dioxide capacity is slated for 10,200 ton/yr on stream by late 1985 (380, 391, 393, 394).

Australia's BHP Limited intends to capture a significant slice of the natural manganese dioxide market for dry-cell batteries using the Groote Eylandt deposits in the Northern Territory. Natural manganese dioxide sells for \$200-\$240/metric ton, compared to \$70/metric ton for metallurgical grade ore. Shelf life and leakage tests take 6-12 months before results are known (388, 395).

Companhia Vale do Rio Doce (CVRD), the Brazilian manganese ore producer, is now making 10,000 ton/yr of electrolytic manganese dioxide, 4,000 tons of which were consumed by Brazilian battery makers. CVRD is supplying the U.S., Japan, Germany, France, Norway, and Denmark with test quantities of its electrolytic manganese dioxide (397).

New mining investments in manganese and ferromanganese are listed in Table XXXIV.

Nickel.—Domestic primary nickel consumption increased 17% over 1983 (see Table XXXV) (398).

The low point of 1982 remains, with 1984 being the second consecutive year of increase in primary nickel consumption. On the 1983 base, nickel demand is expected to increase at 2.5% per year through 1990 (398).

1984 mine production increased over 1983, because the sole U.S. nickel mine at Riddle, Oregon, was reopened this past year. Principal impediments to domestic mining and production were low-grade ore, poor market conditions, and energy costs (398).

Identified world resources in deposits averaging 1% nickel or greater contain 143 million tons of nickel. Eighty percent of the nickel is in laterites and 20% is in sulfide deposits (398).

World production and reserves of nickel are tabulated in Table XXXVI.

Nickel consumption by noncommunist nations is shown in Table XXXVII.

Table XXXV. U.S. production and consumption (short tons)

	1983	1984 (est.)

Canada, as the Western bloc's largest producer of nickel, must improve productivity and at the same time reduce SO₂ emissions by 50% to 2.3 million metric ton/yr (401).

Falconbridge Limited, Toronto, is negotiating with BCL Limited, Botswana, and Amax to acquire BCL's nickel copper ore, currently reserved for Amax in a 15 yr contract, set to expire in 1989 (402).

For Inco Limited the only road to profitability appears to be cost cutting moves, although the market could speed the recovery. Inco is predicting market stability at about 1.25 billion lb for next year. Inco is trying to join the ranks of producers with \$2/lb or below production costs (403-405).

The Nickel Development Institute, an international organization to develop new markets for nickel and to pro-

mote nickel containing products, was formed. The institute was formed because of the significant drop in the growth of nickel consumption (406).

World nickel mine production increases are shown in Table XXXVIII.

The Falconbridge nickel copper mine, scheduled to close in 1989, will be closed by its owner after 55 years of operation. A rockburst in June that killed four miners and registered 3.9 on the Richter scale finalized the decision. Rockbursts are not unknown in the Sudbury nickel deposits, but nothing of this intensity has ever been recorded (407).

Inco, Limited will use a dredge to take the overburden off its crown pillar underground Thompson mine as a first step in developing a new mine in the Thompson nickel belt of northern Manitoba. Only two of the original Thompson mines are now operating, the Pipe and the Thompson. Birchtree, Soab North, Soab South, and Pipe 1 have temporarily suspended operations (408).

Inco announced that a recently completed \$10 million improvement program will allow it to produce 25 ton ingot using ESR, electroslag remelting technology. The ingots will be 43 in. diam, some 30% larger than previous capacity sizes. Inco also installed a 15 ton vacuum induction melting furnace. Inco is responding to what it feels will be increased demand for the oil and gas industry's problems of drilling deeper to find reserves (407).

Hanna Mining Company reopened its Riddle, Oregon, facility after an 18 month closure. The company is not sure how long the mine and plant will remain open. The Bonneville Power Administration made an agreement with Hanna to use reduced cost off-peak power, 12h/day during the week, 15h on Saturday, and 24h on Sunday (410, 411).

The Department of Defense is opposing an amendment to a pending military authorization bill which would require the Pentagon to certify that "all" specialty metals purchased contain no Russian or Cuban nickel (412, 413).

Nickel stainless is finding increasing use in the chemical processing industry due to its corrosion resistance. Ammonia plants overseas also appear to be big consumers (414).

The threat of auto industry strikes helped keep demand and prices depressed for nickel. The strength of the dollar also helped keep prices depressed (415).

Nickel supplies in the Western World are expected to be in line with increase in demand, since the U.S.S.R. is no longer attempting to increase its market share (416).

Raznoimport wants to increase its exports to Japan and reduce its sales to Japan through international traders. In 1983, Japanese traders purchased 5000 tons from Raznoimport, the equivalent of 20% of total Japanese imports (417).

The Cuban government announced that it plans to raise nickel production from 40,000 ton/yr to 100,000 ton/yr within 10 years. The new Punta Gorda 30,000 ton/yr nickel plant will start up late next year and the Camariocas plant, now being built, will increase the total to 100,000 ton/yr in the mid-1990's (418).

Demand for nickel has strengthened mainly as a result of an economic upturn, especially due to the steel industry. The U.S embargo on Cuban nickel has also aided the demand cycle (419).

During 1984, prices were at \$2.08/lb in mid-March, and by year's end, the prices were in the \$2.10-\$2.20 range. The year was largely flat, with the London Metals Exchange unloading metal and producers minimizing inventories (420, 421).

Operation resumed at Marinduque Mining and Industrial Corporation's Nonoc Island nickel refinery, but not at normal production levels. Lack of working capital and supplies have been cited as the major constraints (422).

A typhoon inflicted heavy damage on the Surigao nickel refinery. Operations were suspended for at least one month. The refinery was actually down for two months for typhoon related damage (423, 424).

The refinery and the Marinduque nickel mines are owned by two Philippines banks, which formed the Nonoc Mining and Industrial Corporation. Marinduque's nickel mine has an estimated daily output of 10,000 dry tons of ore/day (424).

Outokumpu Oy will undertake immediate development of a new nickel mine at Enonkoski in eastern Finland. Proven reserves total 3.8 million tons grading 1.2% nickel and 0.3% copper. First year plans are for 400,000 metric ton/yr of ore (425).

Cabot Corporation announced the development of two new nickel alloys designated C-214 and C-22. C-214 is undergoing testing for replacement of ceramic materials in kilns. C-22 will be used for high temperature applications involving acids and offering corrosion resistance over that of previous nickel chromium alloys (426).

Marko Materials, Incorporated, entered a partnership to produce and market amorphous powder alloys based on nickel, iron, copper, and cobalt. The "Markomet" alloys will be used for electronics, carbide tools, and specialty machine tools (427).

Peugeot, the French automaker, announced development of a prototype electric vehicle. The car is powered by twelve 6V batteries of nickel-iron, which drive a 17.5 kW motor. It has a range of 124 miles, with a top speed of 62 mph. The batteries are reportedly good for 125,000 miles and 1500 recharge cycles (427).

MINPRO in Sweden has now successfully completed a nickel segregation process using calcium chloride and coke as additions to the calcining process. The process is kept below 950°C compared to over 1600°C for smelting (428).

Ni-Cal Developments, Vancouver, established Ni-Cal Technology to market its proprietary Acid Leach Process to offshore customers. The technology is presently used at the Gasquet Mountain, California, nickel-cobalt mine. The Ni-Cal Process is based on the commercial pressure acid leach process developed by Freeport Minerals (429, 430).

SKF Engineering has begun the first commercial use of plasma technology for production of nickel and other metals for the dusts of steel smelters. The plant at Sala,

Sweden, is expected to process 70,000 metric tons per year of metal (431).

Ni-Cal Technology Limited announced that it received a letter of interest from Marinduque Mining and Industrial Company for a retrofit of the Surigao nickel refinery with Ni-Cal's pressure leach technology. This would be the first commercial application of Ni-Cal's technology and is expected to significantly reduce energy cost at the Philippine refinery (432, 433).

A hydrometallurgical high pressure sulfuric acid leach process for treating a variety of oxidized nickel bearing ores is ready for commercial application. COFREMME, a joint venture between France's BRGM and Amax (Greenwich, Connecticut) have been testing the process at Golden, Colorado. The process shows wide utility and high nickel and cobalt recoveries combined with low energy and operating costs (434).

Sodium.—There are three domestic producers of sodium. Their estimated production capacities are given in Table XXXIX (435, 436). Because of the high demand for antiknock agents for gasoline, which require sodium for their manufacture, U.S. production has been 70-85% of world production for many years. Estimated foreign production capacity is also given in Table XXXIX (435). Domestic sodium production figures are summarized in Table XL (437).

The major use for metallic sodium is in the manufacture of tetra ethyl lead and other organometallic compounds. Because gasoline additives are being phased out in the U.S., sodium consumption for that market has declined steadily from a high of over 120,000 ton/yr in the late 1960's and early 1970's to less than 80,000 ton/yr in 1980 (435).

Sodium is also used in manufacturing refractory metals by sodium reduction of their halides. It is used as a reducing agent in dye, herbicide, and pharmaceutical manufacture. Some polymerization processes require sodium catalyst. Other uses include hydrocarbon desulfurization and heat-transfer in the primary and secondary loops of liquid metal fast breeder reactors (435).

Titanium.—Production and prices.—Production and consumption statistics for titanium are given in Tables XLI and XLII (438).

After several years of increased worldwide production capacity, 1984 was marked by some important changes among major firms in the industry. At a time when titanium prices were low and production capacity was well in excess of demand, the two largest domestic titanium producers were for sale (439). The owners of both RMI and the Timet division of Titanium Metals Corporation of America either publicly announced or intimated their willingness to sell. Titanium buyers expressed confidence that the companies would continue operating and that product focus would not be changed.

Timet, the largest integrated domestic producer of titanium, was sold to a group of investors including its top management (440). The former owners, Allegheny International and NL Industries, each retained a 5% share. Timet has the capacity to produce about 30 million lb of

World total (rounded)	74,000	92,000	131,500

sponge and 34 million lb of ingot per year at its Henderson, Nevada, plant.

The joint venture between Kobe Steel and RMI Company, which called for Kobe to convert semifinished titanium products supplied by RMI into mill products, failed to reach expected levels of shipments (441). Weak markets and high transportation costs have hindered progress in the February 1983 agreement. RMI's strategy, including the deal with Kobe, is to increase sales in industrial and commercial markets as the growth in aerospace demand slows. At present, commercial and industrial markets account for about 20% of RMI sales. According to RMI president, Frederick Gieg, the plan is to increase this to about 50% by 1990.

Some companies announced plans to expand production or explore new processing routes. Wyman-Gordon Company constructed a \$13.5 million titanium melting facility in Millbury, Massachusetts (442). The facility, scheduled to become fully operational at the end of 1984, will melt titanium ingot under computer control to improve process repeatability. Also planned is a \$13 million open die forging facility at Grafton, Massachusetts, to be used mainly for converting titanium ingots to forging billets.

Tiline, Incorporated, began commercial production on a new titanium investment casting facility (443). The Albany, Oregon, firm will use a computer-controlled, \$250,000 furnace to penetrate the market for precision medical and aerospace parts. Tiline anticipates \$1 million in additional sales in the first year of the facility's operation.

Albany Titanium, Incorporated, is using a \$4 million grant from the Defense Department to build two pilot plants (444). The plants will use a newly patented process to produce titanium sponge and powder from domestic il-

menite. According to Fred Mullins of Wright Patterson's Aeronautical/Materials Laboratories, the process could "revitalize the industry." The Air Force will receive 10,000 lb of sponge and 2,000 lb of powder for analysis and evaluation. Pilot plant production startup was scheduled to begin between October and February. A production facility with an annual production capacity of 10 million lb of sponge or powder was planned for 1985. The Albany Titanium process is not expected to have a significant effect on the plentiful supply of ilmenite, or on its low price, currently \$40-\$45/ton.

Howmet, one of the largest nonintegrated producers of titanium ingot, announced that it was seeking to develop a position in titanium sponge production (445). The company did not plan to install in-house facilities, but was expected to seek equity in an existing producer or a long-term supply contract.

As nonintegrated melters sought sources of sponge, marketing executives at Oremet and RMI said they would be able to supply independent melters who had been buying Japanese material (446). Oremet announced that it was only operating at about 60% of its 9 million lb capacity to meet its mill product needs (447). Oremet expressed willingness to sell sponge to nonintegrated producers, with the ability to add 3 million lb production in six months. RMI, with a 9,500 short ton/yr estimated capacity, was soliciting sponge customers. The announcement came as nonintegrated melters claimed they had no alternative to Japanese sponge, with RMI and Timet both operating at or near 100% capacity.

Frankel Metal Company, a newly created, employee-owned firm, announced that it will specialize in recycling titanium scrap and doing toll processing in high temperature alloys (448).

Titanium producers also moved to improve distribution networks and to form joint ventures that would improve their production and marketing positions. As a response to maturing of industrial titanium products, ALS Metal Company announced that it would expand distribution of sheet, strip, plate, and welded tubing products through Metal Goods, Incorporated service centers (448). ALS followed a similar move by RMI Company, who will distribute titanium products through A. M. Castle and Company. Oremet, following the trend of domestic producers to establish national distribution networks, announced that five companies had been lined up as distributors of its titanium products (450). The service centers will sell Oremet titanium bar and billet to small customers. This movement is a departure from the earlier policies of integrated titanium producers involving captive warehouses and direct sales. The most likely distributor customers will be chemical processors, including the chlor-alkali industry.

Martin Marietta Corporation and Nippon Kokkan KK signed an agreement to establish a joint venture for production and worldwide marketing of titanium and aluminum fabricated products (451). Sixty percent of the venture will be held by Martin Marietta. Dynamet, Incorporated, of Washington, Pennsylvania, and Sumitomo Metal Industries have signed an agreement under which Sumitomo will help market Dynamet's titanium mill products in Japan (452). The two companies will work together to develop new materials and processes. Dynamet converts titanium billet into finished products at its Washington, Pennsylvania, and Clearwater, Florida, plants, which have a total estimated annual capacity of 7 million lb per year.

Foreign producers continue to press for greater market share, and to seek new markets for their products in the U.S. Billiton BV entered the titanium business by acquiring a 62.5 percent interest in Deeside Titanium, Limited in Deeside, Wales (453). British Aerospace will substantially increase commercial production of a superplastic and diffusion bonding titanium alloy in the next three years, under a \$10.3 million development program (454, 455). The material may eventually account for 8-10% of the average aircraft's structural weight.

Some of Japan's major commercial pure Ti producers have begun gearing up to produce Ti alloys (456). Long-term targets are the aerospace industries in Japan, the U.S., and Europe. Japan's alloy output is small, amounting to 130-200 metric tons in 1983, or only 2-3% of Japanese titanium mill products. Overseas markets are viewed as difficult to capture, with U.S. and European tariffs on Ti imports at 16.5 and 7%, respectively. A Sumitomo Metal Industries spokesman claimed that new Ti alloy products would be used in both aerospace and automotive applications.

The Chinese government has given high priority to developing titanium refining and processing technology (457). China, rich in ilmenite, rutile, and other rare earth minerals, is building an integrated metals industry around them. Estimated titanium sponge production capacity has grown from 1,000-2,000 ton/yr in 1980 to a current level of 3000 ton/yr. China's main export market is the United States. However, China's major interest in developing its titanium resources is to provide material for domestic consumption (458).

Demand.—Defense-related consumption of Ti sponge in 1984 was estimated at 7,933 tons (459). This is roughly the same as 1982 consumption, and 1,000 tons more than in 1983. Demand will increase at about 1,000 ton/yr through 1986, and will then level off through 1988.

Most of the defense demand arises from aircraft production. In each of the five years covered by the Pentagon prediction, more than 60% of all defense-related demand is accounted for by airframe parts. Aircraft engines and engine parts account for an additional 30%. Engine-related Ti use is spread among all aircraft programs, while airframe needs are limited to high performance bombers and fighters.

Production of the B-1B bomber, begun this year by Rockwell International, plays a major role in the growth of Ti sponge demand by the military. The first bomber was funded in fiscal 1982, followed by seven in 1983 and ten in 1984. Thirty-four have been requested by the Pentagon for 1985.

Titanium industry executives view the military demand as the most stable of their markets. Douglas Blair, Oremet's vice president of marketing, stated, "if it wasn't for the defense business, the titanium industry would be in a sad state of affairs." In nonmilitary areas, major program changes in the past have hurt the titanium industry. A prime example is the SST program, where expected demand never materialized.

An increase in titanium buying was expected toward the end of the year, as commercial airframe makers began work on orders received in the spring (460). Sustained demand into 1985 was expected as engine builders begin to produce new engines which are exiting the development stage. According to a Wyman Gordon Company spokesman, projected shipments of U.S. mill products were expected to reach 50 million lb in 1985, up from the estimated 43 million lb in 1984 (461). In the low year of 1983, only 32 million lb were shipped. It was predicted that titanium sponge would be in ample supply through 1988, leading to price stability. Peak demand of titanium sponge in the 1985-1988 period was expected to be about 58 million lb/yr. Positive factors in the turnaround are increases in the industrial and commercial aircraft markets.

