The mechanisms involved in the anodic evolution of ozone are not well understood. The reaction does not seem to depend much on specific electrocatalytic properties of the electrode material, the only prerequisite apparently being a sufficiently high overpotential for oxygen evolution. However, the ozone yield strongly depends on electrolyte properties, such as its concentration and the electronegativity of its anion. The different location of the temperature maximum of the ozone yield for lead dioxide electrodes in different electrolytes also suggests that the observed temperature dependence is mainly governed by the physical chemistry of the electrolyte solution, rather than by the surface properties of the electrode. The electrolyte influence on ozone yield has been rationalized in two ways by Foller and Tobias (2, 18). First, the adsorption of oxyanions competes with the adsorption of oxygen intermediates and hence influences the free energy of adsorption of oxygen. An optimum free energy of adsorption of oxygen exists at low to intermediate anion coverages. Ozone is believed to be formed by a heterogeneous catalytic mechanism on the electrode surface. Second, the electrolyte anions stabilize the free intermediate species that might be formed at high anodic potentials. This argument holds mainly for fluoroanion electrolytes. The kinetics of this process would then be determined mainly by a homogeneous mechanism in the electrolyte.

An electrocatalytic mechanism as suggested by the anion adsorption model seems improbable since any adsorbed intermediate irrespective of its adsorption energy would be an intermediate for both, O_2 and O_3 . A mechanism via solute species seems more probable. With platinum as a catalyst the cathode overpotential is estimated to be in the order of 50 mV (3). This means that the iR free anode potential derived from Fig. 4 is in the order of 2.5V over the current density range of maximum ozone yield. This is sufficiently high to form free or loosely adsorbed

atomic oxygen, which reacts readily with molecular oxygen to form ozone (14). Assuming a mechanism of the kind outlined above, one would expect the ozone current yield to depend on the oxygen concentration in the immediate vicinity of the electrode. It has been shown by gas diffusion measurements that supersaturation in the order of 10 bars can occur at gas evolving electrode-membrane interfaces (15). One reason for the relatively high current yield of the Membrel ozone generator at moderate temperatures might be connected with the high oxygen supersaturation of the solid polymer electrolyte structure. The assumption of a high supersaturation of oxygen at the electrode-membrane interface, and, consequently, of ozone as well, also explains the independence of the yield from ozone concentration in the feed water. The concentration range of ozone in the feed water was 5-25 ppm and probably smaller by at least an order of magnitude than in the region of supersaturation. Hence, no dependence on the concentration is to be expected. In order to get more information about the influence of the concentrations of dissolved gases, a pressure electrolysis system for ozone generation is being built (16).

Conclusions

Nafion membranes have some unique physical and chemical properties that make them suitable for use as electrolytes in solid polymer electrolyte cells for ozone generation: current efficiency of 15%; a relatively low cell voltage; operation at room temperature; and a long lifetime of the cell components. Together, these make this system an economically interesting new electrolytic technique. The main advantage is the fact that the Membrel cell directly produces an aqueous solution of ozone ready for various oxidizing and/or disinfectant applications.

The mechanisms of ozone formation are not well understood, and more fundamental and applied research is necessary to guide further improvement of the system.

Computer Simulation of Dendritic Electrodeposition

Department of Physics, Brooklyn College of CUNY, Brooklyn, New York 11210

ABSTRACT

We have generalized the single-particle diffusion-limited aggregation process to both multiparticles and aggregation on an initially smooth surface. The computer simulation is done as a function of "concentration" of the particles and the sticking coefficient to the surface. These parameters are correlated with electrochemical parameters such as overpotential, limiting current, exchange current, and electrolyte concentration. The correlations between the two sets of parameters permits direct comparison between simulation and experiment. The transition between "mossy" deposits and fully developed dendritic growth is recorded. The simulation reproduces the presence of a critical overpotential and an initiation time. The fundamental interdependence of these parameters and their dependence on the concentration of the electrolyte, quantitatively resemble that of the observed dendrite growth in electrodeposition of Zn and other metals.

The subject of dendritic growth during electrodeposition of metals has fascinated electrochemists for many years. Part of this fascination is, no doubt, due to the technological importance of this phenomenon, particularly in conjunction with battery technology. Equally important, however, is the challenge that is being presented in the complexity and the unique morphology that is be-

ing created and the realization that this unique morphology can be generated, under appropriate conditions, regardless of the metal involved.

The interdependence between ionic transport in the electrolyte, the kinetics of charge transfer at the metal solution interface and the solid state properties of the deposit was emphasized in numerous review articles on electrodeposition (1). Closer to home, the system in which dendrite formation was most thoroughly studied is the

*Electrochemical Society Active Member.

electrodeposition of Zn in alkali zincate electrolyte. All the comparisons with experiment that will be made in this paper are based on this system. In this system, three kinds of deposits are encountered (2): (i) smooth deposits at low overpotential in vigorously stirred electrolytes, (ii) in quiescent concentrated solutions, dark gray porous (mossy) deposits are formed at low overpotential, and (iii) at higher overpotentials, dendritic deposits are invariably formed. Phenomenologically, it was recognized that an initiation overpotential is required to produce dendrites, and at least one initiation time was observed. Beyond the initiation time, the velocity of dendrite propagation was found to be approximately constant. The issue of both an initiating time and overvoltage as two separate requirements is still unsettled. Their presence will imply a critical overvoltage with an infinite initiation time and a finite initiation time for an infinite overpotential.

Morphologically, it was observed that, after the initiation stage, the dendrite tips are parabolic in shape with approximately constant radius of curvature (3) that decreases with overpotential (4).

The most recent attempt at a comprehensive theoretical analysis of the phenomena can be found in a series of papers by Landau and his group (4) which expand on earlier concepts that were advanced by Bockris and his group (5).

These theories divide the dendrite growth into two stages: initiation and propagation. During the initiation stage arbitrary roughness at the substrate (1), or, more specifically, pyramids arising from rotation of screw dislocations (3), are being exponentially amplified by preferential transport of the deposited ions from the electrolyte. At the propagation stage, equations which include diffusion, reaction kinetics, and surface energy were solved for either maximum velocity at the tip (5) or to obey marginal stability criteria (4). From the results, it was possible to obtain the radius of the tip, the critical overpotential, and/or the induction time. Attempts were made to determine the interdependence of these parameters and their dependence on electrolyte concentration, temperature, and hydrodynamic conditions. It is not our intention in this paper to challenge any of these theories. We would like to explore here what aspects of the dendritic growth can be simulated without making any physical assumptions about the system. The system consists only of an arbitrary featureless surface in contact with an "electrolyte" at a given concentration. Each particle in the electrolyte undergoes random walk until it reaches the surface. At the surface, a finite, given probability will determine whether the particle will stick to the surface or will be reflected back to the solution.

Methodology

Our work was stimulated by the recent interest among physicists in growth or aggregation phenomena that result in fractal clusters (6, 7) with power-law correlations over wide ranges of length scales. Such correlations are reminiscent of those found in equilibrium-phase transitions at the critical point. Much of the recent widespread interest in understanding the computer simulations of simple aggregation processes (8-10) have been successful in reproducing the scale invariant properties. In particular, a simple model has been presented (8, 9) for the aggregation process when the limiting step is diffusion to the growth sites. This model is based only on local constraints (Brownian motion, connectivity to aggregate) yet it reproduces the long-range fractal behavior. This model and its variations have also stimulated theoretical treatments based on mean field (11) and continuum (12-14) approximations and real space renormalization (15).

The models presented here are a generalization of the single-particle diffusion-limited aggregation process (8) to both multiple particles and aggregation on an initially smooth surface. In the original model (8), a single particle would undergo a random walk until reaching the boundary of the aggregate of cluster. At this point, it became part of the cluster and a new particle began its walk.

Here, we begin with a two-dimensional square lattice (typically 600×400) where a fraction of the sites are initially occupied with mobile particles. The bottom edge is the initial active area for growth while the top edge is held at fixed concentration (9). The mobile particles undergo simultaneous diffusion (random walks) under the constraint that no two particles can occupy the same site at the same time. During a time step, each of the mobile particles is examined in random order. One of its four neighbor sites is selected by chance as a possible next position. If unoccupied, the particle moves to this new site. If occupied, the particle remains fixed. Periodic boundary conditions are used in the horizontal direction, particles that leave to the right enter from the left. If the new site borders a growth site, it becomes part of the aggregate with probability k . Once part of the aggregate, the particle is immobile and is itself a new growth site. The sticking probability k is related to the electrochemical parameters during electrolyte deposition. The process is repeated for different k and c , where c represents the fraction of occupied sites until an either fixed number of particles have aggregated (typically 100,000) or until a fixed number of time steps have elapsed.

Since this paper represents a collaborative effort between a theoretical physicist and an electrochemist, we feel that the appropriate procedure to present the results is in terms of intrinsic system parameters which are independent of electrochemical terminology. Thus, the kinetics at the interface is represented by sticking probability, the electrolyte concentration in terms of percentage of occupied sites and distance, and time in terms of arbitrary displacement units and number of steps in a Brownian motion in which the diffusion coefficient is taken as unity. These units have the advantage that they are independent of any particular system. In the discussion section, we will transform these units to the conventional electrochemical units, using the Zn system as an example.

Results

Figures 1 and 2 show the time evolution of the morphologies which develop with 10% electrolyte concentration and different sticking probabilities. In addition, one can observe the concentration gradient in the electrolyte as one approaches and enters the deposited surface.

By comparing the figures, one can observe the first important result from this work: at low sticking probability (1%), one observes a morphology which is similar to the mossy deposit that is observed with metal deposition at low overpotential and a "typical" dendrite formation with side branching, etc., at the higher sticking probab-

Fig. 1. Simulation of growth for concentration of 0.1 (fraction of occupied sites) and sticking coefficient of 0.3. The transition between black and gray indicates time evolution in units of 2×10^5 Brownian motion steps.

Fig. 2. The same conditions as Fig. 1, but with sticking coefficient of 0.01.

In Fig. 3, we show the time evolution of the surface height for various sticking probabilities at a fixed electrolyte concentration (10%). In Fig. 4, we show the time evolution of the surface height for various electrolyte concentrations at a fixed sticking probability (10%). Since both figures can be directly compared with experiment, all the quantitative analysis will be based on them. From Fig. 1, it is obvious that dendrites of various heights are formed across the surface. The surface height in Fig. 3 and 4 was calculated by taking an "average" of the dominating dendrites. This procedure clearly deviates from the experimental determination of this parameter (3), which was done by following the growth of an arbitrary, single dendrite. Figures 3 and 4 are presented in logarithmic scale; they cover at least three orders of magnitude in length and six orders of magnitude in time. Even without quantitative analysis of the data in these figures, the existence of an initiation time for dendrite growth, which changes with the sticking probability and the concentration of the electrolyte, is evident. The exact significance of the initiation time is not so obvious. One can observe that all the curves are approximately linear in the logarithmic scale, down to a height of 1. Below that height, the curves deviate from linear behavior in a non-systematic way with considerable amount of noise. In the linear portions of the curves, the slope is approximately constant, with value of 2/3 for the high electrolyte concentrations with increase in slope as we increase the concentration of the electrolyte. This is a clear deviation from the experimentally observed behavior (3), in which, over a

Fig. 3. The average surface height as a function of time in Brownian motion steps, for fixed concentration (0.1) and varying sticking probability.

Fig. 4. The same as Fig. 3 with fixed sticking probability (0.1) and varying concentration.

much more limited range of time and distance, a linear dependence which implies constant rate of growth was observed. We do not wish to speculate here as to the possible origin of these differences. The dimensionality of the problem, the method of measurement of the height, the available range, are all different.

Arbitrarily, we will stipulate that a height of 1 is the threshold of dendritic growth. Figure 5 shows the time it takes to reach this height as a function of the sticking probability for $c = 0.1$, and at a sticking probability of 0.1 as a function of concentration. If we associate this time with the initiation time and the sticking probability with the overvoltage, this curve can also be directly compared with experiment. This will be done in the discussion section, after we introduce the correlation between the sticking probability and the overvoltage.

Discussion

Correlation Between the Numerical Calculations and Electrochemical Parameters

Sticking coefficients and overpotential.—Suppose that the deposition occurs under mixed activation and diffusion control (1). The current density is given by

$$I = I_0 \left\{ \left(\frac{I_{l,c} - I}{I_{l,c}} \right) f_c(\eta) - \left(\frac{I_{l,a} - I}{I_{l,a}} \right) f_a(\eta) \right\} \quad [1]$$

where

$$f_c(\eta) = \exp(\alpha_c F \eta / RT) \quad [2]$$

$$f_a(\eta) = \exp(\alpha_a F \eta / RT) \quad [3]$$

I_0 is the exchange current, $I_{l,c}$ and $I_{l,a}$ the limiting currents, α_a and α_c the transfer coefficients of the anodic and cathodic reactions, F the Faraday number, R the gas constant, T the absolute temperature, and η the overpotential. For the numerical simulation, we assume that when the reaction is diffusion controlled, i.e., $I = I_l$, the sticking coefficient of the solute on the electrode is 1. Under these conditions, every encounter between solute and substrate results in deposition. Following this assumption, we define the sticking coefficient at any potential as

$$\kappa = \frac{I}{I_l} \quad [4]$$

and assume that the limiting currents for the anodic and cathodic reactions are the same in magnitude and opposed in sign, then, by rearranging Eq. [1], we obtain

$$\frac{1}{\kappa} = \frac{f_c(\eta) + f_a(\eta)}{f_c(\eta) - f_a(\eta)} + \frac{I_l/I_0}{f_c(\eta) - f_a(\eta)} \quad [5]$$

For a stationary electrode the limiting current density is given by

Fig. 5. The variation of the initiation time (taken at surface height of 1) with the sticking probability and concentration (insert). The data were taken from Fig. 3 and 4.

$$I_0 = ZFDC_0/\delta_0 \quad [6]$$

where D is the diffusion coefficient of the depositing ions, C_0 is their concentration, Z the charge, and δ is the thickness of the diffusion layer. For illustration purposes, let us take the Zn system as a prototype. Diggle *et al.* (3) have found that in zincate solutions $D/\delta = 6.8 \times 10^{-4}$ cm/s. If we now write the exchange current density as (1)

$$I_0 = FkC_0 \exp\left(\frac{-\alpha_c F}{RT} E_0\right) \quad [7]$$

where k is the rate constant of the rate-determining step, C_0 the concentration of the electrolyte, and E_0 the equilibrium potential of the reaction and take typical exchange current for the Zn electrode to be 5.5 A/cm² at $C_0 = 5.5$ M, which is approximately equivalent to the 10% concentration shown in Fig. 3. We will further assume that, for this electrode, $\alpha_c = 1 - \beta$ and $\alpha_a = \beta$, where $\beta \approx 0.5$ is the symmetry factor and $Z = 1$.

Using these data and Eq. [1] and [5], one can correlate the sticking coefficients with the overpotential for a given concentration of the electrolyte. For a quick reference, such a correlation is presented in Fig. 6.

Time and space.—The calculations are presented in units of Brownian steps with normalized diffusion coefficient, $D = 1$.

To convert these units into the conventional units of length and time, we will compare the calculated growth rate to the experimental growth rate of Zn dendrites and introduce the diffusion coefficient of zincate ion. The comparison is not exact because the experimental observations were carried out at considerably lower zincate concentrations and the numerical propagation velocities are not constant. Nevertheless, the comparison should be valid well within an order of magnitude and will add to the clarity of the qualitative comparisons that we try to make here between “theory” and experiment. Two equations will be used for this purpose: from random walk statistics, the root mean square displacement $\bar{\Delta}$ changes with time according to

$$\bar{\Delta} = \sqrt{2Dt} \quad [8]$$

and the “average” velocity of the dendrite propagation is given by

$$v = \frac{l}{t} \quad [9]$$

where l is the length of a dendrite.

Fig. 6. The calculated variations of the sticking probability with the overpotential. The calculations are based on Eq. [1] and [5] and parameters which are given in the text.

Typical experimental value for v in the Zn system is 1 μ m/s, and a “typical” calculated value, taken from Fig. 3, is 5×10^{-3} displacements/no. of Brownian steps. Taking these values together with the measured diffusion coefficient of $D = 6.8 \times 10^{-6}$ cm²/s, we arrive at the following transformations: 1 Brownian displacement ≈ 7 μ m, and 1 Brownian step ≈ 0.03 s.

Comparison with Experiment

Most of the quantitative experimental work on dendritic electrodeposition was done in conjunction with the electrodeposition of Zn. The examples that we took in the previous section to establish the connection between this work and electrochemical systems have originated from the work on the Zn electrode. Most of the work on the Zn electrode was done with electrolyte concentration considerably lower (typically 0.1M) than the one that we have used here. The main reason for that is that considerably larger computer times are required for the lower concentrations and we did not feel that a full quantitative comparison between our results and the experimental observations was called for and would justify our additional expenditures. Morphologically, Fig. 1 and 2 show that the computer is able to reproduce the transition between mossy deposits and the dendritic deposits as one increases the overvoltage. However, on close inspection, the computer simulation results in growth which can best be described in terms of Mandelbrot’s fractal geometry (7) with power-law correlations over wide range of length scales, while, experimentally, the individual dendrites terminate in crystalline, parabolic fronts with optimized radius of curvature which varies with overpotential. This difference is intrinsic to the method of analysis and serves as a reminder that the real dendritic growth on a real substrate is considerably more complex than the simplified model which is presented here.

In addition to the kinetically dependent morphological changes in the deposits, the most convincing analogy with experiment is the dependence of the initiation times for the dendritic growth on the overvoltage and concentration of the electrolyte. Quantitatively, Fig. 4 has similar functional dependence of the initiation time on the sticking coefficient and concentration as the one that was observed experimentally between initiation time and overvoltage (3, 4). However, if we define the critical overvoltage at which the initiation time increases asymptotically to infinity, we find that while, experimentally, for electrolyte concentration of 0.1M, the value for Zn is around 70 mV, from Fig. 4, the critical sticking coefficient approaches zero. Whether this apparent lack

of critical sticking coefficient is due to the scaling relations that were introduced here or is intrinsic to the simplicity of the model that was presented here remains to be determined.

Acknowledgments

We would like to express our special gratitude to Dr. U. Landau from Case Western University and to Dr. S. Szpak from the Naval Ocean Systems Center for making available to us a yet unpublished documentation and photographs of dendritic growth on the Zn electrode. One of us (M. T.) would like to acknowledge the support of the Office of Naval Research.

Technical Notes

Anodic Dissolution of Zinc Electrodes in Alkaline Electrolyte: Mass Transport Effects

Yu-Chi Chang* and Geoffrey Prentice**

Department of Chemical Engineering, The Johns Hopkins University, Baltimore, Maryland 21218

In a previous investigation (1), we proposed a three-step mechanism for the anodic dissolution of zinc in dilute alkaline electrolyte. From that mechanism, we deduced the kinetic parameters, under the assumption that the system was kinetically controlled. Quantitative agreement between calculated and experimental results was obtained in the initial dissolution region, near $-1.23V$ vs. NHE.

In the present analysis, we incorporate mass-transport effects. Because the hydrodynamics and current distribution are well defined on the rotating disk electrode, data from this system are particularly appropriate for analysis. Studies conducted at constant potential show that the reciprocal of the current density vs. the reciprocal of the square root of the rotation rate yields a linear relation (2, 3), where both the slope and the intercept vary with potential. In the following analysis, we show that our proposed mechanism in conjunction with the Levich equation for species mass transport yields the proper relationship between rotation rate and current density. Certain mechanisms, which are valid under kinetic control, are incompatible with these experimental results and can be eliminated on that basis.

Proposed Model

Analysis of rate expressions.—Our proposed model for the anodic dissolution of zinc in dilute alkaline electrolyte is

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

When the fraction of adsorbed ZnOH (θ) is treated in accordance with Langmuir's hypotheses, the rate expressions become (1)

$$\tau_1 = i_1/\mathbf{F} = k_{a1} \exp [(1 - \beta_1)\mathbf{FV}/RT](1 - \theta)c_{\text{OH}^-} - k_{c1} \exp (-\beta_1\mathbf{FV}/RT)\theta \quad [4]$$

$$\tau_2 = i_2/\mathbf{F} = k_{a2} \exp [(1 - \beta_2)\mathbf{FV}/RT]c_{\text{OH}^-}^{2-\theta} - k_{c2} \exp (-\beta_2\mathbf{FV}/RT)c_{\text{Zn(OH)}_3^-}(1 - \theta) \text{ rds} \quad [5]$$

$$\tau_3 = k_{a3}c_{\text{Zn(OH)}_3^-}c_{\text{OH}^-} - k_{c3}c_{\text{Zn(OH)}_4^{2-}} \quad [6]$$

At steady state, all the reactions proceed at the same rate, and the net current density is

$$i = 2i_1 = 2i_2 \quad [7]$$

Since reaction [1] is assumed to be at equilibrium, the fractional surface coverage is obtained from Eq. [4]

$$\theta = k_{a1}c_{\text{OH}^-}/[k_{a1}c_{\text{OH}^-} + k_{c1} \exp (-\mathbf{FV}/RT)] \quad [8]$$

Substitution of Eq. [8] into Eq. [5] yields

$$i_2/\mathbf{F} = i/(2\mathbf{F}) = k_{a2}k_{a1}c_{\text{OH}^-}^{-3} \exp [(2 - \beta_2)\mathbf{FV}/RT] / [(H + 1)k_{c1}] - k_{c2}k_{c3}c_{\text{Zn(OH)}_4^{2-}} \exp (-\beta_2\mathbf{FV}/RT) / [(H + 1)k_{a3}c_{\text{OH}^-}] \quad [9]$$

where

$$H = k_{a1}c_{\text{OH}^-}/[k_{c1} \exp (-\mathbf{FV}/RT)] \quad [10]$$

Analysis of mass-transport effects.—The surface concentration of a reacting species can be estimated from Levich's equation

$$c_i = c_i^b - 1.6\nu^{1/6}\omega^{-1/2}i/(n_i\mathbf{F}D_i^{2/3}) \quad [11]$$

If we assume that the physical properties are constant,

Fig. 1. Reciprocal of the current density vs. $1/\omega^{1/2}$. 1M KOH, 25°C, from Ref. (2).

the invariant quantities in the second term can be lumped, and Eq. [11] becomes

$$c_i = c_i^b - A_i \omega^{-1/2} i \quad [12]$$

The surface concentrations of OH^- and $\text{Zn}(\text{OH})_4^{2-}$ can be estimated from Eq. [12] (with the appropriate sign change for anodic dissolution)

$$c_{\text{OH}^-} = c_{\text{OH}^-}^b - A_{\text{OH}^-} \omega^{-1/2} i \quad [13]$$

$$c_{\text{Zn}(\text{OH})_4^{2-}} = c_{\text{Zn}(\text{OH})_4^{2-}}^b + A_{\text{Zn}(\text{OH})_4^{2-}} \omega^{-1/2} i \quad [14]$$

The term $c_{\text{OH}^-}^3$ calculated from Eq. [13], is

$$c_{\text{OH}^-}^3 = c_{\text{OH}^-}^{b3} - 3c_{\text{OH}^-}^{b2} A_{\text{OH}^-} \omega^{-1/2} i + 3c_{\text{OH}^-}^b (A_{\text{OH}^-} \omega^{-1/2} i)^2 + (A_{\text{OH}^-} \omega^{-1/2} i)^3 \quad [15]$$

The terms of order i^2 and i^3 are small compared to the term of order i in the active dissolution regime, where $i < 0.01 \text{ A/cm}^2$; therefore, for $c_{\text{OH}^-}^b \sim 10^{-3} \text{ mol/cm}^3$, the latter two terms in Eq. [15] can be neglected. Substitution of the surface concentrations from Eq. [13]-[15] into Eq. [9] yields

$$i = 2F \{ k_{a2} k_{a1} c_{\text{OH}^-}^{b3} \exp[(2 - \beta_2)FV/RT] / [(H + 1)k_{c1}] - k_{c2} k_{c3} c_{\text{Zn}(\text{OH})_4^{2-}}^b \exp(-\beta_2 FV/RT) / [(H + 1)k_{a3} c_{\text{OH}^-}] \} \{ 1 + 6Fk_{a2} k_{a1} c_{\text{OH}^-}^{b2} A_{\text{OH}^-} \omega^{-1/2} \exp[(2 - \beta_2)FV/RT] / [(H + 1)k_{c1}] + 2Fk_{c2} k_{c3} A_{\text{Zn}(\text{OH})_4^{2-}} \omega^{-1/2} \exp(-\beta_2 FV/RT) / [k_{a3}(H + 1)c_{\text{OH}^-}] \} \quad [16]$$

For rotation rates of the order of 100 rpm, $A_{\text{OH}^-} \omega^{-1/2} i$ is small compared to $c_{\text{OH}^-}^b$ in the initial dissolution region; therefore, the former term can be neglected when compared to $c_{\text{OH}^-}^b$. The second term in the numerator represents the cathodic component; it is generally much smaller than the first and can also be neglected. With these two simplifications, Eq. [16] can be cast in a form showing the explicit dependence of $1/i$ on $1/\omega^{1/2}$

$$1/i = 1 / \{ 2Fk_{a2} k_{a1} c_{\text{OH}^-}^{b3} \exp[(2 - \beta_2)FV/RT] / [(H + 1)k_{c1}] + \omega^{-1/2} [3A_{\text{OH}^-} / c_{\text{OH}^-}^b + k_{c1} k_{c2} k_{c3} A_{\text{Zn}(\text{OH})_4^{2-}} \exp(-2FV/RT) / (k_{a1} k_{a2} k_{a3} c_{\text{OH}^-}^{b4})] \} \quad [17]$$

Results and Discussion

Equation [17] shows that $1/i$ is linearly related to $1/\omega^{1/2}$ at fixed potential. Both the slope and the intercept vary with potential (Fig. 1). The rate constants and equilibrium constants are those that were calculated or estimated previously (1) when only kinetic limitations were taken into account; the values are summarized in Table I.

Table I. Summary of kinetic and thermodynamic quantities

Species	Standard free energy of formation (kcal/mol)	
ZnOH	-65.8	
OH^-	-37.6	
$\text{Zn}(\text{OH})_3^-$	-166.0 to -167.6	
$\text{Zn}(\text{OH})_4^{2-}$	-205.2 to -206.2	
Reaction	Standard free energy of reaction (kcal)	Kinetic rate constant ($\text{cm}^2/\text{s}\cdot\text{mol}$)
1	-28.2	9.3×10^9
2	-25.0 to -26.6	
3	-2.6 to 0	

Thermodynamic quantities were obtained (or derived) from data found in Ref. (5). The free energy of formation of ZnOH and the rate constant were estimated [see Ref. (1)].

Because the equilibrium constants are exponentially related to the free energy of reaction, Eq. [17] is particularly sensitive to the uncertainty in the thermodynamic data. The first term in Eq. [17] corresponds to the intercept of the $1/i$ vs. $1/\omega^{1/2}$ plot. This term depends on the rate constant for the second reaction and the equilibrium constant for the first reaction. The slope of the line, which is the coefficient of the second term, is related to the equilibrium constants of the three reactions. Variations in the values of the equilibrium constants result from assuming that $\text{Zn}(\text{OH})_2$ exists in different crystalline forms and from the uncertainty in the experimental determinations. The range of these values is shown in Table I. The sensitivity of the slope and the intercept to the thermodynamic values is shown in Table II.

Several assumptions were made in the derivation of Eq. [17]. The assumption that the bulk concentration of hydroxide is large compared to the term $A_{\text{OH}^-} \omega^{-1/2} i$ is generally valid. We are primarily interested in bulk hydroxide concentrations greater than 10^{-3} mol/cm^3 , rotation rates greater than 200 rpm, and current densities less than 10 mA/cm^2 . Within this range of parameters, the term $A_{\text{OH}^-} \omega^{-1/2} i$ is less than 10% of the bulk hydroxide concentration and can legitimately be neglected. The assumption that the second term in the numerator of Eq. [16] can be neglected is appropriate at low zincate concentrations and at relatively anodic potentials. At -1.20V vs. NHE and at a bulk zincate concentration of 10^{-9} mol/cm^3 , the second term is less than 0.01% of the first term; however, at more cathodic potentials (-1.23V vs. NHE), the current density becomes extremely sensitive to bulk zincate concentration (Fig. 2). This sensitivity occurs when approaching the reversible potential, which is approximately

Table II. Sensitivity of the $1/i$ vs. $1/\omega^{1/2}$ curve to thermodynamic quantities

Species	Free energy of formation (kcal/mol)		
	Case I	Case II	Case III
Zn	0	0	0
OH^-	-37.60	-37.60	-37.60
ZnOH	-65.85	-65.85	-67.00
$\text{Zn}(\text{OH})_3^-$	-166.0	-167.6	-166.0
$\text{Zn}(\text{OH})_4^{2-}$	-205.2	-206.2	-205.2

Case I represents the best estimate of the parameters.

Fig. 2. Reciprocal of the current density vs. $1/\omega^{1/2}$. Solid curves represent simulated results for $c_{Zn(OH)_4^{2-b}} = 10^{-9}$; dashed curves for $c_{Zn(OH)_4^{2-b}} = 10^{-5}$. All simulations for 1M hydroxide. Upper curves (Δ) show high sensitivity to zincate concentration near the reversible potential. Lower curves (\circ) show that the current density is not sensitive to zincate concentration at more anodic potentials.

-1.23V vs. NHE (10^{-3} mol/cm³ KOH, 10^{-5} mol/cm³ zincate).

Armstrong and Bulman (3) assumed that the finite slope of the $1/i$ vs. $1/\omega^{1/2}$ plot is due to the diffusion of $Zn(OH)_4^{2-}$ from the electrode. Analysis of our model shows that the slope of this line is due to mass-transport limitations of both the zincate and the hydroxide ions. From the second term of Eq. [17], we can determine the contributions of the mass-transport limitations from each of the two species. At -1.20V vs. NHE (-1.31V vs. Hg/HgO), the contribution from each of the two sources is approximately equal, while at -1.23V (-1.34V vs. Hg/HgO) only 10% of the contribution is due to hydroxide ion mass-transport limitations. The change in the slope as a function of potential is related to the slow transport of the zincate ion.

Certain mechanisms are incompatible with the data displayed in Fig. 1. For example, if we postulate that we can neglect the reverse reaction in the rate-determining step, Eq. [17] becomes

$$1/i = 1/[2Fk_{a2}k_{a1}c_{OH}^{-b3} \exp[(2 - \beta_2)FV/RT] / \{(H + 1)k_{c1}\} + 1/\omega^{1/2}[3A_{OH} - c_{OH}^{-b}]] \quad [18]$$

Although a plot of this equation yields a straight line with a finite slope, the slope is no longer potential dependent. A similar analysis applied to the mechanism proposed by Bockris *et al.* (4) shows that the reverse reaction in the rate-determining step must also be included in order to obtain a potential-dependent slope.

From Eq. [17], the dependence of $d(1/i)/d(1/\omega^{1/2})$ on potential is given by

Fig. 3. $d(1/i)/d(1/\omega^{1/2})$ vs. potential. The solid lines are simulated, and the points represent data from Ref. (3). The data are for 1M NaOH and 2M NaOH.

$$S = d(1/i)/d(1/\omega^{1/2}) = k_{c1}k_{c2}k_{c3}A_{Zn(OH)_4^{2-b}}/$$

$$(k_{a1}k_{a2}k_{a3}c_{OH}^{-b4}) \exp(-2FV/RT) + 3A_{OH} - c_{OH}^{-b} \quad [19]$$

The derivative of the potential with respect to the logarithm of S is

$$dV/d(\log S) = -2.3RT\{3A_{OH} - k_{a1}k_{a2}k_{a3}c_{OH}^{-b3} / [A_{Zn(OH)_4^{2-b}} - k_{c1}k_{c2}k_{c3} \exp(-2FV/RT)] + 1\}/2F \quad [20]$$

Evaluation of Eq. [20] at 298 K yields a value of approximately 30 mV/decade. This is in agreement with experimental results (3) obtained with 1 and 2M NaOH (Fig. 3).

From Eq. [17], we can determine the effects of zincate concentration and of hydroxide concentration on current density

$$\begin{aligned} \partial \log i / \partial \log c_{Zn(OH)_4^{2-b}} &= 1/[1 - k_{a1}k_{a2}k_{a3}c_{OH}^{-b4} \exp(2FV/RT) / \\ &\quad (k_{c1}k_{c2}k_{c3}c_{Zn(OH)_4^{2-b}})] \quad [21] \end{aligned}$$

and

$$\begin{aligned} \partial \log i / \partial \log c_{OH}^{-b} &= \{(3 + 2H) / \\ &\quad (2Fk_{a2}K_1c_{OH}^{-b3} \exp[(2 - \beta_2)FV/RT] + \omega^{-1/2}3A_{OH} - c_{OH}^{-b} \\ &\quad + \omega^{-1/2} [4A_{Zn(OH)_4^{2-b}} \exp(-2FV/RT) / \\ &\quad (K_1K_2K_3c_{OH}^{-b4})])\}i \quad [22] \end{aligned}$$

These expressions represent an apparent reaction order when mass transport is taken into account. The apparent reaction order with respect to zincate is approximately 0 at relatively positive potentials; it only becomes significantly larger at more negative potentials, near the reversible potential. The apparent reaction order with respect to hydroxide is generally between 3 and 4 in the range of interest. In these calculations, we incorporated activity

Table III. Apparent reaction orders with respect to hydroxide and zincate

	Calculated	Experimental	Potential (vs. NHE)
$\partial \log i / \partial \log c_{OH}^{-b}$	3.33		V = -1.23
	3.66	3.6	V = -1.26
$\partial \log i / \partial \log c_{Zn(OH)_4^{2-b}}$	-0.01		V = -1.23
			$c_{Zn(OH)_4^{2-b}} = 10^{-7}$
			V = -1.20
	-9.6×10^{-6}		$c_{Zn(OH)_4^{2-b}} = 10^{-9}$

Values computed when mass transport is taken into account. Potentials are with respect to the NHE. Rotation rate is 800 rpm. The experimental value was computed from only two concentrations taken from Ref. (3).

coefficients appropriate for KOH: 0.76 for 1M KOH and 0.92 for 2M KOH (6). Values of calculated and experimental apparent reaction orders appear in Table III.

In further work, we plan to extend these results to more anodic potentials and to develop a more comprehensive model describing anodic dissolution and passivation for this system.