At a Metal Bulletin conference, titanium industry executives expressed optimism for the future, while stressing that growth depends heavily on Washington (462). Increased orders arising from military aircraft and government antipollution efforts were seen as the key to slow but steady growth for the rest of the decade. Frank Caputo, president of Oremet, estimated industry production at 43.7 million lb in 1984, with shipments of 40.8 million lb. The difference between shipment and production figures comes from customer inventories built up several years ago when reports of shortages led to panic buying. Caputo predicted that titanium consumption will reach 50 million lb/yr by 1990, with major increases coming

from new industrial applications and less from the aerospace industry.

After the worst sales year since 1979, Western European producers of semifinished titanium mill products predicted some increased demand as inventories were replenished, but noted that real consumption had not improved (463). Production remained depressed as low price products from the U.S. and Japan were imported. It was estimated that Western Europe's demand for semifinished titanium would be a maximum of 5,000 metric tons in 1984. About half of the demand was being met by U.S. and Japanese producers. A number of factors were cited as preventing an increase in real demand over the next few years. The civil aircraft industry is very slow. Airbus Industrie, a European consortium, will use between 5 and 10 tons of titanium for each passenger aircraft it builds. However, production rates are now running at about 30 plane/yr, well below original expectations of 50-100 plane/yr. Military aircraft construction is also low, and recent cutbacks in capital spending have reduced demand in nonaerospace applications.

Japan's two leading titanium sponge producers reported significantly higher sales in the six months ended September 30, 1984, compared to the same period in 1983 (464). Spurred by the general economic recovery, Osaka Titanium reported a 59.8% jump in titanium sales. Titanium accounted for 75% of Toho Titanium's total sales, compared to 69% a year earlier.

A critical review and evaluation of future prospects for the worldwide titanium industry was announced by Gorham International (465). The study will forecast titanium demand, industry capacities, and price levels for the next ten years, as well as provide information on new technologies and competitive materials.

Markets.—The Titanium Development Association, formed in 1983, is looking for ways to smooth the cyclical nature of the titanium business (466). The titanium industry has followed trends in the aerospace industry, which accounts for about 90% of Ti consumption. The association, open to North American producers only, lists new market development as its number one priority. Several industries have been identified in which titanium could make significant inroads including pulp and paper, chemicals, power generation, and oil production. Association officials say they must convince potential users that the metal is cost effective and that adequate supplies exist, so that new users will not be squeezed short during aerospace industry upswings. The Titanium Industries Association had some 50 members registered by May and 25-30 more were expected by the end of the year.

In the mature pulp and paper industry, which is operating at 90-95% capacity, titanium usage jumped about 6% in 1984 (467). A growth rate of about 2.5% is expected through this decade. The chemical industry usage of titanium is expected to grow about 5%. The advent of membrane cell chlor-alkali technology, which reduces titanium requirements, may slow growth somewhat. The nuclear industry is stagnant, but titanium usage could increase by 2.5%. Other markets include the agricultural chemicals industry, electrowinning of metals, air conditioning systems, flue gas desulfurization units, and deep oil and gas well applications.

Titanium has lost markets to substitutes because of user fears of another titanium shortage similar to the one in the late 1970's. In some cases, substitutions were made even though titanium was preferred on the basis of its properties. Expanded titanium melting capacity will help titanium to reach its potential as a structural metal. Current worldwide sponge capacity appears to be adequate to handle anticipated market growth through the end of the decade (468). However, new alloys and composite materials continue to be developed as titanium replacements for the aerospace industry (469). Advanced nonmetallic composites consisting of high strength fibers in an epoxy base offer modulus or stiffness usually superior to metals. Yields are also high, and investments in tooling and dies are lower. Composites also make inroads on aluminum in

flat surfaces on aircraft. Here, aluminum replacement often increases the demand for titanium fasteners.

Within the commercial aircraft industry, the amount of titanium used in airliners may continue to increase, despite the threat of new material substitutes (460). Aluminum-lithium alloys and composites were both viewed as more of a threat to aluminum than to titanium. According to a Boeing official, "with each succeeding generation of aircraft, there will be a greater percentage of titanium used. The curve started with the 707 and has been moving up since the 1950's."

In aircraft engines, some substitutions for titanium are being made in the latter stages of compression, where temperatures reach 1050°F. However, this will not lead to an overall drop in titanium usage. Pratt and Whitney engineers, for example, anticipate that their jet engines will continue to contain 20-25% by weight.

In recent years, titanium has gained market share in the electric utility condenser market. The titanium condenser tube business, however, has been hurt by the decline in nuclear power plant construction.

If testing confirms, as RMI Company officials suspect, that titanium is technically superior to steel in automotive valve trains, Ti valve trains may be introduced in the near future (470). Bruce Bannon of RMI estimated that the new market would require more than 1 million pounds of titanium/yr. RMI has strengthened its research and development group to find new applications for titanium. In the future, use of titanium in small structural components and in other motor segments may be considered.

Dumping actions.—In October 1983, the General Services Administration purchased 4,500 tons of titanium sponge for the national defense stockpile. All but 1,000 tons of the purchase went to producers from Japan and the United Kingdom. The purchase provoked dumping complaints from domestic producers. As a result, the Department of Commerce issued a preliminary finding that the foreign sponge was bought at prices ranging from 16 to 94% below fair value (471-472).

Lobbying was intense before the final decision was rendered (467). The chairman of the Senate Armed Services Committee took the position that critical and strategic materials were exempt from antidumping and countervailing duties. Nonintegrated producers maintained that integrated producers pushed the dumping charge to gain a competitive edge in the sale of ingot and mill products by driving up raw materials costs. There was widespread concern over a possible price squeeze (473). RMI Company, the primary dumping petitioner, claimed that "exemption from duties does not mean exemption from unfair trade practice."

In its final decision, the Commerce Department found high dumping margins, but also ruled to exclude the 1983 purchases from any requirements to post bonds or duties (474). Both domestic producers and sponge importers claimed a measure of victory in the decision (475).

Subsequent to the Commerce ruling, the International Trade Commission held injury hearings. RMI maintained that, although operating at a 100% rate, it suffered from a low return on investment because of artificially low pricing (474). According to RMI president, Frederick Gieg, additional profits were needed to invest in capital equipment and remain technologically competitive (473, 476).

Confirming the Commerce Department preliminary findings, the ITC ruled in October that Japanese sponge imports had caused material injury to domestic producers, clearing the way for assessment of dumping duties (477). British imports, however, were not found to have been injurious. Following the ITC decision, titanium prices rose as a major U.S. melter relying on Japanese sponge hiked prices (478). The move by Teledyne Allvac was expected to be followed by other major producers.

A formal investigation into alleged dumping of titanium mill products from the U.S. and Japan was opened by the European Economic Community (479). According to EEC estimates, U.S. and Japanese imports climbed from 48 to 61% of the market in the last two years, resulting in a 35%

drop in European capacity utilization. The investigation concerned titanium plate, sheet, strip, bars, and rods, but tubing was excepted. Sponge prices climbed from about \$3.50/lb in 1983 to over \$4/lb (480), while there was no corresponding price rise in mill products in the European market. U.S. producers named in the complaint included RMI, Timet, Oremet, Teledyne Allvac, Martin Marietta, and NF&M. In November, a team of EEC investigators was scheduled to travel to Japan on a fact finding investigation, followed by a similar investigation in the U.S. (481).

Zinc.—Zinc was among the major gainers in the non-ferrous metal industry as the general business recovery begun in 1983 continued (482). The upturn in the automotive industry was a large factor in the strength of zinc markets.

Production and prices.—The 1984 production and consumption statistics for zinc are given in Tables XLIII and XLIV (483).

St. Joe Minerals Corporation, of Clayton, Missouri, acquired the National Zinc Company from its parent company in mid-August (464, 465). Under the agreement, St. Joe paid approximately \$16.5 million for National's fixed assets, and also bought National's inventories and accounts receivable. The total purchase price exceeded \$30 million. Prior to the acquisition, St. Joe's production capacity was about 100,000 ton/yr at its Monaca, Pennsylvania, electrothermic zinc smelter. National operated a 55,000 ton/yr electrolytic zinc refinery in Bartlesville, Oklahoma. The combined production capacity of 155,000 ton/yr results in the largest U.S. zinc producing company. Other major domestic producers include Asarco (107,000 ton/yr capacity), Amax (80,000 ton/yr), Jersey Miniere Zinc (90,000 ton/yr), and Huron Valley Steel (35,000 ton/yr). The purchase of National, which can produce High Grade and Special High Grade material, broadens St. Joe's product line, which was primarily prime western and continuous galvanizing grades, as well as zinc oxide and dust. It was announced that all future St. Joe list prices would reflect zinc products available from both the Monaca and Bartlesville plants (486). In a related development, St. Joe announced that some of its excess zinc concentrates will be refined at the Bartlesville facility (464). Previously, the concentrates, which could not be treated at the Monaca refinery, were sold on the open market and to Amax under a long-term contract.

Sherritt Gordon Mines decided to continue operations at its Ruttan mine, which has a current output of about 30 million lb of zinc/yr (487).

North Broken Hill Holdings of Australia gained majority control of EZ Industries (488). EZ has 210,000 ton/yr of zinc smelting capacity, and has treated nearly all of North Broken Hill's zinc concentrates for almost 25 years.

Gulf and Western sold its 60% interest in Jersey Miniere to its Belgian partner, Union Zinc (489). The acquired company owns a 90,000 ton/yr zinc refinery in Clarksville, Tennessee, as well as mines in Elmwood and Gordonsville, Tennessee. In July, Union Zinc announced

Table XLIV. World zinc mine production and reserve base (thousand metric ton)

Country	Mine production		Reserve base
	1983	1984 (est.)	
United States	275	265	53,000
Australia	695	645	39,000
Canada	1,070	1,185	56,000
Mexico	257	280	8,000
Peru	553	565	12,000
Other market economy countries	1,934	1,950	90,000
Centrally planned economies	1,462	1,460	32,000
World total	6,246	6,350	290,000

a production cutback of 25% of its 90,000 ton/yr capacity (490).

Kidd Creek mines will spend C\$6 million to increase the size of its zinc plant, raising annual capacity by 7,000 metric tons to 127,000 tons by 1986 (491). The expansions will primarily concern upgrading the cellhouse.

Reacting to an oversupply of zinc near year's end, Cominco and its 63% owned Vestgron Mines subsidiary announced one month suspensions of certain zinc operations (492, 493). Cominco suspended operations at its Polaris mine, which produces about 16,000 metric tons of zinc per month. Vestgron shut down its Black Angel zinc-lead concentrator, which produces about 10,000 tons of zinc concentrates per month.

LTV Steel Company and Sumitomo Metal Industries announced a partnership to build a 500,000 ton/yr electrogalvanizing line in Cleveland (494). The jointly managed operation is 60% owned by LTV and 40% by Sumitomo. The \$125 million electrogalvanizing line, scheduled to start up in 1986, will handle widths up to 72 in. Also under discussion was the possibility of Sumitomo providing electrogalvanizing technology to LTV (495). Domestic producers also announced four other electrogalvanizing lines. These include a 400,000 ton/yr line at Great Lakes Steel, a 600,000 ton/yr line owned jointly by U.S. Steel and Rouge Steel, a 400,000 ton/yr line at Armco (494, 496), and a 400,000 ton/yr line jointly owned by Inland Steel, Bethlehem Steel, and Pre-Finished Metals. The latter companies announced that the line would cost \$40 million (497). Product will be available in 1986, in time for the manufacture of 1987 cars.

Outokumpu Metals (U.S.A.), Incorporated, announced that it would begin marketing zinc for Outokumpu Oy, Finland, in January 1985 (498). The company was formed in 1982 to market Outokumpu Oy's products in the U.S. As a result, a 15 year sales agreement between Outokumpu Oy and Afrimet Indussa was ended, eliminating about 35,000 tons of zinc from Afrimet's sales. Afrimet, however, had gained nearly 85,000 tons from its agreement to become the sole sales agent for Union Zinc, Incorporated, of Clarksville, Tennessee.

A plan to cut Zn production capacity by up to 200,000 metric tons was dropped by the European Economic Community (499). In 1982, EEC producers had proposed the capacity reduction as a result of slack demand and excess capacity.

Exxon's Crandon project in Wisconsin is the largest domestic zinc prospect under active investigation, according to a Metals Economics Group publication (500). A production decision was expected during 1984.

Aberfoyle Limited said that zinc and lead reserves at its Hellyer prospect in northwest Tasmania could total ten million metric tons (501). The prospect was said to have a substantial impact on the company's future.

An American Mining Congress spokesman told the Internal Revenue Service in a hearing that Congress should decide to exempt zinc, as well as copper and lead, from the Superfund tax to prevent further serious adverse economic impacts (502). The Washington Conference for Zinc, a group of zinc industry executives, attempted to eliminate the \$14.94/ton cleanup tax in pending Superfund legislation (503).

Table XLIII. U.S. zinc production and consumption (thousand metric tons)

	1983	1984 (est.)
Production		
Mine	275	265
Primary slab zinc	236	260
Secondary redistilled slab	69	70
Imports for consumption		
Ore and concentrates	63	55
Slab	618	630
Exports		
Zinc metal, including scrap	21	35
Ore and concentrates	60	30
Consumption		
Reported, slab zinc	806	890
Apparent, all forms	1,005	1,030

The Lead and Zinc Producers Committee withdrew its petition for the imposition of countervailing duties on Spanish zinc imports (504). The petition, originally filed in 1976, had declined in importance as Spanish zinc imports dropped to 20,643 tons in 1983, representing only about 3% of total imports. Much of the approximately 650,000 ton/yr of imported zinc currently is supplied by Canada, Europe, and Asia, according to an industry consultant.

As worldwide supplies of all zinc grades tightened and LME prices firmed, domestic producer prices of zinc reached an all-time high at the beginning of 1984 (505). Three producers, St. Joe, Asarco, and National Zinc all raised their prices for High Grade Zn by \$0.02, to \$0.51/lb. The price move was quickly followed by EZ America, for slab zinc produced by Electrolytic Zinc Company of Australasia, and by Noranda (506), as well as other producers (507).

The price of zinc dust also jumped by \$0.02/lb to \$0.64/lb (506), in a move by Gulf Metals and its Southern Zinc affiliate. Pointing to the strength of Zn on the LME, industry executives agreed that the price increase was overdue. About two-thirds of zinc dust production is used for anti-corrosion coatings, principally in the auto industry.

Zinc price declines in the spring were not due to consumption, which remained steady, but to production and stock increases (508). According to the International Lead and Zinc Study Group, world production rose from 402,000 tons in April to 417,000 tons in May, a 4.8% increase over May, 1983 production. World consumption was 393,000 tons in April, while producer stocks of refined zinc increased by 23,000 tons, to 407,000 tons in May.

Benchmark High Grade zinc prices plunged to their lowest levels in ten months in August, as Amax and Cominco decreased their prices to \$0.48/lb (509). Price drops were attributed to weak markets resulting from slow-downs in hot dip galvanizing and electrogalvanizing. The move was followed by similar cut backs by European producers (510).

To modernize zinc contracts, the London Metal Exchange board and committee voted in July to initiate trading in High Grade Zinc contracts (511). This reflects the fact that High Grade zinc currently accounts for about 80% of total world zinc production. The existing standard contract for GOB zinc is to be phased out in November 1985. LME participants expressed concern that High Grade stocks would build sufficiently to support trading. At mid year, only 3,700 tons of the LME's 60,125 metric tons of zinc stock were High Grade zinc.

Demand.—The zinc market was predicted to remain fairly strong, with an average price of \$0.46 in 1984 and \$0.48 in 1985 (512).

As total world metal consumption increased by an estimated 5% between the last quarter of 1983 and the first quarter of 1984, a prospect of "supply line bottlenecks" was seen for zinc (513, 514). Zinc stocks were predicted to fall to six-weeks consumption, with prices averaging at least \$0.10/lb higher than a year earlier.

During July, domestic zinc buyers were purchasing zinc on a "hand-to-mouth" basis and drawing on inventories, banking on further decreases in zinc prices (515). Many in the industry agreed that the domestic price had risen too quickly to the \$0.53 level, and expected prices to fall to \$0.47 or \$0.48/lb by summer's end, bringing producer prices in line with prevailing merchant prices. A return to the \$0.53 peak price was not expected for the remainder of the year.

Despite a favorable long-term outlook, short-term zinc fortunes were seen as "iffy" pending the outcome of labor negotiations in the auto industry and the bids offered by zinc suppliers in Bureau of Mint Tenders (516). Although actual zinc consumption had not slowed during the summer, demand decreased as consumers worked off inventories.

The Bureau of the Mint solicited bids for purchases of Special High Grade zinc (517). The offer was for 27 million pounds of zinc, with 18 million pounds for delivery in October and November, followed by an option for 9 million pounds in December. The zinc was to be delivered to Ball Corporation's Zinc Products Division at a rate of 2,250,000 lb/week, beginning the week of October 8 (518).

A 4-5% boost in copper-plated zinc coins was predicted by the U.S. Treasury Department (519). A total of 150 million lb of zinc has been used for the coins since the U.S. Mint began striking the coin in 1981.

Domestic consumption for zinc die casting, in the first upward year-to-year move since 1979, reached 296,863 tons in 1983 (520). Greatest gains in both tonnage and market share were registered in the automotive industry, which accounted for 34% of the overall zinc die casting market.

A Zinc Institute survey showed that the U.S. Big Four car makers used 11.9% more one-sided galvanized steel in 1984 than in 1983, as the average use per car rose to 66 lb (521). Two-sided galvanized growth was even greater, rising from 121 to 136 lb.

Chinese zinc imports jumped 112% between 1982 and 1983, according to Chinese customs figures (522). Expansion in crucial areas requiring intensive metal consumption was expected to keep 1984 demand high.

Markets.—A push for passenger cars with ten year service without rusting through will significantly increase the use of galvanized steel by 1988 (523). Chrysler anticipates that its 1988 cars will employ galvanized steel in almost all of the exterior, exposed body panels. An 850 lb car body will contain about 300 lb of electrogalvanized steel and about 500 lb of hot-dipped galvanized and galvanized steels. A Chrysler spokesman estimated that the steel industry must increase its galvanized capacity by 1.5-2 million ton/yr by 1987, with most of the expansion in electrogalvanizing. The high quality electrogalvanized surface finish is important in exposed body panels.

After-fabrication hot-dip galvanizers anticipated increased business arising from increased highway, bridge, and transit construction and repair (524). As much as one-third of the galvanizers said that they would invest in new equipment if business improves, with capital investments as high as \$550,000/plant. In 1983, about 3 million tons of steel were hot-dip galvanized, with sales of \$750 million. About 180,000 tons of zinc were consumed.

Strong growth for Galvalume™ aluminum-zinc alloy sheet led to projections that the product could grow to 40% of the 40 million ton global market for coated sheet by the end of the century (525). Bethlehem Steel, which developed Galvalume 12 years ago, said facilities already licensed are scheduled to grow to 3 million tons capacity in 1986, up from the present 2 million tons capacity. Galvalume, which contains about 44% zinc, does not compete directly with electrogalvanizing, and is not expected to be used in visible automobile parts because of the surface quality limitations. Strongest growth to date has been in construction and metal building markets, with about 40% of sheet sales going into roofing and sidewall applications.

Increased business was expected for hot-dip galvanizers, leading to possible investment in expansion and modernization projects (524). Highway, bridge, and transit system construction and repair expenditures were expected to benefit from the new \$0.05 Federal Gasoline Tax.

The Electric Utility Industry

In 1984, the electric utility industry continued to rebound from the trough year of 1982, as shown in Table XLV (526, 527). The 2095.2 billion kWh generated in 1984 represented an increase of 8.4% over 1982, and a 3% increase over the peak year of 1981. Nuclear, coal, and gas fueled plants all registered increases; only oil powered plants showed a decline, continuing a trend begun in 1978, when oil powered plants produced 364.2 billion kWh

Table XLV. Electricity generated, by type of fuel (billion kWh)

Year	Nuclear	Coal	Oil	Gas	Total	(Hydro)
1980	251.1	1162.0	245.6	346.2	2010.4	—
1981	272.7	1203.2	206.1	345.8	2034.1	—
1982	282.8	1192.0	146.8	305.3	1932.0	309.2
1983	293.7	1259.4	144.5	274.1	1978.2	332.1
1984	327.6	1341.7	119.8	297.4	2095.2	—

Table XLVI. Fossil fuel consumption, by type

Year	Coal (millions of tons)	Oil (millions of bbl)	Gas (millions of ft ³)
1974	391.2	539.1	3443.4
1975	405.9	506.6	3157.7
1976	448.3	556.5	3080.9
1977	477.0	624.2	3191.2
1978	481.6	635.8	3188.4
1979	527.1	523.3	3490.4
1980	569.5	420.2	3681.6
1981	596.8	351.1	3640.2
1982	593.7	249.8	3225.5
1983	625.2	245.5	2910.8
1984	664.4	204.5	3111.0

(527). These trends are also shown in Table XLVI (526, 527) which shows the industry's fossil fuel consumption.

U.S. electrical generating capacity increased by more than 15,000 MW in 1984, to a total of 673,689.9 MW, as shown in Table XLVII (526, 527). Much of the increase was accounted for by steam plants, while significant gains were also made by nuclear plants and hydro-powered plants. Capital spending by the industry was only about 93.5% of the 1983 level, as shown in Table XLVIII (526, 527). The drop was shared proportionately by investor-owned utilities and other systems. While expenditures on generation equipment declined markedly, the industry increased outlays for both transmission and distribution systems.

Electric Utility Industry Forecast (528).—The September 1984 issue of *Electrical World* presented its forty-fifth annual electric utility forecast. The U.S. economy's upsurge during the latter half of 1983, and its continued strong showing in the first half of 1984, caused short-term projections to be revised upward from those made a year earlier. In general, however long-term projections varied only slightly from those made last year (529, 530).

Important points from the *Electrical World* forecast are summarized below.

Industrial usage.—The sharpest growth in electrical usage during the 1983-1984 economic recovery was registered in the industrial sector. Despite the gradual transition of the U.S. economy toward the service sector, a

growing and vital industrial sector is expected. Although the industrial mix will change, the forecast assumes that industrial sales will continue to account for 35-40% of total electrical utility sales, as shown in Table XLIX. Industrial usage was estimated to be 838.1 billion kWh in 1984, up 4.6% from the 801.1 billion kWh used in 1983. Total U.S. usage was estimated at 2,259.8 billion kWh in 1984, up 4.2% from the 1983 value of 2,163.4 billion kWh. In 2000, industrial and total electricity usage were forecast as 1,320.1 billion and 3,451.6 billion kWh, respectively. An industrial usage breakdown is given in Table L.

Fuel substitution is expected to play an important part in the growth of industrial electric usage, as electricity is substituted for direct use of fossil fuels. In recent years, the country's basic industries have begun to make such a shift.

A number of factors have caused a sharp drop to be made in uranium-enrichment services, compared to last year's forecast. The unsettled state of the enrichment market, a slowdown in nuclear plant construction, and market loss to foreign sources all contributed to lower expectations extending through the end of the century.

The forecast included a pessimistic view for long-term growth prospects of the domestic aluminum industry as shown in Table L. However, some plant capacity additions in the late 1990's were assumed. The actual electric power consumption forecast for the aluminum industry in the long term was no different from last year's forecast.

Recently, industrial customers have taken steps to generate some of their own electricity, for in-house use or resale to electric utilities. However, the forecast assumes that the electric utilities, and those customers that have historically generated electric power, will continue to have favorable electric production economics.

Residential Usage.—This year's residential electric sales forecast was changed only slightly compared to last year's forecast. A downward revision of 2 million in the number of customers anticipated in 2000 reduced the residential sales forecast for that year by 20 billion kWh. In the near term, those factors which will have the biggest influence on residential electricity use are weather-related sales and the higher than expected number of housing starts.

Higher energy efficiency of electric appliances has become increasingly important in recent years. However this has resulted in only minor adjustments to the forecast over the next five years. It is expected that consumers will try to control their utility bills without serious disruption to their lifestyles. The national "Power of Choice" marketing program carried out by investor-owned utilities will also contribute to demand.

In the electric heat housing market, it is projected that the heat pump will come to dominate. Electric heating continues to be the preferred method in new construction. Continuing a pattern in existence for more than a

Table XLVII. U.S. installed generation capacity by plant type (MW)

Year	Total	Hydro	Steam	Nuclear	Gas turbine	Combustion

^r Revised data.

decade, electric heating was installed in more than 50% of new housing units completed last year. It is projected that gas deregulation and the resulting price rise will improve the future market share for electric heat.

A pessimistic view was taken of the growth of the electric vehicle industry. The EV projection was dropped to about one-half of last year's level. The forecast was based on the premise that the EV market had passed a "window of opportunity" without making substantial gains, and that similar opportunities would not arise for the remainder of the century. Fewer than 100,000 electric vehicles, using less than 500 million kWh of electricity, were projected to be in service at the end of the century.

A breakdown of residential use statistics is given in Table LI. Overall, as Table LI shows, residential electricity consumption was expected to be 779.7 billion kWh in 1984, a 3.8% increase over 1983. By the end of the century, the forecast was an annual residential consumption of 1161.5 billion kWh, a 49% increase over the 1984 level.

Commercial usage.—Commercial electricity usage in 1984 was estimated at 556.1 billion kWh, a 4.3% increase

over the 533.0 billion kWh consumed in 1983. As shown in Table XLIX, commercial use of electricity was predicted to rise to 860.0 billion kWh by 2000, for a total growth of nearly 55% over present consumption. No basic changes in the commercial market were evident since the 1983 projection was made. Conservation and energy management were viewed as significant factors in reducing energy use. However increased use of communications and data processing equipment, as well as other developments contributing to greater office use, were expected to produce an overall increase in commercial electricity use.

Generating capacity.—A compound average growth in electrical generating capacity of about 3% has been forecasted through the end of this decade, with growth gradually tapering off through the 1990's, as shown in Table LII. Total electricity output (Table LIII) will climb from 2457.7 billion kWh in 1984 to 3727.7 billion kWh in 2000, an overall increase of nearly 52%. The forecast is predicated on the assumption that smokestack industries are not dying, but are making a transition to more efficient

production from a shrunken labor force, arising from increased energy intensity.

In the next several years, a number of very costly nuclear and fossil fuel plants will come into service. In some cases, as with LILCO's Shoreham nuclear plant, this raises the possibility of 50% electric rate increases. The forecast, however assumes that rate hikes of this magnitude will not be permitted in the short term. Rather, regulatory agencies will phase in cost increases gradually to cushion their impact. This should keep electricity costs competitive with those of other energy forms.

One of the most obvious trends in Table LIII is that the capacity margin in the utility industry will shrink. The capacity margin is defined as the excess of available capac-

ity over peak demand. In 2000, the 14.7% predicted margin will be slightly more than half of what it is today.

Those who run utilities now feel that improved financial health will result from leaving the phase of major capital projects, now that demand for new units is declining. In addition, regulators have begun to demand conclusive demonstrations that such projects are necessary. Another factor influencing future construction is the concept, currently gaining momentum, that existing plants can be updated for much less than the cost of new construction. According to one study, raising the availability of all current plants to the level of the best units would add as much as 12-15% to peak capability, at a cost of about \$200/kW. As a result of these factors, new plant additions

[†] Revised data.

in the years following those already under construction will decline. Availability improvement and life-extension programs will become more important in the 1990's.

The net mix of generating capacity by fuel type will not change drastically in this century. Nuclear steam capacity, which has grown significantly in the last ten years, will reach a maximum in the early 1990's as units under construction are brought on stream. Thereafter, their percentage contribution will decline, with the slack being taken up by fossil-fueled steam generators, which will contribute about 70% of total capacity in 2000. Combustion turbine and internal combustion plants will continue to supply less than 10% of capacity. Hydropower plants will decline slightly in the overall mix. These overall trends are reflected in the generating capacity additions shown in Table LII.

Nuclear power continues to command great attention, despite indications that construction is waning. Although new types of reactors may be proposed in the future, it is expected that the next wave of nuclear reactors will be those now abandoned in advanced stages of construction. The units will probably have to be relicensed and modified. In any case, there will be little effect on capital spending until late in the century.

Capital spending.—As a result of present plant upgrading, capital budget outlays will be reduced in the late 1980's and early 1990's. The cost of output increases from existing plants, on the order of \$200/kW, is considerably cheaper than that of new plant construction, which is in the \$800-\$1,200/kW range for coal-fired units. Some capacity increase from unconventional technologies such as wind, solar, biomass, and cogeneration will also reduce capital outlays for conventional capacity. Much of this capacity will be built by nonutility companies which sell energy to utilities. As a result, the energy bought is absorbed as an operating cost, and little is added to capital budgets. A summary of forecasted capital expenditures is given in Table LIV.

Distribution and transmission.—The future for distribution expenditures appears strong. Expenditures for 1984 and 1985, shown in Table LIV, are the highest since 1976, in constant dollars. A recent upsurge in housing starts and the general strength of the economy contribute to the general optimism.

Transmission budgets, roughly tied to spending on generating capacity, will not fare as well. Environmental opposition to high voltage transmission lines also has a depressing effect on proposed new lines. In the mid-1990's, transmission spending will increase as generating capacity does. It is expected, too, that transmission net-

works will be strengthened at that time, because of the low reserve power levels which will exist on many systems.

Nuclear.—The year began on a sour note for the nuclear industry, as the Department of Energy's Energy Information Administration released a report showing that final construction costs for 77% of the Nation's operating nuclear plants were at least double the original estimates (531). For 23% of the plants, the final cost was more than four times the preconstruction estimate. The EIA, an independent agency within DOE, attributed the cost overruns to inflation, soaring interest rates and construction costs, and long building delays. In 1971, the estimated construction time for a nuclear plant was four years. However, the average construction time has now ballooned to 14 years.

The report, coming amid a wave of nuclear plant cancellations, cast doubt on the fate of 48 reactors now under construction around the country. Citing quality-control failures, the NRC refused to grant an operating permit for

1999	46,000	6,500	10,100	2,817	65,417
2000	46,000	6,500	10,200	2,821	65,521

Commonwealth Edison's nearly completed, \$3.35 billion twin-reactor Byron Plant in Illinois (532, 533). The decision marked the first time in the history of the nuclear industry that the government flatly rejected an atomic power license.

Public Service Company of Indiana, bowing to pressure from state officials, abandoned efforts to complete its twin-reactor Marble Hill plant after spending \$2.5 billion. At the time of cancellation, the first unit was 59% completed and the second unit was 37% completed. Previously, the industry had scrapped no plants more than 27% finished. The Marble Hill decisions brought the total number of reactor cancellations to 100 since 1974.

The cost estimate of the troubled Nine Mile Point 2 nuclear power plant in New York State was raised to \$5.1 billion by major partner Niagara Mohawk Power Corporation (533). The new estimate was \$900 million higher than a projection made 14 months earlier. A consortium of utilities financing the plant has begun a study to determine whether further funding is warranted. The bad news followed on the heels of a Nuclear Regulatory Commission's reporting poor management and inadequate quality control (534), and the pullout of the Long Island Lighting Company, an 18% partner (535). LILCO's departure halted its \$180 million annual payment toward the project (536). The New York Public Service Commission put a \$5.4 billion cap on expenditures, ruling that the utilities involved in the project will have to carry 100% of all spending in excess of that amount (537).

Fifteen years after construction was begun, the first reactor at Pacific Gas and Electric's Diablo Canyon site was started up (538). The \$4.9 billion power plant was originally scheduled for completion in 1976, at a cost of about \$400 million. Elsewhere, work was halted on the Seabrook reactor in New Hampshire (539). However, Seabrook's project manager projected that the plant would be completed on schedule, with the first reactor operational by 1986. The estimated cost was revised down to \$6.9 billion from an earlier \$9 billion (540). The original cost estimate in 1968 was \$850 million.

Because of the uncertainty about completing and licensing the project, three utilities announced that the Zimmer nuclear power plant near Cincinnati would be converted to coal (541). The plant, about 97% finished, had been under construction since 1972. While the original cost estimate was \$240 million, the utilities had already spent \$1.6 billion, and the final cost was estimated in September 1983 at \$2.8-\$3.5 billion. In 1982, a licensing board had conditionally rejected an operating permit for the Zimmer plant, citing inadequate evacuation contingency plans.

According to an EPRI official, preserving and upgrading nuclear plants to extend their life expectancy is under consideration as an option to plant retirement and new plant construction (542). Retirement of old plants carries an ever-increasing decommissioning cost, and the high cost of capital makes new construction expensive.

A Senate-House panel agreed on a tax break to help utilities shut down worn-out nuclear power plants (543). The provisions, worth an estimated \$250 million to the industry through 1987, would allow utilities to avoid taxes on money earmarked for plant decommissioning.

A report by the U.S. Office of Technology Assessment says that, without major reforms, commercial atomic power is unlikely to grow in this century (544). As a result of uncertainties in electric demand growth, very high capital costs, operating problems, increased regulatory requirements, and growing public opposition, nuclear power plants currently involve too many financial risks. According to OTA, only one-third of the public supports nuclear plant construction, while more than half are opposed. However, worldwide, the Uranium Institute projects that installed nuclear capacity will increase from 115 GW in 1980 to 315 GW in 1995. The projection includes only operating and committed nuclear generating capacity, with no new orders.