Passivation Behavior of Titanium-6Al-4V Alloy in Phosphoric Acid Solution

D. D. N. Singh

National Metallurgical Laboratory, Corrosion Section, Jamshedpur 831007, India

Titanium metal, because of its light weight, good mechanical properties, and excellent corrosion resistance, has been increasingly considered for various applications in the process industries through laboratory investigations. The corrosion resistance of the metal is due to its inherent nature to form stable titanium dioxide. The potential-pH diagram of titanium (1) indicates that the formation of oxide film on the metal becomes thermodynamically unstable in nonoxidizing acidic aqueous environments, which results in a general dissolution of the metal. This behavior limits the more widespread use of the metal in many nonoxidizing acids such as sulfuric, hydrochloric, phosphoric, and oxalic in different process industries. The stability of the metal in such environments can be restored by the adjustment of potential by the use of anodic passivation either by means of impressed current or by alloying with other metals, such as palladium or nickel, or by introducing a redox system in the environment (2). Out of all these methods, anodic passivation is considered superior because of high range of passivation potential observed for titanium in most of the environments. For a metal to be protected anodically in an environment, the necessary condition is a low order of passive dissolution current and passive potential.

The frequent failure of titanium materials in nonoxidizing acid solutions has attracted the attention of many workers to the study of the electrochemical behavior of the metal in such media (3-7). However, relatively less attention has been paid to the passivation behavior of titanium in phosphoric acid solution, which is an important chemical in industries. Phosphoric acid is a nonoxidizing acid and has a deleterious action towards titanium and its alloys. The present paper deals with the passivation tend-

ency of an industrially important titanium alloy, Ti-6Al-4V, in different concentrations of phosphoric acid at different temperatures.

Experimental

Titanium alloy of composition 6Al-4V in sheet form (18 SWG) embedded in epoxy resin with 3 cm² of working area was used as working electrode. Prior to immersion in the electrolyte, it was polished with 6/0 grade emery paper, dipped in 5% H₂SO₄ containing 0.01M NaF, followed by a thorough rinsing with distilled water, and then, finally, degreased with methanol. A platinum sheet was used as an auxiliary electrode. A Luggin probe saturated calomel reference electrode assembly was employed; it contained an isolating stopcock to avoid contamination by the chloride solution of the reference electrode. Electrode potentials are reported vs. saturated calomel electrode (SCE) uncorrected for liquid-junction potentials.

Anodic polarization studies were carried out using a Taccussel potentiostat (PRT 20-2X), and potential and current were recorded using a Houston X-Y-T recorder (Model 2000). The potential was swept at the rate of 1 V/h after a steady corrosion potential was achieved.

Analar-grade chemicals were used. NaF was used as a source of F⁻ in the solution. The experiments were performed at 32° ± 1°C.

Results and Discussion

Figure 1 shows the potential-time curves for the alloy in blank 85% H₃PO₄ as well as containing different concentrations of water and F⁻. In all cases, it is found that the potential moves in active direction with time, indicating the dissolution of pre-existing oxide film on the metal

Fig. 1. Potential-time curves for the alloy in different concentrations of phosphoric acid.

surface. Attainment of the steady potential in the presence of fluoride ion is sluggish compared to the blank solution. The addition of small amounts of water in phosphoric acid does not alter the nature of the curves, but it does shift the potential in a more active direction as compared to blank solution.

The anodic polarization behavior of titanium in 85% H_3PO_4 and containing different concentrations of F^- is shown in Fig. 2. In the pure acid, the metal passivates after exhibiting a small range of active dissolution. The addition of F^- increases the critical current density and primary passivation potential considerably. The passive dissolution current is dependent upon the presence of F^- . It is noted that the active-passive curves for titanium (i.e., S-type curves) are recorded for acid solutions containing more than 450 ppm F^- . For solutions containing less F^- , the curves are similar to the one recorded in the absence of any F^- . However, the current increases with increasing F^- at any potential.

Fig. 2. Effect of fluoride ion on anodic polarization of the alloy in 85% H_3PO_4 .

Fig. 3. Variation of critical current density with concentration of fluoride ion.

The dependence of critical current density for the onset of passivity (i_{cr}) on F^- concentration has been plotted in Fig. 3. A straight line with slope 1.0 is observed. That slope is less than the slope reported for titanium in H_2SO_4 solution (3). This may be attributed to the relatively mild corrosive action of H_3PO_4 as compared to H_2SO_4 and stronger adsorption capability of PO_4^{3-} than SO_4^{2-} on the metal surfaces, as well as to the differences in alloy composition. It was not possible to conduct the experiments precisely above F^- concentration of 0.1M because of large fluctuations in the active potential region. Such fluctuations are generally ascribed to the competitive depassivation-repassivation reactions taking place on the metal surfaces, the possibility of which exists in a solution containing PO_4^{3-} and F^- ions.

The influence of the addition of triply distilled water on the steady-state corrosion potential of titanium in phosphoric acid is recorded in Fig. 4. The steady-state corrosion potential initially moves in active direction with the addition of water and subsequently in nobler direction. This indicates that the presence of water (up to 70% of the acid) has a deleterious effect on titanium dissolution. This was further confirmed by the plot of anodic polarization (Fig. 5), where it has been found that the active as well as the passive dissolution rate in 70% H_3PO_4 is considerably higher as compared to lower and higher acid ranges. This change in corrosiveness of the acid is probably related to its change in structure with dilution. In a solution containing 86% H_3PO_4 , the phosphate ions are interconnected by hydrogen bonds. But, in a diluted solution, the phosphate ions are hydrogen bonded to the

Fig. 4. Effect of the acid dilution on the passive dissolution current density and steady-state corrosion potential of the alloy.

Fig. 5. Anodic polarization behavior of the metal in different concentrations of the acid.

water liquid lattice, rather than to other phosphate ions (8, 9). It is, therefore, expected that a dilute solution of phosphoric acid should have poorer solvation effect as compared to a concentrated acid. The reasons for a higher dissolution current observed at and above 70% acid solution is, however, not clear. The possibility of interaction of the newly added water molecule (10), which is considered as a Lewis base, with pre-existing Lewis acid regions in the oxide layer of titanium (10-12) is ruled out because of the presence of excess of water molecules in 85% H_3PO_4 and also because of the presence of Bronsted acid, *i.e.*, hydronium ion in the solution.

Variation of the passive dissolution current with dilution of the acid is shown in Fig. 4. The highest and the lowest current density are observed in an acid concentration range of 60%-55% and in 85%, respectively.

Fig. 6. Weight loss vs. time plot for the corrosion of the metal in 85% and 75% H_3PO_4 .

Fig. 7. Effect of the fluoride ion on the passive dissolution of the alloy in 85% H_3PO_4 .

To determine the nature of the kinetics of corrosion of the metal, some weight loss experiments were conducted for free dissolution in 85% and 75% H_3PO_4 . Weight loss vs. time plots are shown in Fig. 6. The dissolution of the metal in higher acid concentration (85%) is considerably lower than that in 75% acid. Optical microscopic examinations of the corroded surface showed uniform attack by the acid on the metal surface at both concentrations.

Influence of fluoride ion on the passive dissolution of titanium alloy in 85% H_3PO_4 is plotted in Fig. 7. In these experiments, the electrode potential was fixed in the passive range (*i.e.*, at 1.00V or at 2.50V SCE). The passive current density i_{pass} is strongly dependent upon the fluoride concentration but does not change much with potential, indicating a strong and stable passive film on the surface. i_{pass} varies with fluoride concentration $[F]$ as

$$i_{pass} = A [F]^\alpha$$

where A and α are constants at a fixed potential. The value of α was found to be of the order of 0.7 and is not dependent on potential. Nonintegral orders for dissolution of oxides have been reported for other metals oxides (13, 14). A dissolution order of 1.8 has been reported for passive titanium in sulfuric acid containing NaF (15). It has been suggested that the adsorption of fluoride ion on the surface and the role of surface reactions are important factors in the dissolution of such type of oxides (13). As expected, the order of dissolution in passive state of the metal (0.70) is lower than that in the active state (1.0).

Figure 8 shows the effect of temperature on the anodic polarization behavior of titanium in concentrated phosphoric acid (85%) solution. With increasing temperature,

Fig. 8. Influence of temperature on the anodic behavior of the metal.

the active corrosion region is lengthened. The passive current density also increases gradually with temperature. This indicates that the passive film is less resistant in concentrated acid solution at higher temperatures. The initial potential ($-0.40V$ SCE) of stable passivity, however, remained constant at all the temperatures studied.

Conclusion

The passive film on titanium-6Al-4V alloy in different concentrations of phosphoric acid is stable over a wide range of potentials with a low passive dissolution current density. Additions of low percentages of water are found to accelerate the active as well as the passive dissolution of the metal in the acid solution. A sufficiently diluted acid, however, reduces the corrosive action. Metal dissolution in the acid in active region is found to be first order, with respect to fluoride ion; it is less than unity in the passive state. The potential has hardly any effect on the passive dissolution of the metal in the acid solution containing fluoride ion. Increases in temperature accelerate metal dissolution in the active as well as in the passive regions.

A Degradation due to Surface Oxidations in GaAlAs Red Light Emitting Diodes and a Prevention of It

H. Yamanaka and S. Koike

Matsushita Electronics Corporation, Semiconductor Division, Nagaokakyo, Kyoto, 617 Japan

Ga_{1-x}Al_xAs red light emitting diodes (LED's) of 650 ~ 660 nm wavelength are being developed due to interest in new applications such as outdoor signs, crosswalk signals, and light sources for optical plastic fiber communications. This is because of high brightness and the fact that their emission wavelength just corresponds to the wavelength region of low attenuation in plastic fibers (1-3). This technical note describes a degradation due to surface oxidation in these GaAlAs red LED's and gives a method for prevention.

The GaAlAs red LED consisted of p-type Ga_{0.65}Al_{0.35}As and n-type Ga_{0.35}Al_{0.65}As layers grown by a conventional liquid-phase epitaxial method on a p-type GaAs substrate as shown in Fig. 1. The thickness of the epitaxial p- and n-GaAlAs layers are 30 ~ 40 μm and 15 ~ 20 μm, respectively. Figure 2 shows degradation characteristics of epoxy-encapsulated present LED's aged at a current density of $J_f = 16.3$ A/cm² at 85°C with atmospheric relative humidity of 85% (dashed line) and without humidity (solid line), respectively. In the humid atmosphere, there were remarkable fluctuations of output power at about 100h and an output power decrease of 20 ~ 50% at 1000h. However, this degradation could not be observed in the LED's after enforcing a boil test with no bias voltage (no current). These results prove that applying voltage under the humid atmosphere causes this degradation.

A cross-sectional photograph of the degraded LED is displayed in Fig. 3. An absorptive dark layer, which interrupted the radiative light to be emitted outside, formed on the surface of the Ga_{1-x}Al_xAs layer. Figure 4 (left) gives an Auger electron spectroscopy (AES) in-depth profile of the absorptive layer, showing the presence of Al, Al₂O₃, Ga, and As. However, it is not possible to determine whether the Ga and As exist in elemental form or as ox-

ides. Considering that Ga₂O₃, Al₂O₃, and As₂O₃ are optically transparent oxides for the emission wavelength, ele-

Fig. 1. Schematic illustrations of a GaAlAs red LED and a mechanism for the formation of the absorptive layer.

Fig. 2. Degradation characteristics of GaAlAs LED's after aging with and without humidity.

Fig. 3. A cross-sectional photograph of the degraded LED

Fig. 5. Degradation characteristics of GaAlAs LED's with and without native oxide films.

mental Ga, Al, and As seem to act as sources of the absorptive function for the emitting light (4). It should also be noted that in Fig. 3 the absorptive layer grew thicker near the n-electrode. These facts suggest a mechanism for the formation of the absorptive layer, based on an electrochemical process using current paths from the n-electrode to the surface. This is associated with (OH)⁻ ions transported through the medium of the epoxy mold as shown in Fig. 1.

Therefore, in order to prevent the absorptive layer from forming, the surface of GaAlAs LED's must be covered with an optically transparent insulator film to cut off the current path. For this purpose, a native oxide film was grown in a solution with NH₄OH and H₂O₂ in 1:100 volume ratio. It could be formed easily on lateral parts, as well as on the upper part of the LED's surface at the same time. It was verified that the resulting film, uniformly blue and about 30 nm thick, was transparent to emission

Fig. 4. Auger electron spectroscopy (AES) in-depth profile of an absorptive layer (left) and a native oxide film (right)

wavelength by measurement of output power. The AES in-depth profile of the native oxide film is represented in Fig. 4 (right). The elemental Al and products including Ga and As in the native oxide film are easily reduced in comparison with GaAlAs epitaxial layers, which is reasonable because the solution employed is one of well-known etchants for GaAs (5, 6). The solid lines in Fig. 5 show degradation characteristics of the GaAlAs red LED's covered with the former native oxide film aged in the same humidity as that of Fig. 2. The dashed lines in the figure, the characteristics of the LED's without covered layer, are also represented. The fluctuations of the output power of the oxide covered LED did not occur after 1000h, even under the humid atmosphere. These results support the described formation mechanism of the absorptive layer and the presumption that elemental Al, Ga, and As are involved in the absorption of the emitting light. The method described here is one which provides effective prevention.

Chromium-Doped Raney Nickel Catalyst for Hydrogen Electrodes in Alkaline Fuel Cells

T. Kenjo

Department of Applied Science for Energy, Muroran Institute of Technology, Mizumoto-cho, Muroran, Japan 050

Raney nickel is a relatively inexpensive and highly active non-noble metal catalyst for hydrogen electrodes in alkaline fuel cells. Sturm, Richter, and Mund found that its catalytic activity was enhanced by doping transition metals such as titanium, iron, and molybdenum (1, 2).

During the course of attempting to add various dopants to Raney alloys, we have found that tenth percents of chromium markedly enhance the activity of Raney nickel. In this study, hydrogen electrodes catalyzed with this new Raney nickel have been prepared, and their polarization characteristics have been measured. For comparison, the polarization data are shown with those for titanium-doped and nondoped Raney nickels which undergo the same electrode processing.

Experimental

Preparation of the catalyst.—A melt possessing a mass fraction of 60% aluminum and 40% nickel + dopant was prepared with an induction furnace at 0.4 torr using an alumina crucible. It was quenched by pouring into an iron cylinder. The ingot obtained was powdered to a particle size smaller than 37 μm . Aluminum was leached with 6M KOH solution ($1M = 1 \text{ mol/dm}^3$) at 80°C for 12h. Raney nickel obtained as a black precipitate was washed alternatively with water and methylalcohol several times. The BET surface area for 0.4% chromium-doped catalyst was 64.7 m^2/g at this stage.

Preparation of the electrodes.—Polytetrafluoroethylene (PTFE) binder (Polyflon dispersion D-1, Daikin Industrial Company) was mixed with the Raney nickel precipitate, which was covered with water to prevent air exposure. The content of PTFE added was 10% in weight against the dry catalyst. The mixture was milled under blowing at room temperature. It became a paste as the water vaporized off. The paste obtained was callender-rolled by hand into sheets. After dried in air overnight, they were washed in boiled acetone to remove the surfactant which had been originally contained in the PTFE dispersion. This electrode processing results in a natural depyrophorization of Raney nickel catalyst so that the catalyst layer thus obtained can be handled safely in air. The BET surface areas of the nondoped, 0.4% chromium-doped, and 0.4% titanium-doped Raney nickels at this stage are 14.0 m^2/g , 10.8 m^2/g , and 8.8 m^2/g , respectively.

The gas-side layers were prepared by binding nickel black powder (prepared by heating nickel formate at 250°C in hydrogen atmosphere) with PTFE in the same manner as in the catalyst layers. They were reinforced with 100 mesh stainless-steel screens and then heated at 380°C in nitrogen atmosphere. They were attached to the catalyst layers by pressing at 630 kg/cm^2 . The double-layered electrodes thus obtained were heated at 180°C in hydrogen atmosphere to activate the catalyst. The BET surface areas for nondoped, 0.4% chromium-doped, and 0.4% titanium-doped Raney nickels at this stage are 47.7 m^2/g , 59.3 m^2/g , and 64.6 m^2/g , respectively. Most of the surface area loss during the electrode processing is recovered in this activating process.

Measurement of the polarization.—The geometrical working area of the test electrodes was 7 cm^2 . The counterelectrode used was a silver-catalyzed oxygen electrode. The electrolyte used was 6M KOH solution and was circulated between both electrodes at a rate of 5 ml/min. The electrode potential was measured against the Hg/HgO reference electrode. The IR voltage drop was eliminated by the current-interruption method.

Results and Discussion

Polarization curves of the hydrogen electrodes catalyzed with chromium-doped Raney nickels are shown in Fig. 1 with variation of the chromium content in the starting alloys. There are no significant doping effects in a chromium content less than 0.1%, but on exceeding 0.2%, the polarization drops caused by doping become marked.

The polarization curves observed are essentially linear in a load less than 100 mA/cm². The polarization resistance can therefore be calculated from the slope in this load range and used as a measure for the catalytic activity. Figure 2 shows the plots of polarization resistance vs. chromium content in comparison with the similar plots for titanium-doped Raney nickel. Chromium lowers the polarization resistance by a factor of about 4, whereas titanium does so by a factor of 2.4 at the minimum. This indicates that the chromium-doped Raney nickel is more active than the titanium-doped catalyst.

Although high activities are maintained at chromium contents ranging to 2%, the upper limit for practical use should be 1% because the alloy powder becomes too soluble in 6M KOH solution when it exceeds this limit.

As seen in Fig. 2, the polarization resistance for the titanium-doped catalyst is minimized at a content of 0.4%, and the bottom of the curve is very narrow. According to the study done by Mund, Richter, and Sturm, the minimum value is found at higher titanium contents of 1.5-2%, and the bottom of the curve is much wider than that in the present study. The discrepancy between these two seems to be ascribable to different depyrophorization methods. Mund, Richter, and Sturm exposed dried catalyst slowly to oxygen. In this study, mixing the wet catalyst with the PTFE dispersion in air results in a natural depyrophorization. The surface oxidation in wet probably maintained the catalytic surface at a lower temperature than that in dry, resulting in a different surface condition.

The limiting current density (i_L) also is increased by doping chromium, as seen in Fig. 1, but the optimum dopant concentration is lower than that for the polariza-

Fig. 3. Pressure dependence of the polarization characteristics. Catalyst loading: 30 mg/cm². Electrolyte: 6M KOH 60°C. Chromium content: 0.2%. IR drop eliminated.

Fig. 4. Influence of the catalyst loading on the polarization characteristics. Chromium content: 0.2%. Electrolyte: 6M KOH 60°C. Catalyst loading: (■) 13.3 mg/cm²; (▲) 24.6 mg/cm²; (□) 30.5 mg/cm²; (△) 37.6 mg/cm²; (○) 39.3 mg/cm²; (●) 91.5 mg/cm². IR drop eliminated.

tion resistance. The i_L value is maximized at a dopant content as low as 0.2%, where the polarization resistance is still decreasing. This suggests that the i_L value obtained is very close to the upper limit of Raney nickel electrodes that can be attained by the activity improvement alone. A further increase is possible when a higher gas pressure is applied; 1.2 A/cm² is sustained at 1.5 atm, as shown in Fig. 3. This is probably due to an accelerated gas transportation through the electrode pores.

The dependence of polarization characteristics on the catalyst loading is shown in Fig. 4 for 0.2% chromium-doped catalyst. The polarization observed is lowered with increasing catalyst loading. This can be explained on the basis of the electrolyte film model (2). The polarization resistance ω is expressed as a function of the thickness of catalyst layer d

$$\omega = \sqrt{\rho \cdot k} \coth \sqrt{\rho \cdot d^2/k} \quad [1]$$

where ρ is the resistivity of the electrolyte film covering the catalytic surface, k the interfacial resistance at the film/catalyst interface. The catalyst loading is proportional to the thickness; 1 mm = 300 mg/cm² in this case. The parameters k and ρ , which characterize the catalyst, are obtained as values providing the curve fitting best to the experimental data. Figure 5 contains such plots of ω^{-1} vs. d for the 0.2% chromium-doped catalyst. The best-fit curve (solid line) gives parameter values of $k = 1.3 \times 10^{-3} \Omega \text{cm}^2$ and $\rho = 7.5 \Omega \text{cm}^2$. With the nondoped Raney nickel catalyst, $k = 4.5 \times 10^{-3} \Omega \text{cm}^2$ and $\rho = 11 \Omega \text{cm}^2$ were obtained with the same procedure. The k value is a measure of the catalytic activity such that a smaller value corresponds to a higher activity. An activating effect of the chromium dopant has thus been shown from the comparison of these two k values.

Fig. 5. Reciprocal polarization resistance ω^{-1} as a function of the catalyst loading. Chromium content: 0.2%. Electrolyte: 6M KOH 60°C. Solid line calculated from Eq. [1]. IR drop eliminated.

The Arrhenius plots of the polarization resistance for 0.8% chromium-doped catalyst are shown in Fig. 6 in comparison with the plots for 0.8% titanium-doped catalyst. The activation energies calculated from the slopes are 34.5 and 31.6 kJ/mol for the titanium-doped and chromium-doped catalysts, respectively. This suggests that the lower activation energy results in a lower polarization resistance at a temperature range studied. Their BET surface areas are very close to each other, as described in the experimental section. The chromium-induced high activity is thus attributed to a low activation energy for the polarization.

Fig. 6. Arrhenius plots of the polarization resistance for chromium- or titanium-doped Raney nickel. Dopant content: 0.8%. Catalyst loading: 40 mg/cm². Electrolyte: 6M KOH 60°C. IR drop eliminated.

Fig. 7. Polarization change of the nondoped Raney nickel electrodes when the loading-unloading cycle is repeated. Catalyst loading: 21 mg/cm². Electrolyte: 6M KOH 60°C. (○) 1st run; (□) 2nd run; (△) 3rd run; (●) 4th run. IR drop eliminated.

Fig. 8. Polarization change of the 0.8% chromium-doped Raney nickel electrodes when the loading-unloading cycle is repeated. Catalyst loading: 52 mg/cm². Electrolyte: 6M KOH 60°C. (○) 1st run; (△) 2nd run; (□) 3rd run; (●) 4th run. IR drop eliminated.

The limiting current density for the electrode with the chromium-doped catalyst is not very dependent upon temperature. The electrode catalyzed with 0.2% chromium-doped Raney nickel sustains a load of 900 mA/cm² at 60°C (Fig. 3) and still maintains a value as large as 500 mA/cm² at 30°C.

The polarization for the nondoped Raney nickel increases with repeating loading-unloading cycle, as Fig. 7 shows. This polarization change is probably due to an unstable surface condition of the nondoped catalyst. The chromium doping can prevent this. Figure 8 shows the case of 0.8% chromium-doped Raney nickel. In contrast to the case of nondoped Raney nickel, the polarization essentially does not change with every cycle, although a slight decrease can be seen. This is a stabilizing effect of the chromium dopant.

Figure 8 also shows the best performance obtained in the present study. In this case, 52 mg/cm² and 0.8% were chosen as a catalyst loading and chromium content, respectively. A polarization of 20 mV is attained at a load of 500 mA/cm² and 60°C. The polarization resistance calculated from the slope is 0.04 Ωcm². This is one-fifth as large as the lowest value for nondoped catalyst.

In conclusion, we can say that chromium is a good dopant for Raney nickel used for hydrogen electrodes. It improves and stabilizes the polarization characteristics of Raney nickel electrodes. The chromium-doped Raney nickel is more active than the titanium-doped catalyst and provides a high activity over a wide range of the dopant content.

Porous Anodic Films on Aluminum at Low Potentials

D. Y. Jung* and M. Metzger*

Department of Metallurgy and Mining Engineering and Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

There exists a considerable literature on the formation conditions and structures of thick porous anodic films formed on aluminum in sulfuric, phosphoric, oxalic, or chromic acids at high potentials. As formed at room temperature at cell voltages from about 10 to > 100V with respect to a platinum cathode, these films are composed of columnar cells (typically 2.5-2.8 nm/V diam) with a central pore (diameter varies somewhat, near 1 nm/V), which terminates in a barrier layer of thickness about 1.0 nm/V (1-5). The "cell voltage" here serves as an approximation to the forming overpotential across the film. Film growth, i.e., pore lengthening, occurs across the barrier layer the thickness of which is maintained constant by electrochemical decomposition of the layer at its external surface (6, 7). There is also a slow purely chemical dissolution of the pore walls, causing them to taper during film growth, and the film reaches a limiting total thickness at the pore length at which the cell wall has tapered to zero thickness (8, 9). This body of information may have value as a guide in investigating and understanding the behavior of films on aluminum at potentials in the corrosion range.

In the course of a study on selective dissolution in Al-Cu alloys, some capacitance and other observations on aluminum in sulfuric acid pertinent to this question were made, and these are reported here. The differential capacitance of aluminum electrodes in 1, 5, and 10N H₂SO₄ was measured some years ago by Petrocelli (10), who found evidence of films he estimated as 1-5 nm thick, with 1/C linear with potential increment above the corrosion potential (near -0.9 V_{SCE}) over a 3V range. Films formed in 2.4M H₂SO₄ at 1.0 V_{SCE} have been examined by transmission electron microscopy by Zahavi *et al.* (11), who found them to be porous, although the details of the pore structure were too fine to measure. The total thickness of these films was much greater than the values given by Petrocelli, which would be expected if his films were porous and the measured capacitances sensed only the barrier layer thicknesses (12).

The capacitance of annealed specimens of 99.999% Al sheet mechanically polished through 0.05 μm alumina was measured at various potentials by modulating the control potential (from a PAR 373 potentiostat with risetime < 10⁻³s) with a 1 kHz 1 mV peak to peak signal from a lock-in amplifier (Ithaco 391A) and measuring the out-of-phase current. Measurements were made at 25.0 ± 0.2°C without deaeration or stirring. The specimen was allowed a few minutes to come to its steady corrosion potential near -1.04 V_{SCE}, and then it was scanned upward at 0.1 V/12 min and the scan reversed at 1.0 or 1.2 V_{SCE}. In the case of the porous films formed at higher potentials, it is known that a substantial reduction in cell voltage, say, from 10 to 5V, produces a period of low current lasting many minutes ("recovery"), during which the barrier layer thins, initially only by slow chemical dissolution, until the field across it increases sufficiently for the

forming current to reach the new steady state (13). In the present experiments, steady state was achieved in a few minutes because of the small potential step of 0.1 or 0.2V, and the currents and capacitances attained the same steady-state values for upward or downward scans. Duplicate runs gave almost identical results.

Inverse capacitance *vs.* potential at steady state is shown in Fig. 1. 1/C was linear in potential down to 0 V_{SCE}, but the slope decreased at lower potentials. The nonlinear region had not been observed by Petrocelli. His values for 5N H₂SO₄ lay below the values in Fig. 1, presumably because his surfaces had been finished on coarser abrasive and were rougher, and his slope for this concentration was lower than that of the linear part of Fig. 1. The present observations could be extended to somewhat lower potentials than his and were terminated at -1.3 V_{SCE} because of fluctuations in the measurements accompanying increased hydrogen evolution at lower potentials.

The measured capacitance represents the film capacitance, C_f, in series with the double-layer capacitance, C_{dl}, at its external surface. If the latter is assumed independent of potential, then 1/C_f has the shape of the 1/C curve of Fig. 1 but lies below this by 1/C_{dl}. This would not affect the linearity or slope of the region above 0 V_{SCE}. With the estimated dielectric constant 9 and a roughness factor 1, this linear region gives for barrier layer thickness a ratio 1.0 nm/V, which agrees with the value determined electronmicroscopically at much higher potentials [for films formed in phosphoric or oxalic acids (2, 5)]. This suggests that classical porous film behavior applies down to 0 V_{SCE}.

It is readily deduced that the films formed in the nonlinear region of Fig. 1 must also have been of some porous type. As part of the study of electrode structure, AES depth profiles had been determined after exposure at

Fig. 1. Steady-state inverse capacitance at 1 kHz vs. potential for aluminum in 2.4M H₂SO₄.

two potentials in this region. The sputtering rate had been calibrated employing a compact anodic film, and it was found that the steady-state total film thickness at $-0.50 V_{SCE}$ was equivalent to a 4 nm thick compact film and at $-0.10 V_{SCE}$ to a 30 nm compact film. At these potentials, the capacitance measurements yielded apparent film thicknesses of ≤ 1 nm. The formation of a porous film is consistent with other evidence. When a specimen is potentiostated at these potentials, the cell current is initially high and passes through a minimum and a shallow maximum before leveling off; this behavior is characteristic of porous film formation by constant-voltage anodizing (14, 15). The rapid increase in steady-state total film thickness with increasing potential is also a characteristic of porous films, since the pore wall is thicker and the rate of pore lengthening higher, so that the limiting thickness determined by tapering of pore walls through chemical dissolution is reached at greater pore lengths. The steady-state total thickness increased to a compact film equivalent of 110 nm at $+0.5 V_{SCE}$, at which point it became inconvenient to measure by sputtering under the calibrated conditions.

Another point of comparison is the known incorporation of sulfur into sulfuric acid anodic films (6, 14). Cherki and Siejka (6), for example, found by Rutherford backscattering 3.6 atomic percent (a/o) S in films formed in 15% sulfuric acid at 10V. In the present work, AES spectra on the surface of films formed at -0.50 , -0.10 , or $+0.50 V_{SCE}$ confirmed the presence of S at ~ 0.5 a/o (within a factor of two). This would not be directly compared with figures in the literature, which are bulk analyses.

The nonlinear behavior in the lower part of the curve of Fig. 1 is thought to arise in two ways. For $E \leq -1.0 V_{SCE}$, i.e., on attaining potentials near and below the corrosion potential, the rise of $1/C$ would reflect blocking of many pores by trapped hydrogen gas bubbles so that the apparent capacitance is lowered. Such an explanation is not applicable in the higher part of the nonlinear region of Fig. 1, which extends a little above the hydrogen reversible potential. However, another reason for a deviation from the classical behavior comes from consideration of the dimensions of the classical pore structure. In this potential range, the film forming potential difference can be at most something like 1V, and this would make the pore diameter only about 1 nm, according to the classical ratio. It is not realistic that the electrochemical behavior and the geometry of such a fine structure will remain quantitatively the same as that of much coarser structures. Even at slightly higher potentials in the linear part of Fig. 1, where the slope of $1/C$ agreed with the classical ratio for barrier-layer thickness, the pore and cell dimensions may not have conformed to their classical values.

For formation of the supposedly classical porous film above $0 V_{SCE}$, the minimum potential which is required for the presence of a forming overpotential, η_{ox} , across the barrier layer may be examined with reference to the linear region in Fig. 1. Without correction for the unknown double-layer capacitance (i.e., for very large C_{dl}), this line would extrapolate to $1/C = 0$ at about $-1.4 V_{SCE}$. The potential for zero classical film thickness cannot be lower than this. If C_{dl} were 40 or $20 \mu F/cm^2$ independent of potential, $1/C$ would extrapolate to zero film thickness at -1.2 or $-1.0 V_{SCE}$. The reversible Al/Al_2O_3 potential depends slightly on the form of oxide assumed; it may be taken for the present solution as $-1.7 V_{SCE}$. Thus, if the total overpotential is written as the sum of the overpotentials at the interfaces plus that across the barrier layer of the film, $E - E_{eq} = \eta_m + \eta_s + \eta_{ox}$ (16, 17), the two interface overpotentials would add to at least 0.3V and probably

substantially more. Siejka *et al.* (17) examined this question in studies employing nuclear microanalysis of oxygen for compact films formed in ammonium citrate and found the interface overpotentials to add to zero within $\sim 0.1V$ for unpolished aluminum. This is to be expected in the absence of significant film dissolution, according to the analysis of Dignam and Kalia (18). That the sum of the interface overpotentials was larger in the present case can be attributed to the formation of a porous film requiring a substantial overpotential at the barrier layer-solution interface to effect the rapid electrochemical decomposition of the film occurring there.

From the above, the formation of a classical porous film is possible only above a certain minimum potential, which is higher than $-1.4 V_{SCE}$. The film, which is present according to Fig. 1 from 0 to $-1.3 V_{SCE}$, may be considered a nonclassical porous film. This would be able to form below the minimum potential for the classical film if the sum of the interface overpotentials were smaller for the nonclassical film. A nonclassical porous film could also form above the minimum potential for the classical film if the kinetics were favorable. According to the present interpretation, this situation prevails over much of the nonlinear range of $1/C$ below $0 V_{SCE}$.

From the considerations presented here, it is concluded that for aluminum in sulfuric acid the classical porous film formalism developed in anodizing studies at high potentials is not quantitatively valid at potentials in the corrosion range, but this information has value in understanding at least the qualitative aspects of film-formation behavior in this range.

Electrical Resistivity of Aluminum Carbide at 990-1240 K

W. R. King and R. C. Dorward

Kaiser Aluminum and Chemical Corporation, Center for Technology, Pleasanton, California 94566

In the conventional aluminum electrolytic reduction process, a molten metal pool is contained in a carbon cell bottom. Since the standard free energy of the reaction

is about -145 kJ/mol at 1273 K (1), it is not surprising that aluminum carbide (Al_4C_3) can form at the interface between the metal and the carbon. An Al_4C_3 reaction layer is thought to be responsible for a significant voltage drop, thereby reducing the energy efficiency of the reduction process (2). To gain a better understanding of the voltage drop that could be expected in this region, the electrical resistivity of Al_4C_3 was measured at temperatures of interest (990-1240 K).

Several methods of preparing Al_4C_3 , including reactions of carbon with Al_2O_3 , AlPO_4 , and aluminum metal at tem-

peratures up to 1770 K , were tried before one was found that produced material of sufficient purity and yield. The process finally used consisted of heating a mixture of 0.5 mm diam aluminum shot, high purity graphite, and natural cryolite in a graphite boat to about 1570 K in purified argon. The temperature was then raised to about 1770 K , allowing the cryolite to volatilize. The amount of carbon used was only 97.8% of theoretical stoichiometric quantity, as it was found that a slight excess of aluminum was necessary, especially when conducting the reaction in a graphite boat. When the boats were removed from the furnace, a dark crust covered the Al_4C_3 , which was bright orange in color. The Al_4C_3 reaction product was analyzed for aluminum and carbon and found to contain 75.0 weight percent (w/o) Al and 24.2 w/o C, indicating that the purity was at least 99% . X-ray diffraction analysis of the material suggested a trace of carbon impurity.