In New York State, the Court of Appeals upheld a Public Service Commission decision that four utilities could recover about \$80 million invested in a nuclear power plant project which the state first approved and later ordered scrapped (545). The PSC found that Rochester Gas and Electric, Niagara Mohawk, Orange and Rockland, and Central Hudson Gas and Electric had acted prudently and were entitled to recover costs from their customers.

A world record for continuous operation was established by the 582 MW Connecticut Yankee plant, which reached 401 days operation without a halt on July 16 (546). The previous world record of 400 days was set by Tokyo Electric's Fukushima units in 1983. The previous U.S. record of 392 days was held by Maine Yankee.

On behalf of nuclear utilities, Kidder-Peabody will form a group called For Responsible Energy Action (547). The organization will lobby for federal aid to utilities struggling with nuclear construction projects.

A joint effort between Israel's Tel Aviv and Ben Gurion Universities is developing thorium-powered light water reactors (548). Thorium is three to four times more plentiful than uranium. The new reactor design should be complete in two years and may be used to produce power within a decade. The reactor uses small quantities of uranium and produces no plutonium by-product.

Uranium oxide prices dropped from about \$24/lb in the fall of 1983 to \$17.50/lb in March, approaching the recent low of \$17/lb in late 1982 (549). The drop was not expected by speculators who predicted the price would remain in the \$20-\$25/lb range because most of the bad news about nuclear plants was known and utilities had reduced stocks.

Conventional fossil fuels.—Coal's future in the utility industry appears secure, as nuclear power plant costs and public acceptance problems have become prohibitive, and economic recovery has restored a growth of electrical demand (550). The American Coal Investment Company president, Zachariah Allen, claimed that coal generation was "the most secure and cost-effective option available to meet this increasing demand." However, indecision on coal purchasing strategies among utilities has led to a mix of long-term coal contracts and spot purchasing.

U.S. demand for bituminous and lignite coal in 1984 was estimated at 740 million tons, up 3.7% from 1983. Electric utilities, which consume about 75% of U.S. coal output, were expected to use about 560 million tons, up 7.2 million tons from 1983 (551). A National Coal Association forecast showed that electric utilities will continue to be the major market for coal, and will also be the highest growth sector (552). With moderate economic growth, it is forecasted that utilities will consume 811 million tons, or 82% of domestic consumption, in 1995 (553).

Mobil Coal Producing, Incorporated, signed a 25 yr contract, valued at \$100 million, to provide 1-2 million ton/yr of coal to Grand River Dam Authority (554). The coal will be shipped to GRDA's 520 MW number 2 generating station near Chouteau, Oklahoma.

A Virginia legislative committee approved a \$1 billion proposal to build a coal slurry pipeline across the state (555). The 450 mile pipeline will connect Western Virginia coal fields with Tidewater electric plants.

EPRI selected New York State E&G's Somerset Station for an \$11 million, advanced high sulfur test center (556). A ten-year research program will be carried out to improve SO₂ removal when burning high sulfur eastern coal. Tests at the center will range up to pilot-plant scale.

DOE and EPRI have agreed to spend about \$4 million in 1985 and 1986 to test coal cleaning techniques (557, 558). New methods to reduce the level of sulfur and other impurities before the coal is burned in utility boilers will be evaluated. The work will be done at EPRI's \$15 million testing site at Pennsylvania Electric's Homer City, Pennsylvania, plant.

The Environmental Protection Agency signed an agreement with Babcock and Wilcox to help fund a test demonstration of B&W's limestone injection technology in a multistage burner (559). The test will be conducted in a

100 MW burner at Ohio Edison's Edgewater generating station.

After eight years of research, TRW planned to conduct 4000h of tests of its atmospheric coal combustion in a 50 million Btu/h unit (560). In small tests, the combustor removed 80-90% of solid coal particulates as well as high percentages of nitrogen and sulfur oxides.

In the Department of Energy's FY-1985 budget, coal-related research and development was scheduled for more than \$327 million in funding (561). Projects within the office of fossil energy account for almost \$253 million of the total. A total of \$750 million was earmarked for a clean coal technology program, designed to fill the gap between small- and large-scale research, with intermediate size facilities using advanced clean coal concepts.

Electrophoresis is being tested at Indiana University to help remove organic sulfur and pyrite from Indiana coals (562). Coal will be inserted into a conductive fluid to see if sulfur-rich particles can be collected at one electrode and coal at the other, by manipulating the chemistry of the particle surfaces and the suspension medium.

Synthetic fuels.—The U.S. synthetic fuels effort lost much support in 1984. Criticism of existing programs, as well as an easing in the fuel-supply picture, combined to cloud the future of synfuels development.

Energy Secretary Donald Hodel called on Congress to reach a consensus on the direction of the federal synfuels program, and supported proposed bills which would slash SFC spending by \$9 billion (563). According to Hodel, "developing a commercial synthetic fuels industry at the pace envisioned by the Energy Security Act of 1980 would require enormous direct budget outlays that would not be offset by economic benefits." The spending cuts, proposed by the President and sponsored by Representative Silvio Conte of Massachusetts, proposed cutting SFC spending to \$5.1 billion (564).

A statement by the President, which accompanied the bill, noted that the energy outlook had improved dramatically since the Synthetic Fuels Corporation was established in 1980 with a budget of \$19 billion (565). Crude oil prices have dropped by 25%, oil imports are down by 33%, and the Strategic Petroleum Reserve contains nearly 400 million barrels of oil.

A spending freeze on the Nation's synfuels program was urged by a bipartisan group of 12 House and Senate members (560). The group, calling the program "highly questionable and very costly," asked the President to hold \$14.8 billion that the Synthetic Fuels Corporation had at its disposal, until Congress can review and approve the company's long-term strategies.

The General Accounting Office, claiming that the SFC will fall far short of production goals, said that it will be relatively ineffective in encouraging private investment, improving the Nation's balance of payments, and providing greater energy security (567).

Similar criticism came from the Office of Technology and Assessment, which found that, as a result of long lead times required to construct coal and oil shale conversion projects, synfuels would not help in the first five years of a prolonged oil supply disruption (568).

SFC Chairman Edward Noble pursued congressional support. According to Noble, in testimony before the House Science and Technology subcommittee, U.S. taxpayers will make \$6 billion from SFC projects if oil prices increase at higher than inflationary rates and the projects come onstream efficiently (569).

The House Appropriations Committee narrowly voted down the administration's synfuels spending cuts, as well as a compromise \$5 billion spending cut (570). However, the House later voted to allow further amendments which would rescind up to \$10 billion from the Energy Security Reserve (571). Intense lobbying resulted in an amendment which would rescind \$5 billion (572), leaving SFC with a budget of \$8.25 billion. In December, the Synfuels Corporation was put back into business as appointments were made to its board of directors, which had lacked a quorum for seven months (573).

Eighteen proposals for financial assistance were received by the Synthetic Fuels Corporation under its fourth solicitation in June (574). Seven proposals were for coal gasification, three were for indirect liquefaction, four for tar sands, and four for oil shale. Only six of the proposals were for new projects.

Coal Gasification.—The \$300 million Cool Water Coal Gasification Project at Daggett, California, began producing electricity from synthetic gas in May (575). According to Southern California Edison, the unit ran for five hours at from 10 to 32 MW using 100% synthetic gas. The project combines two existing technologies for the first time—Texaco's coal gasification process and General Electric's combined-cycle power plant technology—to produce an integrated coal gasification combined-cycle plant (576). The 100 MW project is a commercial-size module which will be used to provide a technological and economic basis for 500 MW or larger facilities. If successful, a new breed of power plants without the pollution problems of coal may be in commercial operation by the 1990's. An EPRI study found that such plants have the potential to be as much as 10% more efficient than conventional coal-fired steam plants with competitive capital costs (577). Both NO_x and SO_x emissions could be substantially reduced. Power will be produced from 1,000 ton/day of coal, the equivalent of 4,000 bbl/day of oil, and will serve 50,000 customers of Southern California Edison (576).

Allis Chalmers planned to modify its KILnGAS coal gasification plant by adding cogeneration equipment, at a cost of \$30 million, depending on Synfuels Corporation aid (578). The existing plant can deliver 409 Btu/h of gas from 600 ton/day of high sulfur coal. With cogeneration, 89% of the input coal energy will be converted into product gas energy.

Site development and construction was set to begin in November at Dow Chemical Company's coal gasification plant near Plaquemine, Louisiana (579). Start-up of the \$139 million project is expected in 1987. The plant will process 2,900 ton/day of Texas lignite into 30 million Btu of gas.

DOE awarded a \$33.7 million development contract, to be cost-shared with KRW Energy Systems, to conduct technical, economic, and environmental risk assessments of commercial introduction of advanced coal gasification technology (580). The project will focus on linking the gasifier to an advanced hot gas cleanup system. The goal is to develop a system for cleaning impurities from coal gas without the energy robbing necessity of cooling the gases.

Encouraged by a feasibility study that the government could save about \$1.4 million per launch in the first year of operation, NASA is considering building a coal gasification plant at Kennedy Space Center to provide fuel and electricity for the space shuttle program (581). The proposed facility would cost about \$151 million, and would process 635 tons of coal/day.

Coal liquids and slurries.—Northern States Power Company awarded a \$20 million contract to Foster Wheeler Energy Corporation to design and build a fluidized bed combustion retrofit (582). The unit, to be completed in 1986, will be the largest FBC boiler in the world. At a cost of about \$50 million, Northern States Power will install an atmospheric fluidized bed boiler in its coal fired 85 MW plant at Burnsville, Minnesota (583). SO₂ and NO_x emissions will be reduced, and electrical output will increase to 125 MW. Start-up is scheduled for 1986.

Occidental Petroleum Corporation and Combustion Engineering will jointly conduct research and development on coal slurry fuels (584).

Shale oil and tar sands.—A continuing world oil surplus reshaped once-ambitious U.S. oil shale production plans (585). However, a number of projects remained active. Geokinetics' shale oil project in northeast Utah has produced more than 90,000 bbl of oil since 1976, and the latest two retorts are producing 250-300 bbl/day. Ameri-

can Syncrude and Stone and Webster Engineering announced formation of the Indiana Shale Oil Project (586). The project will produce 2,011 bbl/day of shale oil.

Chevron Oil Shale and Conoco Shale announced that a \$130 million mining and oil shale retorting operation would begin producing oil early in the spring (587). The Utah plant will produce about 200 bbl/day of oil from 318 tons of Colorado shale using Chevron's staged turbulent-bed retorting process.

Reassessing its timetable for oil shale development, Sohio Shale Oil Company announced that it had withdrawn from the Paraho-Ute oil shale partnership (588). At issue was the interest of other partners in developing technology for licensing rather than commercial production.

Alberta Oil Sands Technology and Research Authority believes new technology can unlock about 95% of an estimated 1 trillion bbl of tar sands oil reserves in Alberta (589). AOSTRA plans to begin construction of a \$100 million project next year to begin production in 1987. By 1990, production should reach 5000 bbl/day.

Fuel cells.—The House Appropriations Committee approved a large boost in spending on fuel cells (590). Fuel cell spending of \$39.9 million was approved, a \$26.2 million increase over the administration request. Of the total, \$27.8 million was earmarked for phosphoric acid cells, and molten carbonate technology was awarded a \$9 million budget. The committee approved \$3.1 million for solid oxide fuel cell work. It also recommended development of an integrated gasified/phosphoric acid fuel cell system of at least 7 MW output. Concern was expressed that "other countries will manufacture fuel cells . . . for our commercial markets before such cells are manufactured in the United States."

Westinghouse Electric Corporation received a contract from Southern California Edison to begin designing a 7.5 MW prototype fuel cell plant for use in the utility's transmission and distribution system (591). The system will include air-cooled, phosphoric acid cells and an advanced steam methane reforming process to convert natural gas to hydrogen for use in the cells. The prototype plant is expected to come on stream no earlier than 1988.

A Consumers Power Company 40 kW fuel cell plant in Jackson, Michigan, has operated for more than 1,500h. The fuel cell ran so smoothly that a scheduled shutdown for routine maintenance after 2,000h of operation was canceled. The project is part of the Onsite Fuel Cell Energy System being developed by the Gas Research Institute, DOE, and a group of gas and electric utilities. About 30 utilities plan to conduct similar experiments across the country.

The Electric Power Research Institute (EPRI) announced that it would not run the Consolidated Edison fuel cell demonstration plant without completely refurbishing the stacks (593, 594). According to an EPRI official, the job could require an additional investment of \$20 million. The present stacks are too old and pose too much of a hazard to continue. They were built before United Technologies Corporation had solved the problem of electrolyte and water leakage. Con Ed and UTC have petitioned Congress for a \$15 million supplement to DOE's budget to refurbish the plant, which would keep the \$80 million project alive.

Meanwhile, a similar demonstration plant in Japan, using newer technology, has been running since April, 1983. Tokyo Electric Power Company's 4.5 MW fuel cell plant has operated for more than 196h.

Magnetohydrodynamics.—In a letter to Congress, DOE requested an additional \$12 million for its magnetohydrodynamics program (595). The additional funds would be used for a multiyear proof-of-concept program which would lead to design, construction, and operation of an integrated, coal-fired MHD retrofit.

A \$33 million budget for fiscal year 1985 was approved by the House Appropriations Committee (596). This represented a 10% increase over FY 1984. The bulk of the funding would go toward preparing a utility-scale MHD

retrofit and testing topping and bottoming systems. The committee also called for significant cost sharing by the private sector.

Solar energy.—Alabama Power and Chronar Corporation formed a joint venture to build a photovoltaic manufacturing plant in Alabama (597). Pending stockholders' approval of the venture, Chronar would supply technology and would buy plant output for the first four years.

Solarex Corporation, a division of Standard Oil Company of Indiana, is constructing a second photovoltaic generating station in Adelanto, California (598). The station is expected to provide 2 MW of power, about 25% more than Atlantic Richfield's Hesperia plant. The Solarex plant will use semicrystalline cells with up to 18% efficiency.

The Solar Energy Research Institute (SERI) estimates that almost 300 MW of windfarm capacity has been installed in the U.S. as of December 1983 (599). About 295 MW of this total is in California. SERI estimated the ultimate planned U.S. windfarm capacity at 687 MW, with 683 MW in California. The SERI figures do not include prototype units or those on government test sites.

California's lead in windpower is partially due to the state's Public Utility Commission, which has ordered investor owned utilities to buy power from qualified small producers and cogenerators. Special tax treatment is also provided.

There are currently more than 50 windfarm developers in the U.S. Some windfarms are being developed by windpower equipment manufacturers such as Boeing, U.S. Wind Power, Incorporated, and Hamilton Standard.

Standard Oil Company and Energy Conversion Devices plan to build two facilities to begin production of photovoltaic cells under their Sovonics Solar Systems partnership (600). The two facilities, costing \$6 million, were expected to be operational in October. The cells, made from silicon alloy deposited on stainless steel, will be made by the proprietary Ovonic roll-to-roll mass production process.

Geothermal.—The northern California geysers area is the most active area in the world for geothermal electricity production (601). Twenty units are now in operation, providing a total generating capacity of 1,379 MW, or enough to meet the needs of 1.3 million people. This is roughly the capacity of one large nuclear plant.

Electric vehicles.—The Lead Industries Association noted that the electric car is making progress, despite a lack of penetration into the market place (602). The Energy Department has continued to fund electric car research, and utility companies are working to promote electric vehicles. Hope Automobil Industri of Denmark planned to begin mass producing the Whisper, a small electric car, by the end of 1984. The car will be marketed in the U.S.

Peugeot unveiled an electric drive version of its Model 205 super mini (603). The car was developed using the same body and interior configurations of the conventional gasoline or diesel powered Model 205. The prototype contains 12 nickel-iron batteries with a life of 200,000 km and a range of up to 140 km. The batteries, developed with SAFT, produce twice as much power as lead-acid batteries having the same size and weight.

Sinclair Vehicle Project and Hoover were reportedly negotiating to build an electric car (604). The new car was planned to be unveiled by early 1985. A novel feature is the minimized weight, achieved by building a battery as the car frame. Reportedly, the car can reach speeds of 30 mph and will cost less than \$3,000.

Environmental issues.—Despite pressure from environmental groups, no clear consensus emerged on what actions should be taken to reduce acid rain and CO₂ emissions. Indeed, disagreement remained over both the causes and the seriousness of the problem.

The degree of concern over the acid rain problem varies considerably (606). Despite the threat of damage to forests, the American Paper Institute and the National Forest Products Association believe the situation is not criti-

cal, concluding that "at the present time, there is no . . . need to reduce acidic deposition . . . to protect the timberlands of North America." Similar conclusions resulted from studies by EPA and the National Acid Precipitation Assessment Plan.

A U.S. Geological Survey review of published reports on acid rain research found that the acidity of precipitation in the Northeast, where the acid rain problem is most acute, has changed little in recent years (606). The review found that acidification increased primarily before the mid-1950's and has been roughly stable since the mid-1960's.

EPA Administrator, William Ruckelshaus told the Senate Committee on Environment and Public Works that the country was not yet ready to adopt an acid rain control program (606). Ruckelshaus said that "before launching the country on an expensive and potentially divisive control program, we feel we need more scientific information." However, Ruckelshaus did say that EPA was taking preliminary steps to prepare for a possible national acid rain control program (607). EPA will work with states to strengthen data bases and reduce implementation time of a control program, when required.

Following the theme for more acid rain research, the President announced, in the State of the Union message, a commitment to double acid rain research funding to \$55.5 million in 1985 (606). As part of the expanded effort, EPA will launch a 12 month, \$6.5 million study of water chemistry in up to 3,000 lakes.

William Karis of Consolidation Coal Company told the Senate Environment and Public Works committee that the costs of major acid rain control legislation have been underestimated by billions of dollars (608). He noted that more than 100,000 jobs could be lost in high sulfur coal producing areas, and that the potential impact on the coal industry could be up to \$10 billion.

Testifying before the Senate Committee on Environmental and Public Works, the chairman of the National Association of Manufacturers electricity task force claimed that proposed acid rain legislation could cost the utility industry up to \$40 billion by 1995, result in major job losses, and still not solve the acid rain problem (609). The NAM endorsed EPA Director William Ruckelshaus' proposal to increase acid rain research funding, and called for a closer look at the effect of electricity rate increases on industries which are heavy electricity users.

According to John Wooten, research director for Peabody Coal's parent firm, legislative proposals calling for 50% cuts in SO₂ emissions from midwestern utilities will actually reduce their contributions to acid deposits by only 10% (610). The finding resulted from a computer simulation of atmospheric chemistry processes, and refutes opinions in a report of the National Academy of Science. Further, according to Wooten, one current bill would cost electricity users more than \$100 billion.

However, the use of air-quality models has been challenged by Ralph Perhac, director EPRI's Environmental Assessment Department (605). According to Perhac, who cites a similar conclusion by the National Academy of Sciences, "present air quality models have an uncertainty factor that is too large to be useful for designing control strategies."

By a 24 to 10 vote, the National Governors Association called for a 5 million ton/yr cut in SO₂ emissions in the 31 states east of the Mississippi River (611). Under the plan, the reduction would be phased in during a six year period.

An EPA report showed that total U.S. SO₂ emissions were actually reduced by 26% between 1973 and 1982 (612). During the same period, utilities SO₂ emissions dropped by nearly 15%, while coal use rose almost 53%. The reductions were attributed to use of lower sulfur coal and compliance with new regulations.

Electric utility spending on pollution control topped all other industries in 1984 (613). A total of \$2.8 billion in expenditures was planned, down 22% from 1983's record \$3.6 billion. In 1985, pollution control spending of \$2.1 bil-

lion is planned. Air pollution control will account for nearly \$1.3 billion in 1984, while water pollution control equipment and solid waste control will consume \$700 million and \$314 million, respectively. Since 1967, the electric utilities have spent about \$33 billion on pollution control, including planned 1985 outlays.

During the period 1975-1982, U.S. air became significantly cleaner (614). According to Joseph Cannon of EPA, the improvement figures included 33% for SO₂, 31% for carbon monoxide, and 15% for particulate matter.

The Tennessee Valley Authority staff recommended approval of a \$35 million contract to Combustion Engineering, Incorporated, for development of boiler technology regarded as a potential solution for acid rain and other power-generation problems (615). The boiler uses fluidized-bed combustion of coal with limestone injection to help remove sulfur during combustion. Currently, more-expensive scrubbers are used to remove sulfur from smoke. The boiler also operates at lower temperatures than conventional boilers, so that nitrous oxide emissions are reduced.

In September, a similar contract was awarded to Pyropower Corporation of San Diego by the Colorado-Ute Electric Association. The project is also being supported by EPRI and the coal industry. A 30 year old coal unit is being converted to fluidized bed combustion by Northern States Power Company, in Minneapolis, in a project with Foster-Wheeler.

Representatives John Serberling and Dennis Eckart of Ohio announced a bill that would attempt to fashion a political consensus on acid rain (614). The bill calls for a 10 million ton annual reduction of SO₂ emissions by no later than 1996. Also, there would be Federal controls on the 50 largest electrical power plant emitters. A trust fund for emission controls would be financed by an indexed 1.5 mill/kWh fee of electricity from nonnuclear power plants and nondomestic sources.

New York State lawmakers approved a bill which, if signed by the governor, would make the state the first in the nation to take anti-acid rain measures at the state level (616). The bill, contingent on the absence of a Federal enactment, would reduce New York's emissions by 12%, or 100,000 ton/yr, by 1988, and by an additional 18% in the early 1990's.

The "Acid Rain Panel Report," a study sponsored by the White House, was criticized by both proponents and foes of increased acid rain control measures (617). The report was written by a panel of U.S. and Canadian scientists and engineers. Both the Edison Electric Institute and the EPA charged that the panel exceeded its mandate by commenting, speculating, and drawing conclusions. Concluding that the Federal government's acid rain research program has been a disappointment, the report called for measures to reduce SO₂ and NO_x emissions. The report also recommended that funding should be increased and that future research should be shifted to nonfederal laboratories. Creative, innovative, and potentially low cost approaches to acid rain control were given a high priority.

Canada doubled its commitment to reducing the acid rain problem, pledging to reduce sulfur dioxide emissions by 50%, instead of the earlier-announced 25%, by 1994 (618). Individual provinces will decide how best to implement controls in their regions. Companies most affected will be Inco, whose Sudbury plant is the largest SO₂ emitter in North America, Noranda Mines, and Ontario Hydro, Ontario's electric utility.

A strong diplomatic protest was delivered by the Canadian government to the State Department against U.S. failure to seek air pollution measures (619). Canada's ambassador stated that the intent was to convince Washington that acid rain was the most important issue between the two countries, threatening to raise "high level concerns" among Canadians.

A recent book, "The Secret Alliance," provoked considerable reaction by accusing Canadian officials of lobbying for U.S. acid rain legislation to allow Canada to increase electricity exports (620). The U.S. and Canada have

exchanged electricity since 1901, although the amount exchanged was small. In 1968, the U.S. was a net exporter of electricity to Canada. However, the exchange balance shifted heavily in the 1970's, as U.S. imports of Canadian electricity burgeoned. Between 1976 and 1982, net U.S. imports rose by 240% from 9,214 to 31,371 GWH.

Susan E. Morris

David P. Wilkinson

The following students were awarded Energy Research Summer Fellowships for the summer of 1985. Each Award carried with it a grant of \$2000.

Mr. Mark R. Deakin, of Indiana University, Bloomington, Indiana.

Mr. Phelps B. Johnson, of the University of Wisconsin, Madison, Wisconsin.

Ms. Debbie A. LaHurd, of the University of Akron, Akron, Ohio.

Ms. Susan E. Morris, of the University of Illinois, Urbana, Illinois.

Mr. David P. Wilkinson, of the University of Ottawa, Ottawa, Ontario, Canada.

The Energy Research Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need. They are made to graduate students pursuing work between the degrees of B.S. and Ph.D., in a college or university in the United States or Canada." The recipients' projects are in fields relating to energy research or of interest to The Electrochemical Society. The Awards are sponsored by the U.S. Department of Energy and are made by the Summer Fellowship Committee of The Electrochemical Society.

Mark R. Deakin was born in Painesville, Ohio, and he received B.S. degrees in Geology and in Chemistry from Florida State University, Tallahassee, Florida, in 1977 and 1982, respectively. He is currently working toward receiving his Ph.D. degree in analytical chemistry at Indiana University.

Deakin's research background includes work on electron transfer at microelectrodes, electrochemical kinetics at carbon electrodes, surface-enhanced Raman spectroscopy, and the electrochemistry of ligated metalloporphyrins. He has published his work in *Analytical Chemistry*, *Journal of Electroanalytical Chemistry*, *Inorganic Chemistry*, and other leading journals.

Mr. Deakin's report appears below.

Quasi-Reversible Electron Transfer at Microcylinder Electrodes

Over the last few years, the availability of very thin conductive fibers, wires, and films (thicknesses on the micron and submicron scale) along with improvements in amplifiers necessary for low current measurement, has led to the development of ultramicroelectrodes (1). These electrodes have been employed in such diverse areas as neurochemistry (2-4), liquid chromatography (5), and stripping voltammetry (6).

The small size of these structures separates them in several respects from conventional electrodes. Microdisk electrodes, for example, are characterized by extremely

small currents. The result is a very small RC time constant for the electrochemical cell and the near elimination of uncompensated voltage drop between the reference and working electrodes (7, 8). Another difference relates to diffusion to these small structures. During a conventional electrochemical experiment in a stagnant solution, the diffusion layer thickness is expected to exceed the width of the electrode. Nonlinear diffusion profiles result (9, 10). Since this leads to higher current densities than observed at conventional planar electrodes, the opportunity exists for near-steady-state measurements of electrochemical kinetics without forced solution convection. Indeed, several authors have explored this possibility at microdisk electrodes (11-13). However, only the case of reversible electron transfer has been treated at microcylinder electrodes (14).

Experimental

All compounds were reagent grade and used as received. Tetraethylammonium perchlorate (TEAP) was obtained from GFS Chemicals (Columbus, Ohio). Solutions were prepared from doubly distilled water and degassed with ultrahigh purity nitrogen before use. A platinum button electrode (Bioanalytical Systems, Purdue, Indiana) with an area of 0.0258 cm² was employed as a conventional planar electrode. A platinum wire electrode [construction described in Ref. (10)] with a radius of 5 μm and a length of 510 μm was employed as a microcylinder electrode. Cyclic voltammetry was performed with a Princeton Applied Research Model 174A potentiostat. A three-electrode cell with a platinum auxiliary and SSCE reference was used. All potentials are reported vs. SSCE.

Digital simulations of cyclic voltammograms at cylinders were performed on an IBM PC equipped with a 8087

numeric coprocessor. The algorithm employed is most fully discussed in Ref. (15).

Theory

The diffusion equation for a cylinder of radius r_0 , ignoring the ends of the cylinder, is

$$\frac{\partial C_A}{\partial t} = D \left[\frac{\partial^2 C_A}{\partial r^2} + \frac{1}{r} \frac{\partial C_A}{\partial r} \right] \quad [1]$$

Assuming the reaction $A + e^- \rightarrow B$ and the equality of the diffusion coefficients for A and B, the boundary conditions are

$$t = 0, r \geq r_0 : C_A = C^0 \quad [2]$$

$$t > 0, r \rightarrow \infty : C_A \rightarrow C^0 \quad [3]$$

$$t > 0, r = r_0 : i = nFAD(\partial C_A / \partial r)_{r_0} \quad [4]$$

where

$$i = nFA[k^0 \exp(\alpha\xi)] \{ C_A^{r_0} - C_B^{r_0} \exp(-\xi) \} \quad [5]$$

$$\xi = [(-nF)/(RT)](E - E^0) \quad [6]$$

The use of dimensionless variables simplifies the solution of Eq. [1] considerably. As is shown elsewhere (15), the diffusion equation can be reduced to the following form with the proper selection of variables

$$\frac{\partial a}{\partial \tau} = [\exp(-\beta y)] \frac{\partial^2 a}{\partial y^2} \quad [7]$$

where the dimensionless variables are defined as

$$a = C_A / C_A^0 \quad [8]$$

$$\tau = (nFvt)/(RT) \quad [9]$$

$$y = [(nFvr_0^2)/(DRT)]^{1/2} \ln(r/r_0) \quad [10]$$

$$\psi = i[(DRT)/(nFv)]^{1/2} / (nFAC_A^0 D) \quad [11]$$

$$\Lambda = k^0[(RT)/(nFvD)]^{1/2} \quad [12]$$

$$\beta = 2[(DRT)/(nFvr_0^2)]^{1/2} \quad [13]$$

Where β is a dimensionless cylindrical factor which is a function of both the electrode radius and time. Thus, the new boundary conditions are

$$\tau = 0, y > 0 : a = 1 \quad [14]$$

$$\tau > 0, y \rightarrow \infty : a \rightarrow 1 \quad [15]$$

$$\tau > 0, y = 0 : \left[\frac{\partial a}{\partial y} \right]_0 = \Lambda [\exp(\alpha\xi)] \{ 1 - (1 - a_0)[1 + \exp(-\xi)] \} \quad [16]$$

For large values of β , it is possible to solve Eq. [7], for cyclic voltammetry, in the Laplace plane. For the electrochemically reversible case, the solution is given by Aoki *et al.* (14). For the more general case, with quasi-reversible or irreversible charge transfer, the following solution by Amatore *et al.* (15) is applicable

$$\frac{i}{i_{lim}} = \left\{ 1 + \exp(-\xi) + \frac{1}{\Lambda^*} \exp(-\alpha\xi) \right\}^{-1} \quad [17]$$

$$\Lambda^* = \frac{2\Lambda \ln \beta}{\beta - 1.1(\beta/\ln \beta)} \quad [18]$$

where i_{lim} is given in Ref. (10).

As β decreases toward zero, the problem reduces to the case of linear diffusion. The region intermediate between linear diffusion and the solution of Amatore is best resolved by digital simulation. For this reason, a finite difference approach was applied to Eq. [7].

Results

A finite difference method with an exponentially expanding grid, as described in Eq. [10], was employed. Hopscotch, an algorithm described by Gourlay (16) and previously employed by Shoup and Szabo (17), was used

to decrease memory requirements and to lower computation time. This method is fully explicit and unconditionally stable. The quantity $\Delta\tau/(\Delta y)^2$ may increase beyond the conventional limit of 0.5 and take any value. This combination of an exponential grid and a Hopscotch algorithm allowed the calculation of voltammograms on a microcomputer (IBM PC), with less than 0.01% error, in less than 10 min. The current was calculated from the concentration profile at the electrode surface using a three-point approximation of $\partial a/\partial y$

$$\psi_1 = \{(-3/2)a_0 + 2a_1 - a_2/2\}(\Delta y)^{-1} \quad [19]$$

The validity of the simulation was tested both by comparison of reversible simulations with the result of Aoki (14) and by comparison of quasi-reversible simulations with the limiting case described in Eq. [17]-[18]. Less than 0.01% error was found with a $\Delta\tau$ value of 0.005.

The simulation shows that, as β approaches infinity, the cyclic voltammogram tends to the sigmoidal shape described in Eq. [17]. Thus, a quasi-steady state is achieved at electrodes of small radius and at long times. Under these conditions, a measurement of the peak potential is difficult, especially if the background current varies with potential. Thus, the traditional measurement of ΔE_{peak} is not a reliable indication of the rate of electron transfer. A better parameter is the shift of the half-peak potential, $E_{p/2}$, away from E^0 . The variation of the dimensionless half-peak potential, $\xi_{p/2}$, with the dimensionless kinetic parameter, Λ^* , is shown in Fig. 1. At small radii cyl-

Fig. 1. Variation of the dimensionless half-peak potential with the kinetic parameter, Λ^* . Values taken from simulated voltammograms with $\beta > 100$ (solid line) and $\beta = 10$ (broken line). The circles represent points taken from experimental voltammograms in Fig. 2.

Fig. 2. Experimental voltammograms obtained at a platinum microcylinder with a radius of $5 \mu\text{m}$. Scan speeds of $0.01 \text{ V}\cdot\text{s}^{-1}$ (a, b) and $0.10 \text{ V}\cdot\text{s}^{-1}$ (c, d). Supporting electrolytes: 0.1M TEAP (a, c) and 1.0M NaCl (b, d). Current density bar equals $2 \times 10^{-4} \text{ A}\cdot\text{cm}^{-2}$.

Table I. Comparison of the apparent rates of heterogeneous electron transfer determined by cyclic voltammetry at a planar electrode and quasi-steady-state voltammetry at a microcylinder electrode

Supporting electrolyte	E^0 (V vs. SSCE)	k^0_{planar} ($\text{cm}\cdot\text{s}^{-1}$)	k^0_{cyl} ($\text{cm}\cdot\text{s}^{-1}$)
1.0M NaCl	0.224	$\sim 5 \times 10^{-2}$	^a
0.1M TEAP	0.118	3.0×10^{-3}	3.6×10^{-3}

^a Measurement not possible; see text.

inders and at long times ($\beta > 100$), the curve coincides with the theory presented in Eq. [17]. When β takes an intermediate value there is some deviation from theory, but the overall trend is preserved.

Experimental voltammograms recorded at a platinum microcylinder with a radius of $5 \mu\text{m}$ are shown in Fig. 2. The oxidation of $\text{Fe}(\text{CN})_6^{4-}$ is depicted at two scan rates and with two different supporting electrolytes. The rate constant for this oxidation is known to depend on the type and concentration of the supporting electrolyte employed (18).

At planar electrodes, conventional voltammetric curves are observed. From measurements of the peak potentials, the values for the formal potential and the apparent rate constant shown in Table I are obtained. At microcylinder electrodes, peak potential measurements become unreliable as the system tends toward polarographic behavior. Therefore, for the microcylinder, the half-peak potential and the curve in Fig. 1 were used to obtain values for the apparent rate constant. The results are shown in Fig. 1 and Table I.