Fig. 1. Electrical resistance apparatus for measurement of elevated temperatures. 1: Inconel rods (0.635 cm diam). 2: Brass collets. 3: Quartz tube. 4: Alumina tube sample holder.

Fig. 2. Resistance of Al_4C_3 as a function of temperature. Solid symbols: heating. Open symbols: cooling. 1.00 cm specimen 57% dense, 0.46 cm specimen 61% dense.

Fig. 3. Specific resistivity of Al_4C_3 as a function of temperature. Circles (1.00 cm specimen) and squares (0.45 cm specimen) based on $\rho = AR/l$. Dashed line based on $\rho = A\Delta R/\Delta l$, assuming both specimens 60% dense. Data were corrected for density by Bruggemann equation.

Pellets of 0.635 cm diam and 0.5-1.0 cm length were pressed from powder wetted with petroleum ether in a steel die at a pressure of about 650 MPa. The pellets had apparent densities of about 60% of theoretical (2.99 g/cm^3), and were not strong enough to allow surface contacts to be made as in the conventional four-point resistivity method. They had sufficient strength, however, to hold together when restrained between two Inconel rods in the electrical resistivity apparatus shown in Fig. 1. The Inconel rods, sample holder, and pellet were enclosed in a quartz tube, which had provision for flowing argon gas through it. One of the Inconel rods was hollow, but closed on one end allowing a thermocouple to be placed within a few millimeters of the sample. The apparatus was placed in a Leco tube furnace so that the center portion could be heated. Before heating, the system was flushed with purified argon for several hours. The electrical resistance measurements were made with a Wheatstone bridge connected across the ends of the Inconel rods.

The resistance data for two samples of lengths (l) 0.46 and 1.00 cm are shown in Fig. 2 as $\ln R$ vs. $1/T$ plots. Apparent resistivities were calculated by two procedures: (i) from the one-dimensional conduction equation $\rho = AR/l$, and (ii) from the differential relation $\rho = A\Delta R/\Delta l$, where ΔR and Δl are the differences in resistance and length of the two specimens. The latter method eliminates any potential contact resistance effects, provided they are the same in each test. An attempt was also made to correct for density using the Bruggemann equation, which has been shown to apply in aqueous systems containing non-conducting spheres (3)

$$\rho_0 = \rho(1 - \epsilon)^{1.5}$$

ρ_0 and ρ are the specific and apparent (measured) resistivities, respectively, and ϵ is the void fraction. The results in Fig. 3 show good agreement between the two samples, and indicate that contact resistance effects were minimal. The data are well represented by the expression

$$\rho_0 = 2.17 \times 10^{-4} \exp(1.71 \times 10^4/T)$$

The activation energy of 143 kJ implies a bandgap of almost 3 eV (290 kJ).

At a typical reduction cell temperature of 1225 K, the resistivity of Al_4C_3 is about 250 $\Omega\text{-cm}$. The thickness of Al_4C_3 corresponding to a voltage drop of 0.1V is therefore only 4 μm at a current density of 1 A/cm^2 .

Modeling of the Reaction for Low Pressure Chemical Vapor Deposition of Silicon Dioxide

Arthur J. Learn*

Anicon, Incorporated, San Jose, California 95134

ABSTRACT

A reaction model developed by Hitchman and Kane for semi-insulating polysilicon (SIPOS) deposition is adapted to the case of silicon dioxide growth on silicon wafers at low temperature and pressure. The model is used to explain the radial nonuniformities associated with the oxide deposition process and the function of a cage surrounding the wafers. The effect of providing openings in the cage for introduction of reactants is examined. The proportionality of oxide growth rate and silane flow rate, as well as a near-linear dependence of growth rate on wafer spacing, are also interpretable in terms of the reaction model.

The significant benefits resulting from chemical vapor deposition at reduced pressures are generally recognized (1). Mass-transfer limitations become relatively unimportant under this condition. Consequently, close wafer spacing on the order of a few millimeters can be utilized, and large processing load sizes result. In addition, excellent deposit-thickness uniformities are typically achieved. One exception (1) in this regard has historically occurred in the deposition of silicon dioxide at temperatures near 400°C. Reasonable within-wafer uniformities are achieved in this case only by placing a tube (cage) around the wafers. The necessity for a similar configuration in the case of semi-insulating polysilicon (SIPOS) deposition at low pressures has been established (2). A reaction model to explain the radial nonuniformity was proposed, which involves the generation of a homogeneous intermediate (SiH_2) on a heterogeneous oxygen containing site. The depositions were performed in a horizontal, hot-wall tube-type reactor with gas flow parallel to the axis of the wafer carrier.

In the present study, deposition of silicon dioxide at low pressure and temperature with a different flow pattern was investigated. In this case, reactant gases are introduced perpendicularly to the axis of the wafer carrier. The SIPOS model of Ref. (2) was adapted to the growth of oxide, where similarities to the SIPOS growth were noted. The results obtained for oxide growth are largely interpretable on this basis.

Experimental

The reactor design used is shown schematically in Fig. 1. The silane and oxygen reactants are introduced into the deposition chamber through separate injection tubes located at the center of the system. Wafers are held in caged carriers (boats) on either side of the injectors. A series of holes in the cage allows for introduction of reactants to the wafers. Typical deposition parameters were flow rates for each reactant of $250 \text{ cm}^3 \text{ min}^{-1}$, total pressure of 100 mtorr and temperature of 400°C.

Thickness measurements were made with a NanoSpec/AFT (Nanometrics, Incorporated, Sunnyvale, CA) using a refractive index of 1.46. The correct refractive index was separately determined by ellipsometry. Normally, thickness readings were taken at the wafer center and four

points (top, bottom, left, right) 6 mm inside the wafer edge. The ratio of the center thickness, t_c , to the average of the edge thicknesses, \bar{t}_e , was utilized as a measure of thickness uniformity. A more conventional uniformity parameter is the one-standard-deviation value divided by average thickness. As revealed in Fig. 2, there is a very good correlation between these two measures of uniformity. The data points shown are averages for a number of experimental runs. The solid lines are least mean squares fits to the data.

Theoretical Background

The deposition of SIPOS is performed by reacting SiH_4 and N_2O at temperatures of 600°-700°C. In this case, it is postulated (2) that four gaseous species can be adsorbed on the substrate surface. These are SiH_4 , N_2O , H_2 , and SiH_2 . It is proposed, and given empirical substantiation, that SiH_2 arises from pyrolysis of SiH_4 on an oxygen containing site at the growth surface. The formation of SIPOS occurs on the surface through reaction of Si (arising from pyrolysis of adsorbed SiH_4 at a silicon site) and adsorbed N_2O . Adsorption of SiH_2 at silicon sites can alter the rate of the SIPOS reaction. Because of the two

Fig. 1. Schematic of the reactor configuration

*Electrochemical Society Active Member.

Fig. 2. Correlation of the within-wafer uniformity on a one-sigma basis to the ratio t_c/t_s .

types of adsorption sites and the multiplicity of adsorbed species, the SIPOS growth rate is expected to have contributions related to each of the species.

The considerations for silicon dioxide growth are not substantially different from those above. Rather than the oxygen bearing species N_2O , O_2 is the second reactant. Making the appropriate substitutions, Eq. [30] of Ref. (2) then yields as the growth rate, GR, for SiO_2

$$GR = \frac{kK_s}{2} (1 - X_s) \left[\frac{2(1 + X_s)}{n_s} + 2K_h + K_o \gamma(1 - X_o) + K_c k_m (1 + X_s) \frac{n_m A}{n_s V} \right]^{-1} \quad [1]$$

Fig. 3. Unit cell for silane-oxygen reaction in a caged boat

where k is rate constant for decomposition of adsorbed SiH_4 , K_s is equilibrium constant for SiH_4 adsorption, X_s is SiH_4 depletion, n_s is input SiH_4 concentration, K_h is equilibrium constant for desorption of H_2 , K_o is equilibrium constant for adsorption of O_2 , γ is flow rate O_2 /flow rate SiH_4 , X_o is oxygen depletion, K_c is equilibrium constant for SiH_2 desorption, k_m is a modified rate constant, n_m is density of oxygen containing surface sites, and A and V are an area and volume defined with the aid of Fig. 3. The total area on which deposition can occur is A and V is the volume of the hatched region in Fig. 3. Certain of the results discussed in the following section imply that the last term in Eq. [1] is predominant. Chief among these are a weak dependence of GR on γ for $\gamma \approx 1$ and an approximately linear dependence of GR on wafer spacing. Under this assumption

$$GR = \frac{k}{2k_m} \frac{K_s}{K_c} \frac{(1 - X_s)}{(1 + X_s)} \frac{n_s}{n_m} \frac{V}{A} \quad [2]$$

The term V/A can be expressed as a function of radial position r on a wafer as follows

$$V/A = \frac{d}{2} \frac{(r_c^2 - r^2)}{r_c d + r_w^2 - r^2} \quad [3]$$

where, as defined in Fig. 3, d is wafer-wafer spacing, r_w is wafer radius, and r_c is the inner radius of the cage surrounding the wafers. In general, this term will result in a radial variation of GR and hence thickness. The positioning of the cage can, however, be optimized to eliminate such a variation. The required condition is that $d(GR)/dr = 0$, i.e., $d(V/A)/dr = 0$. From Eq. [3], this translates into the condition that $r_c^2 - r_c d - r_w^2 = 0$. Therefore

$$r_c = 1/2 [d + (d^2 + 4r_w^2)^{1/2}] \quad [4]$$

For dimensions such that $d \ll r_w$, Eq. [4] becomes

$$r_c = r_w + d/2 \quad [5]$$

Thus, in the ideal case, the spacing, X , of the cage from the wafer edge is approximately one-half of the wafer spacing. For larger X , the deposit is thicker at the wafer edge than at the center. For smaller X , the converse is true.

In addition, for the ideal case, $V/A = d/2$ and from Eq. [2], GR is directly proportional to wafer spacing. Under other than ideal conditions, the form of V/A (and hence GR_c) at the wafer center ($r = 0$) is

$$GR_c \propto d \frac{r_c^2}{r_c d + r_w^2} \quad [6]$$

Again, for $d \ll r_w$ and $r_c \approx r_w$, $GR_c \propto d$, as before.

If introduction of reactant gases must occur through the cage, as in the system of this study, then, obviously, holes must be present in the cage. This to some degree increases V and decreases A so that V/A is increased. The consequence is to produce a relatively thicker deposit near the wafer edge than at the center.

Results and Discussion

Growth rate is shown as a function of d in Fig. 4 for r_c and r_w equal to 52.5 and 50.0 mm, respectively. Growth rate is proportional to spacing for the smaller d and is sublinear for the larger d . This behavior is functionally consistent with Eq. [6]. Somewhat less falloff of GR is, however, observed than expected from Eq. [6]. For example, for d equal to 19 mm a GR of 36 nm min⁻¹ would be expected.

Two implications of this particular dependency of GR on d are noteworthy. Where wafers are held in slots within the boat, the effective d will be relatively small and little deposition will occur in such areas. This is the origin of the "boat marks" that appear for low pressure oxide deposition. The variation of GR with d also dictates strict parallelism of the wafer surfaces. Random tilting of some wafers will result in thicker or thinner deposits in certain

Fig. 7. Radial thickness profiles according to Eq. [3]. Data presented are for conditions indicated in the inset.

regions of these wafers. Accordingly, the within-wafer uniformity will be degraded.

Growth rate as a function of total volumetric flow rate is presented in Fig. 5 for d equal to 9.5 mm. To a good approximation, GR is directly proportional to the total flow rate. Such a dependency is consistent with Eq. [2]. A linear dependence of GR on the SiH_4 concentration n_s is predicted.

Growth rates are presented in Fig. 6 as a function of O_2/SiH_4 mole ratio γ for d equal to 9.5 mm and two total flow rates. Again, the approximate proportionality of GR to total flow rate is noted. There is about a 20% change in GR over the range of γ from 0.5-2.0 with a peak value for $\gamma \approx 1$. Comparable results were obtained in an earlier investigation under similar deposition conditions (3). This weak dependency on γ , in conjunction with the above results for flow rate and d , lends credence to the assumption made in arriving at Eq. [2].

Additional verification of the correct functionality of Eq. [2] is gained through examination of thickness uni-

Fig. 8. Within-wafer uniformity as a function of cage open area for $d = 9.55$ mm and $X = 2.5$ mm.

formity of the deposits. Equation [3] is plotted in Fig. 7 as a function of normalized wafer radius for $r_c - r_w$ equal to 2.5 mm. Three values of d are considered. Data are shown for 100 mm diam wafers with an open area on the cage of approximately 0.75% of the total cage area. The functional form of the data closely approximates that of Eq. [3] although actual values are somewhat larger. Increasing the open area to 3% greatly reduces the thickness variation along the wafer radius, as shown in Fig. 7. The plot for d equal to 4.8 mm in Fig. 7 illustrates that the same degree of uniformity is achievable only for the percent open area approaching zero, *i.e.*, for the ideal case of Eq. [3].

Uniformity as a function of open area on the cage is further explored in Fig. 8 for d equal to 9.5 mm. The measure of uniformity used is t_c/\bar{t}_c , which ideally should be unity. Consistent with the data of Fig. 7, this condition is satisfied for an open area of about 3%. As mentioned in the preceding section, increased open area results in increased thickness at the wafer edges. The value of t_c/\bar{t}_c extrapolated to zero open area is 1.20. This is in excellent agreement with the value of 1.19 calculated from Eq. [3] and plotted in Fig. 7.

A final comment may be made regarding the apparent similarity in type of the SIPOS and oxide reactions. Both are strongly temperature-activated, characteristic of heterogeneous reaction. The activation energy for the SiH₄, N₂O reaction is on the order of 1 eV, with the exact value depending on the ratio of flow rates for the two reactants (2). The activation energy for oxide growth (4) in the reactor of this study is 0.52 eV for γ equal to one.

Conclusions

The reaction model of Ref. (2) for SIPOS deposition was found to be equally applicable to the deposition of silicon dioxide at lower temperatures. In particular, the linear dependence of oxide growth rate on silane flow rate and near-linear dependence on wafer spacing are explained by such a model. The necessity for opening holes in the cage surrounding wafers, because of the unique reactant-gas-flow pattern in the reactor used, allows comparison of uniformity data to the model only for results extrapolated to a closed cage. Agreement is, however, excellent in this case.

ABSTRACT

Zinc borosilicate glass was electrophoretically deposited on silicon substrates in IPA solutions containing Y⁺⁺⁺ and Mg⁺⁺ additives. The deposition rate as well as the surface structure of deposits was greatly influenced by the Mg/Y ratio in the solution. Most of the deposits formed in the Y⁺⁺⁺ ion-rich solutions can be removed by rinsing, whereas the glass deposits formed in the Mg rich solutions are tightly attached to the substrates. Preferable deposits for filling of the moats between high voltage transistors are formed at Mg/(Mg + Y) = 0.5.

Glass passivation, a technique for protecting junction surfaces with multicomponent glass, is known to promote semiconductor device reliability (1-6). Many glass passivated diodes (5), thyristors (3, 6), and power transistors (4) have been developed and are commercially available. The authors also developed glass passivated high voltage power transistors, which are used in the horizontal oscillation circuits for color television sets (7). In this device development, it was necessary to improve a new glass coating method which enables filling the glass in deep beveled moats. A cross-sectional photograph of the device moat is shown in Fig. 1.

This paper describes an improved electrophoretic coating method which is utilized in high voltage power transistor production. There have been several reports published concerning electrophoretic coatings of the passivation glass (8-11). Sheldom (8) and Miwa *et al.* (9) described the deposition of zinc borosilicate glass dispersed in isopropanol (IPA), with ammonium hydroxide

or hydrofluoric acid as the additives. The deposition of lead borosilicate glass in ethyl acetate or acetone with a small amount of methanol is reported in Ref. (10). Trap (11) cited the deposition of the germania containing lead aluminosilicate glass in IPA with aluminum chloride. The author's method uses yttrium and magnesium ion additives in alcohol (IPA) solutions. The concentration ratio for each cation plays an important role in the deposition rate, as well as the surface features of the deposit. Several other factors which affect deposition rates were also examined, and their deposition mechanisms are discussed.

Experimental

The glass of SiO₂ 10, B₂O₃ 25, ZnO 59, PbO 5.0, and Al₂O₃ 1.0 weight percent (w/o) composition was prepared using the standard glass making method; reagent-grade raw materials were mixed and melted in a platinum crucible with an electric furnace at about 1450°C for 4h. The melt was then poured between two water-cooled rollers to make thin glass foils. The glass was crushed and pulver-

ized in a ball mill. With one side polished, (100) silicon wafers (p type, 2-3 Ωcm) 50 mm in diameter were chemically cleaned (12) and used for deposition-rate studies. For surface-morphology studies, grooves with rectangular crossing were formed on polished silicon surfaces with 5 mm pitches, using a diamond saw after thermal oxidation in wet oxygen atmosphere. Width and depth of the grooves were 100 and 150 μm , respectively. Thickness of the oxide layer was about 1.2 μm .

The electrophoretic deposition vessel was a 600 ml Teflon beaker with a platinum-plate counterelectrode. The substrate wafer was fixed on a vacuum holder, which permitted retaining electric contact, and immersed in the vessel vertically. The distance between the wafer and the electrode was 2 cm. Negative electric potential was applied to the wafer, with a regulated dc power supply (max 300V) at constant voltage. Electrophoretic current was measured by using a laboratory recorder. The glass powder, passed through a 325 mesh sieve, was dispersed in IPA, in which magnesium nitrate and/or yttrium nitrate had been dissolved. Total concentration of the electrolytes was 0.25 or 0.5×10^{-3} mol/l.

The usual glass/solvent ratio and water content in the solutions were 10g/100 ml and 0.5%, respectively. The dispersed solutions were decanted before the electrophoresis studies in order to eliminate large particles ($>10 \mu\text{m}$). The solution was not stirred during deposition. After deposition, the substrate was rinsed with ethyl acetate, dried, and weighed. The glass firing temperature was 700°C.

For *in situ* deposition-rate measurement, wafer weight change during deposition was measured (10). A silicon wafer, 2 in. in diameter, was hung from a load cell (Kyowa Electric Instruments Company) in the electrophoresis vessel containing the solution using 0.6 mm diam Pt wire and a quartz glass hook. The wire was fixed on the rear surface of the wafer with electroconductive silver paste. The rear surface and the wire in the solution were insulated with Apiezon wax. An electric potential was applied through the Pt wire. The counterelectrode was the Pt plate. The electrophoretic conditions and concentration for the solutions were similar to those described previously.

The cation concentration in the solutions before and after glass dispersion were chemically analyzed, and concentration differences obtained were considered to correspond to the adsorbed cations on the glass particles. For the glass-dispersed solutions, the glass was precipitated by centrifuge before analysis. A glass deposit, formed by electrophoresis, was dissolved in concentrated nitric acid, and the amount of Y and Mg ions in it was also chemically analyzed.

Results

Deposit surface morphology.—Figure 2 shows microscopic photographs of glass deposited on the surface at

Fig. 2. Microscopic photographs of the deposit surface on silicon wafers. Electrophoretic conditions: 300V, 2 min. Total cation concentration: a) 0.25×10^{-3} mol/l, b to f) 0.5×10^{-3} mol/l. Cations ratio (Mg/Mg + Y): a and b) 0; c) 0.25; d) 0.5; e) 0.75; and f) 1.0.

various Mg/Mg + Y ratios. When the additive cation is Y ions only, the deposits become rough and nonuniform in their appearance. However, the surface roughness is improved when the Y ion concentration increases.

When Mg ions are dominant in the solutions, crater-like pits are formed on the deposits. Smooth and uniform de-

Fig. 6. Deposition rate vs. applied potential with various Mg/Mg + Y ratios. Total electrolyte concentration: 0.25×10^{-3} mol/l. Deposition time: 2 min.

Fig. 7. Total cation concentration effect on deposition rate. Mg/Mg + Y = 0.5. Applied potential: 300V.

mum conditions seem to be near the Mg/Mg + Y = 0.5 point. Figure 3f is a cross-sectional photograph of the groove after firing the glass deposits shown in Fig. 3c. The amount of glass in the groove was able to be controlled within 10% of meniscus height if proper solution conditions were chosen.

Deposition rate studies.—Figures 4 and 5 show deposition rates for wafers without grooves at various Mg/Mg + Y ratios with two different total electrolyte concentrations. The accuracy of this study is about $\pm 20\%$. Some of this low reproducibility may be caused by breakoff of the deposits attached around wafer fringes. The rate increases with increasing Mg ion percentages. The deposition rate increases linearly with the applied voltage, as is shown in Fig. 6. The electrolyte concentration effect at Mg/Mg + Y = 0.5 is shown in Fig. 7. The deposition rate increases with an increase in the concentration, up to 0.5×10^{-3} mol/l, then gradually reduces. The glass content effect in the solutions is shown in Fig. 8. The rate has a maximum at about 10g glass/100 ml IPA. The deposition rate vs. Mg/Mg + Y ratio with two different water contents in the solutions is shown in Fig. 9. The rate increases with increased water content, especially at the low Y ions range.

Glass deposition in situ measurement.—Figure 10 shows the results of *in situ* deposition measurement for

Fig. 8. Glass concentration effect on deposition rate. $Mg/Mg + Y = 0.5$. Total cation concentration: 0.5×10^{-3} mol/l. Deposition time: 2 min.

grooveless wafers. Contrary to the previous measurement, the deposition rate increases with increasing Y ions content when the $Mg/Mg + Y$ ratio is less than 0.5. However, a considerable amount of glass is removed when the applied voltage is removed (dashed lines in Fig. 10). In this concentration range, most of the deposit is washed off after shaking and rinsing the substrates. In the $Mg/Mg + Y \geq 0.5$ range, the deposition rate becomes small, but the deposits adhere strongly to the substrates.

Reproducibility of this measurement was about $\pm 10\%$. Hence, final weight difference between each curve in Fig. 10 in this low $Mg/Mg + Y$ range has little meaning.

Fig. 9. Deposition rate vs. $Mg/Mg + Y$ ratio with different water concentrations. Total cation concentration: 0.25×10^{-3} mol/l. Applied potential: 300V. Deposition time: 2 min.

Fig. 10. *In situ* measurement of the deposition rate with various $Mg/Mg + Y$ ratios. Total cation concentrations: 0.5×10^{-3} mol/l. Applied potential: 300V. Substrate: 2 in diam silicon wafer.

Current measurements and adsorbed cations estimation.—Electric conductivities (electrolytic currents) were measured for solutions with cation additives but without glass dispersion. Results are shown in Fig. 11. The conductivity increases with $Mg/Mg + Y$ ratio increase. Dur-

Fig. 11. Electrolytic currents vs. $Mg/Mg + Y$ ratio in solutions before glass addition.

Fig. 12. Electrophoretic currents during glass deposition with various Mg/Mg + Y ratios.

ing these current measurements, the cathode wafers are covered with Mg and/or Y hydroxides. The electrophoretic currents during the glass deposition are shown in Fig. 12. The initial current increases with increasing Mg ions content, but current decay with time also increases.

The amount of adsorbed cations, estimated from concentration difference in the solution, is shown in Fig. 13 in relation to Mg/Mg + Y ratio of the additive electrolytes. A considerable amount of each cation is adsorbed from each solution. However, Y ions are selectively adsorbed when both Mg and Y ions are in the solutions.

The amount of the cations included in the electrophoresis deposits changed within about 0.1-0.01% when solution conditions and/or electrophoresis conditions were changed.

However, the amount always exceeded that of the adsorbed cations from the solution.

Discussions

General mechanisms of electrophoretic coating were briefly discussed by With (13). Grosso *et al.* (14) reported

Fig. 13. Adsorbed amount of cations per unit glass in relation to Mg/Mg + Y ratio. Total cation concentration: 0.5 × 10⁻³ mol/l. Glass concentration: 10g/100 ml solution.

Fig. 14. A schematic view of glass powder electrophoretic deposition process.

the electrophoretic deposition of phosphor powders in polar organic solvents with inorganic cation additives. Similar mechanisms can be applied to the results described here. The additive cations are adsorbed on the glass particles to make positive charges and stabilize the dispersion. When an electric field is applied, the particles are transported toward the cathode and agglomerate on it. During this process, water in the solutions is electrolyzed to produce OH ions around the cathode. Then, cation hydroxides precipitate between the particles and bind them tightly on the substrates. This process is shown in Fig. 14.

When Y ions are dominant in the solution, the deposits are attached loosely on the substrate. In this case, electrode polarization by the deposited layers is small, so the deposition rate becomes large, in spite of the small electric conductivity of the solution. However, the deposits are released during rinsing, and only a small layer remains. When Mg ions dominate, dense and highly adhesive deposition layers are formed. However, the deposition rate reduces with time caused by the insulating nature of the deposits. Besides, large electric conductivity of the solution may promote the hydrogen evolution reactions which cause pits in the deposited glass. When using grooved substrates, the deposited layers spread out from the grooves along the equipotential lines, because the electric potential concentrates on the fringes of the grooves. However, if the deposit's binding force is reduced by selecting the proper ratio of Mg to Y in the solution, glass deposited away from the grooves is washed off during rinsing, and remaining layers are localized on the grooves. Moderate electric conductivity for solutions containing both cations may also contribute to the proper deposition rate without hydrogen evolution.

Conclusion

Electrophoretic deposition of zinc borosilicate glass powder in IPA solution containing Y and Mg ions enables the glass passivation of high voltage power transistors at more than 1500V breakdown voltage.

The Y/Mg composition ratio in the solution has a great effect on the surface structure of the deposits and the deposition rate. When Y ions are dominant in the solution, weak-bonded deposits, most of which fall off during rinsing, are formed. In the range where Mg ions are dominant, tightly bonded deposits are formed, but hydrogen gas evolution causes pits in the glass surface. For glass deposition in the device moats, adding the same amounts of Y and Mg ions is preferable, since glass deposited away from the moats was washed off and the remaining glass was localized on the moat. The glass deposits contain 0.1-0.01% of additive cations. Incorporation of small amounts of additive Y⁺⁺⁺ and Mg⁺⁺ cations in the deposited and fused glass films was shown to have no influence on device characteristics.

Acknowledgments

The authors wish to thank M. Uchida, K. Gotoo, and T. Ozawa for planning and developing the glass passivated transistors, which was the motivation for this work. S. Iiri

and I. Suzuki carried out chemical analysis, and S. Tai produced the glass powder.

Dangling Bonds in Memory-Quality Silicon Nitride Films

Shizuo Fujita and Akio Sasaki

Department of Electrical Engineering, Kyoto University, Kyoto 606, Japan

ABSTRACT

Origin of memory traps in chemically vapor-deposited silicon nitride films was investigated. Electron-spin resonance and infrared absorption measurements revealed the existence of silicon dangling bonds which have three-folded configuration. Correlation between the spin density and the metal-nitride-oxide-semiconductor (MNOS) memory characteristics was studied, and it was suggested that silicon dangling bonds are responsible for the trap states which cause not only hopping conduction, but also memory behavior. A model is presented suggesting that the dangling bonds are positively, neutrally, or negatively ionized. The MNOS memory behavior and the energy level of the traps were well interpreted by taking into account the transition of the dangling bonds.

A great interest has been focused on a metal-nitride-oxide-semiconductor (MNOS) field-effect transistor as an electrically alterable nonvolatile memory device (1-4). Its write-in, erasure, and retention behavior are indebted to the charging and discharging of trap states at silicon oxide-silicon nitride interface and in silicon nitride bulk. Because memory characteristics greatly depend on silicon nitride deposition conditions (5), investigation of trap characteristics and understanding of trap origin are indispensable in realizing high-quality, reliable memory devices.

Various microscopic models have been proposed as the memory traps. Kirk (6) suggested variation of electron configurations around nitrogen atoms as the charge storage mechanism in a silicon nitride layer. Kapoor *et al.* (7) showed association of the trapped charges' density with oxygen impurity concentration. More recent studies reported that excess silicon atoms (8) or hydrogen bondings (Si-H and N-H) (9) are responsible for memory behavior. Other reports suggested that the memory traps originate from silicon dangling bonds (10, 11) whose charged states are changed by electron trapping and detrapping (11).

However, we have to mention that the model should clearly illustrate the following fundamental characteristics of the memory traps: (i) they are both negatively and positively ionized due to capture or emission of carriers, because the flatband voltage (V_{FB}) in a MNOS device is changed for both positive and negative values; (ii) they can be judged to lie deep in the forbidden gap of silicon nitride (12, 13). From these points of view, the idea of silicon dangling bonds being considered as the memory traps seems to be well supported by Robertson and Powell (14), who have theoretically showed that silicon dangling bonds create energy levels almost in the middle of the forbidden gap of silicon nitride. However, experimental investigation of the dangling bonds and of the correlation between the dangling bonds' density and the memory behavior have not been fully carried out.

In this paper, we will present observation of existence of silicon dangling bonds in chemically vapor-deposited (CVD) silicon nitride from electron-spin resonance (ESR) and infrared absorption measurements. The results are discussed in terms of the silicon nitride deposition conditions, and the memory behavior is well interpreted by taking into account the transition of charged states of silicon dangling bonds in the silicon nitride layer.

Silicon Nitride Deposition

Silicon nitride films were prepared by the pyrolysis of SiH_4 and NH_3 with Ar carrier gas at 700°C in a conventional normal-pressure CVD system. The flow ratio $R = \text{NH}_3/\text{SiH}_4$ was varied between 10 and 1000. Quartz and (100)-oriented p-type silicon substrates were used for ESR measurements and fabrication of MNOS diodes, respectively.

Electron-Spin Resonance

Typical spectrum.—ESR measurements were performed at room temperature with the use of an x-band spectrometer with a magnetic field modulation of 100 kHz frequency and 2.5 Gauss width. The microwave power was 100 μW , because the absorption intensity tends to saturate when increasing the power beyond this value.

Figure 1 shows an absorption derivative of typical ESR signal for our CVD silicon nitride. The ESR signal will be attributed to silicon or nitrogen dangling bonds. However, nitrogen dangling bonds should largely split the signal into three lines, because nitrogen atoms have nuclear spin of unity (15). A large number of N-H bonds with the order of 10^{20} cm^{-3} has been observed in CVD silicon nitride through the infrared absorption studies (10, 16), and thus nitrogen dangling bonds would be effectively passivated with hydrogen due to higher bonding energy of N-H than Si-H. Therefore, the results suggest that the ESR signal originates mainly from silicon dangling bonds whose silicon atoms have three-folded configuration and are symbolized as T_3^0 (17, 18). We have

Fig. 1. Absorption derivative of typical ESR signal observed at room temperature.

confirmed that the dangling bonds exist in silicon nitride bulk, because the absorption intensity is larger for thicker films.

g-value and linewidth.—The *g* value and the peak-to-peak linewidth were determined by referring the spectrum from Mn^{2+} in MgO . The *g* value was found to be 2.002, which is lower than that of amorphous silicon, 2.0055 (19). The linewidth was 12.6 Gauss for the sample shown in Fig. 1, and this value is twice as large as that of amorphous silicon having similar spin density to the present silicon nitride (20). The lowering of *g* value and the spread of linewidth would be attributed to interaction between silicon and nitrogen atoms, as was theoretically calculated and experimentally observed in sputtering-deposited (21) or plasma-deposited (22) silicon nitride films.

Variation of spin density and linewidth.—The spin density N_s and the linewidth ΔH_{pp} are shown in Fig. 2 as a function of NH_3/SiH_4 ratio. The dangling bond decreases with the increase of the NH_3/SiH_4 ratio. One of the reasons for this result would be approach of the film composition from slightly silicon-rich to more complete stoichiometric value (23), although the composition variation was not so large that it could be identified by Auger-electron spectroscopy. However, we would like to mention here that

Fig. 2. Spin densities (solid line) and peak-to-peak linewidths (dashed line) obtained from ESR measurements against NH_3/SiH_4 ratio.

there is no inevitability of the dangling bonds' density being decreased with the approach to the stoichiometric composition, because the film is amorphous. If the silicon nitride is crystallized, lack of a nitrogen atom creates a vacancy surrounded by three silicon atoms, and thus three silicon dangling bonds remain. Amorphous films have various types of disorder, and the relationship between the defect density and the composition cannot be directly stated. We can only say that much incorporation of nitrogen would relax somewhat the atomic network to create more complete bonding.

It is interesting that these spin-density values are comparable to or smaller than those in the plasma-deposited silicon nitride (22). It is well known that spin density in CVD amorphous silicon is many orders of magnitude greater than that in a plasma-deposited film, because the latter contains many hydrogen atoms passivating silicon dangling bonds (24). However, in the CVD silicon nitride, the atomic network of silicon and nitrogen atoms itself would be much more complete than that in the plasma-deposited film, and thus, without much hydrogen passivation, the dangling bonds' density could be reduced to an order comparable to that in plasma-deposited, *i.e.*, hydrogen-passivated, silicon nitride.

Correlation between spin density and memory behavior.—Thin-oxide MNOS diodes, whose silicon nitride and oxide thicknesses were 950 and 20 Å, respectively, were fabricated. Figure 3 shows flatband-voltage hysteresis loops subjected to the pulse voltage of 100 ms width applied to the metal electrodes. The retention characteristics were evaluated by the decay rate of the flatband voltage $\partial V_{FB}/\partial \log t$ measured at 10^3 min after write-in, and they are shown in Fig. 4 as a function of initial flatband voltage measured just after write-in. The experiments were performed at room temperature. Larger memory

Fig. 3. Flatband voltage hysteresis loops of thin-oxide MNOS diodes under application of 100 ms pulse.

Fig. 4. Decay rates of the flatband voltage $\Delta V_{FB}/\Delta \log t$ measured at the time 10^3 min after write-in.

window and larger decay rate were observed, as the silicon nitride layer was deposited with smaller NH_3/SiH_4 .

Figure 5 represents the memory window, the decay rate, and the leakage current as a function of the spin density in the silicon nitride. The memory window is defined as the flatband-voltage difference between those achieved by +80 and -80V pulse application. For the decay rate, the values in Fig. 3 obtained when the initial flatband voltage was set at +10 and -20V were plotted. The leakage current was measured at the electric field of 5 MV/cm in the silicon nitride layer.

With increase of the spin density, the memory window increases, *i.e.*, more electrons or holes are trapped in the silicon nitride, suggesting that silicon dangling bonds are responsible for deep trap states which cause memory behavior. Further, increase of the leakage current with the spin density shows that the silicon dangling bonds can also be hopping sites. The larger decay rate for higher spin density is attributed to stronger Coulombic repulsion among trapped charges and/or larger conductivity of the film.