It is apparent from Fig. 1 that the lack of variation in $\xi_{p/2}$ at larger values of Λ^* limits the quasi-steady-state measurement of k^0 to relatively slow rates of electron transfer. Quantitation of the rate for ferrocyanide oxidation in 1.0M NaCl is not possible with a $5 \mu\text{m}$ electrode using the quasi-steady-state method. Theoretically, this rate could be measured with a thinner electrode. Construction of a cylinder electrode with a $1 \mu\text{m}$ radius may be possible, but that is probably the experimental limit. Cylinders of smaller radius will not support themselves in solution.

Assuming that an electrode with a radius of $1 \mu\text{m}$ could be constructed, and taking a lower limit of $0.02 \text{ V}\cdot\text{s}^{-1}$ for the scan speed, a diffusion coefficient of 1×10^{-5} gives an upper limit on β of 72. Thus, if a 0.01 V shift in $E_{p/2}$ is sufficient for a rate measurement, then the maximum rate that can be quantified is about $3.5 \times 10^{-2} \text{ cm}\cdot\text{s}^{-1}$. Unfortunately, this analysis shows that the quasi-steady state at cylinders is only useful for measuring rates which are already easily obtained at conventional planar electrodes. For the quasi-steady-state method to become useful, the radius of the effective cylinder must be significantly reduced. This is possible with construction of thin line electrodes (19). Thin films of metals have already been used for this purpose. Using this technique, the effective radius of the electrode can be decreased by at least two orders of magnitude (19). This should allow quasi-steady-state measurement of significantly faster rates. The theory for diffusion to these microline structures is a more complex problem than the microcylinder discussed above. However, simulation of the problem is possible and is now under study.

Acknowledgment

The support of The Electrochemical Society and the U.S. Department of Energy is gratefully acknowledged.

Mr. Johnson's report appears below.

Stabilization and Photoluminescent Characterization of n-GaP/n- GaAs_{0.4}P_{0.6} Strained-Layer Superlattice Electrodes

The variety of electronic materials amenable to photoelectrochemical characterization is increasing owing to developments in semiconductor growth and device technology. Strained-layer superlattices (SLS's) are a class of materials of potential interest to photoelectrochemists (1, 2). Created by the deposition of alternating thin (40-300Å) layers of two lattice-mismatched semiconductors, SLS's afford the opportunity to study carrier quantization effects, produced by variations in the conduction and valence band offsets (3), and the influence of the terminating (surface) layer composition on electrodes with identical bulk properties.

In this report, we discuss the stabilization against photoanodic corrosion, photoelectrochemical cell (PEC) properties, and photoluminescence (PL) of n-GaP/n-GaAs_{0.4}P_{0.6} SLS electrodes. In particular, we demonstrate that thin (0.37-0.75 μm) SLS structures can be stabilized in PEC's employing aqueous ditelluride electrolyte to yield monochromatic optical-to-electrical energy conversion efficiencies of a few percent. Also, field-induced PL quenching studies on the SLS electrodes are in approximate accord with a dead-layer model (4) previously applied to homogeneous and isotype heterojunction electrodes (5, 6). Some of these results are detailed in a recent publication (2).

The SLS's were grown at Sandia National Laboratories by the metalorganic chemical vapor deposition technique (7-9). Prior to the deposition of the SLS layers, a $1.2 \mu\text{m}$ thick ($1.5 \mu\text{m}$ for SLS-957) graded buffer layer, terminating in a composition of GaAs_{0.2}P_{0.8}, was grown on a GaP substrate. This was followed by alternating layers of

GaP and $\text{GaAs}_{0.4}\text{P}_{1-x}$, terminating in the alloy layer. Four samples were studied, one with $x = 0.39$ and fifty 150Å thick layers (SLS-957), another with $x = 0.43$ and thirty 125Å thick layers (SLS-471), a third with $x = 0.41$ and thirty 200Å thick layers (SLS-472), and the fourth with $x = 0.39$ and thirty 140Å thick layers (SLS-473). Samples were nominally undoped and were not etched prior to use. Telluride electrolyte, synthesized as described previously, had a composition of 7.5M KOH/0.2M ($\text{Te}^{2-} + \text{Te}_2^{2-}$) (10). Potentiostatic experiments were conducted with a standard three-electrode setup, and samples were mounted as previously described (11). The instrumentation and techniques used in PEC and PL quenching experiments have also been described (2, 12).

A 5.5h stability experiment was conducted on SLS-472 at -1.0V vs. SCE with 458 nm excitation. The $\sim 0.8\text{C}$ passed through the $\sim 0.06\text{ cm}^2$, $0.6\text{ }\mu\text{m}$ thick illuminated area was several times the amount required for total SLS decomposition, assuming a photoanodic decomposition stoichiometry of six moles of holes per mole of crystal. Adequate stability was indicated by a modest 7% decline in the initial current density of 0.7 mA/cm^2 , and the unchanged PL quenching behavior of the SLS (*vide infra*). An upper limit to photocurrent density was not firmly established, although $\sim 5\text{ mA/cm}^2$ resulted in the decomposition of SLS-473, as evidenced by loss of the SLS PL and visible damage to the illuminated portion of the electrode.

The bottom panel of Fig. 1 shows a current-voltage (*i-V*) curve for SLS-957, obtained with 488 nm excitation. Such *i-V* curves indicate that SLS-based electrodes have fairly modest optical-to-electrical energy conversion efficiencies. A summary of *i-V* results on SLS-471 and SLS-472 is given in Table I. Sample-to-sample variations in maximum energy conversion efficiency with 473 nm excitation ranged from 2 to 4%. The sharp decline in photocurrent quantum efficiency and maximum energy conversion efficiency with increasing optical penetration depth is attributed to the presence of hole barriers in the valence band perpendicular to the surface of the SLS, limiting the contribution of excess carriers generated in the neutral region to the photocurrent. Small hole diffusion lengths ($\sim 0.1\text{ }\mu\text{m}$) have been reported for GaP/GaAs_{0.2}P_{0.8} SLS's (13).

A photoaction spectrum is shown in Fig. 2 for SLS-957 in telluride electrolyte. Photoaction spectra were studied

Fig. 1. Photocurrent (bottom panel) and PL intensity (top panel) for the SLS-957 electrode as a function of potential in a PEC employing 7.5M KOH/0.2M ($\text{Te}_2^{2-} + \text{Te}^{2-}$) electrolyte; PL intensity was monitored at 610 nm for two consecutive cycles, averaged, and smoothed. The electrode ($\sim 0.10\text{-cm}^2$ illuminated area) was excited with 488 nm light from a beam-expanded Ar⁺ laser. Both curves were swept simultaneously at 5 mV/s. The electrolyte redox potential, -1.18V vs. SCE , defines the short-circuit potential.

Table I. Optical-to-electrical energy conversion by GaAs_{0.4}P_{0.6}/GaP SLS photoelectrodes in (di) telluride electrolyte^a

in both selenide and telluride electrolyte, and were found to be insensitive to the different redox potentials of the solutions. Spectra exhibit a potential dependence, with the relative response to near-bandgap excitation enhanced by biasing the electrode further into depletion. The photocurrent onset at $\sim 620\text{ nm}$ is slightly potential dependent, but corresponds approximately to the bandgap of the SLS, 2.04 eV from uncorrected 295 K PL.

A study of the weak 295 K PL of these SLS electrodes has shown that, at low resolution, only the PL intensity, and not the spectral distribution, is perturbed by applied potential. The top panel of Fig. 1 shows the PL quenching behavior of SLS-957 excited with 488 nm light. The observed PL quenching of SLS electrodes is in rough accord with the dead-layer model. The quantitative form of this model is given by Eq. [1], where D is the change in dead-layer thickness over the experimental voltage thickness

$$D = (-1/\alpha) \ln(\text{PL}/\text{PL}_{oc}) \quad [1]$$

where α is the absorptivity of the SLS for the excitation

Fig. 2. Relative photocurrent quantum efficiency for SLS-957 in telluride electrolyte at -1.0V vs. SCE . The excitation was chopped, and lock-in techniques used to monitor the photocurrent. The spectrum is corrected for the wavelength dependence of the lamp/monochromator excitation source and is uncorrected for sample reflectivity.

wavelength¹ and PL and PL_{oc} are the in-circuit and open-circuit PL intensities, respectively. Consistent *D* values were obtained for SLS-472 at -1.0V vs. SCE: 260, 290, and 280Å, corresponding to 413, 458, and 473 nm excitation, respectively. Luminescence from an unassigned deep level (uncorrected λ_{max} ~ 780 nm) did not exhibit quenching.

In summary, n-GaP/n-GaAs_{0.4}P_{0.6} SLS electrodes have been stabilized in aqueous telluride electrolyte. Energy conversion efficiencies of these electrodes are modest, because, in part, of small hole diffusion lengths perpendicular to the SLS layers. Studies of SLS structure and surface composition influences (*i.e.*, GaP or alloy terminating layer) upon cell photovoltage and conversion efficiency are currently in progress.

DEHAC04-76DP00789 is gratefully acknowledged.

¹To estimate α , we used the absorption curve in Ref. (14), Fig. 4. We shifted this curve (presented for a n-GaP/n-GaAs_{0.44}P_{0.56} SLS with 30 alternating 180Å thick layers and $E_g = 1.92$ eV) 0.07 eV to correspond to our observed PL peak at 1.99 eV. This yields α of 2.7×10^4 , 4.1×10^4 , 4.9×10^4 , 7.4×10^4 , and 1.0×10^5 cm⁻¹ for 514, 502, 488, 473, and 458 nm excitation, respectively. An α value of 1.8×10^5 at 413 nm was estimated by extrapolating the SLS curve parallel to the GaAs absorption curve, which has been shifted to the SLS bandgap in the above-mentioned figure.

Simplified Models for Use in Electrochemical Reactor Scale-Up and System Studies

Electrochemical reactor design is, at best, an empirical art owing to the large number of design parameters and their complex interactions. The scale-up from laboratory designs could be expedited by the use of an appropriate mathematical model. Such models use assumptions to simplify the phenomena into a workable set of equations which can predict the relative importance of the kinetics, mass transfer, and ohmic contributions. Numerous mathematical models are available in the literature (1-4), but many of these are cumbersome and expensive to use because their specific nature requires the use of time-consuming complex numerical procedures to obtain a solution. The goal of this research is to develop a simplified model which may be applied to a large number of electrochemical reactors to predict their performance. The verification of this model begins by comparing its predictions with more rigorous model predictions.

Flow electrochemical reactors often utilize two or more redox couples, and some include a membrane separator. The following represents an example of redox reactions occurring at the electrodes of an electrochemical reactor

A general model must be able to incorporate side reactions which occur at an electrode surface. Reaction [3] of the above example can be considered to be a side reaction occurring at the cathode. Many systems require membranes to separate the species by discouraging a chemical discharge reaction. Additionally, many flow electrochemical reactors use high surface area porous electrodes to reduce kinetic and mass-transfer limitations. The porous electrodes can generate up to half of the total cell pressure drop (5), thus reducing the electrical efficiency. Furthermore, porous electrodes are often nonuniform, which causes uneven flow distribution in multiple cell stacks. This modeling effort is uniquely suited to evaluate different types of uniform turbulence promoters which increase mass transfer while effecting a small hydraulic pressure drop. For the purposes of comparison, the model is evaluated by applying it to the iron-chrome energy storage system developed by the NASA-Lewis Research Center (6).

The VOLBAL model has been developed for a single cell and is a one-dimensional simulation easily modified for different flow characteristics (*i.e.*, planar electrode flow or porous electrode flow) by way of the mass-transfer coefficient. The model can be verified experimentally for different flow configurations and different cell sizes or by comparison with a more rigorous model. The purpose of this paper is to present the results of comparing VOLBAL with a more rigorous two-dimensional model developed by White and others at Texas A&M University (1, 7). The White model was developed for channel flow and has been modified for membrane separation of the half-cells (7). Their model also accounts for the effects of migration and multiple reactions.

Model Development

The VOLBAL model.—The VOLBAL model is based upon the overall local voltage balance across a single cell. The mathematical model is simplified by allowing the concentration and current density to vary in only one direction. This model takes into account mass-transfer effects by introducing a correlation for the mass-transfer coefficient such as the Leveque approximation (8). The

assumptions used in the development of the VOLBAL model are: (i) isothermal conditions exist; (ii) there exists one-dimensional variation in concentration and current density; (iii) gas generation effects are ignored; (iv) physical and transport properties are constant; (v) there is a well-developed laminar flow; (vi) a mass-transfer coefficient was used to predict the mass-transfer effects of planar electrodes; (vii) no heterogeneous or homogeneous chemical reactions occur; (viii) steady-state conditions exist; and (ix) for each half-cell, the reference electrode reaction is the same reaction as the main reaction at the electrode and the reference electrode concentrations are the same as the reference concentrations.

The overall cell potential is the difference between the anode potential and the cathode potential. A schematic of the cell is shown in Fig. 1. Imaginary reference electrodes are placed across the cell in order to divide the overall cell potential into components due to concentration gradients, reaction kinetics, and contributions due to resistances associated with electrolytes in the cell cavities and the membrane. The difference in potential due to concentration gradients and ohmic resistances can be expressed in terms of the concentration overpotential

$$\begin{aligned} \nu_c &= \Delta\phi - \Delta\phi_{IR} \\ &= \frac{RT}{nF} \sum_i S_i \ln \left[\frac{C_{i,bulk}}{C_{i,s}} \right] \end{aligned}$$

where η_c is the concentration overpotential, $\Delta\phi_{IR}$ is the ohmic potential drop, and $\Delta\phi$ is the potential difference between two reference electrodes. The concentrations $C_{i,bulk}$ and $C_{i,s}$ are the bulk and surface concentrations of species i , respectively. Substituting these expressions into the overall cell voltage balance, the following function of bulk and surface concentrations is obtained

$$\begin{aligned} U &= \phi_a - \phi_1 + \frac{2RT}{F} \ln \left[\frac{C_{Fe^{2+},bulk} C_{Cr^{3+},bulk}}{C_{Fe^{3+},bulk} C_{Cr^{2+},bulk}} \right] \\ &+ \frac{RT}{F} \ln \left[\frac{C_{Fe^{3+},s} C_{Cr^{2+},s}}{C_{Fe^{2+},s} C_{Cr^{3+},s}} \right] + \Delta\phi_{IR} \\ &+ V_{formal} + \frac{RT}{F} \ln \left[\frac{C_{Cr^{2+},ref} C_{Fe^{3+},ref}}{C_{Cr^{3+},ref} C_{Fe^{2+},ref}} \right] + \phi_6 - \phi_c \end{aligned}$$

The above equation, in dimensionless form, forms the basis of the VOLBAL model. Full Butler-Volmer kinetic expressions are used to evaluate the potential contributions ($\phi_a - \phi_1$) and ($\phi_6 - \phi_c$). The species concentrations are determined using material balances and reaction stoichiometry. The solution technique requires the assumption of an initial current-density distribution to calculate the

$$\begin{aligned} U &= \phi_A - \phi_C = \\ &\phi_A - \phi_1 + \phi_1 - \phi_2 + \phi_2 - \phi_3 + \phi_3 - \phi_4 + \\ &\phi_4 - \phi_5 + \phi_5 - \phi_6 + \phi_6 - \phi_C \end{aligned}$$

Fig. 1. Schematic of reactor used in the development of the VOLBAL model.

bulk and surface concentrations along the electrode. The calculated concentrations are used to estimate a new current-density distribution. Iterations continue until the new current distribution agrees with the previous values to within three decimal places.

Rigorous model.—The more rigorous model formulated by White is based upon a steady-state material balance for each species [See Ref. (1) for a full development]

$$\nabla \cdot \text{Ni} = 0$$

The model also assumes a small aspect ratio (ratio of the cell gap between the electrodes to the cell length). The resulting system of partial differential equations can be solved for the values of the concentration of species and the potential. The solution technique involves using Newman's technique (BAND) (8) in the normal direction (y) and employing an implicit finite difference technique in the direction parallel to the electrode length. This method yields a two-dimensional field of concentration and potential. The model incorporates a membrane separator through the use of the MacMullin number, which is the ratio of the membrane resistance to the resistance of an equal area of electrolyte. Perhaps the most important difference between the White model and the VOLBAL model is that the former considers well-developed laminar flow and cannot account for other types of mass transfer, such as entrance effects and use of turbulence promoters.

Both models incorporated the hydrogen side reaction into the Butler-Volmer kinetic expression for the cathode. The general kinetic expression as given by White *et al.* (9) can be written as

$$\begin{aligned} i &= i_0 \left\{ \exp \left[\frac{\alpha a F}{RT} \eta_{sj} \right] - \exp \left[\frac{-\alpha c F}{RT} \eta_{sj} \right] \right\} \\ \eta_{s,j} &= V - \phi_0 - U_{j,0} \end{aligned}$$

The final form of the kinetic expression for the side reaction becomes

$$\begin{aligned} i_{H^+} &= i_0 \left\{ \exp \left[\frac{\alpha a F}{RT} (\phi_c - \phi_6 - U_{j,ref}) \right] \right. \\ &\left. - \exp \left[\frac{\alpha c F}{RT} (\phi_c - \phi_6 - U_{j,ref}) \right] \right\} \end{aligned}$$

where

$$\begin{aligned} U_{j,ref} &= U_j^\theta - \frac{RT}{n_j F} \sum_i S_{ij} \ln \left[\frac{C_{i,ref}}{\rho^\circ} \right] - U_{RE}^\theta \\ &+ \frac{RT}{n_{RE} F} \sum_i S_{i,RE} \ln \left[\frac{C_{i,RE}}{\rho^\circ} \right] \end{aligned}$$

This is the same form for the hydrogen reaction as was used by Trainham and Newman (10).

Parameter values.—The predictions of the two mathematical models were compared by applying them to the NASA redox cell. During charge, in the positive half-cell, ferrous ion is oxidized to ferric ion. In the negative half-cell, chromic ion is reduced to chromous ion with some inefficiencies due to proton reduction. The values of the parameters used in calculations with both models are shown in Table I. A membrane resistance of $0.6 \Omega\text{-cm}^2$ is equivalent to a MacMullin number of 3. The simulations appear to incorporate different values for the open-circuit potentials of the electrode with respect to the reference electrode, $U_{j,ref}$. The White model assumes a common reference electrode in both half-cells: the hydrogen reference electrode. VOLBAL assumes that the reference electrode in each half-cell is based on the same reaction as the main reaction occurring at the electrode. This was done to simplify the overall cell voltage expression. The values of $U_{j,ref}$ for VOLBAL are zero for reactions [1] and [2], while the hydrogen side reaction value is given with respect to a chrome reference electrode. The exchange cur-

rent densities are considered valid for solutions containing 0.45M chrome species and 0.55M iron species at 25°C (11).

Results and Discussion

The predictions of the White and VOLBAL models are compared. In these studies, the VOLBAL model required about nine to ten times less cpu time (IBM 3033U Operating System) than the more rigorous two-dimensional model for three significant digit accuracy. The time savings make the simplified model more attractive for incorporation into multicellular stacks and for optimization studies.

The models have been compared for their predictions of performance after cell scale-up, specifically varying the length of the electrode. The effects of electrolyte velocity as well as the predictions at different states of charge were also compared.

In the comparison of the VOLBAL model and the rigorous White model, the following quantities and their method of calculation should be clarified. The current density calculations are based upon Butler-Volmer kinetics, which allows the current densities predicted by each model to be compared. The bulk concentration predicted by the White model is a "mixing cup" concentration in that the predicted concentrations across the cell are weighed by the velocity and are integrated to generate the average bulk concentration. This effect is similar to the bulk concentration achieved by collecting the electrolyte flowing from a cell and then mixing it well. The VOLBAL model assumes two distinct regions across the gap: the bulk solution and diffusion layers where the concentration variation occurs. Since the diffusion layers are assumed to be very thin, the bulk concentrations of the White model should be comparable to the bulk concentrations calculated by the VOLBAL model. The surface concentrations predicted by VOLBAL depend on the value of the mass-transfer coefficient, whereas the White model solution technique yields concentrations across the cell, including the surface concentration. The reactant species considered in the interpretation of the results is the ferrous ion. The convergence per pass (CPP) of the ferrous species is a measure of the amount of this reactant consumed during one pass through the cell. Through Faraday's law, it is proportional to the total current delivered to the cell. The CPP is obtained by subtracting the di-

Fig. 2. Calculated anodic and cathodic (main reaction only) current densities at 50% state of charge and $L = 31$ cm.

mensionless bulk concentration at the cell outlet from the dimensionless feed concentration.

Figure 2 shows the predicted current density distribution along the length of the electrode. In this comparison, the electrode length was 31 cm and the solution velocity was 3.0 cm/s. The electrolyte composition corresponds to a 50% state of charge. We found that better agreement in predictions of current density between the two models occurs with larger systems. In this instance, the White model predicts a 23% larger average current density compared to the VOLBAL model. The CPP for the VOLBAL model was 3.2%, and the White model calculated a value of 4.2%. This reflects the differences in the predicted total charging current between the two models.

In order to adjust the VOLBAL model to predict the same average current density as the White model, the mass-transfer coefficient was multiplied by a factor of 1.4. The increased mass-transfer coefficient predicts a current density distribution identical to the White model. The bulk concentrations along the electrode predicted under the three modeling conditions are compared in Fig. 3. The bulk concentration distributions simulated by the VOLBAL model with a modified mass-transfer coefficient closely approaches the White model predictions. In this case, the CPP of the VOLBAL is 4.1%.

The coulombic efficiency predicted by the mathematical models reflects the occurrence of the hydrogen side reaction. Under the conditions reported above, the VOLBAL model calculated a 99.16% coulombic efficiency, while the White model predicted a coulombic efficiency of 99.2%. The calculations using the VOLBAL model with the adjusted mass-transfer coefficient predict a coulombic efficiency of 99.4%. The efficiency increased because of the larger mass-transfer coefficient, which represents an increase in the transport of the chromic reactant to the surface. The larger surface concentration of chrome

Fig. 4. Anodic current density predictions for 50% state of charge and $L = 5$ cm.

reactant produces a larger overall current density, while the side reaction contribution remains the same.

A cell with an electrode length of 5 cm at 50% state of charge (still with 3.0 cm/s average electrolyte velocity) was simulated next. Figure 4 shows the predicted current density distributions along the length of the electrode. The model predictions for average current density differ by 28% for the small cell. This was expected, since larger gradients will occur in shorter cells. The coulombic efficiencies are identical for both models, at 99.5%. Although the current densities are generally larger for smaller cells, the shorter electrodes mean less area available for reaction and thus a decrease in CPP. The VOLBAL model calculates a CPP value of 0.79%, while the White model prediction is 1.13%.

Lowering the flow rate to 1.6 cm/s while keeping the other conditions constant results in an increase in CPP because more reactant can be consumed at the electrode surface before leaving the cell. The CPP value calculated by the VOLBAL model is 1.3% and by the White model is 1.8%. A lower flow rate also results in a small decrease in coulombic efficiency, 99.4%. Figure 5 shows the bulk concentration distributions simulated by the two models under these conditions.

In general, the more rigorous model predictions of current density are larger than those predicted by the VOLBAL model. The rigorous model accounts for effects of migration while VOLBAL does not, but migration in redox systems generally would cause an effect of only 10% or less (8). In comparing the calculations of the two models, the surface concentrations of the reacting species predicted by the rigorous model are less than those predicted by the VOLBAL model. However, the surface overpotential values calculated by the rigorous model are greater than those of the VOLBAL model. In the Butler-

Fig. 5. Model predictions of bulk solution concentration for iron species at 5% state of charge, $L = 5$ cm and average velocity 1.6 cm/s.

Fig. 6. Anodic current density predicted for 5% state of charge, $L = 31$ cm and average velocity 1.6 cm/s.

Volmer expression, the two effects tend to cancel, allowing for moderate agreement between the two models in predicting current density and bulk concentration distributions. An increase in mass-transfer coefficient in the VOLBAL model causes an increase in surface concentration and surface overpotential, thus resulting in a calculated increase in the current density.

The predictions of the models were compared for the 5% state of charge condition. In this case, the larger cell with 31 cm electrodes having a velocity of 1.6 cm/s was considered. The model predictions of current density distributions are shown in Fig. 6. For the 50% state of charge, the surface overpotential dominated. At 5% state of charge, the concentration overpotential is dominant. The differences in calculated surface concentrations between the two models cause this great disparity. There appears to be a significant boundary-layer effect under these conditions which we cannot explain at this time. Better agreement could probably be achieved if the position dependency of the local mass-transfer coefficient was further investigated.

Conclusions

The predictions of cell performance using the simplified VOLBAL model and a more rigorous model were compared. The VOLBAL model uses about nine to ten times less cpu time than the rigorous model on an IBM 3033U operating system. Comparisons show that the rigorous model generally predicts a higher current density. The model predictions are in closer agreement for large cells. Agreement between model predictions at extreme conditions (i.e., 5% state of charge) is poor, which can be attributed to disagreement between the calculated surface concentrations. Both models need rigorous testing against experimental observations.

Acknowledgments

The generous support of The Electrochemical Society through an Energy Research Summer Fellowship sponsored by the U.S. Department of Energy is gratefully acknowledged. I am grateful to Dr. R. E. White and Mike Mader of Texas A&M University for their modeling code. The help, support, and good-natured guidance provided by my advisor, Dr. Savinell, is deeply appreciated.

LIST OF SYMBOLS

$C_{i,bulk}$	bulk concentration of species i (mol/cm ³)
$C_{i,ref}$	reference concentration of species i (mol/cm ³)
$C_{i,RE}$	concentration of species i in reference electrode solution (mol/cm ³)
$C_{i,s}$	local surface concentration of species i (mol/cm ³)
d	the distance between the electrode and the membrane separator (cm)
D_i	diffusion coefficient of species i (cm ² /s)
F	Faraday's constant (96,487 C/mol)
i	current density (A/cm ²)
i_0	exchange current density (A/cm ²)

$i_{o,ref}$	exchange current density at reference concentrations (A/cm ²)
K_m	mass transfer coefficient (cm/s)
L	electrode length (cm)
n_j	number of electrons transferred in reaction j
R	universal gas constant (8.3143 J/mol-K)
s_{ij}	stoichiometric coefficient of species i in reaction j.
T	absolute temperature (K)
U	overall cell potential (V)
$U_{j,o}$	theoretical open-circuit potential for reaction j at the surface concentrations of species i which participate in reaction j (V)
$U_{j,ref}$	theoretical open-circuit potential evaluated at reference concentrations (V)
U_j^θ	standard electrode potential of reaction j (V)
V_{avg}	average velocity (cm/s)
z	charge number of species

Greek Symbols

α_a	anodic transfer coefficient
α_c	cathodic transfer coefficient
θ_o	solution potential adjacent to the electrode surface (V)
θ_i	reference electrodes; i = 1, 6.
θ_a	anode potential (V)
θ_c	cathode potential (V)

Susan E. Morris was born in Durham, North Carolina, in 1960. She received her B. S. degree in chemistry from Western Carolina University, Cullowhee, North Carolina, in 1981.

Morris is studying to gain a Ph.D. degree from the University of Illinois at Urbana-Champaign, and has been a Kodak Graduate Scholar.

Ms. Morris' report appears below.

O₂ Diffusion as a Probe of Fluidity in Polymer Films

Polymer films on electrodes provide a convenient narrowly defined spatial region in which redox centers may be immobilized for electrocatalysis or sensing of electrochemically inaccessible analytes. One of the considerations in the use of films is that three-dimensional dispersion within a polymer increases the amount of catalyst, by comparison with monolayer coverage of the electrode, increasing catalytic efficiency (or increasing signal, in the case of a sensor). Within the film, availability of substrate for reaction with the catalyst depends on both the ability of the substrate to partition into the film and to freely diffuse to catalyst centers. Most studies of charge and mass transport in films have focused on the electrochemical response of the catalyst, relying on its adherence to simple diffusion laws which were formulated for systems resembling dilute solutions. Enhancement of mass transport by charge transfer reactions is commonly evaluated using the Dahms-Ruff equation (1, 2)

$$D_{eff} = D_m + D_{ex} = D_m + (\pi/4) \delta^2 k C^*$$

where D_{eff} is the observed diffusion coefficient, D_m is the diffusion coefficient observed in the absence of charge

transfer, δ is the intersite charge transfer distance, and k is the charge transfer rate constant.

Difficulty in evaluation of these processes from the electrochemical response of the catalyst within the film using the Dahms-Ruff expression is twofold; both problems stem ultimately from the use of the catalyst as a probe which is inextricably involved with both transport processes and structure of the film. First, the catalyst is present in very high local concentration (catalyst loadings of 10^{-9} - 10^{-8} mol-cm⁻² in films of a few hundred angstroms thickness are common), often rivaling the electrolyte concentration in solution and certainly that within the film. Unavoidable convolution of diffusion and migration contributions to catalyst charge and mass transport result, ensuring that purely diffusional behavior in the film will not be observed. Perhaps more important is the problem created by the inclusion of the catalyst as an integral structural component of the film: stimuli (large amplitude potential steps, for example) which result in observable electrochemical responses should be reasonably expected to simultaneously affect film structure. The result will be time-dependent changes in film physical characteristics such as viscosity or film thickness, both of which will affect apparent diffusional behavior within the film.

A kinetic model for the processes occurring in or at catalyst-loaded films on electrodes has been developed by Andrieux *et al.* (3-5). Catalyst (or mediator) couple in film and oxidized and reduced forms of substrate are represented below

In the model, which was developed for steady-state techniques such as rotating disk voltammetry, the catalytic current may be studied via the use of closed-form equations which represent the catalytic current in terms of characteristic currents which are related to kinetic and mass transport limiting behaviors. Where $K (= k_1/k_2)$ is allowed to take any value, four cases have been identified; the present study utilizes a system of catalyst/substrate which corresponds to the true catalytic situation (Fig. 1). The component currents in which we are interested are i_A and i_s . It is the substrate mass transport as a function of film control by the catalyst, and not the mass or charge transport of the catalyst, with which we are concerned

$$i_A = nFAC^*_o D_o / \delta = 0.62nFAC^*_o D_o \omega^{1/2} \nu^{-1/6}$$

$$i_{R,S} = nFAk_t \kappa C^*_o D_s / \phi$$

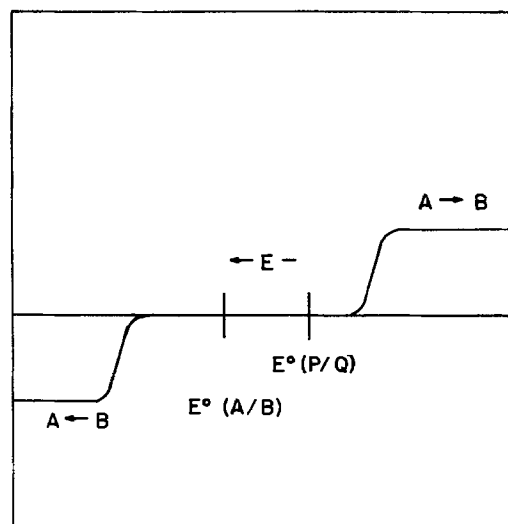

Fig. 1. Relationship of reversible catalyst couple and irreversible substrate couple on potential scale.

where n is the number of electrons transferred, A is the electrode area, C^* is the bulk concentration of substrate in solution, D_s is the solution diffusion coefficient of substrate, ω is the electrode rotation rate, ν is the kinematic viscosity of the supporting electrolyte solution, κ is the partition coefficient of the substrate between the film and solution, D_f is the diffusion coefficient of the substrate in the film, and ϕ is the film thickness. Standard electrochemical units are used.

Transient experiments are performed by applying a large amplitude potential step ($\geq 1.0V$) to the loaded film in the presence and absence of substrate in the solution. Substrate diffusion information is extracted by subtraction of curves generated in the absence of substrate from those generated in substrate-saturated films. Differential charge is plotted against time (ΔQ vs. t or ΔQ vs. $t^{1/2}$) in order to determine the functional time dependence of substrate transport in the film.

We are investigating the physical nature of poly(4-vinylpyridine) (PVP) films loaded at pH 3 with ferricyanide (catalyst) in an ion exchange process. Molecular oxygen (substrate) has been chosen as a structurally independent probe of mass transport in films, having the advantages of electroactivity, neutral charge, and nearly universal solubility. Very small k_f allows simple study of O_2 without complication of catalytic currents. Films are applied to a rotating disk electrode, allowing comparison of steady-state (hydrodynamic) and transient behavior.

All reagents except PVP were reagent grade and were used as received. Loading and ferricyanide-free supporting electrolyte solutions had the following composition: 0.065M potassium nitrate, 0.035M potassium biphthalate, and 0.015M nitric acid in ultrapure water (Continental Millipore Water Systems). Poly(4-vinylpyridine) (Mw = 300,000) received as a sample (Reilly Tar and Chemical Company, Indianapolis, Indiana) was cross-linked using 1,4-dibromobutane in methanol solution, to the extent that 2% of pyridine moieties are involved in cross-links. PVP solution (5% w/v) was dispensed as a drop to completely cover the surface of a static glassy carbon electrode (0.28 cm²) which was then accelerated to 4500 rpm under a methanol-saturated atmosphere to spin coat a thin uniform film. Films were dried 20 min at 80°C in air to complete solvent evaporation and cross-linking. Initially, the dry film has an interference color of blue or deep purple; after loading in 0.1 mM ferricyanide at pH 3 to 2×10^{-8} mol-cm⁻², the dry film is yellow or yellow-green in color.