Discussions

Theoretical backing.—Robertson and Powell (14) theoretically calculated local density of states by the tight binding recursion method (25) for principal defects in silicon nitride, namely, silicon and nitrogen dangling bonds (neutral and charged centers), $\equiv\text{SiH}$ and $=\text{NH}$ units, and $\equiv\text{Si}-\text{Si}\equiv$ unit. Among these, silicon dangling bonds can produce a density-of-states peak near midgap. The long-term traps for memory behavior (memory traps) should be energetically localized away from both the conduction band and the valence band, because if their density of states is much overlapped with the tail states, trapped charges will be fairly easily released to the conduction band or to the valence band obtaining thermal energy and/or electrostatic energy. In fact, Robertson and Powell proposed that silicon dangling bonds can become the long-term (memory) traps of silicon nitride in MNOS devices. These theoretical results support quite well our considerations experimentally derived from the correlation between the ESR and memory characteristics.

Calculations by Robertson and Powell showed that neither $=\text{NH}$ nor $\equiv\text{SiH}$ centers produce localized states in the bandgap. From these results, it becomes apparent

Fig. 5. Variations of V_{FB} windows, decay rates, and leakage currents against the spin densities in the silicon nitride films.

that hydrogen-related defects cannot be responsible for memory behavior. However, a distinct relationship between the hydrogen density and the trapped charge density has been reported (9). Therefore, further discussions on origin of memory traps will be continuously required.

Model for charging and discharging of traps.—We will consider carrier trapping and detrapping phenomena of silicon dangling bonds. In an amorphous silicon, silicon dangling bonds are negatively or positively ionized depending on the Fermi-level position. They are symbolized as T_3^- and T_3^+ , respectively (17, 18). The similar behavior can be expected in the CVD silicon nitride. In other words, silicon dangling bonds have either T_3^+ , T_3^0 , or T_3^- states, and thus the flatband voltage is shifted according to the charged states of the memory traps.

When the memory traps capture electrons, their charged states change as

and when they emit electrons

Here, note that if the trap states capture electrons from or emit electrons to the valence band, they are equivalent in that they emit or capture holes, respectively. The transition is shown schematically in Fig. 6.

More precisely, we can consider by taking into account thermal equilibrium states the following two possibilities.

(i) See Fig. 7(a). At thermal equilibrium, silicon dangling bonds have a T_3^0 state. When positive voltage is first applied to the metal electrode of an MNOS structure, they capture electrons and transit as $T_3^0 \rightarrow T_3^-$. After the transition, when negative voltage is applied, the

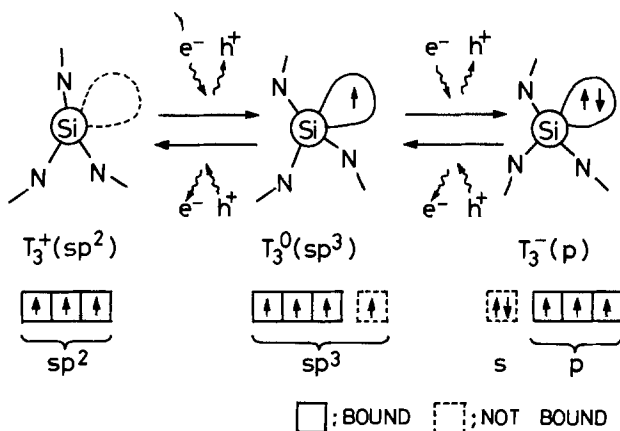

Fig. 6. A model for transition of the dangling bonds among three charged states: positive, neutral, and negative, symbolized as T_3^+ , T_3^0 , and T_3^- , respectively.

Fig. 7. Transition of charged states of dangling bonds is shown besides the V_{FB} hysteresis. Two possibilities, (a) and (b), can be considered.

dangling bonds emit one of the electrons occupying the orbital and transit as $T_3^- \rightarrow T_3^0$. If the negative voltage of higher intensity is further applied, they emit another one of the electrons remaining there, and transit as $T_3^0 \rightarrow T_3^+$. When the voltage polarity is reversed, the dangling bonds capture electrons to become T_3^0 , then capture another electron to become T_3^- .

(ii) See Fig. 7(b). This model is based on negative correlation energy (U) concepts (26). Adler (27) and Elliot (28) proposed the negative U for $2T_3^0 \rightarrow T_3^- + T_3^+$. If this model can be also applied to the dangling bonds in silicon nitride, they will have T_3^- and T_3^+ states in the film rather than T_3^0 at thermal equilibrium condition. When positive voltage is applied to the metal electrode of an MNOS structure, the dangling bonds having T_3^+ state capture electrons to its empty orbital to become T_3^0 , then two T_3^0 's exchange their electrons to make one T_3^- and one T_3^+ . The resultant transition may be written as

After reversing voltage polarity, T_3^- emit electrons to become T_3^0 , and two T_3^0 's make one T_3^- and T_3^+ , i.e.

The total amount of charges in silicon nitride or the flatband voltage of an MNOS structure is determined by the ratio of the T_3^- to the T_3^+ states' densities.

Trap density.—Various authors have investigated the trap density in CVD silicon nitride. Here, we will discuss one correlation between the trap density and the spin density.

Ross and Wallmark (29) investigated charge transfer in an MNOS structure under direct tunneling mode and derived a memory trap density of $6 \times 10^{19} \text{ cm}^{-3}$. We have studied the dependence of the memory trap density determined by a technique similar to theirs (10). The results are shown in Fig. 8 as a function of the spin density. Arnett and Yun (30) measured the charge propagation in a silicon nitride layer in a MNOS structure and reported the memory trap density to be $6 \times 10^{18} \text{ cm}^{-3}$. Krause (31) investigated the transient current due to filling-up of the traps, and Kapoor *et al.* (7-9, 32) studied the amount of charges ionized by ultraviolet light illumination. Their results on the memory trap density were $4.4 \times 10^{17} \sim 1.5 \times 10^{19} \text{ cm}^{-3}$ and $3 \times 10^{17} \sim 2 \times 10^{18} \text{ cm}^{-3}$, respectively.

We recognize that the reported memory trap density values differ so much by authors. These differences would not completely arise from the difference of the deposition conditions, but from the problems involved in the measurement techniques. For example, when we deposited the sample with $\text{NH}_3/\text{SiH}_4 = 100$, the trap density shown in Fig. 8 was $3.5 \times 10^{19} \text{ cm}^{-3}$, whereas if we measured it by the photoionization technique (33), it was found to be $5 \times 10^{17} \sim 6 \times 10^{18} \text{ cm}^{-3}$, depending on the layer thickness. One of the reasons for this dependence on the measurement techniques would be lack of knowledge of spatial distribution of the memory traps and of detailed charge-transport phenomena.

Fig. 8. Memory trap density, determined by the procedure proposed by Ross and Wallmark (29), as a function of the spin density.

Because many silicon nitride layers for MNOS memory devices have been conventionally deposited with $\text{NH}_3/\text{SiH}_4 = 30 \sim 1000$ (11, 34 ~ 36), we can see that the reported memory trap density values are somewhat larger than the spin density. In addition, we cannot see in Fig. 8 the linear relationship between the memory trap density and the spin density.

However, we would like to emphasize here that these differences do not deny our conclusion that the silicon dangling bonds become the memory traps, because there seem to be no inevitability of the memory trap density's coinciding with the spin density, due to following reasons.

(i) The memory traps would not be uniformly distributed in the silicon nitride (31, 37). Those which exist close to the silicon oxide-silicon nitride interface are mainly responsible for the memory behavior. It might be possible that the dangling bonds density is higher around here than in the bulk, due to oxygen incorporation (7) and/or mechanical stress arising from difference of thermal expansion coefficients between silicon oxide and silicon nitride. The ESR has been measured on the sample whose thickness is more than $1 \mu\text{m}$, because the signal intensity was under detectable limit when the sample was thinner. Therefore, the averaged spin density might become much smaller than that close to the interface.

(ii) Such T_3^- and T_3^+ states have no spin, and only the dangling bonds having T_3^0 state can be identified by ESR. If the memory traps are the negative U defects, i.e., most of them have T_3^- or T_3^+ states, the spin density becomes much lower than the memory trap density.

Photoinduced ESR, or dependence of the spin density on the V_{FB} or on the nitride thickness, would give further information on the origin, distribution, and properties of the memory traps.

Conclusions

In this paper, we have described the origin of memory traps in CVD silicon nitride films. Electron-spin resonance revealed the existence of silicon dangling bonds in the film. Correlation between the spin density and the MNOS memory behavior was studied and discussed, and the following results have been obtained.

(i) Silicon dangling bonds can be an origin of trap states in CVD silicon nitride which are responsible for not only hopping conduction, but also memory behavior in MNOS devices. (ii) Transition of the dangling bonds among positive, neutral, and negative states causes nonvolatile memory behavior in MNOS devices. (iii) The trap density

might be higher near the silicon oxide-silicon nitride interface region and/or the memory traps might be the negative U defects.

More precise ESR measurements would disclose more detailed characteristics of the memory traps in the silicon nitride films.

Acknowledgments

The authors would like to thank Dr. Takashi Kawamura of the Division of Molecular Engineering, Kyoto University, for his valuable assistance in the ESR measurements. Difficulties with the Lag-Time Measurement of Oxygen Diffusion in Thermally-Grown SiO₂

Chien-Jih Han* and C. R. Helms**

Stanford Electronics Laboratory, Stanford University, Stanford, California 94305

ABSTRACT

The diffusion coefficient of oxygen in SiO₂ during thermal oxidation was recently measured by Irene using a "lag-time" method and found to be $D = 2.3 \times 10^{-13}$ cm²/s at 1000°C, much smaller than values obtained by Norton for oxygen permeation through fused silica. We have found a subtle difficulty with the "lag time" formalism which appears to explain this discrepancy. In addition, our reanalysis of Irene's results shows a "memory effect" for the parabolic rate constant for sequential oxidations first observed by Hamasaki for the linear rate constant.

Many experiments have been performed in the past to determine the diffusion coefficient for oxygen molecules through SiO₂. Using measurements of O₂ permeation through vitreous SiO₂, Norton (1) found diffusion coefficients of 4.2×10^{-9} - 1.2×10^{-8} cm²/s over a temperature range of 950°-1078°C. In contrast to these results, numerous investigators, using exchange methods, found diffusion coefficients $\sim 10^5$ times smaller than Norton's results (2-4). This discrepancy is related to the assumed diffusion mechanism for O₂ diffusion through SiO₂. It is clear from Ref. (5-8) that the majority flux of oxygen through SiO₂ during the oxidation of SiO₂ in dry O₂ is due to "interstitial" diffusion, with little exchange with the previously grown SiO₂. The exchange experiments mea-

sure only that component of the diffusing oxygen that has exchanged with the SiO₂. Additional evidence for the correct relationship between Norton's results and Si oxidation in dry O₂ comes from the good agreement between Norton's value for the product of the diffusion coefficient and the oxygen solubility compared to the parabolic rate of Si oxidation (9).

In order to independently measure the diffusion rate for oxygen in SiO₂ layers responsible for the oxidation process, Irene (10) applied a "lag time" method to determine the diffusivity of oxygen, with *in situ* ellipsometry measurements of the oxide thicknesses during the oxidation of silicon. His measurements of the lag time for subsequent oxidation of 1 μm-thick SiO₂ layers on Si showed a measureable lag time only for the highest temperature investigated (1000°C over a 600°-1000°C range), exactly the opposite of what might be expected for a simple singly

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

activated diffusion process through a medium with temperature independent properties. We previously suggested that these results may be due to the nature of the sequential oxidations performed, rather than to an actual lag time for a constant-temperature process (11), but more recently we have found a subtle difficulty with the "lag time" formalism which appears to explain Irene's findings. In addition, our reanalysis of Irene's results shows a "memory effect" for the parabolic rate constant first observed by Hamasaki for the linear-rate constant (12). This "memory effect," which appears in the linear and parabolic-rate constants has significant consequences for

the values of the activation energy and the pre-exponential factor associated with the constants.

The lag-time method assumes that the oxygen diffusion through a silicon-dioxide layer obeys Fick's law for diffusion. For large thicknesses where the interface reaction rate is much faster than the diffusion rate, the growth rate of the silicon-dioxide corresponds to the permeation rate of the oxygen through silicon dioxide. As described by Irene, during a sequential oxidation process where the dissolved oxygen is removed from the initial oxide during an intervening annealing step, there is an inherent time

Fig. 2. Steady-state growth rate of a SiO_2 layer on a Si(100) surface at 800°C after an initial 10,000 \AA thick oxide. (a) Thickness, L , vs. time, t . (b) L vs. t/L . (c) L vs. $t/(L + L_0 + A)$. (Note, the ordinate begins at $L = 10,000\text{\AA}$.)

delay between the time of the first exposure to the oxygen gas and the time the oxidation rate reaches a steady-state value caused by the finite diffusion rate of oxygen.

In the lag-time analysis, the oxide thickness is assumed to remain constant during the oxidation to make the diffusion equation solvable in an analytic form. Hence, the second oxide layer grown must be thin, compared to the initial oxide, for the analysis to be valid. A plot of the total thickness, L vs. time over thickness, t/L , is made, and a linear extrapolation of this curve from the steady-state growth region down to the initial oxide thickness L_0 , should intercept the t/L axis at a point corresponding to the lag time. This value is related to the diffusion coefficient by the expression $\tau = (L_0^2/6D)$. In Irene's analysis, this "constant-thickness" assumption led to significant errors in the interpretation of the experimental results.

To illustrate these errors, we generated two sets of data for oxides grown at 1000° and 800°C, assuming steady-state conditions which have zero lag times. Initial oxide thicknesses of 10,000Å were used to compare with Irene's conditions. In the steady-state limit, the growth may be characterized by the linear-parabolic rate law (13)

$$\frac{(L^2 - L_0^2)}{B} + \frac{(L - L_0)}{B/A} = t \quad [1]$$

where L is the oxide thickness during the second oxidation step, L_0 is the initial oxide thickness and B and B/A are the parabolic and linear rate constants. The fitting parameter in the Deal-Grove model that corresponds to the native oxide thickness is incorporated in the term L_0 . The values used for B and B/A were 235 Å²/s and 0.247 Å/s at 1000°C and 14.8 Å²/s and 0.0113 Å/s at 800°C (14). Plots of the thickness as a function of time are shown in Fig. 1(a) and 2(a) for the 1000°C case and the 800°C case, respectively. (Note, the ordinate begins at $L = 10,000$ Å.)

Figures 1(b) and 2(b) show plots of L vs. t/L for the data in Fig. 1(a) and 2(a), respectively. Rather than a straight line, Fig. 1(b) has a noticeable curvature caused by the error in the "constant-thickness" approximation. The lag time one finds from extrapolating the data in Fig. 1(b) is $\tau \approx 8000$ s, even though the "data" were generated with zero lag time. At 800°C, the L vs. t/L plot is linear and goes through the origin because the additional oxide grown on top of the 10,000Å oxide is very thin, which makes the "constant-thickness" approximation reasonably good. These results can be compared with those obtained by Irene and can explain the large "lag time" observed at 1000°C and the small "lag time" observed at 800°C. There is an alternative to plotting L vs. t/L which can eliminate the nonlinearity shown above. If we rearrange Eq. [1], we obtain

$$L - L_0 = \frac{B(t - \tau)}{L_0 + L + A} \quad [2]$$

where $\tau \approx (L_0^2/6D)$. Hence, a plot of L vs. $t/(L_0 + L + A)$ for the two sets of steady-state data should give straight lines with the intercept on the $L = L_0$ axis at τ . Figures 1(c) and 2(c) show these results. The spurious lag time from the L vs. t/L analysis at 1000°C disappears in this new plot.

Based on this type of plot, however, Irene's results still seem inconsistent with the steady-state growth model. Using the new analysis technique, a slight curvature is

still observed for his 1000°C data. It is unlikely that this rate increase was caused by a lag-time delay from the diffusion process because of the results of the isotopic tracer experiments (5-7). The solubility of oxygen molecules in thermally grown SiO₂ was below the detectability limit of these experiments ($<10^{20}$ cm⁻³). In order to attain the reported oxidation rate, the diffusion coefficient must be two orders of magnitude greater than Irene's reported value. This diffusion rate would be too fast for Irene's lag-time experiment to measure. A more likely explanation for the increase is a result of variations in the diffusion coefficient and the solubility of oxygen in SiO₂ caused by a structural change in the oxide during the anneal and the subsequent oxidation.

Another result from Irene's experiment is the permeation rate obtained at 1000° and 800°C. The oxidation rate from his experiment at 1000°C was approximately the same as the rate obtained from Lie *et al.* (14) or Irene's previous work (15). At 800°C, however, Irene found an oxidation rate which is more than four times greater than the calculated rate from Lie *et al.* (14). (A comparison to Irene's previous work does not exist at this temperature.) As we previously suggested (11), this discrepancy may be attributed to the same "memory effect" observed by Hamasaki (12). Hamasaki's finding, however, were for thinner oxides and therefore related primarily to the linear rate constant B/A . Our reanalysis of Irene's data for thicker oxides indicated that this same memory effect is present in the parabolic-rate constant as well. This "memory effect" in the parabolic-rate constant indicates that the transport properties of oxygen in SiO₂ depend on the growth temperature of the oxide.

Phosphorus Incorporation Effects in Silicon Dioxide Grown at Low Pressure and Temperature

Arthur J. Learn*

Anicon, Incorporated, San Jose, California 95134

ABSTRACT

The manner and effects of phosphorus incorporation in oxides grown from silane and oxygen at low pressure and low temperature were investigated. Phosphine incorporation is avoided through proper selection of the oxygen/hydride mole ratio. Typical reflow processing results in removal of phosphine from oxides grown under other than optimum conditions. Although the majority of the phosphorus appears in the form of phosphorus pentoxide in all cases, the trioxide also is present, except when the total phosphorus content is less than approximately 2 weight percent. The efficiency of phosphorus incorporation is reduced for increased growth temperature, flow rate, or pressure. This temperature effect, as well as a reduction in activation energy for doped-oxide growth, is in large part interpretable in terms of a temperature-insensitive phosphine/oxygen reaction. The oxide growth rate is increased and the stress level is reduced through phosphorus incorporation.

Phosphorus-doped silicon dioxide has a wide range of applications in integrated circuit manufacture (1). Among these are use as reflow glass layers, interlevel dielectrics in multilevel metallization systems, and passivation over metallization. Early films were provided by chemical vapor deposition in reactors operated at atmospheric pressure. More recently, low-pressure chemical vapor deposition of oxide, as well as of other materials, has come into common use. In addition to the lower pressure, other deposition parameters can differ significantly for the newer process. Accordingly, it would be anticipated that the details of phosphorus incorporation in the oxide may differ for the two processes. Recently refined analytical techniques (2) aid in studies of this phenomenon. Also, the nature of the reactant-gas flow can affect the phosphorus incorporation. The reactor (3) utilized in this study directs flow parallel to the wafer surface, rather than perpendicular to it, as in most conventional low-pressure systems. In particular, this can result in different reactant depletion effects for the two configurations.

The effects associated with phosphorus incorporation in oxides deposited in a vertical-flow reactor were investigated. The manner of phosphorus incorporation was determined as a function of mole ratio of oxygen to hydride, phosphine mole ratio, deposition temperature, total mass flow rate, pressure, and reflow conditions. Tracking of the growth rate with many of these deposition parameters aided in the data analysis. Finally, the effect of phosphorus incorporation on stress was established.

Experimental

The reactor configuration is described in detail elsewhere (3). Briefly, wafers reside in quartz boats, with their axes aligned parallel to elongated reaction-gas injectors. Line of sight between the injectors and exhaust slots on either side of the injectors passes through the centers of the wafer stacks. One injector is used for oxygen, and a second for the hydrides. The PH_3 mole ratio is adjusted by combining a PH_3/SiH_4 mixture with pure SiH_4 upstream of the injector. Here, as in subsequent discussion, the PH_3 mole ratio is defined as the ratio of PH_3 flow rate to the total hydride flow rate. The PH_3 mole ratio was varied up to 0.15. Deposition temperatures of 300°-500°C and total flow rates of up to 1200 $\text{cm}^3 \text{min}^{-1}$ were investigated. The typical system pressure was 100 mtorr.

Thickness measurements were made with a NanoSpec/AFT (Nanometrics, Incorporated, Sunnyvale, California) using a refractive index of 1.46. The refractive index was separately determined by ellipsometry. Stress was determined from wafer bow measurements. Curvature of a given wafer was measured before and subsequent to deposition, after removal of the deposit from the wafer back side.

* Electrochemical Society Active Member.

The majority of analyses for phosphorus content were performed by Balazs Laboratories, Mountain View, California, using wet-chemical methods (2). This approach distinguishes between phosphorus incorporated as P_2O_5 , P_2O_3 , or PH_3 . In other cases, electron beam x-ray microprobe analysis (EDX) was employed to determine total phosphorus content. As may be seen from Fig. 1, an almost 1:1 correlation of total phosphorus is noted for the two techniques.

Results and Discussion

Different boat designs were utilized in the course of this investigation which can alter the details of the chemical vapor deposition process (3). Consequently, total self-consistency of the data may be lacking from one series of experiments to another. Within a series, however, care was taken to insure the comparative validity of results.

Mole ratio effects.—It is known (2) that phosphorus can be incorporated in oxides deposited at low pressure in compound form as P_2O_5 , P_2O_3 , or PH_3 . Initial studies were devoted to elimination of PH_3 because of the concomitant safety issues. As is illustrated in Fig. 2, for a PH_3 mole ratio of 0.15 (corresponding to a doping level of about 10

Fig. 1. Correlation of measurement techniques for total phosphorus content in phosphorus-doped oxide.

weight percent [w/o] phosphorus), detectable PH_3 can be present in the deposit. For O_2 /hydride mole ratios ≤ 1.5 , the PH_3 level decreases as this ratio increases and falls below the detectability limit of 0.05 w/o at an O_2 /hydride mole ratio of 1.5. When the O_2 /hydride mole ratio is increased to 2.0, however, PH_3 reappears. Consequently, an O_2 /hydride mole ratio of 1.5 was selected for all subsequent experimentation requiring such high phosphorus doping concentration. The P_2O_5 content passes through a minimum, and the P_2O_3 content through a maximum, for an O_2 /hydride mole ratio of 1.5. The sum of the phosphorus contributions from the two oxides, however, remains relatively constant at the 10.5 w/o level, independent of O_2 /hydride mole ratio. This result differs from that obtained in another study (4) of oxides deposited at low, though unspecified, pressures. In that case, the phosphorus content decreased with increased O_2 /hydride mole ratio over the range shown in Fig. 2.

The effect of reflow conditions on those films with the highest PH_3 content was also determined. As indicated in Table I, procedures in either an inert ambient or an oxidizing ambient were tested. Regardless of ambient, exposure to a temperature of 920°C is apparently sufficient to remove PH_3 . Another notable effect is the reduction of P_2O_5 content in the oxidizing ambient. Somewhat surprisingly, the trioxide is not further oxidized to appear as P_2O_3 , but rather is abstracted from the film.

For phosphorus doping levels less than 10 w/o, the O_2 /hydride mole ratio was scaled to match a ratio of 1:1 for undoped oxide. For example, at a PH_3 mole ratio of 0.09, an O_2 /hydride mole ratio of 1.3 was used. On this basis, results for a range of phosphorus concentrations down to 2 w/o are presented in Fig. 3. No PH_3 is detectable in any of these deposits. A monotonic increase in P_2O_5 and in total phosphorus content is observed with increasing mole ratio of PH_3 . A tendency toward saturation at the highest concentrations is indicated. The P_2O_3 content is maximum near midrange concentrations of 6-8 w/o for the data of Fig. 3. Presumably, further optimization of the O_2 /hydride mole ratio could reduce the P_2O_3 levels for such concentrations.

Growth rate, under the above conditions, as a function of total phosphorus content is presented in Fig. 4. As with

Fig. 2. Concentration of phosphorus bearing compounds as a function of O_2 /total hydride mole ratio.

Table I. Effect of reflow processing on concentration of phosphorus-bearing compounds

Reflow process	PH_3 (w/o)	P_2O_3 (w/o)	P_2O_5 (w/o)
None	0.12	21.2	1.8
920°C , 30 min N_2	BDL ^a	21.2	1.8
920°C , 10 min O_2 + 5 min steam + 10 min N_2	BDL ^a	20.8	0.3

^a Below detectable limit of 0.05 w/o.

undoped oxide (3), the growth rate is roughly proportional to wafer spacing. To a good approximation, growth rate also depends linearly on phosphorus content, with a slope of 0.86 nm min^{-1} per w/o. Similar results are obtained when the O_2 /hydride mole ratio is held constant. Such a dependence is different than previously observed (4-6) where a minimum in growth rate appears at a few weight percent phosphorus. The difference may be accounted for by a lower pressure used in the present work or by less depletion with the single-pass gas flow at each wafer.

The latter property provides quite uniform incorporation of phosphorus within a wafer and from wafer to wafer. Such uniformities are shown in Fig. 5 for different phosphorus doping levels. For within-wafer uniformity determination, four points 6 mm from the wafer edge were measured, as well as the wafer center. Wafer-to-wafer data are for centerpoint readings. All uniformities are within ± 0.2 w/o phosphorus. On a rather limited data base, the within-wafer uniformity does not exhibit a dependence on phosphorus content. Wafer-to-wafer uniformity, however, appears to degrade somewhat with increased phosphorus content.

Temperature effects.—Arrhenius plots of the logarithm of growth rate *vs.* the reciprocal of absolute deposition temperature are shown in Fig. 6 for undoped and phosphorus-doped oxide. In the lower temperature regime ($T < 400^\circ\text{C}$), an activation energy E_a can be defined for the different films. The values of E_a are presented in Fig. 6 and are seen to decrease with increasing phosphine mole ratio, *i.e.*, increasing phosphorus concentration. If it is assumed that the PH_3/O_2 reaction is relatively temperature independent, then a reduced effective E_a would be expected for the phosphorus-doped films, as observed. At the higher temperatures shown, growth rate saturates for undoped and doped films. Presumably, this occurs as a consequence of nearly complete utilization of the SiH_4 under the flow conditions for the experiments. The incremental increases in saturation growth rate would thus arise from the PH_3/O_2 reaction. The percentage of SiH_4

Fig. 3. Phosphorus concentration incorporated as P_2O_5 or as P_2O_5 plus P_2O_3 as a function of PH_3 mole ratio and the oxygen/total hydride mole ratios indicated.

Fig. 4. Growth rate as a function of total phosphorus content

consumed in the deposition chamber can, of course, be calculated if the surface area and associated growth rate are known. Because, as mentioned above, the latter depends on spacing of the deposition surfaces and there is some roughness on chamber surfaces, such a calculation is not quantitative. With these uncertainties in mind, about 50% consumption of the SiH₄ is indicated for the saturation condition.

The efficiency of phosphorus incorporation in the films increased with decreased growth temperature, as shown in Fig. 7. Saturation of the phosphorus content occurs at the highest temperature of 500°C. The trend is similar for the two doping levels and is primarily accounted for by increased P₂O₅ content at reduced temperatures. A similar trend was observed for doped oxides grown at atmospheric pressure (7, 8). Tests performed for PH₃ at the temperature extremes proved negative. The increase in phosphorus content at lower temperatures is again qualitatively explainable in terms of a temperature-insensitive PH₃/O₂ reaction. The ratio of growth rate for P₂O₅ and SiO₂ would then increase with decreased temperature.

Fig. 5. Phosphorus-incorporation uniformity variation with total phosphorus concentration.

Fig. 6. Arrhenius plots of growth rate for undoped and phosphorus-doped oxide.

Additional information concerning phosphorus incorporation can be extracted from the saturation growth rates discussed above. The assumptions made are that the SiH₄/O₂ and PH₃/O₂ reactions contribute independently to growth rate, that the densities are equal for SiO₂ and P₂O₅, and that all phosphorus is incorporated as P₂O₅. The growth-rate ratio for P₂O₅ and P₂O₅ + SiO₂ is then proportional to the weight-content ratio of P₂O₅. In addition, the latter is 2.29 times the weight ratio of phosphorus in the oxide. From Fig. 6, the saturation growth rates for undoped, moderately doped, and heavily doped films are approximately 25.5, 27.5, and 31.0 nm min⁻¹, respectively. The corresponding phosphorus concentrations calculated are 3.2 and 7.7 w/o for the films of medium and heavy doping. These values are in reasonable agreement with

Fig. 7. Phosphorus concentration incorporated as P₂O₅ or as P₂O₅ plus P₂O₃ as a function of growth temperature.

the measured values of 3.8 and 7.6 shown in Fig. 7 at the highest growth temperature. The assumption of independent contributions from the PH_3/O_2 and SiH_4/O_2 reactions is apparently invalid at lower temperatures, where utilization of the SiH_4 is less complete. The differential growth rate above then becomes much larger than the weight content ratio of P_2O_5 .

It is noteworthy that the near-saturation doping levels are approximately those expected for stoichiometry of the combined $\text{SiH}_4/\text{PH}_3/\text{O}_2$ reaction. The values calculated in that case are 2.6 and 6.8 w/o. The calculated values are roughly independent of whether the reaction product is P_2O_5 or P_2O_3 because the stoichiometry is identical for the two reactions and the mole percent ratio is approximately equal to the w/o phosphorus for each of the oxides. A similar concurrence of calculated and measured phosphorus concentration for comparable growth temperature was observed (7) for oxides grown at atmospheric pressure. Phosphorus concentrations exceeding the stoichiometric values at lower temperatures, as in Fig. 7, were also noted previously (4) for low pressure growth at 360°C . This effect was interpreted (4) as kinetic inhibition of the silane oxidation relative to the phosphine oxidation.

Flow rate and pressure effects.—The growth rate exhibits a linear dependence on total mass flow in the $300\text{--}1200\text{ cm}^3\text{ min}^{-1}$ range for a phosphine mole ratio of 0.12 and an $\text{O}_2/\text{hydride}$ mole ratio of 1.4. This dependency is the same as for undoped oxide and is consistent with the model established for such growth (3). Phosphorus incorporation as a function of total flow is illustrated in Fig. 8. The P_2O_5 content decreases with increased flow, whereas the P_2O_3 content increases. The latter increase is insufficient to balance the P_2O_5 decrease, so the total w/o phosphorus decreases with increased flow. The decrease in total phosphorus and P_2O_5 concentrations may be attributable to the PH_3 becoming less competitive for adsorption sites as the SiH_4 concentration increases with increased flow. Such a reduced reaction rate could also account for the greater prevalence of the suboxide, P_2O_3 .

Increasing the total system pressure from 100 to 300 mtorr yielded an increase in growth rate from 28 to 32 nm

min^{-1} . This result is for films grown with the same mole ratios listed in the preceding paragraph. The weight percent phosphorus incorporated as P_2O_5 and P_2O_3 is reduced from 7.8 to 6.0 and from 1.4 to 1.2, respectively, at the higher pressure. Similar to the effect of high flow rate, the longer residence time at higher pressure may favor SiH_4 over PH_3 adsorption.

Film stress.—The room-temperature stress in deposits is shown as a function of phosphorus content in Fig. 9. The stress becomes less compressive as phosphorus content increases to about 8.5 w/o. For larger concentrations, the stress is tensile. The compressive stress for undoped films is reduced for lower deposition temperature. Such a decrease is largely attributable to differential thermal expansion of oxide and silicon. The stress arising from this source (9) is proportional to $(\alpha_o - \alpha_{\text{si}})(T - T_r)$, where α_o and α_{si} are the thermal expansion coefficients for silicon dioxide and silicon, T is the growth temperature, and T_r is room temperature. The values of α_o and α_{si} are 0.5 and 2.5×10^{-6} per degree centigrade, respectively. Thus the stress is expected to be negative (compressive), as observed for undoped films. The stress ratio calculated from the above expression as T is reduced from 400° to 300°C is 0.73. The ratio of 0.60 observed is not substantially different. The indication, therefore, is that the majority of the stress in undoped films is a consequence of differential thermal expansion and there is little intrinsic stress. The role of phosphorus is not certain, but may be to increase α_o . For phosphorus concentration greater than 8.5 w/o, the effect is sufficient to reverse the sign of the stress and place the film in tension at room temperature.

Conclusions

Phosphine can be eliminated from phosphorus-doped oxides grown at low pressures through optimized adjustment of the growth conditions. The same goal is achieved with conventional reflow processes. The ratio of P_2O_3 to P_2O_5 incorporated in the silicon dioxide can also be minimized through proper choice of growth parameters. The efficiency of incorporation of phosphorus under

Fig. 8. Phosphorus concentration incorporated as P_2O_5 or P_2O_3 as a function of total flow rate.

Fig. 9. Room-temperature film stress as a function of total phosphorus concentration and growth temperature.

standard conditions is no worse than 80% up to a PH_3 mole ratio of 0.15. The efficiency is reduced by increasing growth temperature, flow rate, or pressure. The growth rate exhibits a decreased activation energy with increased phosphorus content at low temperature, and it saturates at high temperatures. The temperature effects can be largely explained by a temperature-insensitive PH_3/O_2 reaction. The flow rate and pressure effects may be related to relative PH_3 - SiH_4 adsorption properties. The film stress becomes less compressive through phosphorus additions and, at least for undoped oxide, arises primarily from differential thermal expansion. Finally, the ability to discern the above trends is in substantial measure due to the tight control of growth conditions in the vertical reactor used.

Modified Phosphosilicate Glasses for VLSI Applications

K. Nassau, R. A. Levy,* and D. L. Chadwick

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In this study, the glass transition temperature T_g is determined from thermal expansion measurements in a series of glass compositions prepared by bulk fusion of a phosphosilicate matrix to which oxides of boron, germanium, or arsenic are added. On a per-molar basis, addition of boron was observed to be the most effective in lowering the glass transition temperature of the phosphosilicate matrix, as compared to arsenic or germanium, which is found to be the least effective. For borophosphosilicate glass with concentrations of B_2O_3 less than 13 m/o, values of T_g are observed to be reduced by increasing the P_2O_5 content. Near 13 m/o B_2O_3 , the temperatures become independent of P_2O_5 , while at a still higher B_2O_3 content they are actually raised upon increasing the P_2O_5 concentration. For the germanophosphosilicate glass, no such reversal is noted as values of T_g decrease slightly with P_2O_5 additions at all GeO_2 concentrations. Glass compositions with potential VLSI applications can, thus, have the P_2O_5 content reduced to the minimum value required to provide gettering without significantly affecting the glass transition or associated viscous flow parameters. From a comparison of the measured values of T_g in bulk glasses with reported values of the flow temperature T_f for films with corresponding compositions, a correlation factor relating those two parameters is established. Thus, the relatively simple thermal expansion technique can now be used to survey for glass compositions with promising flow characteristics without the rigorous and time consuming effort of conducting the more difficult bulk viscosity experiments or developing deposition processes for films with possibly unsuitable viscous characteristics.

Phosphosilicate glass (PSG) deposited by low pressure chemical vapor deposition (LPCVD) is widely used in the fabrication of integrated circuits (1). It serves as a dielectric to insulate gate interconnects from metallization, as a passivation overcoat to provide mechanical protection, and as a solid diffusion source to dope silicon with phosphorus. In the processing of 2.5 μm Twin-Tub CMOS devices (2), PSG is exclusively used for its function as an intermediate dielectric providing, due to the phosphorus presence, added capabilities for effective gettering of sodium and other rapidly diffusing metal ions (3). Following deposition, PSG films typically undergo two high temperature processing steps (*i.e.* flow and reflow) to smooth the topography and drive in the junctions (4). The ability of PSG to undergo viscous deformation at a given temperature is primarily a function of the phosphorus content in the glass (5). With the ongoing emphasis on fine line geometries with design rules requiring short channel lengths ($\leq 1 \mu\text{m}$) and shallow junctions ($\leq 0.25 \mu\text{m}$), a reduction in thermal cycle to minimize lateral and vertical diffusion of dopants becomes essential. Reduction of the flow and/or reflow temperature can generally be achieved by an increase in the phosphorus concentration of PSG, with a decrease of 50°C requiring an addi-

tional 3 weight percent (w/o) P(6). However, glasses with high P concentrations become extremely hygroscopic and may, due to chemical as well as electrochemical reactions, corrode the Al metallization (7).

Reported studies of CVD dielectric films for potential applications in silicon devices have focused on the investigation of silica with oxides of boron, phosphorus, boron plus phosphorus, aluminum, boron plus aluminum, zinc, boron plus zinc, arsenic, and several other combinations (8, 9). To meet future VLSI requirements, the initial development of a ternary glass system ought to retain the well-characterized phosphosilicate glass matrix for gettering purposes and also for minimizing major process changes. The choice of an additional oxide component should then be based on the overall properties and process compatibility of the ternary glass system.

In this study, we examine a series of glass compositions prepared by bulk fusion of a phosphosilicate matrix to which oxides of boron, germanium, or arsenic were added. The purpose here is to evaluate the contributory effect of these oxide additions on the viscous properties of the matrix. Since determination of the glass transition temperature T_g from thermal expansion data is known to yield a measure of viscosity, we shall demonstrate that values of T_g can be empirically correlated to flow temperature by addition of a constant factor equal to $\sim 288^\circ\text{C}$.

*Electrochemical Society Active Member.

Furthermore, we shall establish that this technique offers a relatively quick way of surveying glass compositions with promising flow temperatures without the arduous effort of developing and characterizing a possibly unsuitable LPCVD process.

Sample Preparation and Measurement Technique

Materials used in the preparation of the bulk glasses included hydrolized silica powder (Cab-O-Sil, G. L. Cabot, Incorporated), 99.999% GeO_2 (Apache Chemicals Incorporated), and ACS grade As_2O_3 (Alfa Products); boron was used in the form of a reagent grade ammonium pentaborate $(\text{NH}_4)_2\text{B}_{10}\text{O}_{18}\cdot 8\text{H}_2\text{O}$ (Fisher Scientific Company) and phosphorus as reagent-grade dibasic ammonium phosphate $(\text{NH}_4)_2\text{HPO}_4$ (Baker Chemical Company).

Batches to produce 25g of glass were prepared first by mixing the ingredients with 100 to 200 ml of distilled water (the quantity depending on the amount of Cab-O-Sil); these batches were then ball-milled for a minimum of 10h, dried in an oven at 120°C , ground, and heated in a platinum or a high purity alumina crucible in accordance with the following procedure. After initial firing for 1h at 1000°C , each sample was reground and refired at 1150°C ; this sequence was repeated at 150°C intervals until glass formation was achieved to a maximum temperature of 1600°C . Bulk glass could not be obtained at this temperature in a few high silica concentrations samples which sintered into granular material; since x-ray diffraction showed no signs of crystallinity in these samples, they were pressed at 2500 psi into 9 mm diam pellets suitable for the thermal expansion measurements.

One percent of As_2O_3 was purposely added to each glass composition as a fining agent to remove gas bubbles and assist in homogenizing the melt. This ingredient is not shown in Tables I and II and is expected to have a small and approximately constant effect on the results. Clear glasses were obtained only in the case of low melting compositions, but this is not expected to affect the glass transition measurements. Weighing samples before and after melting showed no significant weight loss due to vaporization of components, except for the two highest arsenic-containing compositions of Table III.

Semiquantitative analysis by x-ray fluorescence on two representative specimens of Table II showed the expected major ingredients, including the arsenic. Other detectable elements were not exhibited; this includes aluminum, a possible contaminant from the ball milling and crucible, which has a detectability limit of less than 0.1% by this technique.

Quantitative analysis of these same specimens by inductively coupled plasma optical emission analysis in mole percent (m/o) oxides (the number in parenthesis is the nominal composition) were as follows. Sample 1: $\text{SiO}_2 = 68.8$ (69), $\text{GeO}_2 = 21.2$ (23), $\text{P}_2\text{O}_5 = 7.1$ (8), $\text{B}_2\text{O}_3 < 0.01$ (0), $\text{As}_2\text{O}_3 = 0.66$ (1), $\text{Al}_2\text{O}_3 = 0.05$ (0), total recovery = 97.8%. Sample 2: $\text{SiO}_2 = 77.1$ (81), $\text{GeO}_2 = 0.11$ (0), $\text{P}_2\text{O}_5 = 2.0$ (2), $\text{B}_2\text{O}_3 = 17.0$ (17), $\text{As}_2\text{O}_3 = 0.69$ (1), $\text{Al}_2\text{O}_3 = 0.01$ (0), total recovery = 96.9%. The standard deviation for these results is about one percent of the result for each value. It can be seen that some arsenic is lost as expected and that a little phosphorus is lost as well at high concentration. In both cases, the aluminum contamination is acceptably low and total recovery as well as agreement with nominal values is very satisfactory.

Thermal expansion measurements were performed on a du Pont 1090 thermoanalyzer using a heating rate of 5 degrees per minute. At least two runs were performed on each sample, the first generally serving as an annealing step. In this technique, a sample typically 3 mm thick is placed on a fused silica holder in a furnace. A fused silica plunger rests on top of the sample and transmits the sample expansion to a linear transducer located outside the furnace. The expansion coefficient of fused silica ($0.55 \mu\text{m}/\text{m}^\circ\text{C}$) was added in all cases to the observed expansion coefficient as is appropriate for the geometry used in this thermoanalyzer.

The glass transition temperature (also known as the glass transformation temperature) specifies a temperature region where many of the properties of a glass change significantly. The glass transition temperature is generally associated with the slowing down of molecular rearrangements in the glass structure during cooling. When these rearrangements occur rapidly within the time frame of an experimental measurement, the glass has the properties of a fluid melt; when the measurements are fast, the glass structure is "frozen" and the glass behaves like a solid. The rate of these molecular rearrangements is closely associated with viscous flow and, as generally noted (10), T_g occurs in all oxide glasses at a viscosity of $\sim 10^{13}\text{P}$ (1 Poise = $1 \text{ g}/\text{cm}\cdot\text{s}$). The softening point of a glass is the temperature at which it has a viscosity of $10^{7.6}\text{P}$. At that viscosity a rod 24 cm in length and 0.7 mm in diameter elongates 1 mm/min under its own weight. The flow temperature T_f in glass films would expectably be close to that softening point. For glass systems in which the viscosity exhibits an Arrhenius-type behavior (or one close to it), differential variations in viscosity η can be directly correlated to differential variations in temperature. Thus, the difference in values of the viscosity at the glass transition temperature and at the flow temperature (i.e. $\eta_{T_g} - \eta_{T_f}$) would reflect from the slope of the η vs. $1/T$ curve, the difference in the values of T_g and T_f (i.e. $T_g - T_f$). It is interesting to note that the phase change from the liquid to the glassy state is a continuous transition. The second-order quantities, such as the coefficient of thermal expansion or specific heat, rather than the corresponding first-order quantities, such as volume or enthalpy, show a discontinuity at T_g . Thus, measurements of the coefficient of thermal expansion as a function of glass composition would specify, in the present investigation, not only changes in the corresponding values of T_g but also the associated changes in the viscosity of the system.

A typical thermal expansion curve, obtained in this case for the ternary 81 m/o SiO_2 , 17 m/o B_2O_3 , 2 m/o P_2O_5 glass system is shown in Fig. 1. Generally, such curves tend to exhibit first a linear increase in length with increasing temperature followed by a slight bend in the curve and then another sharp bend towards a steeper slope; the curve then heads toward a peak before shifting direction toward smaller lengths. This latter shift is due to the slumping of the fluid melt under its own weight as well as the compression of the softened glass by the weight of the plunger and is therefore not really an essential part of the expansion curve. If methods were used where the softening of the sample did not interfere with the measurement, the curve would continue rising with higher temperatures. To a first approximation, the volume of most solids is known to increase linearly with

Fig. 1. Thermal expansion curve illustrating the linear, stabilization, and glass transition regions for the ternary 81 m/o SiO_2 , 17 m/o B_2O_3 , 2 m/o P_2O_5 glass system.

temperature with the thermal expansion adequately represented by a series expression with a small quadratic term (10)

$$l = l_0 (1 + \alpha T + \beta T^2)$$

where α is the linear expansion coefficient. However, a second contribution to thermal expansion may arise from a change in the molecular arrangement of the material. In most crystalline solids, such changes are restricted to abrupt alterations in crystal form at phase transitions, while in the case of glasses, at sufficiently high temperatures, the molecular rearrangements change continuously with temperature and contribute a major portion of the observed expansion. Thus, at the point where structural changes begin to take effect, changes in the slope of the expansion curve are to be expected. Based on such considerations, T_g is then measured, as shown in Fig. 1, at the extrapolated onset point at which the curve shows a sharp bend towards a steeper slope. Glass transition temperatures, recorded by this technique, were generally reproducible to $\pm 10^\circ\text{C}$ and are here given to the nearest 5°C , usually as an average of at least two measurements. In the temperature range between the linear region and T_g , the slight bend observed in the expansion curve is associated with the thermal history of the sample. For rapidly cooled samples this departure from linearity reflects large deviation from thermodynamic equilibrium of the structure. Only small effects are expected for samples slowly cooled from the melt, but then the risk of triggering crystallization also becomes higher. Below this so-called stabilization range, the slope of the linear portion of the expansion curve extending down to room temperature yields the coefficient of thermal expansion.

Since the elemental concentration in a glass may be listed in mole percent (m/o), cation percent (cat/o), or as weight percent (w/o) of the element or compound oxide (*i.e.*, w/o P or w/o P_2O_5), calculations describing the conversion technique as well as some illustrative conversion tables are presented in the Appendix. For sake of consistency, glass compositions will be referred to in m/o throughout this investigation.

Results and Discussion

The glass transition temperature data obtained are summarized in Tables I to III. The smoothed constant P_2O_5 concentration curves of Fig. 2 and 3 were constructed from the data of Tables I and II. Points were next taken from these curves at 25° or 50°C intervals and used to draw the three-component T_g curves of Fig. 4 and 5.

For the binary $\text{SiO}_2\text{-P}_2\text{O}_5$ system, T_g is observed in Fig. 2 or 3 to decrease from 1160°C for pure SiO_2 down to 725°C for PSG with 8 m/o P_2O_5 . That is indeed consistent with the observed decrease in viscous flow with additional P in the glass. For glasses with constant phosphorus concentrations of 0, 2, 4, or 8 m/o P_2O_5 , the effect of adding B_2O_3 results, as shown in Fig. 2, in a monotonic decrease of the glass transition temperature for both the binary $\text{SiO}_2\text{-B}_2\text{O}_3$ and ternary $\text{SiO}_2\text{-B}_2\text{O}_3\text{-P}_2\text{O}_5$ glass systems. instance, in the case of ternary glasses with a 4 m/o P_2O_5 concentration, values of T_g are seen to vary from 700° to 555° and 415°C with corresponding additions of 6, 17, and 40 m/o B_2O_3 . A similar but less pronounced effect is observed in Fig. 3 as the result of adding GeO_2 to the SiO_2 or to the $\text{SiO}_2\text{-P}_2\text{O}_5$ glass matrix. In this case, for a constant 4 m/o P_2O_5 concentration, values of T_g are seen to vary from 680° to 665° and 610°C for corresponding concentrations of 12, 25, and 45 m/o GeO_2 . The difference in the glass structure between these two glass systems presumably produces this variation in the viscous behavior. The strengths of the oxygen-central atom bonds in the simple oxides such as SiO_2 , GeO_2 , P_2O_5 , and B_2O_3 are all of the order of 100 kcal/mol (11). The very large difference in viscosity of these oxides, summarized by Doremus (11) and shown here in Fig. 6, is therefore quite unexpected since the mechanism of viscous flow undoubtedly involves the breaking of oxide bonds. On the other hand, the melting points of the crystalline oxides parallel the variations in viscosity: SiO_2 (cristobalite), 1710°C ; GeO_2 (hexagonal), 1116°C ; P_2O_5 , 580°C ; B_2O_3 , 450°C . Thus, the differences then indicate that the detailed structure of the oxide network is also important in determining the ease of viscous flow. The linked-ring structure of B_2O_3 (12) is probably the reason for the low viscosity of this oxide (at 550°C , $\eta \sim 10^8\text{P}$), since the bonds between rings are expectably weaker than those in the rings. The P_2O_5 network possibly contains sheets of PO_4 tetrahedra where each tetrahedron is bonded to three others instead of four as for SiO_2 and GeO_2 . The lower viscosity (at 550°C , $\eta \sim 10^7\text{P}$), and melting point of crystalline P_2O_5 may then result from this particular structure. One would expect, from the similarity in the structure of GeO_2 and SiO_2 , that these oxides would have a similar viscosity and melting point, since each apparently forms a random three-dimensional network in the glassy state. Thus, the significant difference

Fig. 2. Functional dependence of glass transition temperature on m/o B₂O₃ content in a phosphosilicate glass matrix with 0, 2, 4, and 7-8 m/o P₂O₅.

in the viscosity and melting point between SiO₂ (at 1100°C, $\eta \sim 10^{13}$ P) and GeO₂ (at 1100°C, $\eta \sim 10^6$ P) raises doubt on the presumed structure similarity. Although the random-network structure for vitreous silica is well established, there may be some subtle discrepancies in the germania network accounting for its lower viscosity.

In the process of mixing oxides, such as that being done in the present investigation, the silica network-forming lattice gets broken up resulting in local distortions of the structure and consequently a lower viscous flow. Oxides with vastly different structures from SiO₂, particularly such as in the case of B₂O₃, would then be most effective in distorting the silica structure and achieving low flow characteristics.

In Table IV, published values of flow temperature T_f , for borosilicate (13), phosphosilicate (3-5), and borophosphosilicate (13) glass systems, have been assembled with the corresponding measured values of T_g . Determination of $(T_f - T_g)$ for each of these available data points yielded an average value for the set of 288°C with a standard deviation of 16°C. This, indeed, indicates a very satisfactory fit to the data, especially since T_f is a rather subjective measurement at best determined only to $\pm 25^\circ\text{C}$. Further-

more, the minor variations observed in $(T_f - T_g)$ may derive from differences in the nature of glasses prepared by these different techniques (*i.e.*, CVD *vs.* bulk melting), as well as other factors such as the presence of the 1 m/o As₂O₃ and the occurrence of mixed valencies in P (*i.e.*, P₂O₃ and P₂O₅) and As (*i.e.*, As₂O₃ and As₂O₅). Thus, through determination of the glass transition temperature, with the use of the relatively simple thermal expansion technique, an estimate for the corresponding flow temperature can be achieved by addition of a constant factor. That, indeed, facilitates the task of surveying for glass compositions with promising flow characteristics, without the rigorous and time consuming effort of con-

Fig. 4. Glass transition isotherms for the borophosphosilicate glass system.

ducting the more difficult bulk viscosity viscous experiments (14) or developing deposition processes for films with possibly unsuitable viscous characteristics.

An examination of Fig. 4 indicates that at less than about 13 m/o B_2O_3 concentration, borophosphosilicate glasses can have their T_g and therefore their T_f reduced by increasing the P_2O_5 concentration. Near 13 m/o B_2O_3 these temperatures appear to become independent of P_2O_5 content, while at a still higher B_2O_3 content these temperatures are actually raised on increasing the P_2O_5 concentration. Thus, glasses under present consideration for VLSI applications, with typical concentrations of about 13 m/o B_2O_3 , could have the P_2O_5 content reduced to the minimum value necessary to provide gettering (*i. e.*, even possibly as low as 2 m/o) without significantly affecting the flow characteristics. In view of the fact that these glasses are expected to be densified during flow and/or reflow at a relatively low temperature ($\leq 950^\circ C$) where the surface depletion of P becomes less pronounced, the beneficial option of reducing the phosphorus in the glass would minimize corrosion-related problems with Al and furthermore allow for reliable encapsulation of devices in economical plastic packages.

Although borophosphosilicate glass appears now to be the choice material for meeting the reduced thermal glass requirements, there may still be, associated with its use, a few technological challenges to overcome. One of the present problems worth noting is the lack of reliable analytical techniques for determining the boron content in the glass. The fact that B is a light element ($Z = 5$, AMU ≈ 11) excludes the use of x-ray related techniques (*i. e.*, x-ray fluorescence, electron microprobe analysis, EDS,...) since most of the emitted energy is low and absorbed by

Fig. 6. Viscosities of various glass forming oxides as a function of reciprocal temperature.

the detector window. Although there are ongoing efforts by equipment manufacturers to develop windowless detectors, the technology is still in its infancy. On the other hand, the insulating character of borophosphosilicate glass hampers the use of surface techniques (*i. e.*, AES, XPS, SIMS,...) because of the inevitable interference of electronic or ionic charging effects. Furthermore, the presence of both P and B in the glass complicates the interpretation of results generated from indirect analytical methods (*i. e.*, refractive index determination, etch rate variation, diffusion techniques,...). Thus, the choice of available techniques narrows down to possibly neutron activation, infrared absorption, and/or chemical analysis. Neutron activation requires the use of an accelerator, not generally available on premises and extensive monitoring equipment, a situation certainly not suitable for a VLSI production environment. Infrared absorption has been extensively used in the characterization of borophosphosilicate glass films and appears at this stage to be one of the more promising techniques. However, inherent problems associated with poor resolution of overlapping bands and the limited sensitivity of the technique to dilute concentrations are recognized drawbacks. Furthermore, as typical of all other analytical techniques which yield relative results, IR absorption requires proper standardization, a task hard to achieve with the current lack of absolute standards. The focus, thus, becomes chemical analysis, which is now being extensively explored and promises to be the only accurate, if nonetheless destructive, procedure for determining boron in borophosphosilicate glass.

Another area of concern arising from the use of borophosphosilicate glass in VLSI devices pertains to the high nuclear cross section of B^{10} (4017 ± 32 barns) for thermal neutrons (15). Through an (n, α) reaction B^{10} which is $\sim 20\%$ naturally abundant in B dissociates following neutron capture, releasing in the process α particles which in turn may trigger soft errors within the device. However, based on background count rate measurements of thermal neutrons in a laboratory environment, calculations by Yaney and Filo (16) have predicted such nuclear transmutations to have a negligible effect on device performance.

The possibility of phase separation in borophosphosilicate glass is another potential complication resulting from the significant difference in the molecular structures of the oxides (*i. e.*, B_2O_3 , SiO_2 , and P_2O_5) (17). In the B_2O_3 - SiO_2 system, Charles and Wagstaff (8) have predicted and experimentally confirmed the occurrence of a sub-liquidus miscibility gap below $520^\circ C$ that extends across the complete binary. The addition of P_2O_5 would presumably further enhance such phase separation due to the relatively high ionic potential (defined as the ratio of ionic charge to ionic radius) of phosphorus (19). Thus, devices with borophosphosilicate glass heat-treated below the metastable two-liquid coexistence boundary, as typically done, for instance, at the H_2 annealing steps, could precipitate a borate-rich phase leachable during subsequent wet chemical or dry etching.

Another limiting feature associated with the use of B_2O_3 is the hygroscopic character of the oxide. In general, borate glasses are known to react readily with atmospheric water and degrade. However, borophosphosilicate glass films containing ≤ 4 w/o B have been shown to be relatively stable chemically during storage and exposure to humid ambients. At higher B concentrations, the extended exposure of undensified films at high humidity has been reported to cause some surface devitrification and in the case of the fused glass, some leaching of the boron and phosphorus oxides. Thus, as in the present case of phosphosilicate glass where control of P concentration is essential to prevent Al corrosion, control of both B and P concentrations in borophosphosilicate glass now becomes imperative for fabrication of a reliable product.

Most of these technological difficulties, associated with the use of borophosphosilicate glass, can be avoided by considering the alternate selection of a phosphogermano-

silicate glass. Germanium, being a relatively heavier element ($Z = 32$, $AMU = 73$), can be readily detected by standard analytical x-ray techniques (*i. e.*, x-ray fluorescence, electron microprobe, EDS,...). The nuclear cross section of all Ge isotopes (*i. e.*, Ge^{70} , Ge^{72} , Ge^{73} , Ge^{74} , and Ge^{76}) for thermal neutrons is relatively low (15) (in worst case situation, $\sigma = 14 \pm 1$ barns for Ge^{73}), thus eliminating the potential threat of nuclear transmutations affecting device performance. The reported tendency (20) of both germanium and phosphorus to substitute for silicon in the silicon-oxygen network eliminate the risk of phase separation. Finally, based on working knowledge of the chemical behavior of crystalline and amorphous phases, the tendency of GeO_2 to react with moisture is considered significantly lower than that of P_2O_5 or B_2O_3 but still higher than that of As_2O_3 , ZnO , Al_2O_3 , or SiO_2 .

Examination of Fig. 5 reveals that the glass transition temperature for the germanophosphosilicate glass decreases with P_2O_5 additions at all GeO_2 concentrations. However, the decrease is relatively modest in the region of interest, so that a reduction in the P_2O_5 concentration to minimize hygroscopicity could again be achieved with no significant changes in the viscous behavior of the system. Thus, the choice of a silica glass containing 35 m/o GeO_2 and 4 m/o P_2O_5 , exhibiting an interpolated value of $T_g \approx 635^\circ C$, is predicted to have a flow temperature below $950^\circ C$. That would, indeed, provide us with the necessary margin to optimize the flow and/or reflow cycle so as to achieve the desirable junction depths.

The characteristic properties of the phosphogermanate system are worth noting within the context of the present discussion. The measured value of T_g for the $GeO_2 - 8$ m/o P_2O_5 composition was $\sim 515^\circ C$, which would suggest a value of T_f close to $800^\circ C$. The possibility of reducing the flow temperature to such levels is attractive from a processing standpoint. It would decouple the diffusion from the flow and/or reflow requirements. Implants could first be thermally driven to required depths, and the glass subsequently deposited, flowed, and/or reflowed to generate the desirable topographical profile. Furthermore, for such a chemically stable binary system, the characterization and control of glass composition could be significantly simplified. The commercial availability of a source gas such as germane, compatible with present CVD deposition equipment, provides added justification for exploring the developmental feasibility of a CVD process for phosphogermanate glass films.

Examination in Table III of the T_g values for As_2O_3 containing glasses indicates that the effect of arsenic on the viscous characteristics of the system lies, on a per-molar basis, between that of boron and that of germanium. However, due to the fact that some volatilization did occur during the fusing process, and since the $As^{3+} - As^{5+}$ equilibrium in arsenic-containing glasses depends on the specific processing atmosphere and temperature (21), there is expressed doubt for this particular case in the premise of translating bulk results directly into actual flow temperatures for corresponding CVD films.

Conclusions

In this study, we have determined the glass transition temperature from thermal expansion measurements in a series of glass compositions prepared by bulk fusion of a phosphosilicate matrix to which oxides of boron, germanium, or arsenic were added. On a per-molar basis, addition of boron was observed to be the most effective in lowering the glass transition temperature of the phosphosilicate matrix, as compared to arsenic or germanium, which was found to be the least effective. For borophosphosilicate glass with concentrations of B_2O_3 less than 13 m/o, values of T_g were observed to be reduced by increasing the P_2O_5 content. Near 13 m/o B_2O_3 , these temperatures became independent of P_2O_5 , while at a still higher B_2O_3 content they were actually raised upon increasing the P_2O_5 concentration. For the germanophosphosilicate glass, no such reversal was noted, as values of T_g decreased slightly with P_2O_5 additions at all GeO_2 concentra-

tions. Glass compositions with potential VLSI applications could, thus, have the P_2O_5 content reduced to the minimum value necessary to provide gettering without significantly affecting the phase transition and associated viscous flow parameters. The anticipated difficulties in the use of borophosphosilicate glass in devices have been outlined, and ways of avoiding them have been proposed by exploring the alternate use of a germanophosphosilicate or even the simple binary phosphogermanate glass system. From a comparison of the measured values of T_g in bulk glasses with reported values of T_f for films with corresponding compositions, we have established empirically a correlation factor relating the two parameters. Thus, the relatively simple thermal expansion technique can now be used to survey for glass compositions with promising flow characteristics, without the rigorous and time consuming effort of conducting the more difficult bulk viscosity experiments or developing deposition processes for films with possibly unsuitable viscous characteristics.

APPENDIX

Consider a glass containing A grams of M_xO_y plus S grams of SiO_2 . If W_M is the atomic weight of M , W_O of O , etc., then $W_{M_xO_y} = xW_M + yW_O$ is the molecular weight of M_xO_y , and so on. Then

$$\text{w/o of } M_xO_y = \frac{100 \cdot A}{A + S} \quad [\text{A-1}]$$

$$\text{w/o of } M = \frac{100 \cdot A}{A + S} \times \frac{W_M}{W_{M_xO_y}} \quad [\text{A-2}]$$

$$\text{m/o of } M_xO_y = \frac{100 \cdot A/W_{M_xO_y}}{A/W_{M_xO_y} + S/W_{SiO_2}} \quad [\text{A-3}]$$

$$\text{cat/o of } M (= \text{m/o } MO_{y/x}) = \frac{100 \cdot x \cdot A/W_{M_xO_y}}{x \cdot A/W_{M_xO_y} + S/W_{SiO_2}} \quad [\text{A-4}]$$

For a glass containing multiple ingredients A , B , C , ..., and SiO_2 it is only necessary to replace A by $A + B + C + \dots$ in Eq. [A-1] and [A-2], and $A/W_{M_xO_y}$ by $A/W_{M_xO_y} + B/W + \dots$, in Eq. [A-3] and [A-4]. For a GeO_2 based glass, W_{GeO_2} would replace W_{SiO_2} , and so on. In the following table the conversions are given for various oxides present one at a time at the 10 m/o level in silica and in germania.

ABSTRACT

The growth of silicon dioxide film is one of the major steps in any silicon IC fabrication. The quality of the silicon dioxide film is of paramount importance in MOS LSI/VLSI circuits, just as the "process design" many times requires tailoring of oxidation time and temperatures of the growth. Pyrogenic growth of oxide films is an ideal aid in achieving both of these objectives. A large number of "nomograms" giving oxide growths at various partial pressures of water vapor and temperatures are presented here as an aid to process design. Also, a simple model of pyrogenic oxide growth is given here which can be used for computer simulation of the process.

Until the advent of MOS technology, the silicon-dioxide films were generally used only as a mask during diffusions of impurity atoms in the fabrication of bipolar devices and integrated circuits. But due to present day emphasis on MOS LSI/VLSI circuits, the techniques for obtaining good quality films of silicon dioxide have received a great deal of attention. Apart from dry-oxygen ambient, water containing ambients have been used during oxidation of silicon to obtain SiO₂ films (1-6). The wet oxidation, however, is liable to contamination from the water container and is due to presence of undesirable impurities dissolved in water itself. Another technique, suggested first in 1967 (7) and called "pyrogenic oxidation," is now widely used. In this case, oxidation of silicon is carried by direct reaction of H₂ and O₂ at elevated temperatures in the oxidation furnace itself. Due to *in situ* water formation and the fact that oxygen is never saturated with water vapors, the pyrogenically grown oxides are "cleaner" oxides. Despite wide use of pyrogenic technique for SiO₂ growth, it is rather surprising that little data are available in literature on growth rates and other properties of pyrogenically grown oxide films. For example, Deal *et al.* (8, 9) have reported growth rates and other properties for a maximum of 10% partial pressure of H₂O, and Enomoto *et al.* (10) have given similar data at a fixed temperature and at three partial-pressure values. The purpose of this work, therefore, is to report extensive data acquired by us on silicon dioxide films pyrogenically grown at temperatures varying from 800° to 1200°C and at partial pressures of H₂O varying from 0 to 100%. The data

obtained by us are further presented here in simple nomograms. The importance of this work lies in the fact that by use of these nomograms, it is possible for anybody now to choose a growth rate of oxide films consistent with other technological considerations, such as diffusion temperature. Also, standard dry-wet-dry drive-in cycles can easily be simulated by changing one of the gas-flow rates.

Silicon wafers used for the present experiment were of (100) orientation and were n-type phosphorous-doped, with resistivity of 4-6 Ωcm. The wafers were cleaned by standard RCA procedure, rinsing in deionized water (18M Ωcm resistivity), and spin drying, prior to loading in oxidation furnace. The oxidation setup is shown in Fig. 1. The system consists of a quartz capillary of 2 mm diam enveloped by another quartz tube of 15 mm diam. This can be easily fitted to standard furnace tube (75 mm ID) with the help of a ball-and-socket joint. The furnace used in the experiment was "Thermco Brute XL," which keeps the temperature within ± 0.5°C of any set temperature. Hydrogen gas is passed through the capillary tube extending into the end zone of the furnace, which is maintained above 600°C. The oxygen is passed through the enveloping tube into the furnace. The combustion of hydrogen thus occurs in oxygen ambient, providing *in situ* water vapors. The partial pressure of H₂O vapor is a function of ratio of hydrogen to oxygen gas and is defined as

$$(H_2O)_p = (2 \times \text{Vol. of } H_2) / (2 \times \text{Vol. of } O_2 + 1 \times \text{Vol. of } H_2)$$

Fig. 1. Pyrogenic oxide-growth system

The oxide-growth tube was purged with 5% HCl gas in presence of O₂ for half an hour prior to each set of oxide growths. However, no HCl was passed during oxide growth because it was found to affect the partial pressure of the water vapor generated. Total gas flow of 2.25 l/min was maintained throughout this experiment by use of standard flowmeters which are calibrated to gas inputs at 14 psi pressure. To obtain oxide-growth rates at various values of temperature, time, and partial pressure, the following sequence was followed: (i) partial pressure was set

to a fixed value by choosing oxygen-to-hydrogen gas ratio; (ii) furnace temperature was set to a value, and oxide films were grown for times of 300, 600, 900, 1800, 3600, 5400, 7200, and 10,800s; (iii) for the same partial pressure, sequence (ii) was repeated for various temperature values from 800° to 1200°C at an interval of 100°C; and (iv) sequences (ii) and (iii) were then repeated for various values of partial pressures, namely, 0, 0.25, 0.4, 0.5, 0.75, and 1.0. Clearly, the use of 0.0 partial pressure implies absence of hydrogen and hence simulates dry-oxidation, while the case of 1.0 partial pressure corresponds to "steam" oxidation.

The thickness of each oxide film grown as discussed above was measured using an ellipsometer (Gaertner Scientific Corporation Model no. L 117). A computer program simulating ellipsometry was used to compute oxide thickness and refractive index of the film. The input to the program are the measured values of positions of "polarizer" and "analyzer" in two modes, expressed in degrees. Each of Fig. 2-7 gives oxide thickness in angstroms (Å) at various times of growth, having temperatures and partial pressures as variable parameters.

The quality of the oxides was judged by making C-V (high frequency) measurements on MOS capacitors fabricated on oxides grown at 1000°C for thickness of ~1000Å at each of the specified partial pressures. The results of

Fig. 2. Oxidation thickness against oxidation time for silicon, (100) orientated n-type, at partial pressure of 0.0% (dry oxidation) for various temperatures.

Fig. 4. Oxidation thickness against oxidation time for silicon, (100) orientated n-type, at partial pressure of 40% for various temperatures.

Fig. 3. Oxidation thickness against oxidation time for silicon, (100) orientated n-type, at partial pressure of 25% for various temperatures.

Fig. 5. Oxidation thickness against oxidation time for silicon, (100) orientated n-type, at partial pressure of 50% for various temperatures.

Fig. 6. Oxidation thickness against oxidation time for silicon, (100) orientated n-type, at partial pressure of 75% for various temperatures.

C-V measurements show Q_{ox}/q values of approximately $2 \times 10^{19}/\text{cm}^2$ for all the oxides under study. MOS capacitors were fabricated on oxides grown under various partial pressures and having thicknesses of 600Å, 1000Å, 6000Å and 1μm. These were subjected to high voltages to test the dielectric strengths of the oxides. It was found that almost all the types of oxides show a dielectric strength of the order of 6×10^6 V/cm. The refractive index of films grown was observed to be between 1.44 and 1.45. These results indicate that the pyrogenically grown oxides have properties which are compatible to standard MOS technology requirements, with the aided advantage of flexibility in choice of temperatures and times for desired oxide-thickness growth.

To simulate the pyrogenic oxide growth, we have been able to fit the data, (total of 240 points) within $\pm 5\%$ rms error, into the oxidation model suggested by Deal *et al.* (8, 11). The model presented by Deal *et al.* gives oxide thickness as

$$2Z_{ox} = (-K_p/K_l) + [(K_p/K_l)^2 + 4K_p(t + t_0)]^{1/2} \quad [2]$$

where K_p and K_l are the parabolic rate constant and linear rate constant, respectively. Using curve fitting techniques, the rate constants for pyrogenic oxide were evaluated and given as

$$K_p = 2.438 \times 10^6 (0.05 + p^{0.75}) \exp(-0.58q/kT) \quad [3]$$

$$K_l = 1.408 \times 10^6 (0.096 + p^{0.75}) \exp(-1.5q/kT) \quad [4]$$

and $t_0 = 400$

where p is the partial pressure of the H₂O vapor given by Eq. [1].