Potentiostatic control was maintained using a Z-80 microprocessor-controlled cybernetic potentiostat (6) modified for performance of chronocoulometry on a time scale up to 12.5s. All experiments were performed in a specially built hydrodynamic voltammetry cell (7) with Pt wire counter and Ag/AgCl reference electrodes. A variable speed rotator and controller were used to set rotation speed (Pine Instrument Company).

A film of PVP spin coated at 4500 rpm from a dilute MeOH solution of lightly cross-linked PVP leads to a quasi-steady state from 0.1 mM ferricyanide in around 5 min, cycling at 50 mV/s, in an ion exchange-like process (Fig. 2) (8). The electrode is transferred to O_2 -saturated electrolyte solution after shaking away excess loading solution. In Fig. 3, the small peak separation ($\Delta E_p = 39$ mV) and narrow symmetrical peaks of the ferricyanide redox process at +0.25V are indicative of a surface response. The irreversible wave for O_2 reduction observed at $E_{1/2}$ of -0.7V is well separated from the ferricyanide response, and is at the same potential where it is observed on the bare GC electrode.

For longer time experiments ($\tau = 2000$ ms) at varying rotation rates, the limiting penetration current $i_{k,s}$ can be evaluated. The slopes of linear ΔQ vs. t plots are the limiting currents observed at the given rotation rates. When these currents are plotted in the Koutecky-Levich format (i^{-1} vs. $\omega^{-1/2}$) the intercept reflects the rotation-independent substrate penetration current, $i_{k,s}$. For the films studied, this current was found to be $1.2 \times 10^{-3}A$.

Fig. 2. Cyclic voltammetric scans of loading PVP film in 0.1 mM ferricyanide (pH 3 buffered supporting electrolyte). Scan rate = 50 mV/s. Solution stirred by nitrogen bubbler.

Fig. 3. Cyclic voltammetric scan of a ferricyanide-loaded film in O_2 -saturated ferricyanide pH 3 buffered electrolyte solution. Scan rate = 75 mV/s. Rotation rate = 500 rpm. Electrode area = 0.28 cm².

The corresponding current measured (using i_A^{-1} vs. $\omega^{-1/2}$) for the bare GC electrode is i_k (i_k arises because the oxygen reduction is completely irreversible: the rate constant k_f is also included in $i_{k,s}$). i_k was found to be $8.3 \times 10^{-3}A$. If the expressions for $i_{k,s}$ and i_k are ratioed, the resulting relation is derived

$$\kappa D_s / \phi = 0.145$$

$$i_k = nFAk_f C^*$$

Using reasonable hypothetical values for κD_s and ϕ , ($\kappa D_s = 5 \times 10^{-6}$ cm²-s⁻¹, $\phi = 3000\text{\AA}$), an estimate of $\kappa D_s / \phi$ of 0.17 was reached. These values agree fairly closely, indicating that the method is returning results which agree with the expected behavior.

For diffusion within the film, short time transients ($\tau < 30$ ms) were observed; such short times were necessary to ensure that the initial oxidation state of the film was fundamentally preserved on the experimental time scale (in the case of the initially oxidized film). Differential charge-time plots for O_2 diffusion in an initially oxidized and reduced film (Fig. 4 and 5) show that the diffusion behavior is markedly different depending on the initial state of the film. Slopes of plots are shown in Table I. A $t^{1/2}$ dependence for the oxidized film is similar to the diffusion seen in solution at the bare GC electrode. The ability of the electrode to draw down the concentration of O_2 at a rate faster than it can be diffusively replenished is seen. By contrast, in the initially reduced film a linear charge-time response indicates that the surface concentration of O_2 (at the GC) is not drawn down, indicating that the environment of the reduced film is less viscous than in the oxidized form. If it is assumed that the

Fig. 4. Transient (ΔQ vs. $t^{1/2}$) plot generated at a rotating disk electrode for an initially oxidized film in O_2 -saturated solution. Rotation rate = 1000 rpm.

oxygen concentration in the film is the same in both states of the film, the diffusion coefficient of oxygen in the reduced film appears greater, allowing diffusive replacement of oxygen faster than it can be replaced. That this phenomenon is occurring within the film, and not homogenizing the oxygen concentration to the film boundary on the time scale of the experiment, is evidenced by the insensitivity of these transients to electrode rotation rate.

A possible explanation for the apparent lower viscosity of the reduced film, where the loading is the same as in the oxidized form, lies in the relative amounts of charge incorporated by both. The negative charge associated with the reduced form, ferrocyanide, is 25% greater than that for the oxidized, ferricyanide. This requires uptake by the film of compensating positive charge: K^+ or H^+ , possibly solvated. For a film which is cross-linked, the polymer structure is limited in its capacity to accommodate excess volume, while it is also under the structural control imposed by the incorporated catalyst. Since cycling the electrode potential over the ferricyanide reduction potential drastically speeds the exchange process, it is likely that the film resists the uptake of electrolyte species, excepting those with large formation constants for complexation within the film (protons and ferricyanide). The excess charge density and volume due to reduction and compensating charges may account for a polymer structure so "stretched" that it acts rigid and porous, allowing very rapid diffusion of O_2 . Indeed, these films have been observed to change interference color upon ox-

idation or reduction, indicating a change in film thickness. Alternatively, it could be supposed that a rearrangement of the film to allow increased association of protonated pyridine groups with the ferrocyanide, expelling excess negative charge as anions, would occur. This would also change the film thickness by thinning and tightening the film, but since it should lead to an apparent increase in viscosity this mechanism does not seem to correlate with the results. In addition, if the film does not contain a large excess of counterions to begin with, then compensating charge must be drawn from solution rather than expelled from the film.

Continuing work in this project is directed toward determination of the diffusion coefficient of O_2 in PVP films by a spectroscopic technique utilizing fluorescence quenching of an immobilized fluorophore in the film. The results of the electrochemical and spectroscopic experiments will be compared to prove the validity of these methods for study of physical characteristics of polymer films on electrodes.

David P. Wilkinson was born in Duncan, British Columbia, Canada. In 1978, he received a B.A.Sc. degree in chemical engineering from the University of British Columbia, Vancouver, British Columbia, Canada.

After being graduated, Wilkinson worked as a research engineer for Ballard Research, Incorporated, Vancouver, on primary and secondary lithium battery systems, particularly with the Li/SO_2 system. Currently, he is working for a Ph.D. degree at the University of Ottawa, Ottawa, Ontario, Canada.

Mr. Wilkinson's report follows.

Comparison of "True" Kinetic Parameters for H_2 Evolution from Various Proton Donors in Water, Acetonitrile, and N,N -Dimethylformamide

The electrochemical hydrogen evolution reaction (HER) has often been regarded as a useful model for the

kinetic study of simple and other complex multistep electrode reactions. The mechanism of the activation process in such a coupled atom/electron-transfer process is not yet well understood, despite many papers on HER kinetics published in earlier years.

Study of the temperature and potential dependence of the HER from different proton sources in different solvent media allows the determination of the individual enthalpic and entropic components of the free energy of activation. These quantities for the activation process of proton transfer and neutralization at Hg should lead to a substantially improved understanding of the nature of activation in the elementary act of complex electron and atom transfer. The HER can be studied at a Hg electrode without the complication of a potential-dependent coverage of the electrode by adsorbed H such as arises at Pt or Ni.

Several investigators (1, 2) have studied the HER at Hg from methanolic HCl, but aside from these contributions very little work has been conducted in nonaqueous media. Conway and Tessier (3) have made a comparative study of the kinetics of the HER at Hg from the unhydrated H_3O^+ ion in pure $\text{CF}_3\text{SO}_3\text{-H}_3\text{O}^+$ and the hydrated H^+ aq ion in 1M aqueous $\text{CF}_3\text{SO}_3\text{H}$. Significantly different "apparent" activation parameters (constant overpotential) are found for the HER from different media. Krishtalik and co-workers (4-7) have examined the question of medium and bond stretching activation effects in proton discharge. They emphasized the proton discharge theory of Dogonadze *et al.* (8), the most developed of the continuum solvent reorganization models. In this approach, emphasis is placed on the role of the solution medium in bringing the proton donor into a state from which proton tunneling to a state of equal energy can occur. The observation of equal "apparent" activation energies for CH_3CNH^+ and H_3O^+ in acetonitrile solution at Hg (5) and the significantly different "apparent" activation energies for H_3O^+ in water and acetonitrile was taken to indicate that the activation energy is completely determined by reorganization of the solvent. However, Khan (9) has pointed out that, according to the bond stretching and activation models, one would expect a different free energy of activation on the basis of force constants alone, since the stretching frequencies of CH_3CNH^+ and H_2OH^+ bonds are different. Also, on the basis of a continuum solvent reorganization model, different free energies of activation should be expected because of the unequal radii of the H_3O^+ (0.14 nm) and CH_3CNH^+ (0.25 nm) ions. All of the above studies involved a comparison of "apparent" activation parameters in which the reference electrode metal-solution potential difference, $\phi_{\text{M-S}}^{\text{R}}$ is reversible to the proton source and varies with temperature and solution environment. Under these conditions, a quantitatively meaningful comparison of the proton donor discharge kinetics is difficult.

In view of the criticized but promising line of investigation of the above investigators, "true" activation parameters were investigated for proton donors in the aprotic solvents, acetonitrile (AN) and N,N-dimethylformamide (DMF) and in the protic solvent water. "True" activation parameters correspond to the condition of constant electrode potential (or field) rather than constant overpotential, that is, measurements are made with respect to a reference electrode potential $\phi_{\text{M-S}}^{\text{R}}$ invariant with temperature and solution composition at the working electrode. It is a well-known problem (10) that only "apparent" activation parameters are accessible from experimental electrode-kinetic measurements, but this problem can be circumvented by reasonable extra-thermodynamic assumptions. Temkin (10) first treated the problem of the relation between the "apparent" and "true" heats of activation, but a more direct analysis was given by Conway (11).

The reference electrode potential can be maintained constant with varying temperature by conducting polarization measurements with a reference electrode at the same but varied temperature of the working electrode

(isothermal measurement) and then correcting the potential scale used with a separately measured nonisothermal reference cell potential under conditions, as used in the work reported here, where the thermal junction potential is minimized. This approach was adopted by Weaver and co-workers (12) in their studies of complex ion redox reactions. The reference electrode potential can be fixed for different proton donors and solvents by using appropriate reference electrode cells and correcting polarization data to a common potential scale. For all reference cell corrections, the extrathermodynamic assumption is made that the unknown irreversible liquid-junction potential can be made negligible compared to the difference of the metal-solution potential difference at the two single electrode interfaces. "True" kinetic parameters are then obtained from the relation between $\ln i_v$ and T^{-1} at a fixed electrode potential following previously employed procedures (13) in the analysis of kinetics from Arrhenius plots.

Experimental

Steady-state polarization measurements were made potentiostatically over a range of temperatures for the HER at liquid Hg, from 0.1M aq HCl, 0.1M aq $\text{C}_2\text{H}_5\text{NH}_3\text{Cl}$, 0.1M aq $(\text{C}_2\text{H}_5)_3\text{NHCl}$, 0.1M $\text{CF}_3\text{SO}_3\text{H}$ in DMF, 0.1M $(\text{C}_2\text{H}_5)_3\text{NHCF}_3\text{SO}_3$ in DMF, 0.1M $(\text{C}_2\text{H}_5)_3\text{NHCF}_3\text{SO}_3$ in CH_3CN , and 0.1M $\text{CF}_3\text{SO}_3\text{-H}_3\text{O}^+$ in CH_3CN . No supporting electrolyte was used, as all the acids and salts are strongly dissociated in the respective solvents employed at the concentrations used (14, 15). The Ag/AgCl reference electrode was used in the aqueous systems, and the 0.01M AgClO_4/Ag reference electrode was used in the aprotic solvents. These reference electrodes were referred to the reference half-cell H_2/H^+ 0.1M HCl (H_2O)|KCl sat. (H_2O)| so that all the potential scales could be adjusted to one fixed reference electrode potential.

Pure liquid Hg (Aldrich Gold Label, 99.99999%) was contained in a silanized Pyrex glass cup giving an electrode area of ca. 0.393 cm^2 . The glass cup was resilanized regularly to prevent solvent creep, and the Hg was replaced regularly to minimize any accumulation of impurities at the Hg surface.

Triply distilled water and Burdick and Jackson spectroscopically pure DMF and AN (0.008% and 0.006% H_2O by Karl Fischer titration, respectively) were used directly. High purity $\text{CF}_3\text{SO}_3\text{H}$ (3M Company) was prepared by double distillation (16), and the monohydrate, $\text{CF}_3\text{SO}_3\text{-H}_3\text{O}^+$, was prepared and purified as described previously (3). For the $\text{CF}_3\text{SO}_3\text{H}$ in DMF system, a small amount ($\approx 0.01\text{M}$) of the anhydride $(\text{CF}_3\text{SO}_2)_2\text{O}$ was added to react with any residual H_2O as a "getter" to attain "ultra-dry" conditions. The salt $(\text{C}_2\text{H}_5)_3\text{NHCF}_3\text{SO}_3$ was prepared by adding $\text{CF}_3\text{SO}_3\text{H}$ slowly to a large excess of $(\text{C}_2\text{H}_5)_3\text{N}$ at 233 K. The salt was recrystallized several times from diethyl ether and then vacuum dried at room temperature for several days. For the aqueous systems, high purity Aristar HCl was used directly and the Fluka salts $(\text{C}_2\text{H}_5)_3\text{NHCl}$ and $(\text{C}_2\text{H}_5)_3\text{NH}_3\text{Cl}$ were recrystallized twice from methanol and vacuum dried at 333 K for several days. The melting points of the salts were used as criteria of purity.

Results

Table I shows the "true" activation energies and frequency factors for the different proton donors in their respective solvents. The "true" entropies of activation ΔS^{\ddagger} (proportional to $\ln [A]$, where A is the frequency factor) have also been included. These entropies were derived from the intercepts, $\ln A$, of the electrochemical Arrhenius plots at constant metal-solution potential difference according to the relation

$$\Delta S^{\ddagger} = R\{\ln A - \ln(zFAC(1 - \theta)KT/h)\} \quad [1]$$

where c is the bulk concentration in moles per cubic centimeter and θ is the coverage by H assumed $\ll 1$ for Hg so that $(1 - \theta) \approx 1$.

In the context of a particular rate theory, the magnitude and sign of the entropy of activation are determined by

Table I. "True" kinetic parameters for the HER from different proton donors in H₂O, DMF, and AN

Proton donor	ΔH^\ddagger (kJ·mol ⁻¹)	ΔS^\ddagger (J·K ⁻¹ ·mol ⁻¹)	log [A]	i_0 (A·cm ⁻²) (298 K)	pK _a
H ₃ O ⁺ (H ₂ O)	91.2	-202	3.9	9.1×10^{-13}	-3
C ₂ H ₅ NH ₃ ⁺ (H ₂ O)	101.3	+15	14.9	4.9×10^{-15}	10.81
(C ₂ H ₅) ₃ NH ⁺ (H ₂ O)	181.5	-203	3.4	1.1×10^{-17}	11.01
DMFH ⁺ (DMF)	71.8	-163	5.6	9.3×10^{-8}	-1.5
(C ₂ H ₅) ₃ NH ⁺ (DMF)	95.5	-180	4.7	8.5×10^{-13}	9.25
H ₃ O ⁺ (AN)	68.3	-206	3.3	2.4×10^{-9}	—
(C ₂ H ₅) ₃ NH ⁺ (AN)	116.7	-128	7.4	9.0×10^{-14}	18.46

the choice of standard state for reactant and activated complex as well as by chemically significant factors such as structural or electrostrictive changes. Useful conclusions can be drawn from the relative ordering of frequency factors and entropies of activation, but caution has to be exercised in rationalizing or interpreting the sign and magnitude of entropies of activation. The rates of proton discharge at 298 K for the different systems are all compared at the same metal-solution potential of the hydrogen electrode in 0.1M aqueous HCl. The rates are related to the standard chemical free energy by

$$i = B \exp[-\Delta G^\ddagger/RT] \quad [2]$$

where B is a combination of constants. Double-layer effects at Hg for the systems studied here are expected to be similar except for specific adsorption of the alkyl ammonium ions.

It is evident from a comparison of the kinetic parameters that there are appreciable differences for the same proton donor in different solvent media and for different proton donors in the same solvent. The similar size and bond length where the charge is centered of the proton donors implies a similar electrostatic interaction with the same medium, but the significant activation energy differences indicate that the nature of the ruptured bond and specific solvational and solvent-structure aspects are important in addition to the influence of the medium. An electrochemical Brønsted relation (17) between the rates of proton discharge and the state of solvation of the proton donor is indicated. From the results obtained, it is found that specific as well as general medium effects have to be included in any interpretation of electrode reaction rates involving cathodic H₂ evolution and, probably, in other electrode processes.

The results described briefly above, together with other work related to the HER, will be presented in detail in a forthcoming publication.