Because in the case of pyrogenic oxide growths the partial pressure of H₂O varies from 0 to 100%, the model given in (8, 11) is not strictly valid for our case. A generalized two-species model is more appropriate for this case,

Fig. 7. Oxidation thickness against oxidation time for silicon, (100) orientated n-type, at partial pressure of 100% for various temperatures.

but for simplicity of use in a computer simulation model, we have accepted the model given by Eq. [2]. The choice is justified because the data of oxide growths could easily be simulated through this model within $\pm 5\%$ rms error.

Therefore, we presume that the extensive data in the form of nomograms, as well as the simple process-simulation computer model for pyrogenic oxides in the present form will be of great help to device technologists.

Acknowledgments

We wish to thank Shri Dinesh Sharma and Shri P. R. Apte for their help in the curve fitting of the data. We would also like to acknowledge the help rendered by Shri S. Pai and Miss A. M. Patel during experimental work. Discussions with Dr. A. S. Vengurlekar have helped a great deal in refining the presentation of this paper.

Novel Passivation Dielectrics—The Boron- or Phosphorus-Doped Hydrogenated Amorphous Silicon Carbide Films

C. Y. Chang,* Y. K. Fang, C. F. Huang, and B. S. Wu

Department of Electrical and Computer Engineering, National Cheng Kung University, Tainan, Taiwan, China

ABSTRACT

Hydrogenated amorphous silicon carbide (a-SiC:H) thin films were prepared and studied in a radio-frequency glow-discharge system, using a gas mixture of SiH₄ and one of the following carbon sources: methane (CH₄), benzene (C₆H₆), toluene (C₇H₈), *o*-xylene (C₈H₁₀), trichloroethane (C₂H₃Cl₃), trichloroethylene (C₂HCl₃), or carbon tetrachloride (CCl₄). The effect of doping phosphorus and boron into those a-SiC:H films on chemical etching rate, electrical dc resistivity, breakdown strength, and optical refractive index have been systematically investigated. Their chemical etching properties were examined by immersing in 49% HF, buffered HF, 180°C H₃PO₄ solutions, or in CF₄ + O₂ plasma. It was found that the boron-doped a-SiC:H film possesses five times slower etching rate than the undoped one, while phosphorus-doped a-SiC:H film shows about three times slower. Among those a-SiC:H films, the one obtained from a mixture of SiH₄ and benzene shows the best etch-resistant property, while the ones obtained from a mixture of SiH₄ and chlorine containing carbon sources (*e.g.*, trichloroethylene, trichloroethane, or carbon tetrachloride) shows that they are poor in etching resistance (*i.e.*, the etching rate is higher). By measuring dc resistivity, dielectric breakdown strength, and effective refractive index, it was found that boron- or phosphorus-doped a-SiC:H films exhibit much higher dielectric strength and resistivity, but lower etching rate, presumably because of higher density.

Recently, hydrogenated amorphous silicon carbide (a-SiC:H) films have been investigated intensively (1-8) because of their applications in photovoltaic devices. Some properties of undoped hydrogenated amorphous silicon carbide films were reported by Anderson and Spear in 1977 (9). However, only few efforts have been made to discover the effect of doping boron or phosphorus into hydrogenated amorphous silicon carbide films. Therefore, for the first time, properties of boron- or phosphorus-doped a-SiC:H films have been systematically investigated which include chemical etching rate, dc resistivity, breakdown strength, pinhole density, and optical refractive index.

In previous articles (9, 10), hydrogenated amorphous silicon carbide films have been prepared by radio-frequency glow-discharge decomposition of a gas mixture of silane (SiH₄) and one of the following hydrocarbon gases: methane (CH₄), ethylene (C₂H₄), or propane (C₃H₈), or decomposition of tetramethylsilane (Si(CH₃)₄) alone. It was believed that optical, electrical, and chemical properties of a-SiC:H film might be significantly dependent on the kind of hydrocarbon gas source (3) used.

Hydrogenated amorphous silicon (a-Si:H) alloy has been shown to be an excellent passivant for pn junction (11) in which two-order-of-magnitude reduction in reverse leakage current and sharper breakdown behavior were revealed, compared with the one passivated only by thermally grown silicon dioxide. Furthermore, Bind *et al.* and others (12-15) reported that 1 weight percent (w/o) of boron or boron carbide was found to be effective additive to enhance density of silicon carbide material, and thus can be used as a barrier material from Na⁺ ions or moisture contamination.

It is the purpose of this study to develop a new passivation material by doping boron or phosphorus into various kinds of amorphous silicon-carbon alloy, which were prepared from a mixture of silane and different kinds of carbon-based organic materials, *i.e.*, methane (CH₄), *o*-xylene (C₈H₁₀), toluene (C₇H₈), benzene (C₆H₆), trichloroethylene (C₂HCl₃), trichloroethane (C₂H₃Cl₃), or carbon tetrachloride (CCl₄). Chemical etching rate, electrical dc resistivity, dielectric breakdown strength, pinhole density, and optical refractive index of those films were systematically investigated.

Film Preparation

The films were prepared by 13.56 MHz RF plasma-enhanced chemical vapor deposition from a gas mixture of silane (SiH₄) and methane (CH₄), *o*-xylene (C₈H₁₀), toluene (C₇H₈), benzene (C₆H₆), trichloroethylene

(C₂HCl₃), trichloroethane (C₂H₃Cl₃), or carbon tetrachloride (CCl₄) by adding up to 1% doping species of phosphine or diborane. Corning 7059 glass plates or single-crystal silicon wafers were used as substrates. Typical preparation conditions of these samples are listed in Table I. An Anelva Plasma CVD-301 system was used in our experiment. The diameter of the electrode was 200 mm. Spacing between electrodes was adjustable from 15 to 45 mm. A capacitively coupled glow-discharge plasma was created by a radio-frequency generator with a power of 300W and frequency of 13.56 MHz. Figure 1 shows the schematic diagram of plasma CVD system.

Initially, substrates were subjected to a standard cleaning process before loading into the reaction chamber. Prior to the onset of deposition, nitrogen plasma is ap-

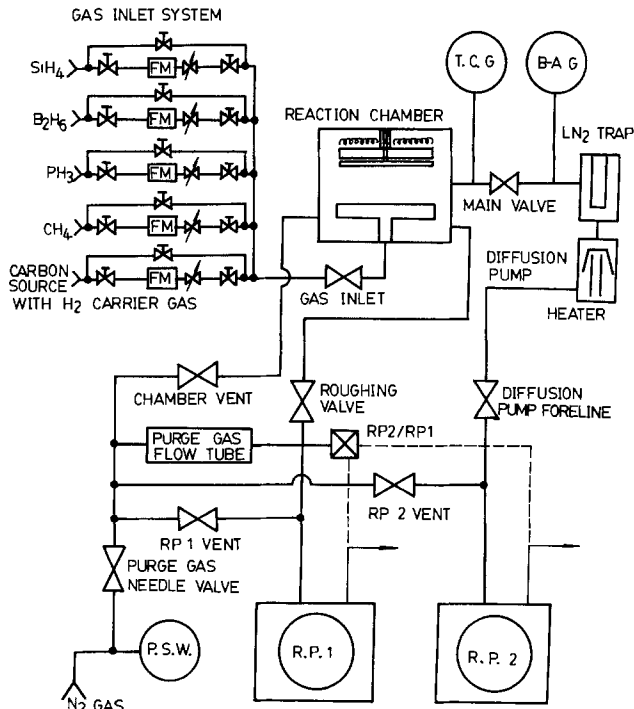

Fig. 1. Schematic diagram of the plasma CVD system used in this experiment.

plied in order to clean the substrate. Then, the chamber was evacuated to a pressure lower than 10^{-7} torr. Substrate temperature was raised up to 250°-270°C, RF power to 40W, chamber pressure to 1-1.5 torr, and the total gas flow rate to 20 sccm.

The reaction gases were SiH_4 (25.9% in H_2) and one of the following carbon sources: CH_4 , C_6H_{10} , C_7H_8 , C_6H_6 , C_2HCl_3 , $\text{C}_2\text{H}_3\text{Cl}_3$, or CCl_4 . The doping gas was B_2H_6 (1% in H_2) or PH_3 (1% in H_2). After deposition, H_2 plasma treatment was performed for 10 min.

The various carbon sources used in this study were all extra-pure reagent solution, except for CH_4 (1% H_2 based), which was in gaseous form. The carrier gas was pure hydrogen. The flow rates of various carbon sources were properly controlled in order to obtain stoichiometric compositions, which are shown in Table I.

Measurement and Discussion

Measuring techniques, results, and interpretation of the results concerning the properties of boron- or phosphorus-doped a-SiC:H film are presented below.

Chemical etching rate.—Chemical etching properties of B-doped, P-doped, and undoped a-SiC:H film were examined by immersing a-SiC samples in concentrated HF

acid (49%), buffered HF solution, 180°C H_3PO_4 solution or by $\text{CF}_4 + \text{O}_2$ plasma etching. The average etching rate was determined conventionally by measuring the time required to remove the entire film completely.

Table II shows the wet etching rate for a-SiC:H films obtained from different carbon sources. Benzene and methane groups reveal lowest etching rate; while chlorine containing groups, *i.e.*, trichloroethylene, trichloroethane, and carbon tetrachloride, reveal higher etching rates. Groups of σ -xylene and toluene show that they are also good candidates of carbon source.

Investigating boron or phosphorus doping effect on chemical properties of a-SiC:H film shows that benzene may be a good carbon source because of its excellent etching resistance, availability, and convenience in processing. It was found that boron-doped a-SiC:H films possessed five times slower etching rate than the undoped one; while phosphorus-doped films possessed only about three times slower. From this evaluation, it suggested that boron doping is superior to phosphorus doping in a-SiC:H film for device passivation. However, phosphorus impurity also reveals a prevailing effect in a-SiC:H film than the undoped one, as etching resistance was concerned.

Etch rate may be used as a sensitive indicator of dielectric film quality (16, 17). Film density, stoichiometry, and composition of the film can be directly revealed by etching. It is believable that the surface free energy in grain boundary of the doped a-SiC:H film is modified, which leads to a more dense state. Thus, protection against moisture and contamination can be improved (12, 13).

A "Plasmaline" plasma etching system was employed for dry etching by using tetrafluorine-oxygen gas mixture as etchant. Typical plasma etching conditions were: RF power = 100W, pressure = 1 torr, and total gas flow rate = 100 sccm. The etching rates are shown in Table III. Both the etching rates of doped and undoped a-SiC:H films vary dramatically for different carbon sources. There are similar tendency with that of wet etching. Table IV also shows that of G.D. doped a-SiC:H films obtained from benzene source exhibits a slightly smaller etch rate than that of a-SiC_x films (20).

DC resistivity.—DC resistivity was determined by using a six-point-probe meter (Four Dimension Company, Model 101), as shown in Fig. 2. This is an excellent tool for measuring higher sheet resistivity films like hydrogenated amorphous silicon layer, which would be impossible to measure by using conventional four-point probe method.

The six-point probe method can measure resistivity from 10^{-1} to 10^{12} Ω/\square , which is accomplished by using a low probing force (about 10g force with 500Å penetration depth) with an extremely high insulation.

Table IV is a summary of the measured dc resistivity of boron- or phosphorus-doped a-SiC films which were pre-

Unit: Ω-cm

Carbon source Dopant	CH ₄	C ₃ H ₁₀	C ₇ H ₈	C ₆ H ₆	C ₂ HCl ₃	C ₂ H ₃ Cl ₃	CCl ₄
	B-doped	9.9×10^{10}	2.3×10^9	9.1×10^{10}	9.0×10^{10}	2.2×10^9	3.7×10^7
P-doped	9.0×10^9	1.3×10^9	5.4×10^9	8×10^9	1.1×10^9	5.8×10^7	3.9×10^6

The undoped a-SiC:H (C₆H₆ carbon source) is 5×10^{12} Ω-cm, while the G.D. SiN is 6×10^{12} Ω-cm.

pared from different carbon-based sources and silane. As can be seen from this table, films with dc resistivity in the range of 10^{10} - 10^{11} Ω-cm were obtained by adding 1 w/o diborane or 1 w/o phosphine into the main flow of SiH₄ gas. The resistivity of the undoped one is around 5×10^{12} Ω-cm, which is higher. However, the doped ones are still good enough as a passivation material.

Dielectric breakdown strength.—a-SiC:H films prepared from various carbon sources exhibit different breakdown strength. A metal-silicon carbide n-type crystalline Si capacitor (18) was fabricated and was biased in the accumulation region by applying a ramp voltage. Since the sheet resistivity of n-type crystalline silicon is as low as 2-5 Ω-cm, the value of the dielectric breakdown strength was measured by assuming that the dc voltage is uniformly distributed across the silicon carbide layer, and no voltage drop is developed beyond the metal dot.

As is seen from Table V, the dielectric breakdown strength of doped a-SiC:H film is improved by one order of magnitude than the undoped one. It also exhibits a better result compared with conventional glow-discharged

a-SiN_x film (18). The boron-doped a-SiC:H film prepared by decomposing silane and methane reveals the best and stable results among these carbon-based films.

The same effects of boron- and phosphorus-doped films on breakdown strength have also been found for BPSG, PSG (19), and doped a-SiN_x film (20). For comparison, dielectric constants which were calculated from refractive index (21) are listed in Table VI. Among these, it is found that boron doped G.D. a-SiC:H film possesses higher dielectric constant than the others, with an average value of 7.

Pinhole density.—The pinhole test is one of the important methods for both locating defects in dielectric film and evaluating quality of the films. Many methods for decorating the dielectric film defects have been explored, including replica electron microscopy, electrochemical autograph, etc. (22). However, none of these methods are found to be both simple and reproducible except the copper decoration technique.

A copper decoration setup which consists of a constant-voltage power supply and a dc ampere meter was em-

ployed. A low resistivity silicon wafer deposited the dielectric film and was placed on a conductive, flat aluminum plate, then was put into a glass beaker in which acetic acid (CH_3COOH) solution was employed as electrolyte. A copper plate was used as another electrode.

The experimental results are listed in Table VII, which shows that boron-doped a-SiC:H films possess substantially fewer decoration sites than phosphorus-doped and undoped ones. The thickness of the films are around 1000Å.

Optical refractive index.—In order to investigate optical refractive index and thickness of the films, the ellipsometer was used to characterize the a-SiC:H films with layer thickness ranging from 3000 to 3500Å.

Table VII shows that the refractive index also changes with different kinds of carbon source employed. Typical refractive indexes for thermally grown silicon dioxide (SiO_2) and plasma-enhanced CVD silicon nitride (SiN_x) are about 1.45 and 2.0, respectively. In the present work, all of the doped a-SiC:H films are larger than 2.5, and even the undoped one possesses a value of 2.4.

Interestingly, the boron-doped films obtained from silane and methane exhibit the highest refractive index of 2.85. This high value may be due to the higher carbon content in the a-SiC:H film or boron doping, which affects the surface free energy of the film (12). Further study is underway.

There is some relationship between film quality and deposition rate, which can be derived from film-thickness measurement. The low deposition rate of the doped films is presumably due to their higher density.

Table VIII shows the deposition rates of the a-SiC:H films for different kinds of carbon sources. In each case, pressure during the deposition process was kept at the same conditions as described in Table I. The experimental results coincide with the previous experimental studies, that is: the boron-doped a-SiC:H film using methane or benzene as carbon source exhibits the slowest deposition rate, though almost all of the deposition rates of the a-SiC:H film are varied within a range of 90-125 Å/min.

Conclusions

In this paper, plasma-enhanced chemical vapor deposited amorphous silicon carbide films were prepared by using wide variety of carbon sources. The effects of boron or phosphorus doping were also investigated. Some newly discovered results are as follows.

1. Hydrogenated amorphous SiC films which were boron- or phosphorus-doped or undoped can be successfully prepared from silane and organic carbon-based sources, including methane, *o*-xylene, toluene, benzene, trichloroethylene, trichloroethane, and carbon tetrachloride in a glow-discharge deposition system.

2. It is concluded that only methane and benzene are good candidates from the point of view of chemical, electrical, and optical properties, while chlorine containing carbon sources, *e.g.*, trichloroethylene, trichloroethane, and carbon tetrachloride, reveal poorer properties. However, benzene is highly recommended because of availability and ease of handling.

3. Boron-doped films always show chemical, electrical, and optical properties superior to phosphorus-doped ones. This may be due to surface free energy modification by dopant participation. In addition, owing to the fact that the ionic radius of boron is smaller than that of phosphorus, the modification effect is more evident in boron-doped a-SiC:H film.

4. The deposition temperature is low (250°-270°C). The best G.D. a-SiC:H film for passivation has been obtained from silane and benzene gas mixture with 1 w/o boron doping, which possesses the following properties: HF etching rate = 30 Å/min, buffered HF etching rate = 30 Å/h, 180°C H_3PO_4 etching rate = 740 Å/h, $\text{CF}_4 + \text{O}_2$ plasma etching rate = 320 Å/min, resistivity = 10^{11} (Ω-cm), and refractive index = 2.65. These data are superior or competitive to the conventional passivation films, *e.g.*, thermally grown SiO_2 , G.D. SiN_x , CVD SiN_x , and thus the boron-doped G.D. a-SiC:H film may be adopted as a novel passivant for semiconductor devices or optical dielectric film.

5. It is believable that MNS and MNOS devices using boron-doped a-SiC:H film as the insulator layer may pos-

sess the better diffusion barrier against environmental contamination and radiation (*i.e.*, ion implantation, etc.) because of its better passivation performance and less leakage.

It is also presumably applicable to VLSI device passivation. Nevertheless, its use as an active part in energy conversion devices, sensors, or light emitting diodes are also promising.

Crystallographic Growth Forms of Silicon on a Free Melt Surface

T. F. Ciszek*

Solar Energy Research Institute, Golden, Colorado 80401

ABSTRACT

Crystallographic growth forms and radial growth-rate anisotropies of point-nucleated, dislocation-free silicon sheets spreading horizontally on the free surface of a silicon melt have been measured for (100), (110), (111), and (112) sheet planes. 16 mm movie photography was used to record the growth process. Analysis of the sheet edges has lead to predicted geometries for the tip shape of unidirectional, dislocation-free, horizontally growing sheets propagating in various directions within the above-mentioned planes and provides a crystallographic description of the radial leading edges of the solid/liquid interface during flat-top transition growth in Czochralski pulling.

Two applications of silicon crystal growth from the melt which involve lateral growth on the free melt surface are flat-top transition growth in the Czochralski process (1) and horizontal ribbon growth with a large-area solid/liquid interface (2). In this paper, observations of (100), (110), (111), and (112) sheets propagating radially from small-diameter sources on a free melt surface are presented. From 16 mm films and postgrowth examination of the crystals, it was possible to deduce the idealized polygonal growth shapes of the sheets. In addition, information about growth rate anisotropies in the sheet planes has been obtained. Generally, the crystal faces that grow most slowly are those with the closest packing. As Jackson pointed out (3), these should also be the faces with the lowest specific surface free energy. Thus, there is reason to expect that the equilibrium form and the observed macroscopic growth form will be similar.

Equilibrium forms are governed by the variation of surface free energy with crystal orientation, as described by the classic work of Wulff (4). Further amplification of Wulff's concepts was provided by Herring (5). In these treatments, a polar plot of specific surface free energy *vs.* crystal orientation (called a Wulff plot) is constructed. The distance from the origin in a particular direction is proportional to the surface free energy for the crystal orientation corresponding to that direction. In general, the plot is a three-dimensional closed surface with a number

of minima and maxima. If planes perpendicular to the radius vector are imagined at each point on the closed surface, then the volume that can be reached from the origin without crossing any planes defines the equilibrium shape or form of the crystal. Since sharp minima or cusps in the polar plot have the shortest radius vectors, planes normal to the radius at these cusp positions will dominate the equilibrium shape.

Sheet crystals are approximately two-dimensional; hence, a planar section through the Wulff plot coincident with the sheet surface plane is useful in describing the equilibrium shape. On the hypothesis that growth forms and equilibrium forms are similar for the crystals grown in this study, qualitative Wulff plots that locate the cusp minima in the various sheet planes were constructed. Detailed data for the variation of surface free energy with orientation is not available for silicon. However, it is generally acknowledged that the (111) planes have the lowest surface free energy, and vestiges of these planes are responsible for the observable "growth lines" on crystals constrained to grow in a cylindrical ingot form. As mentioned earlier, the value of the surface free energy for a particular crystal plane is a function of the free bond density. This is lowest for (111) planes.

From the geometry of the sheet edges, a crystallographic description of faceting effects during flat-top Czochralski transition growth was obtained. Similarly, it is possible to determine the criteria that govern the tip

* Electrochemical Society Active Member.

shapes of single-crystal silicon ribbons growing horizontally from a melt surface.

Experimental

Silicon was melted in a quartz crucible of 60 mm diam and 25 mm height. Induction heating with a graphite susceptor was used. The susceptor was insulated by a cylindrical opaque quartz tube with a 6 mm wall thickness. An inert atmosphere of argon was maintained in the growth chamber. Sheet growth was initiated by dipping a seed crystal of the desired orientation into the melt and growing a thin neck from the seed at 15 rpm rotation rate in order to produce a dislocation-free, small (0.5-1.5 mm diam) cylindrical crystal. A sheet was then allowed to propagate radially in all directions on the melt surface by setting the vertical pulling speed to zero, dropping the RF generator power level to 94.7% of the value at which the neck was grown, and lowering the rotation rate to 1 rpm. A slow rate was used to avoid imposing a round shape on the spreading sheet. However, a nonzero rate was needed to allow measurements of all crystal faces on movie films of the growth. For each seed orientation, a second sheet was grown from a larger diameter (3.8-6.2 mm), dislocation-free, round cylindrical starting condition. Since the transformation from round to equilibrium shape occurs in a distance which is a function of initial round diameter, this allowed the transformation to be viewed on two different size scales.

The sheets did not grow perfectly flat and tended to have a slightly convex bottom since some growth occurred downward into the melt while the sheets were spreading radially. The radial growth rate of the sheets as they approached their equilibrium shapes typically ranged from 7 to 15 mm/min for the 5.3% power reductions used in these studies. At some point in the growth, icing from the crucible walls moved radially inward to close proximity with the spreading sheets. The sheets were removed from the melt at this time by quickly pulling the seed upward.

Records of the sheet growth experiments were made with 16 mm movie photography. The camera was located outside a window of the growth chamber, and a polished silicon mirror was used to direct light rays from the growth area to the camera. A filming speed of 10 frame/s was used in the sheet growth studies. The typical growth duration was 140s and, since a rotation rate of 1 rpm was used, the crystal revolved just over two times during the filming. This allowed any particular diameter of the growing sheet to be measured five times. Measurements were made of the distance between parallel flat faces and of the diameters of the faster growing diagonally opposed regions located angularly between two successive flat faces. Figure 1 is the view the camera sees. In this case, a (110) sheet growing at its limiting shape is shown. The measurements were made from the film by passing it un-

Fig. 1. A 16 mm frame from a film showing the limiting growth shape of a (110) sheet.

der a low-power (8-40 \times) microscope with a reticle placed over the film.

Sheet Shapes

The limiting shape of a (100) dislocation-free silicon sheet is a square. Figure 2a shows this form for a sheet grown from a 1.2 mm diam, round starting shape. The transformation to the square shape occurs in about 3-4 seed diameters; thus, the sheet is square at a small size. The idealized square shape is shown in Fig. 2b. The edges are in the four $\langle 011 \rangle$ directions, and the corners lie along the four $\langle 001 \rangle$ directions. The Wulff plot in the (100) plane is expected to have minima at the four (011) planes normal to the sheet surface and larger values in other directions. This is qualitatively shown by the curved, four-lobed figure surrounding the equilibrium shape.

Sheets nucleated in the (111) plane transform from round to hexagonal with equal 120° angles (Fig. 3a). The sides of the hexagonal shape are in $\langle \bar{1}\bar{1}2 \rangle$ radial directions, while the corners are in $\langle \bar{1}10 \rangle$ directions. The hypothetical Wulff plot is drawn with six cusps on the $(\bar{1}\bar{1}2)$ planes bounding the idealized sheet shape shown in Fig. 3b.

At first glance, the growth form of (110) sheets also appears to be a regular hexagon (Fig. 4a). However, closer examination shows that there is less symmetry in the (110) shape. Four of the six polygonal sides lie in $\langle \bar{1}11 \rangle$ directions, and the angle between two such adjacent sides is only 109.471° , as shown in Fig. 4b. The corners between two such sides lie in $[\bar{1}10]$ and $[1\bar{1}0]$ directions. Two sides of the polygonal shape are opposite each other and in the $[001]$ and $[00\bar{1}]$ directions. These sides make an angle of

Fig. 2. a(top): Final shape of a (100) sheet. b(bottom): Idealized growth form and qualitative Wulff plot for a (100) sheet.

Fig. 3. a(top): Final shape of a (111) sheet. b(bottom): Idealized growth form and qualitative Wulff plot for a (111) sheet.

125.264°, with the $(\bar{1}11)$ type sides. Minima occur on both (001)- and $(\bar{1}11)$ -type planes in the qualitative Wulff plot. Since growth in the $[001]$ -type directions appears to proceed more rapidly than growth in the $[\bar{1}11]$ -type directions (Fig. 4a), it is possible that after long growth times the (001) faces may vanish, leaving only $(\bar{1}11)$ bounding planes.

The (112) plane sheets are observed to also have six sides, as can be seen in the sheet crystal of Fig. 5a. However, the bounding faces and included angles are different from both the (111) and (110) sheet cases. Two opposite sides are in $\langle \bar{1}11 \rangle$ directions. The other four sides correspond to predicted Wulff plot cusps on $(2\bar{4}1)$ -type planes. Two adjacent sides of this type make an angle of 135.585° with each other. The corners between these sides are in $[\bar{1}10]$ and $[\bar{1}10]$ directions. The angle between $(2\bar{4}1)$ - and $(\bar{1}11)$ -type sides is 112.208°. The deduced Wulff plot shows minima on both $(\bar{1}11)$ - and $(2\bar{4}1)$ -type planes (Fig. 5b). The growth rates in the $[2\bar{4}1]$ - and $[\bar{1}11]$ -type directions appeared to be very similar (Fig. 5a). However, it is again possible that for long growth times one or the other may dominate.

The Wulff plots in Fig. 2-5 are only hypothetical. It is reasonably certain that minima occur where they are shown. Whether the minima are sharp cusps or only shallow valleys is not known. There is more uncertainty about the nonminima portions of the plots. Thus, they are shown as dotted lines in the figures. Since no special effort was made to reduce thermal asymmetry in the hot zone, the sheet crystal forms were sometimes asymmetrical. That is, the distance from the seed to two equivalent flat edges was not always equal.

Fig. 4. a(top): Final shape of a (110) sheet. b(bottom): Idealized growth form and qualitative Wulff plot for a (110) sheet.

Sheet Edge Geometries

A strong (111) faceting effect was observed on the edge regions of the sheets, largely because dislocation-free growth was employed for the sheet experiments. In the absence of dislocations, nucleation of new growth is more difficult, and larger levels of supercooling arise at the leading edges of the growth front. Faceting accompanies this situation. One (100) sheet was grown from a dislocated starting configuration. Two effects were noted with this sheet. The edge faceting was much less pronounced and, in fact, was nearly absent. Also, the idealized square shape did not completely form, at least not in the growth times available in our experimental setup. The corners of the sheet remained well-rounded.

The edge faceting in dislocation-free sheets always appeared on (111) planes. An example is depicted in the photograph of Fig. 6, which shows a (111) sheet mounted in wax to allow viewing of the edge. The central edge facet in the photograph makes a 70.5° acute angle with the top of the sheet. It is located in a $\langle 2\bar{1}\bar{1} \rangle$ -type direction from the seed. To the left and right of this facet are other edge facets that make a 109.5° obtuse angle with the sheet's top surface. These are in $\langle 2\bar{1}1 \rangle$ directions from the seed. All told, there are three obtuse facets and three acute facets alternating around the sheet edge. Careful scrutiny of Fig. 6 also reveals a (111) facet on the sheet top adjacent to the central edge facet. There are six of these, one adjacent to each edge facet.

In addition to describing the radial growth crystallography for flat-top Czochralski transition growth, these observations have implications for high perfection sheet growth solid/liquid interfaces in the horizontal growth mode. It is possible to predict, for example, the sheet tip geometries for a large number of growth orientations

Fig. 5. a(top): Final shape of a (112) sheet. b(bottom): Idealized growth form and qualitative Wulff plot for a (112) sheet.

from the observations on radially spreading sheets. Figure 7 shows the expected tip geometries for (111) dislocation-free sheets growing in the $\langle 2\bar{1}\bar{1} \rangle$ - and $\langle \bar{2}1\bar{1} \rangle$ -type directions, with a 5° pulling angle. Note the retrograde tip angle for $\langle \bar{2}1\bar{1} \rangle$ growth.

For (100) sheets, four (111) edge facets appear in $\langle 011 \rangle$ directions from the seed. All make 54.7° acute angles with the top of the sheet. The expected tip geometry for dislocation-free (100) silicon sheets growing in one of these four directions is given in Fig. 8.

The edges of (110) sheets displayed two types of (111) facets. In the four $\langle 1\bar{1}\bar{1} \rangle$ -type directions, a 90° facet with respect to the sheet plane was found. In the two $\langle 001 \rangle$ directions, the facet made a 35.3° acute angle with the

sheet top. The 144.7° obtuse (111) facets were not observed. Predicted sheet tip geometries for horizontal growth are drawn in Fig. 9.

The greatest variety of edge facets was seen in (112) sheets. Figure 10 shows these in the way they would define the tip geometries of horizontal sheets. In the $[1\bar{1}\bar{1}]$ direction, a facet at 90° to the sheet plane was seen, while in the $[\bar{1}\bar{1}\bar{1}]$ direction, two facets appeared. One was at 90° to the sheet plane, and a second was at 19.5° . These two facets meet at an included angle of 109.5° . In the $\langle 4\bar{2}\bar{1} \rangle$ directions, acute angle facets of 61.9° were seen, while in the $\langle \bar{4}2\bar{1} \rangle$ directions, the angles were retrograde with a 118.1° value.

Growth Rate Anisotropies

As the radially spreading sheets described in this study evolve from the round initial geometry to the polygonal growth form, it is evident that the growth rates in the directions toward the polygon corners must be greater than the growth rates in directions toward the flat polygon sides. Neither of the rates are constant with time. Initially, the growth rate is slow, since the melt temperature does not respond immediately to the drop in RF generator power. The rate increases slowly at first, and then more rapidly, as the expanding top surface of the solid, with its higher emissivity, becomes an increasingly more effective heat radiator. The slope of a size vs. time plot for a particular direction from the seed, at any given time, is the growth rate in that direction at that time. The ratio between rates in different directions is the ratio of slopes of the two size vs. time curves at the same instant.

Figure 11 shows the size of a (100) sheet along the $\langle 011\rangle$ and $\langle 001\rangle$ directions as a function of time for a dislocation-free starting diameter of 1.2 mm. All $\langle 001\rangle$ directions were considered to be equivalent, and all $\langle 001\rangle$ directions were considered to be equivalent. Thus, four measurements for each set of directions were made for each revolution of the crystal. The initially round (100) sheet eventually became square, and the ratio of slopes in the $\langle 011\rangle$ and $\langle 001\rangle$ directions, for large times, is expected to be the geometrically limited value 0.71. The growth rate ratios were determined by evaluating the derivatives of the second-order polynomial regression best fit curves for the diameter vs. time data, for each of the two directions, and taking their ratios. The $\langle 011\rangle/\langle 001\rangle$ growth rate ratio in the (100) sheet plane ranges from 0.4

Fig. 11. Size vs. time for a (100) sheet in two different radial directions.

to a final value of 0.74 over the 150s growth time (Fig. 12) with a relatively quick rise to 0.6 and then a slower approach to 0.74. A growth model for a growth rate in the $\langle 011\rangle$ direction 0.6 times the growth rate in any other direction is shown in Fig. 13. The transformation from a round to a square shape is seen to happen in about three seed diameters.

Similar behavior, but generally with less anisotropy, was seen for the other sheet planes. For example, the $\langle 11\bar{2}\rangle/\langle 01\bar{1}\rangle$ growth rate ratio in the (111) plane ranged from an initial value near 0.6 to a final value of 0.9 (Fig. 12), which is in good agreement with the geometrically limited value of 0.87. The change of growth rate ratios

Fig. 12. Two examples of the change of growth rate ratios with time. a: (Growth rate in $\langle 011\rangle$ direction)/(growth rate in $\langle 001\rangle$ direction) for the (100) sheet plane (lower curve). b: (Growth rate in $\langle 11\bar{2}\rangle$ direction)/(growth rate in $\langle 01\bar{1}\rangle$ direction) for the (111) sheet plane (upper curve).

with time is probably related to the changing temperature. However, the change is moderate, and the growth rate ratios appear to asymptotically approach final values at high growth speeds.

Summary and Discussion

The technique of studying rapid silicon sheet growth via free spreading of point-nucleated sheets on a super-cooled horizontal melt surface has yielded a large amount of information about idealized growth forms, solid/liquid interface sheet tip morphologies, qualitative Wulff surface free energy polar plots, and growth rate anisotropies. The method is versatile in that both very high perfection (dislocation-free) effects and less structured (polycrystalline and dendritic) effects can be studied. In this paper, only dislocation-free growth with (100), (111), (110), and (112) surface planes is discussed in detail.

The low surface free energy (111) planes dominate the sheet tip geometry at the solid/liquid interface, determine the growth form of radially growing sheet crystals (through their intersection with the sheet plane), and contribute to growth rate anisotropies due to the relative difficulty of new growth nucleation on the low free bond density (111) surface. They also play a determining role in fast dendritic growth by virtue of the high free bond density associated with reentrant edges at a (111) twin boundary. Earlier work on edge-supported pulling of silicon sheets (6) showed that (111) twin planes can block the spreading of spurious random grains. A similar mechanism has recently been found to be important in stabilizing the crystal structure of horizontally grown sheets. In dendritic web growth, (111) twin planes are key elements of the growth process and the (111) web surface is very high in quality. The equilibrium structure of long multicrystalline silicon sheets is dominated by longitudinal grains with (111) boundaries and near $\langle 110 \rangle$ surface normals. In summary, the properties of the (111) surface

in silicon are of major importance for sheet crystal growth. In addition, (111) plane faceting dominates the edge geometry for radially spreading growth during the flat-top transition phase of Czochralski crystal pulling.

Acknowledgments

The technical assistance of several individuals is deeply appreciated. M. Schietzelt helped in the crystal growth experiments, the 16 mm film analysis, and the preparation of figures for the manuscript. J. Hurd also assisted in the film measurements. Support for this work was provided by the U.S. Department of Energy and DOE/JPL contract W08746-83. The content of this paper is derived from a presentation by the author at the JPL Research Forum on High-Speed Growth and Characterization of Crystals for Solar Cells, Port St. Lucie, Florida, July 25-27, 1983.

Manuscript submitted April 23, 1984; revised manuscript received Sept. 21, 1984.

The Solar Energy Research Institute assisted in meeting the publication costs of this article.

Epitaxial Growth Rate of GaAs: Chloride Transport Process

J. C. Hong and H. H. Lee

Department of Chemical Engineering, University of Florida, Gainesville, Florida 32611

ABSTRACT

A rate expression is developed for the growth rate of gallium arsenide based on a postulated mechanism of the growth kinetics. This rate expression, when applied to the experimental data reported by Shaw (4), describes the growth rate quite accurately over wide ranges of temperature and concentrations. In particular, it describes in a quantitative manner the temperature and GaCl concentration dependence of the growth rate, which goes through a maximum with the temperature and the concentration. The growth rate as affected by diffusion is given in terms of concentration boundary layer and the intrinsic growth rate obtained. A criterion of negligible diffusional effect is developed. The effect of physical orientation of substrate surface on the growth rate is also presented. These results allow one to determine rather completely the growth rate as affected by temperature, vapor-phase composition, fluid velocity, and the substrate orientation.

The vapor-phase epitaxial growth of GaAs in the Ga/HCl/As/H₂ system has received considerable attention in the literature, and review articles (1, 2) are available. One major interest in the epitaxial growth is the effects of various conditions on the growth rate. In the studies dealing with the effects, the usual approach is to assume equilibrium conditions (2). In this approach, the etching rate at the source is related to the thermodynamic equilibrium constant for the reaction leading to the formation of GaCl, chloride flow rate and the inlet partial pressure of AsCl₃. This etching rate is used for the difference in the etching rates between the source and the substrate to represent the thermodynamic term in the growth rate. Thus, the growth rate is typically expressed as a product of the thermodynamic term and hydrodynamic term in the form used for the growth of Si. The equilibrium approach has been used in one form or another by Hollan *et al.* (3) and

Shaw (4) in the use of a quasi-equilibrium method (5) to diffusion-limited growth rate (6, 7).

The growth process is considered kinetically controlled if the surface reactions are rate-limiting or transport (diffusion)-controlled if the diffusion through the boundary layer on the substrate is the rate-limiting step. Thus, the growth is either kinetically controlled or diffusion controlled, depending on the relative magnitude of rate constant and mass-transfer coefficient in the simplest case in which the growth rate is proportional to concentration. Although the distinction between kinetically controlled and diffusion-controlled growth is based on the relative speed of the two rate processes, this distinction is often used to explain the temperature dependence of the growth rate. In the region where the growth rate increases with increasing temperature, the growth process is considered to be under kinetic control, whereas it is un-

der diffusion control in the region where the growth rate decreases with increasing temperature. It appears that such a distinction is improper since the growth rate would not decrease with increasing temperature if indeed the diffusion process is the rate-limiting step.

The factors that affect the growth rate are temperature, vapor-phase gas composition, physical orientation of substrate with respect to gas flow, flow rate, and crystallographic orientation of substrate surface. For a given crystal plane, the first two factors determine the growth rate in the absence of diffusional effect. This growth rate in the absence of diffusion limitation may be termed "intrinsic growth rate," since it is the intrinsic rate unaffected by diffusion. The latter two factors determine in what manner the intrinsic rate is altered by diffusion for the actual growth rate observed. In this paper, we present results for a quantitative description of the growth rate. For the results, we first develop an expression for the intrinsic growth rate based on a postulated growth mechanism. We then determine the manner in which the intrinsic growth rate is affected by diffusion. This leads directly to the effect of physical substrate orientation on the growth rate. The results are compared with the data reported in the literature. This comparison leads to some insights into the growth mechanism.

Intrinsic Growth Rate

Consider the deposition of GaAs onto the substrate surface. We postulate that the incorporation of vapor-phase molecules onto the substrate requires adsorption of arsenic and GaCl onto the substrate sites as suggested by Shaw (4) and that arsenic is molecularly adsorbed in the form of As_2 . These competitive adsorption steps can be represented as

where K_1 and K_2 are the ratios of the forward rate constant to the reverse rate constant for the elementary steps shown. Here, the vacant site is denoted by S and the adsorbed states are represented by $GaCl \cdot S$ and $As_2 \cdot S$. We postulate further that the adsorbed species interact in the presence of hydrogen, which abstracts chlorine, for the incorporation into GaAs crystal structure

where $GaAs_2(\cdot 2S)$ denotes the lattice state of GaAs already incorporated into the crystal structure. It is postulated that in building up the zinc blende crystal structure of GaAs, one additional As atom is required for successive incorporation of Ga atom into the structure. In reality, there could be several surface reactions for the incorporation. Hence, the reaction shown represents the controlling step in an overall surface reaction scheme rather than the controlling elementary step. In addition, we postulate that two vacant sites can react with HCl, resulting in the etching of GaAs

where the pair of vacant sites is denoted by (2S). Here again, this reaction represents an overall surface reaction scheme rather than an elementary step, as we shall see. According to the postulation, then, the rate of incorporation per unit surface area, r , in mole/(time · area) is

$$r = k' C_{H_2} C_{GaCl \cdot S} C_{As_2 \cdot S} - k_e C_v^2 C_{HCl} \quad [5]$$

where $C_{GaCl \cdot S}$ and $C_{As_2 \cdot S}$ are the surface concentrations of the adsorbed species, $GaCl \cdot S$ and $As_2 \cdot S$. C_v is the surface concentration of vacant sites and C_{H_2} and C_{HCl} are the volume concentrations of hydrogen and HCl. If we use

the site balance per unit surface area given by

$$C_t = C_v + C_{GaCl \cdot S} + C_{As_2 \cdot S} \quad [6]$$

the elementary steps given by Eq. [1] and [2] yield

$$\frac{C_v}{C_t} = \frac{1}{1 + K_1 C_{GaCl} + K_2 C^{1/2}_{As_4}}, \quad K_2 = K_2' K_{As}^{1/2} \quad [7]$$

where K_{As} is the equilibrium constant for $As_4 \rightleftharpoons 2As_2$. Here, C_t is the surface concentration of total sites. Equation [7] can be used in Eq. [5] with the aid of Eq. [1] and [2] for $C_{GaCl \cdot S}$ and $C_{As_2 \cdot S}$ to arrive at the following rate of incorporation

$$r = \frac{k C_{H_2} C_{GaCl} C^{1/2}_{As_4} - k_e C_{HCl}}{(1 + K_1 C_{GaCl} + K_2 C^{1/2}_{As_4})^2} \quad [8]$$

where k and k_e are given by

$$k = k' C_t^2 K_1 K_2 = k' C_t^2 K_1 K_2' K^{1/2}_{As} \quad [9]$$

$$k_e = k_e' C_t^2$$

Since the incorporation rate is given in terms of moles GaAs/(time · area) or length/(time · area), the growth rate G can be expressed as

$$G = Ar \quad [10]$$

where A is a constant. If G is expressed in terms of weight GaAs/(time · area), for instance, the constant A is simply the molecular weight of GaAs. The growth rate G is often given in terms of partial pressure. Thus, we write the growth rate as follows

$$G = \frac{\bar{k} p_{H_2} p_{GaCl} p^{1/2}_{As_4} - \bar{k}_e p_{HCl}}{(1 + \bar{K}_1 p_{GaCl} + \bar{K}_2 p^{1/2}_{As_4})^2} \quad [11]$$

where p_i is the partial pressure of species i and the overbar denotes the quantity including ($R_g T$) factor resulting from the application of ideal gas law ($p_i = C_i R_g T$) in converting C_i to p_i . The rate constants \bar{k} and \bar{k}_e also include the constant A .

Consider the application of the growth rate given by Eq. [11] to experimental data. In particular, consider the extensive data reported by Shaw (4). The data are suitable for determining the intrinsic growth rate since the total

Fig. 1. Arrhenius plots for the rate and equilibrium constants in Eq. [12] as a function of reciprocal temperature for GaAs growth rate.

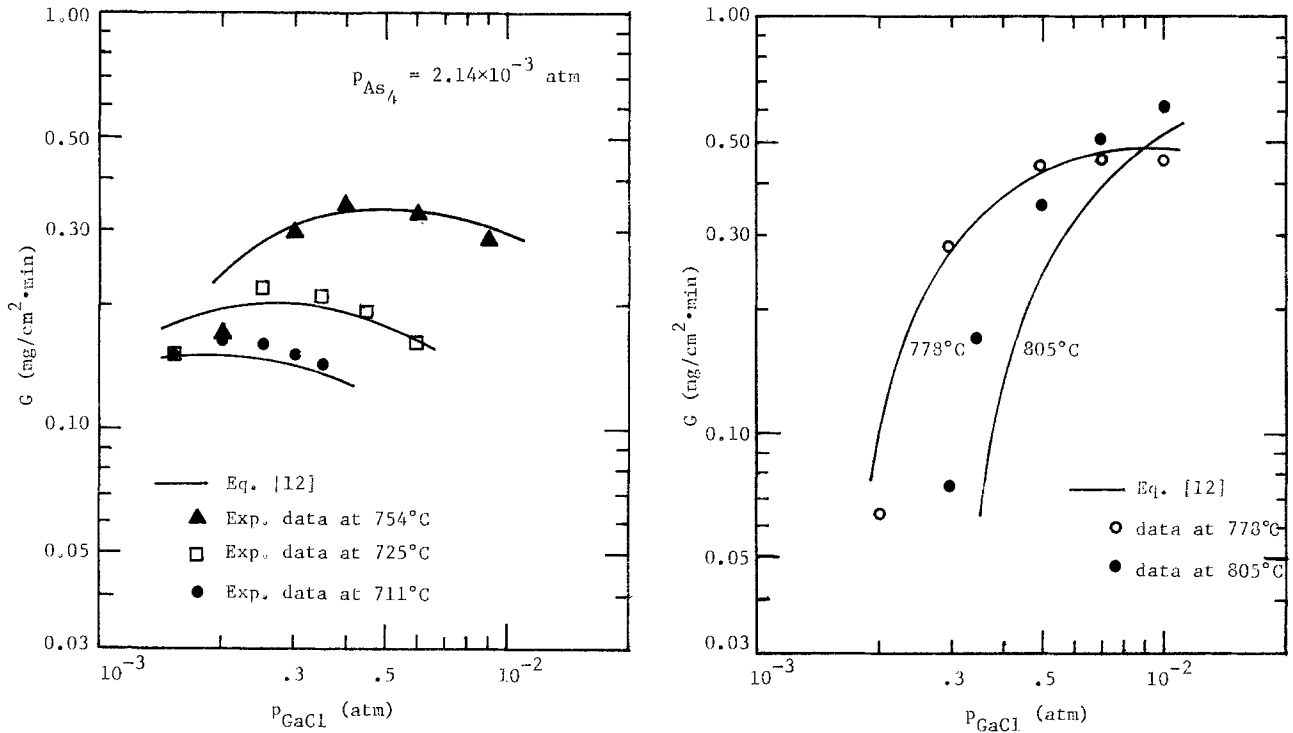

Fig. 2. Comparison between experimental growth rates of GaAs and those predicted by Eq. [12] as a function of GaCl partial pressure at (a, left) low and (b, right) high temperatures.

flow rate is such that the growth rate is unaffected by diffusion (8) and the reactant partial pressures were independently varied. In order to determine the rate and equilibrium constants in Eq. [11], the growth rates reported in Fig. 4 and 5 in the paper by Shaw (4) at temperatures 711°, 725°, 754°, 778°, and 805°C were utilized. A nonlinear regression program was used to calculate the rate and equilibrium constants at each temperature and these results in turn used to obtain the Arrhenius plots shown in Fig. 1. Since p_{H_2} and p_{HCl} in all cases are essentially constant, these were lumped with the rate constants k and \bar{k} , as shown in Fig. 1. Based on the Arrhenius plots, the growth rate can now be written as follows

$$G = \frac{(\bar{k}p_{H_2})p^{1/2}_{As_4}p_{GaCl} - (\bar{k}_e p_{HCl})}{(1 + \bar{K}_1 p_{GaCl} + \bar{K}_2 p^{1/2}_{As_4})^2}, \text{ (mg/cm}^2 \cdot \text{min)}, p_i \text{ in atm} \quad [12]$$

$$\begin{aligned} (\bar{k}p_{H_2}) &= 8.059 \times 10^{-46} \exp(123,400/T), p_{H_2} = 1 \text{ atm} \\ (\bar{k}_e p_{HCl}) &= 2.643 \times 10^{-38} \exp(95,200/T), p_{HCl} = 9.7 \times 10^{-4} \text{ atm} \\ \bar{K}_1 &= 2.337 \times 10^{-31} \exp(81,900/T) \\ \bar{K}_2 &= 1.511 \times 10^{-23} \exp(63,000/T) \end{aligned} \quad [13]$$

Comparisons between the growth rate predicted by Eq. [12] and [13] and the experimental data reported by Shaw (4) are shown in Fig. 2 and 3. It is seen in Fig. 2, which corresponds to Fig. 5 in the paper by Shaw (4), that the growth rate expression of Eq. [12] predicts the experimental growth rates quite accurately at the temperatures 711°, 725°, 754°, and 778°C, although the prediction is higher at 778°C at low pressures when p_{GaCl} is varied at constant p_{As_4} . At 805°C, however, the prediction is lower than the experimental growth rate. An important observation that can be made in Fig. 2 is that the growth-rate expression predicts quite accurately the maximum growth rate with respect to p_{GaCl} at all temperatures. The comparison given in Fig. 3, which corresponds to Fig. 4 in the paper by Shaw (4), shows similar behavior as in Fig. 2, *i.e.*, quite accurate predictions at 711°, 725°, 754° (except at low p_{As_4} pressures), and 778°C, but not as good at 805°C, when p_{As_4} is varied at constant p_{GaCl} . The major characteristics of the epitaxial growth of GaAs by the chloride transport process are that the growth rate goes through a maximum as p_{GaCl} is increased and that it also goes through a maxi-

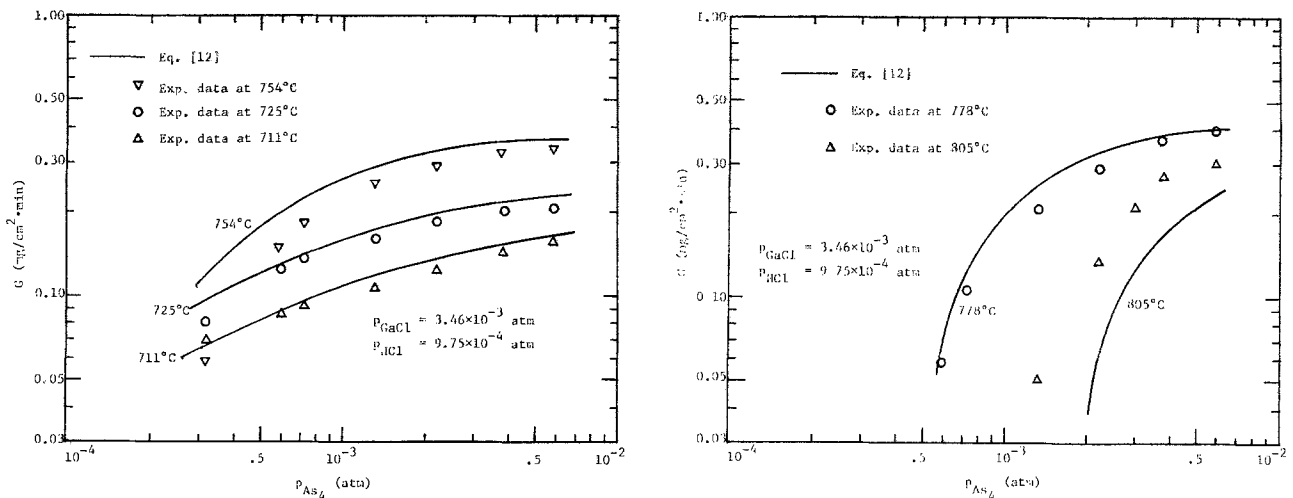

Fig. 3. Comparison between experimental growth rate of GaAs and those predicted by Eq. [12] as a function of As₄ partial pressure at (a, left) low and (b, right) high temperatures.

Fig. 4. Growth rate of GaAs as a function of reciprocal temperature at various partial pressures of GaCl.

imum as the substrate temperature is raised. Although the results shown in Fig. 2 and 3 should reveal the temperature dependence upon close examination, we show for comparison in Fig. 4 the growth rate given by Eq. [12] as a function of reciprocal temperature at various p_{GaCl} values. A comparison of Fig. 4 with Fig. 3 in the paper by Shaw (4) should reveal that there is a good agreement between the two, in particular with respect to the maximum values of the growth rates and the temperatures at which these maxima occur. While not presented, the same can be concluded about the temperature dependence of the growth rate at various arsenic partial pressures.

We have seen that the growth rate given by Eq. [12] describes the epitaxial growth rate satisfactorily and that it can explain quantitatively the major characteristics of the growth. In light of this, let us consider implications of the results as related to the postulated mechanism. According to the temperature dependence of \bar{K}_1 in Eq. [13], which is essentially K_1 , the heat of adsorption for the adsorption/desorption step of Eq. [1] is very high, indicating highly activated adsorption/desorption of GaCl. \bar{K}_2 is essentially K_2 , which is the product of K_2 , the equilibrium constant for the adsorption/desorption step for As_2 , and $K^{1/2}_{\text{As}}$, the equilibrium constant for $\text{As}_2 \rightleftharpoons 2\text{As}$. According to the temperature dependence given in Eq. [13], the heat of adsorption of As_2 is much less than that of GaCl since \bar{K}_2 is a composite of two equilibrium constants. This indicates that the adsorption of GaCl plays a much more important role than the adsorption of As_2 . In this regard, it is noteworthy that the growth-rate expression based on dissociative adsorption of As_2 , which leads to $p^{1/4}_{\text{As}_2}$ dependence of the growth rate rather than $p^{1/2}_{\text{As}_2}$, described the growth quite poorly. While only adsorption experiments would clearly resolve the nature of adsorption, the kinetic information nevertheless points to molecular adsorption of As_2 rather than dissociative adsorption. It is of interest that the apparent rate constants \bar{k} and \bar{k}_c decrease rather than increase with increasing temperature, as is evident from the expressions in Eq. [13]. This is not surprising at least for \bar{k} in light of the fact that the heats of adsorption for K_1 and K_2 (see Eq. [9] for k) are very high since the apparent activation energy given for \bar{k} is the sum of the activation energy of k' and the heats of adsorption for K_1 and K_2 , which are positive. Thus, the rate constant k' can be expressed as $k' = k'_0 \exp(-21,500/T)$, where k'_0 is a pre-exponential factor, the activation energy being 43 kcal/mol. The fact that \bar{k}_c decreases with increasing temperature indicates that the etching of GaAs represented by Eq. [14] is not simple as indicated earlier, but would represent an

overall surface process consisting of several surface reactions.

Transport (Diffusion) Effects

The intrinsic growth rate given by Eq. [13] is the growth rate when the diffusional effect is absent. The diffusional effect on the growth rate is usually treated in terms of boundary layer forming from the leading edge of the substrate (9), the theory of which is due to Schlichting (10). This diffusional effect is important not only for determining the actual growth rate, but also for growing uniform films, as demonstrated by Kuiper *et al.* (11) and Komeno *et al.* (12). The boundary-layer thickness through which the gas molecules have to diffuse to the substrate surface for subsequent incorporation into crystal structure is usually taken as the hydrodynamic (velocity) boundary-layer thickness (2, 12). At steady state, the concentration gradient in the boundary layer is linear and, therefore, the mass-transfer coefficient k_g is given by

$$k_g(x) = \frac{D}{\delta(x)} \quad [14]$$

when the flux through the layer is expressed as the product of k_g and the concentration difference. Here D is the molecular diffusivity of diffusing species, δ is the concentration boundary-layer thickness, and x is the distance from the leading edge of the substrate, which is taken as zero.

While the velocity boundary-layer thickness has been used in the literature for the mass-transfer coefficient, the boundary layer of interest is rather the concentration boundary layer, which is different from the velocity layer. The velocity boundary-layer thickness δ_h is related to the concentration boundary-layer thickness through Schmidt number, Sc , as follows (13)

$$\frac{\delta}{\delta_h} = Sc^{-1/3}; Sc = \nu/D \quad [15]$$

where ν is kinematic viscosity. According to Schlichting (10), the velocity boundary-layer thickness is given by

$$\delta_h = 5(\nu x/v_x)^{1/2} \quad [16]$$

if the thickness is defined as that at which the velocity becomes 99% of the bulk fluid velocity v_x . This can be combined with Eq. [14] and [15] to give

$$k_g = \frac{v_x^{1/2} D^{2/3}}{5 \eta^{1/6} x^{1/2}} \quad [17]$$

The theoretical value of the mass-transfer coefficient for any species of interest can be calculated from Eq. [17] with the aid of the Chapman-Enskog formula (14) for the theoretical value of the molecular diffusivity D . For the binary diffusivity calculation, the molecular diffusivity (for GaCl, for instance) can be taken as that of GaCl in H_2 since the mole fraction of H_2 is close to unity.

Consider now the effect of diffusion. At steady state, the mass flux through the boundary layer should be equal to the rate of reaction at the surface for any species

$$(k_{g,i}[(C_x)_i - C_i] = b_i r, i = \text{GaCl}, \text{As}_4, \text{H}_2, \text{HCl} \quad [18]$$

where C_x is the bulk gas concentration, r is that given by Eq. [8], and b_i is the stoichiometric coefficient for the overall reaction

with the sign convention that it is positive for reactants and negative for products since r is based on the species GaAs. Thus, b_i for As_4 , for instance, is 1/4, whereas it is -1 for HCl. In order to determine the actual growth rate based on bulk gas concentrations $(C_x)_i$, Eq. [8] and [18] written for each i have to be solved simultaneously for the surface concentrations C_i , which in turn can be used in Eq. [8] for the actual growth rate. It is immediately clear

that closed-form expressions cannot be obtained for the diffusional effect on the growth rate because of the non-linearity involved in Eq. [8].

Before proceeding to an examination of the diffusional effect, we consider two items that are noteworthy. If the growth rate is determined in terms of weight or average thickness, the mass-transfer coefficient averaged over the substrate length L may be used

$$(\bar{k}_d)_i = \frac{1}{L} \int_0^L \frac{v_x^{1/2} D_{im}^{2/3}}{5\nu_m^{1/6} x^{1/2}} dx = \frac{0.4v_x^{1/2} D_{im}^{2/3}}{\nu_m^{1/6} L^{1/2}} \quad [19]$$

where $(\bar{k}_d)_i$ is the average k_d for species, ν_m is the kinetic viscosity of the gas mixture, and D_{im} is the diffusivity of species i in the gas mixture. Use of this average mass-transfer coefficient also allows us to arrive at a criterion that can be used to determine whether the growth is affected by diffusion. For this, we consider Eq. [18] rewritten for the limiting reactant j in the following form

$$(\bar{k}_d)_j(C_{xj})[1 - C_j(C_{xj})] = b_jAG \quad [20]$$

where A is the constant relating r to the growth rate G (Eq. [10]). If the diffusional effect is negligible, the surface concentration c_j is very close to the bulk gas concentration and thus $C_j(C_{xj})$ should be very close to unity. If we consider 98% approach of C_j to (C_{xj}) as diffusion-free, we have from Eq. [20]

$$\frac{|b_j|AG}{(\bar{k}_d)_j(C_{xj})} < 0.02 \quad [21]$$

That is, if the criterion of Inequality [21] is satisfied, the concentration of the limiting reactant at the substrate surface is higher than 98% of the bulk concentration. This criterion is particularly useful for planning an experiment under diffusion-free conditions or for determining the extent of diffusion limitation of the growth rate obtained experimentally. It is noted that all quantities involved are readily available. This criterion was applied to the experimental results obtained by Shaw (8), in which total flow rate was varied at 750°C. GaCl was taken as the limiting reactant for which $|b_j| = 1$, A is the molecular weight of GaAs since the growth rate is in terms of weight. Equation [19] was used for \bar{k}_d , and the experimental growth rate of 65 $\mu\text{g/h}$ was used. The value of the left-hand side of Inequality [21] thus calculated is 0.004 at $v_x = 0.315$ cm/s, indicating that the surface concentration of GaCl approaches 99.6% of the bulk GaCl concentration for the total flow rate of 383 ml/min.

In order to assess the effect of diffusion, the growth conditions used by Shaw (4) were used along with Eq. [13], [18], and [19] for the growth rate as affected by diffusion. As detailed in the Appendix, the temperature dependence of physical properties can be expressed as

$$D_{im,T} = D_{im,1000} \left(\frac{T}{1000} \right)^{1.75}, \text{ (cm}^2/\text{s)}$$

$$\nu_{m,T} = \nu_{m,1000} \left(\frac{T}{1000} \right)^{1.65}, \text{ (cm}^2/\text{s); } \nu_{m,1000} = 8 \text{ cm}^2/\text{s}$$

$$(\bar{k}_d)_i = \frac{0.4v_x^{1/2} D_{im}^{2/3}}{\nu_m^{1/6} L^{1/2}}, \text{ (cm/s)}$$

In terms of consistent units, Eq. [18] can be written as

$$\left[\frac{(\bar{k}_d)_i}{R_g T} \right] (p_{zi} - p_i) - 1.657 \times 10^{-6} b_i G = 0$$

(mol /cm² · s), $i = \text{As}_4, \text{GaCl, H}_2, \text{HCl}$

With the aid of Eq. [12] and [13], these equations can be solved for p_i , which in turn can be used in Eq. [12] for the growth rate as a function of fluid velocity and temperature for given vapor-phase composition. The results are shown in Fig. 5 along with the vapor-phase composition used in the calculations. It is seen that for the vapor composition given, the growth rate is practically independent of transport effect, regardless of temperature if the fluid velocity is sufficiently high.

Fig. 5. Effect of diffusion on GaAs growth rate as affected by fluid velocity.

Perhaps the most important lesson to be drawn from Fig. 5 is that diffusion in the usual sense of transport limitation cannot cause the growth rate to decrease with increasing temperature at high temperatures. The growth rate's being diffusion limited simply means that the growth rate cannot reach the intrinsic rate. It is of interest to note in Fig. 5 that the diffusion-limited growth rate can be higher than the intrinsic rate at low temperatures, *i.e.*, $v = \infty$ vs. $v = 0.5$. This is due to the fact that the diffusional effect on the inhibition term for the growth rate (denominator of Eq. [12]) is larger than the effect on the numerator terms in Eq. [12]. Therefore, if a low temperature is preferred for a purer crystal, for instance, it may be advantageous to use a very low flow rate. This would have the added advantage of minimizing the thickness variation in a grown crystal.

Effect of Physical Orientation of Substrate

Consider the effect of substrate orientation with respect to gas flow on the mass-transfer coefficient. Let us define the angle of inclination β as shown in Fig. 6. The diffusional effect considered in the previous section is for $\beta = 0^\circ$. The change of velocity boundary-layer thickness with the angle was obtained by Hartree (15), and the results were given in a tabular form for selected values of β . While the results were obtained for the symmetrical case of two plates separated by $\beta\pi$, they can be used for our purpose provided that deposition occurs only on the side of substrate facing the flow (Fig. 6). The velocity boundary-layer thickness obtained for various β values can be well approximated by

$$\frac{\delta_n(\beta)}{\delta_n(\beta = 0)} = \left(\frac{2 - \beta}{2} \right)^{1/2} \exp(-\sqrt{\beta}/3)$$

Fig. 6. Substrate orientation with respect to gas flow

where $\delta_h(\beta = 0)$ is that given by Eq. [16]. If we assume that Eq. [15] still applies, the mass-transfer coefficient is given by

$$k_{tr} = \frac{1}{\left(\frac{2-\beta}{2}\right)^{1/2} \exp(-\sqrt{\beta/3})} \left[\frac{v_x^{1/2} D^{2/3}}{5\nu^{1/6} x^{1/2}} \right], \beta < 2 \quad [22]$$

Now that the mass-transfer coefficient contains the effect of the substrate orientation, the diffusional effect on the growth rate can be determined in the same manner as in the previous section with the use of Eq. [22].

Concluding Remarks

An intrinsic kinetics of GaAs growth has been developed based on a postulated growth mechanism, which involves molecular adsorption of both GaCl and As₂, surface reaction of these adsorbed species for GaAs formation, and dissociation of two vacant sites to GaCl with vapor-phase HCl. The growth-rate expression thus obtained has been shown to describe the growth behavior quite accurately for the experimental data of Shaw (4) obtained under widely varying temperature and concentrations. In particular, the expression explains the major characteristics quantitatively such as the temperature and GaCl-concentration dependence of the growth rate, which goes through a maximum with respect to both the temperature and the GaCl concentration. The rate and equilibrium constants determined from the experimental data indicate that GaCl adsorption/desorption is a highly selective and activated process. The effect of diffusion on the growth rate has been determined based on concentration boundary layer and the intrinsic growth rate obtained earlier. A simple criterion for negligible diffusion effect has been derived. This criterion can be used for selection of experimental conditions under which the diffusional effect is negligible. The effect of substrate orientation has also been given for the growth rate. The results presented here, when taken together, describe rather completely the growth rate as affected by vapor-phase gas composition, temperature, fluid velocity, and physical orientation of substrate surface.

APPENDIX

Physical Properties

The values of D_{im}(=D_{iH₂}) were calculated by the Chapman-Enskog relationship

$$D_{iH_2} = 1.858 \times 10^{-3} T^{3/2} \frac{[(M_1 + M_{H_2})/(M_1 M_{H_2})]^{1/2}}{P \sigma_{iH_2}^2 \Omega_{iH_2}(T)} \quad (\text{cm}^2/\text{s})$$

where M is the molecular weight. For the calculations, the binary Lennard-Jones parameters σ and Ω were obtained from

$$\sigma_{iH_2} = \frac{1}{2} (\sigma_i + \sigma_{H_2})$$

$$\epsilon_{iH_2} = (\epsilon_i \epsilon_{H_2})^{1/2}$$

The values thus calculated along with the parameter values are given below

Species (i)	σ	ε/k _B	D _{iH₂,T = 1000 K}	D _{iH₂,T = 300 K}
GaCl	(6)	(1000)	3.04	0.370
H ₂	2.827	59.7	10.8	1.31
As ₂	(5)	(1000)	3.02	0.367
HCl	3.339	344.7	5.61	0.682

where k_B is the Boltzmann constant. The parameters were obtained from Ref. (13). The parentheses are used in the table to denote estimated values. The viscosity was obtained from

$$\eta = 26.69 \frac{\sqrt{MT}}{\sigma^2 \Omega_V(T)} \quad (\mu p)$$

The kinematic viscosity ν is η/ρ, where ρ is density. The temperature dependence of ρ and Ω is as follows

$$\rho \propto T^{-1}$$

$$\Omega_{iH_2} \propto T^{-0.25}$$

$$\Omega_V \propto T^{-0.15}$$

Use of these temperature dependences led to the temperature dependences for D_{im} and ν_m given in the text.

Electrochromism in Sputtered Li-W-O Compounds and a Layered Structure

Makoto Kitabatake, Kumiko Hirochi, and Kiyotaka Wasa

Matsushita Electric Industrial Company, Limited, Central Research Laboratories, Moriguchi, Osaka 570, Japan

ABSTRACT

The electrochromic behavior of sputtered Li-W-O thin films was studied. Two types of transparent film were selectively prepared under different sputtering conditions. A clear blue film (film A) was deposited under pure argon gas and a colorless film (film B) was obtained under a mixed gas of argon and oxygen. The blue coloration of film A bleached into another type of colorless film (film A') by heating in an atmosphere of oxygen. Using these films, a new type of electrochromic device (Au/film B/film A'/ITO) was proposed and fabricated with a simple process.

WO₃ has been known as one of the most common electrochromic materials. In general, the electrocoloration in the WO₃ film results from the formation of a tungsten bronze (M_xWO₃, x = 0 ~ 1) (1). The M represent, for example, H, Li, or Na (2). The formation of the tungsten bronze is caused by the double injection of the M⁺ ions and electrons to the WO₃. The blue coloration of the tungsten bronze is attributed to the intervalence transfer of electrons between W⁶⁺ and W⁵⁺ (1, 3, 4). Two types of Li-W-O compounds have been known. One is blue Li₁WO₃, which exhibits tungsten bronze structure (5), and the other is colorless Li₂WO₄, which contains only W⁶⁺. Li₂WO₄ is applicable to a Li electrolyte which supplies Li⁺ ions to the electrochromic materials (6).

We have prepared thin films of the Li-W-O compounds by a sputtering deposition under various sputtering gas compositions. This paper describes their optical properties and their applications to electrochromic devices.

Sample Preparations

An RF sputtering apparatus was employed for the deposition of the Li-W-O thin films. The sputtering conditions are shown in Table I. The sputtering gas was pure argon (purity 6N) or a mixture of argon and oxygen (purity 6N). The mixing ratio (O₂/Ar) of the sputtering gas was varied from 0 to 1. The sintered powder synthesized from Li₂CO₃ (purity 4N) and WO₃ (purity 4N) was put in a stainless steel dish and used as the target. The powder of Li₂CO₃ and WO₃ was mixed in a ratio of 1:1 (molecule). The substrates were fused quartz plates with smooth surfaces of 0.2 mm thickness.

The Sputtered Li-W-O Films

Two types of transparent film were prepared by sputtering deposition. Film A was deposited under the sputtering gas of pure argon. Film B was deposited under the mixture of argon and oxygen. The same sputtering targets were used for the preparation of these films. Film A was colored blue and film B was colorless. Figure 1 shows the absorption of red light (He-Ne laser: 6328Å) of the films sputtered under different sputtering gas compositions. Film A, deposited under pure argon sputtering gas, strongly absorbs red light. The absorption decreases abruptly with the small addition of oxygen to the sputtering gas. Film B deposited under the mixed gas of argon and oxygen scarcely absorbs the red light. Figure 2 shows the visible light-absorption spectra of film A and film B. Film A strongly absorbs from red to infrared regions, compared with film B.

Fig. 2. Absorption spectra of the film A and the film B. Film thickness is about 3000Å.

Fig. 3. RHEED patterns of film A and film B. Film thickness is about 3000\AA .

yses suggested that the compositions of film A and film B were almost the same. The blue coloration of film A was bleached by the radiation of a CO_2 laser ($> 0.5 \text{ W/mm}^2$). Film A crystallized and was changed to film B by this radiation. It is considered that the state of the W^{5+} which causes the coloration is nonequilibrium in comparison with that of the W^{6+} . In the sputtering process, there is a possibility of constructing the nonequilibrium microstates by the effects of the impinging ions and nuclei with high energy on the deposited film during the film growth. In film A of amorphous Li-W-O prepared by sputtering, there are so many nonequilibrium microstates that the density of the W^{5+} , which causes the coloration, is high. In film B of polycrystalline Li-W-O, the presence of

Fig. 4. Structure of the new electrochromic device

oxygen in the sputtering gas plays an important role in the coloration and the crystallization of the film. These considerations suggest that the crystallization of the film is equivalent to the moderation of the nonequilibrium states and the reduction of the density of the W^{5+} .

The coloration of film A was bleached without crystallization when the film was slightly heated at 200°C in an atmosphere of oxygen; in the atmosphere of pure argon, film A was not bleached. This slightly heated film remained amorphous. Oxygen facilitates the moderation of the nonequilibrium microstates in film A in the heating process. We call this slightly heated colorless amorphous film "film A'." The W^{5+} in film A can easily change to the W^{6+} without crystallization. Detailed analysis of the light absorption spectra indicated that film A' weakly absorbed the region similar to that of film A. The density of the W^{5+} in film A' was much smaller than that in film A.

Electrochromic Device Fabrication

We prepared the electrochromic devices with the Au/film B/film A/ITO layered structure shown in Fig. 4. This layered structure was fabricated by the control of the sputtering gas composition during the sputtering deposition. Film A was first deposited under the pure argon gas on the ITO electrode, which was deposited on the fused quartz substrate. Subsequently, film B was deposited on film A under the mixed gas of argon and oxygen without breaking the vacuum. The first-deposited film A was initially colored blue. During the deposition of film B on film A, film A changed to transparent. Film A changed to film A' in the layered structure because film A was slightly heated in the atmosphere of oxygen during the deposition of film B. The thicknesses of film A and film B were 0.7 and $0.3 \mu\text{m}$, respectively. The Au electrode was vacuum deposited on the layered structure.

Figure 5 shows the interrupted voltammogram of the Au/film B/film A/ITO layered structure. The sweeping rate of the applied voltage was 0.2 V/s . The initially transparent layered structure was colored blue under the positive bias to the Au electrode and bleached again under the negative bias to the Au electrode. Film A' reversibly changed to film A by the alternation of the bias voltage. This coloration bleaching was either cycled or memorized in a similar manner to other electrochromic devices already reported (7). Film A operates as the electrochromic layer. Film B operates as the electrolyte layer which supplies the Li^+ ions to the electrochromic layer (film A). Figure 6 shows the time response of this new electrochromic device under different bias voltages. The change in the optical density ($\Delta\text{O.D.}$) of the device was measured

Fig. 5. Interrupted voltammogram of the device. The sweeping rate of the applied voltage is 0.2 V/s .

Fig. 6. Time response of the device

in the reflection mode using the He-Ne laser. Under the bias voltage above 16V, the response time is 200 ms or less.

Conclusions

The electrochromic material and device were prepared by the sputtering deposition of the Li-W-O compound. The deposited or heated films of the Li-W-O compounds can be classified as follows

Film A: deposited using pure argon sputtering gas; amorphous and colored blue.

Film B: deposited using the mixed (O₂, Ar) sputtering gas; polycrystalline and colorless.

Film A': the slightly heated film of film A; amorphous and colorless.

The presence of oxygen played an important role in the coloration and the crystallization of films during both the sputtering deposition and the heating process.

The device fabrication was very simple. The electrochromic and electrolyte layers were fabricated by the selection of the sputtering gas composition. The layered structure Au/film B/film A/ITO operated as the electrochromic device, and its response time was 200 ms or less.

A Structural and Electrical Comparison of BCl and BF₂ Ion-Implanted Silicon

M. Delfino* and M. E. Lunnon

Philips Research Laboratories, Signetics Corporation, Sunnyvale, California 94088

ABSTRACT

The molecular ions BCl⁺ and BF₂⁺ are implanted into <100> silicon at an energy of 16 keV per boron atom in the dose range of 6 × 10¹⁴–1.2 × 10¹⁵ cm⁻² to form shallow p⁺/n junctions. Cross-sectional transmission electron microscopy shows that chlorine is at least four times as effective as fluorine in amorphizing silicon. The increase in thickness of the amorphous layer, however, has a small effect in the reduction of axial channeling of boron as measured by secondary ion mass spectrometry. After annealing for 30 min at 900°C, diffusion of interstitial boron is enhanced by chlorine relative to fluorine, whereas the electrical activity of boron is inhibited. Diodes made with both BCl⁺ and BF₂⁺ implantations have comparable I-V characteristics with low reverse-bias junction leakage currents that are not affected by a band of dislocation loops which remain near the original amorphous-crystalline interface.

The use of ionized molecules such as BF₂⁺, BF⁺, BCl₂⁺, and BCl⁺ for p-type doping silicon by ion implantation was first proposed in 1971 (1). This work and subsequent studies by others (2-5) have demonstrated that BF₂⁺ implantation in particular can be a useful alternative to B⁺ implantation for the formation of shallow junction devices. The increased mass of BF₂⁺ results in a shorter intrinsic range and leads to a reduced ion-dose threshold with an accompanying higher critical temperature for amorphizing the substrate. The amorphous layer, in turn, minimizes channeling and lowers the activation energy for postimplantation annealing. Thus the residual defect density is, in general, reduced, which in principle lowers the sheet resistance and the junction leakage. Also, the trapped fluorine does not appear to be detrimental to device performance or reliability.

In spite of the extensive studies of BF₂⁺ implantation in silicon and its widespread acceptance in integrated cir-

cuit fabrication, a limited amount of work (4, 5) has been done with implanting other molecular boron ions into silicon. This appears to be due to the fact that the accompanying chlorine (4, 5) or bromine (4) adversely affects the electrical activation of the co-implanted boron. More recently (6), implanted chlorine at concentrations on the order of 10²⁰ cm⁻³ has been found to retard the solid-phase epitaxial regrowth of silicon. Nonetheless, in this paper, we demonstrate that, while chlorine does indeed inhibit boron electrical activity, shallow p⁺/n junction diodes with excellent I-V characteristics can be formed by furnace annealing BCl⁺-implanted silicon.

Experimental

BCl⁺ was implanted at 67 keV to a dose of 6.0 × 10¹⁴ or 1.2 × 10¹⁵ cm⁻² into Czochralski-grown n-type <100> silicon doped with phosphorus to a resistivity of 3.4-5.0 Ω-cm. The same dose BF₂⁺ implantations were done at the equivalent energy, i.e., 16 keV per B atom, of 71 keV for

mass spectrometry (SIMS) employed both O₂⁺ and Cs⁺ primary beams depth to profile the atomic concentration of boron and halogens, respectively.¹ Carrier concentration profiles, assuming bulk mobility, were obtained from spreading resistance measurements of beveled samples.² A 0.7 μm thick chemically vapor deposited oxide on the backsurface of the wafer prior to beveling improved depth resolution. Junction measurements were reproducible to within ±0.02 μm. The electrical quality of the p/n junction was evaluated by measuring, in darkness, the I-V characteristics of 0.01 cm diam diodes. The diodes were fabricated using standard photolithographic techniques. A 0.6 μm thick thermal oxide served as a mask during implantation. Aluminum-silicon was sputter deposited, etched, and annealed for 30 min at 410°C in forming gas to form contact pads.

Structural Characterization

Figure 1a-1d shows TEM <100> cross-sectional micrographs of <100> silicon implanted with 71 keV BF₂⁺ and 67 keV BCl₂⁺ to a dose of 6 × 10¹⁴ cm⁻², before and after annealing. The as-implanted samples show that a continuous amorphous layer is formed with BCl₂⁺ implantation only. The thickness of the amorphous layer is 0.078 μm. By comparison, BF₂⁺ at the identical dose and at the same beam current density only forms a thin buried damaged layer, suggesting the onset of an amorphous layer. After furnace annealing, a band of dislocation loops corresponding to the original amorphous-crystalline interface remains.

Results for an implantation dose of 1.2 × 10¹⁵ cm⁻² are shown in Fig. 2a-2d. In this case, BF₂⁺ forms a continuous amorphous layer with an abrupt amorphous-crystalline interface. The thickness of the amorphous layer is 0.072 μm, whereas the same dose BCl₂⁺ implantation amorphizes the surface to a depth of 0.092 μm. After annealing, both samples epitaxially regrow perfect single-crystal material. A band of dislocation loops similar to that observed with the low dose implantations is found.

Figure 3a-3d shows TEM <100> planar-view micrographs after furnace annealing. All samples show a uni-

form density of dislocation loops corresponding to the defect band observed in the cross-sectional specimens. The dislocation loop density of the post-annealed BCl₂⁺ implanted samples is proportional to the implantation dose but four orders of magnitude lower in density. The average diameter of the dislocation loops in both BCl₂⁺ implanted samples is approximately 0.02 μm, whereas the BF₂⁺ implantations result in much larger dislocation loops of irregular shape. These larger dislocation loops arise from a tendency of the smaller loops to coalesce during annealing. The growth of the dislocations appears to be

Fig. 5. Atomic boron depth profiles from SIMS for an implantation ion dose of 1.2 × 10¹⁵ cm⁻².

related to the higher diffusivity of fluorine compared to chlorine as discussed later. There is no evidence of gas bubbles in any samples, suggesting that the retained halogen is chemically bonded.

The atomic concentration profiles of boron, before and after annealing, are shown in Fig. 4 for BCl^+ and BF_2^+ implanted to a dose of $6 \times 10^{14} \text{ cm}^{-2}$. The boron gaussian-like peaks are in coincidence as expected from the energy equivalence of the dissociated molecular ions. The formation of an amorphous layer by BCl^+ implantation affects axial boron channeling with a reduction of the boron tail by $0.026 \mu\text{m}$. After annealing, boron diffuses more than twice as deeply in the BCl^+ -implanted sample. This enhanced boron diffusion is primarily due to the presence of an amorphous layer which increases the diffusivity by a factor of four (7).

At an ion dose of $1.2 \times 10^{15} \text{ cm}^{-2}$, where both BCl^+ and BF_2^+ amorphize silicon, the difference in the boron channeling tail is only $0.017 \mu\text{m}$. The $0.02 \mu\text{m}$ thicker amorphous layer formed with BCl^+ appears to contribute little to any further reduction in boron channeling. The SIMS profiles after annealing show that boron diffuses $0.03 \mu\text{m}$ deeper in the BCl^+ -implanted sample. This enhanced boron diffusion is attributed to the presence of chlorine. In addition there is a pile-up of boron towards the surface in the BCl^+ -implanted sample.

It appears, however, that the boron diffusion does not track the movement of the chlorine. Figure 6 shows that virtually no chlorine diffuses out after the furnace annealing, although slightly more is lost with the higher dose

implantation. By comparison, the BF_2^+ -implanted samples show considerable loss of fluorine after annealing, resulting in a characteristic two peak profile (8, 9). The minima correspond approximately to the original amorphous-crystalline interface in the high dose implanted sample and the buried damaged layer in the low dose implanted sample. It is interesting to note that even the thin damaged layer formed by implanting $6 \times 10^{14} \text{ BF}_2^+ \text{ cm}^{-2}$ is sufficient to cause fluorine to segregate after annealing. The presence of an amorphous layer is not required to form this multiple-peak structure, as previously believed (9). The amorphous layer does, however, retard the outdiffusion of fluorine during annealing. Apparently, the fluorine bonds to silicon during solid-phase epitaxial regrowth. This bond is not easily broken at 900°C .

Electrical Characterization

The carrier concentration depth profiles measured after furnace annealing for 30 min at 900°C are shown in Fig. 7. The relevant parameters obtained from these data are summarized in Table I. In agreement with previous work (4), these results show that less electrical activity is achieved by implanting BCl and that this effect becomes more pronounced as the chlorine concentration increases. The electrical junctions produced with both BCl implantations are identical and $0.044 \mu\text{m}$ shallower than that formed with the high dose BF_2^+ implantation. In all cases, the electrical junctions obtained from spreading resistance measurements are shallower than the metallurgical

Fig. 7. Carrier concentration depth profiles from spreading resistance measurements made on beveled samples. a(left): Implantation ion dose of $6 \times 10^{14} \text{ cm}^{-2}$. b(right): Implantation ion dose of $1.2 \times 10^{15} \text{ cm}^{-2}$.

junctions measured by SIMS. The boron in the implanted tail region is therefore interstitial and does not enter substitutional sites during annealing. This effect is most pronounced with the high dose BCl⁺ implantation, where the metallurgical junction is approximately 0.1 μm deeper than the electrical junction.

The room temperature I-V characteristics of p⁺/n diodes fabricated by implanting either BCl⁺ or BF₂⁺ and furnace annealing for 30 min at 900°C are summarized in Table II. The measurements were made with the p electrode biased and the substrate at ground potential. The statistics are based on an analysis of 20 diodes on two wafers of each implantation. The reverse-bias leakage current density is lower with the BF₂ implantations and increases with an increase in ion dose of either BCl⁺ or BF₂⁺. The breakdown voltage is appreciably lower with the high dose BCl implantation only suggesting that chlorine acts as an ionized impurity scattering site. The forward-bias characteristics could be fit to the expression $J = J_0[\exp(qV/mkT)^{-1}]$ where $kT/q = 25.26 \text{ mV}$. Over the current range from 10^{-11} to 10^{-6} A , we find m equal to 1.01-1.03 with BF₂ and m equal to 1.08-1.11 with BCl. Nonlinearity above 10^{-6} A is attributed to excess diode resistance. The near-ideal behavior of the diodes suggests that current

transport is dominated by diffusion. An increased deviation from the ideal is noted with BCl relative to BF₂ which increases with the ion dose of either species. This implies that the halogen contributes to some minority recombination within the depletion layer and that chlorine is far worse than fluorine in this respect. This could explain the extremely poor electrical characteristics found for annealing high dose BCl₂ implantations in silicon (5). Nonetheless, the diode characteristics are in general excellent and comparable to furnace-annealed B-implanted p/n diodes (2, 10).

Summary and Conclusion

The use of BCl⁺ implantation as an alternative to BF₂⁺ implantation to form shallow p⁺/n junctions in <100> silicon is examined. Because of complete dissociation of the molecular ion upon impact with the lattice, any structural and electrical effects are explained in terms of the influence of the halogen alone.

Chlorine is found to be at least four times as effective as fluorine in amorphizing <100> silicon. The coamorphization of the silicon surface which accompanies a $6 \times 10^{14} \text{ BCl}^+ \text{ cm}^{-2}$ implantation has a small effect in the reduction

of boron channeling compared to BF_2^+ . It is interesting that the amorphous layer does not suppress more of the boron channeling tail. The increase in thickness of the amorphous layer with BCl dose has essentially no effect on boron channeling.

Diffusion of interstitial boron during annealing is enhanced by chlorine relative to fluorine, whereas the transition to electrically active interstitial sites is retarded. This behavior tends to produce deeper metallurgical junctions and shallower electrical junctions with BCl^+ implantations in particular.

The mobility of fluorine during annealing is much higher than that of chlorine. Fluorine appears to segregate in regions of high lattice damage, whereas chlorine shows remarkably little diffusion and essentially maintains the as-implanted profile after annealing.

Shallow p⁺/n junction diodes fabricated with both BCl^+ and BF_2^+ implantations display excellent I-V characteristics, although the higher concentration of chlorine shows some degradation, suggesting minority carrier generation within the depletion region. The electrical properties are clearly more sensitive to the presence of the retained halogen than to the band of dislocation loops remaining near the original amorphous-crystalline interface.

ABSTRACT

The use of an improved microelectronic test structure and associated Kelvin measurement method for determining front contact resistance (circuit loading resistance) of a metal/semiconductor ohmic contact is described. The values of front contact resistance for aluminum/silicon contacts are determined using this Kelvin-cross contact resistance test structure and are compared with values determined by a two-terminal contact chain method and with values determined by a Kelvin voltage divider method. The values of front contact resistance using the Kelvin-cross structure and associated measurement method are shown to be less sensitive to photolithographic process variations and electrical measurement errors than those determined using the other two structures and measurement methods.

The problem of ohmic contact resistance becomes increasingly significant as the critical feature size for VLSI technology decreases. The contact resistance encountered as the current passes between the metal and the semiconductor will increase as the contact-window size decreases, and it can lead to prohibitively large RC time constants. The circuit loading resistance of an ohmic contact is called the front contact resistance (1, 2). The front contact resistance is defined as the ratio of the voltage across the interfacial layer at the edge where the current density is greatest to the entire current through the contact; it is independent of the current polarity.

A common approach to the determination of front contact resistance has been to measure the total series resistance of a chain of alternating diffused layer and metal layer sections serially connected by contact windows. This is usually a two-point measurement in which a dc current is forced from one end of the chain to the other while the voltage is measured between the two ends.

A knowledge of the diffused-layer and metal-layer sheet resistances, the number of diffused-layer and metal-layer squares, and the number of contact windows is then used to calculate an average value for front contact resistance. Because this is not a Kelvin measurement, both the resistance in the current (voltage) taps and the probe-to-probe pad resistance are sensed in the measurement. A Kelvin measurement method can avoid the inclusion of these parasitic resistances because it employs separate pairs of taps to sense the current and the voltage. This paper describes the use of a recently reported microelectronic test structure and electrical measurement method for the Kelvin determination of front contact resistance (1). This improved test structure also allows the Kelvin measurement of the interfacial and end contact resistances. [These parameters are defined by means of a transmission-line model for the metal/semiconductor contact (1).] The sensitivity of this method to measurement interferences and misalignment has also been discussed (1). A comparison of the values of front contact resistance determined by this method and by the contact-chain method,

* Electrochemical Society Active Member.

for 10 μm-square Al/Si contacts, is made. A comparison is also made between values determined by this method and values determined by a Kelvin voltage-divider method (2).

Fabrication of Devices

Three 4 in. wafers patterned entirely with contact resistance test chips were fabricated. These chips contain cross-bridge sheet resistors for the determination of both the sheet resistance and electrical linewidth of diffused and metal layers (3, 4); two two-terminal contact chains which allow the non-Kelvin determination of front contact resistance (Fig. 1); two sizes of a Kelvin voltage-divider structure, previously reported in the literature (2), for the determination of front contact resistance (Fig. 2); and a Kelvin-cross contact resistance test structure for the direct measurement of the end and interfacial contact resistances and for the determination of the front contact resistance (1) (Fig. 3). Table I gives the design values for the contact chains and the Kelvin test structures.

For each of the three wafers, an n-type diffused layer was formed by a 75 keV implantation of arsenic into a p-type 19 Ωcm <100> substrate. The implant dose was 1 × 10¹⁶ cm⁻². The implantation was followed by a drive-in at 1000°C in an N₂ ambient. Drive-in times were 20, 40, and 80 min, respectively. Contact windows were opened by a wet-etching technique. The metallization was 99% Al/1% Si sintered for 20 min at 490°C in an N₂ ambient. The sheet resistance and linewidth, for both the diffused and metal layers, were determined from the cross-bridge sheet resistor structures. Measurements were made at approximately 130 sites on each wafer by means of an automated parametric measurement system. Measured values for resistance and linewidth are given in Table II.

Determination of Front Contact Resistance

Two-terminal contact chains.—For each contact chain (Fig. 1), a non-Kelvin determination of front contact resistance was made by forcing a dc current of 1 mA from one terminal to the other and measuring the voltage between the terminals. The front contact resistance R_f is given by

$$R_f = [VI - (R_{SD})(n_D) - (R_{SM})(n_M)]/N \quad [1]$$

where I is the forced current, V is the measured voltage, R_{SD} and R_{SM} are the sheet resistances of the diffused and metal layers, respectively, n_D and n_M are the number of diffused and metal layer squares, respectively, and N is the number of (10-μm-square-design) contact windows. Lateral diffusion of the dopant and imprecise metal-line etching can cause the true values for n_D and n_M to be significantly different than the design values listed in Table I. In the application of Eq. [1], calculated values for n_D and n_M , obtained by correcting the design values of these parameters for the electrically measured linewidth, are used in place of the design values. Table III gives the calculated values for n_D and n_M corrected for the electrically measured linewidth. For each contact chain, measurements of VI were made at approximately 130 sites across each wafer.

$$R_f = \frac{R_1 L_2 - R_2 L_1}{2(L_2 - L_1)}$$

Fig. 2. Kelvin voltage-divider test structure proposed in Ref. (2) for the determination of front contact resistance. Front contact resistance is calculated from the measurement of R_1 and R_2 .

Fig. 3. Kelvin-cross contact resistance test structure for the determination of R_e , R_c , ρ_c , R_{SDUC} and R_f . The values of R_e and R_c are measured directly; ρ_c is determined indirectly from the measurement of R_e ; R_{SDUC} and R_f are determined indirectly from the measurement of R_e .

Table I. Design values for the contact chains and Kelvin structures. n_D and n_M are the number of diffusion-layer and metal-layer squares, respectively, in a chain. N is the number of contact windows in a chain. L_1 and L_2 are the lengths for the Berger structures (2). For the contact chains, diffused-layer squares under the contacts are not included, but metal-layer squares over the contacts are included.

Kelvin voltage-divider structure.—The Kelvin test structure introduced by Berger (2), shown in Fig. 2, allows the determination of the front contact resistance from the measurement of two resistances, R_1 and R_2 . In Fig. 2, R_1 is measured by forcing a current of 1 mA between contacts 1 and 2 and measuring the voltage across the same. R_2 is measured in a similar fashion using contacts 2 and 3. The resistors R_1 and R_2 are diffused resistors. The resistance of a diffused resistor, including both contacts, is given by

$$R = R_s L/W + 2R_f \quad [2]$$

where R_s is the sheet resistance of the diffused resistor, L is the length between contacts, and W is the width of the resistor. The substitution of R_1 and R_2 and the corresponding lengths L_1 and L_2 into Eq. [2] yields a system of equations that can be solved for R_f

$$R_f = (R_1 L_2 - R_2 L_1) / [2(L_2 - L_1)] \quad [3]$$

The design values for L_1 and L_2 are listed in Table I. For each of these Kelvin test structures, measurements of R_1 and R_2 were made at approximately 130 sites across each wafer.

Kelvin-cross test structure.—The transmission-line analysis of the uniform interfacial contact (5, 1) allows the calculation of R_f from the measured value of the end contact resistance R_e

$$R_f = R_e \cosh [(R_{SDUC}/\rho_c)^{1/2} d] \quad [4]$$

where R_{SDUC} is the sheet resistance of the diffused layer directly under the contact window, d is the length of the contact window, and ρ_c is the specific contact resistance of the metal/semiconductor interfacial layer. The end contact resistance R_e is the ratio of the voltage across

the interfacial layer at the edge where the current density is least to the entire current through the contact (1). A direct Kelvin measurement of R_e can be made by using the six-terminal structure shown in Fig. 3. In Fig. 3, a current of 1 mA is forced from pad 1 to pad 3, while the voltage is measured between pad 5 and pad 4. The ratio of the voltage to the current is R_e . [Pads 2 and 6 are used for other measurements (1).] The value of R_{SDUC} is not necessarily the same as the value of the diffused-layer sheet resistance away from the contact window. This is because the sintering step alters the sheet resistance of the diffused layer directly under the contact window by forming an Al/Si composite. The values of R_{SDUC} and ρ_c are determined by the method described in Ref. (1) using this same structure. A necessary requirement for the validity of the transmission-line analysis is that the interfacial contact layer have areal uniformity. A method for determining the areal uniformity of the interfacial contact layer is described in Ref. (6, 1). The interfacial contact layer, for each of the three wafers used in this study, was determined to be uniform across its area by this method. The end contact resistance R_e was measured at approximately 130 sites across each wafer.

Discussion and Results

The values of front contact resistance determined by the contact-chain method are given in Table IV. The negative values of R_f are attributed to contact window overetching. Measurements of contact-window size at selected sites with an image-shear optical microscope showed that the contact windows (10 μm by 10 μm design) were overetched on each of the three wafers by an amount between 1.4 and 1.7 μm . For chains A and B on wafer 2395-1, overetching of the contact windows by approximately 0.54 and 0.48 μm , respectively, is enough to produce negative calculated values of R_f if this overetching is not taken into account. Calculation of R_f , using values of n_D that are corrected for both measured linewidth and measured contact-window size, yields positive values (Table IV). In the application of the contact-chain method, n_D is seldom corrected for both linewidth and contact-window size. Even with these two corrections, the contact-chain method tends to be highly inaccurate because the calculated value of R_f is always essentially the difference of two large numbers, namely, $R_{SD} n_D$ and V/I (7). It is seen in Table IV that even with the corrections for both linewidth and contact-window size (overetching), there is still great disagreement in the calculated values for R_f on each wafer. A small percentage error in the measurement of either R_{SD} or V/I will tend to cause a very large percentage error in the calculated value of R_f . As an example of this, consider chain A on wafer 2395-1. If, in Tables II and IV, the measured values of R_{SD} and V/I were 2% smaller and 2% larger, respectively, then the calculated value of R_f^A would be 0.783 Ω instead of -1.16 Ω .

Table V gives the values of front contact resistance determined by the Kelvin voltage-divider method (2). As with the contact chains, the calculations of negative values is attributed to overetching of the contact windows. Image-shear optical-microscope measurements

Table IV. Measured values of V/I and calculated values of R_f for the contact chains (10- μm -square-design contact windows). All values of R_f have been calculated using the measured value of linewidth. Superscripts A and B refer to the contact chains A and B, respectively. The prime notation (') refers to values which have been corrected for overetching. Sample standard deviations were less than four percent of sample means for measured values of V/I .

Wafer	Chain A (V/I) (Ω)	Chain B (V/I) (Ω)	R_f^A (Ω)	R_f^B (Ω)	$R_f'^A$ (Ω)	$R_f'^B$ (Ω)
2395-1	2493	1749	-1.16	-1.05	0.391	0.590
2395-5	1841	1282	-1.16	-1.00	0.241	0.411
2395-9	1653	1194	-0.557	-0.332	0.504	0.780

Table V. Measured values of R_1 and R_2 and calculated values of R_f by the Kelvin voltage-divider method (2). (Contact windows have a design value of $7.5 \mu\text{m}$ by $50 \mu\text{m}$.) The superscripts A and B refer to the two sizes of the voltage divider structures. The prime notation (') refers to values which have been corrected for overetching. Sample standard deviations were less than two percent of sample means for the measured values of R_1 and R_2 .

Wafer	R_1^A (Ω)	R_2^A (Ω)	R_1^B (Ω)	R_2^B (Ω)	R_f^A (Ω)	R_f^B (Ω)	$R_f'^A$ (Ω)	$R_f'^B$ (Ω)
2395-1	6.36	64.0	12.7	63.9	-0.022	-0.050	0.319	0.291
2395-5	5.06	50.8	10.1	50.7	-0.011	-0.025	0.277	0.280
2395-9	4.46	42.3	8.65	42.3	0.128	0.119	0.338	0.329

showed that the contact windows (7.5 by $50 \mu\text{m}$ design) were overetched on each of the three wafers by an amount between 1.5 and $2.2 \mu\text{m}$. For voltage-divider structures A and B on wafer 2395-1, overetching of the contact windows by as little as 0.10 and $0.23 \mu\text{m}$, respectively, is enough to produce negative calculated values of R_f if this overetching is not taken into account. Calculation of R_f , using the values of L_1 and L_2 that are based on measured contact-window size, yields positive values (Table V). The Kelvin voltage-divider method (2) shares a common source of error with the contact-chain method; namely, the calculated value of R_f is always essentially the difference of two comparably large numbers. As with the contact chains, a consequence of this fact is that the calculated value for R_f is very sensitive to errors in the measurements. To illustrate this, consider the voltage-divider structure A on wafer 2395-1. If, in Table V, the measured values of R_1 and R_2 were 2% larger and 2% smaller, respectively, then the calculated value of R_f would be 0.122Ω instead of -0.022Ω .

Table VI lists the values of R_{SDUC} , ρ_c , and R_e , and the subsequent calculated values of R_f obtained by using Eq. [4]. When R_f is determined by the Kelvin-cross method (1), i.e., Eq. [4], the primary source of error is the uncertainty in the contact-window length d . The sheet resistance of the diffused layer directly under the contact R_{SDUC} is calculated by means of a transmission line equation that involves the parameters R_e , ρ_c , and d (1). (Since the value of ρ_c is a material property of the interfacial contact layer, any pair of values (R_e , d) can be used to calculate the value of the material parameter R_{SDUC} .) For the $10 \mu\text{m}$ -square-design contact windows on wafer 2395-1, if the windows were overetched by $1 \mu\text{m}$, the method of Ref. (1) would yield a calculated value for R_{SDUC} of $1.91 \Omega/\text{square}$ instead of $2.64 \Omega/\text{square}$ and would yield a calculated value for R_f of 0.508Ω instead of 0.657Ω . It is seen that the value of R_f determined by the Kelvin-cross method, i.e., Eq. [4], is less sensitive to imprecise window etching (or imprecise photolithography) than is the value for R_f determined by either the contact-chain method or the Kelvin voltage-divider method. The Kelvin-cross method is also relatively insensitive to errors in the electrical measurements. For example, consider wafer 2395-1. If in Table VI the measured value for R_e was 2% larger than the value reported, the calculated value for R_{SDUC} would be $2.60 \Omega/\text{square}$ instead of $2.64 \Omega/\text{square}$ and the calculated value for R_f would be 0.652Ω instead of 0.657Ω . [R_{SDUC} is a function of R_e (1).]

Unlike the contact-chain method, both Kelvin methods have the advantage of being insensitive to linewidth. The Kelvin-cross method has the additional advantage of being relatively insensitive to photolithography process variations and to small errors in the electrical measurements. In principle, the contact-chain method and the voltage-divider method can yield accurate values for R_f . But, as illustrated above, the sensitivities of these two methods re-

Table VI. Direct-Kelvin-measurement values for end contact resistance R_e , values of R_{SDUC} and ρ_c determined by the method described in Ref. (1), and values of front contact resistance R_f obtained from Eq. [4]. (Contact windows have a design value of $10 \mu\text{m}$ by $10 \mu\text{m}$.) Sample standard deviations were about twenty percent of sample means for measured values of R_e .

Wafer	R_e (Ω)	R_{SDUC} (Ω/\square)	ρ_c ($\Omega\text{-cm}^2$)	R_f from Eq. [4] (Ω)
2395-1	2.38E-2	2.64	1.64E-7	0.657
2395-5	3.29E-2	2.16	1.67E-7	0.601
2395-9	3.87E-2	1.53	1.49E-7	0.479

quire very careful measurements and very accurate knowledge of various fabrication parameters. Differences between the results reported in Table VI, Table IV, and Table V, normalized for a $10 \mu\text{m}$ -square contact, are attributed to the accuracy with which these factors can be determined and to possible lateral current crowding effects. In particular, the determination of the exact contact-window size is very time consuming and, thus, probably infeasible in a production environment.

Conclusions

The front contact resistance is of significance to the circuit designer because it represents the actual circuit loading resistance of the contact. This paper has shown that the determination of R_f by means of a Kelvin-cross test structure (1) is inherently more accurate than the determination of R_f by means of either the non-Kelvin contact-chain method or the Kelvin voltage-divider method (2). The Kelvin-cross method is inherently more accurate than the other methods because it does not involve the subtraction of two comparably large numbers and because it does not require the precise measurement of linewidths and contact window size. The Kelvin-cross method is a completely electrical measurement procedure, is convenient to use, and is valid for a wide range of contact areas. It allows the measurement of R_f for contact windows with the same design dimensions as those used in production. Because this new structure is relatively small, it is feasible to include it on production chips. Use of the Kelvin-cross test structure and electrical measurement method will significantly improve the accuracy of contact resistance values that are used by circuit designers in circuit simulation codes.

Interfacial Structure of Tungsten Layers Formed by Selective Low Pressure Chemical Vapor Deposition

W. T. Stacy,* E. K. Broadbent,* and M. H. Norcott

Philips Research Laboratories Sunnyvale, Signetics Corporation, Sunnyvale, California 94086

ABSTRACT

We have analyzed the interfacial structure of selectively deposited LPCVD tungsten on monocrystalline silicon, polycrystalline silicon, and polycrystalline aluminum substrates. Cross-sectional specimens were examined by transmission electron microscopy to determine the amount of substrate consumed by the selective deposition process and to assess the degree of lateral encroachment under masking SiO_2 layers for different conditions of deposition and surface preparation. The tungsten-silicon interfacial structure was found to depend strongly on the initial surface preparation. Immersion in a dilute HF solution resulted in a smooth interface, while a glow-discharge treatment ($\text{CF}_4 + \text{O}_2$) led to highly irregular interfaces, which, in extreme cases, contained tunnels extending $1 \mu\text{m}$ or more into the silicon substrate. Layers formed in WF_6 plus H_2 were found to consist of two layers, of which the lower layer is formed by the substrate reduction of WF_6 .

The selective low pressure chemical vapor deposition (LPCVD) of tungsten involves the formation of a tungsten layer on exposed surfaces of silicon, aluminum, and various metal silicides without the tungsten forming on SiO_2 or Si_3N_4 (1-4). This results in a self-aligned tungsten pattern which does not require a lithographic masking step and, consequently, is an attractive option for a number of integrated circuit applications (5-10).

The process by which the tungsten deposits selectively, however, requires the chemical reduction of WF_6 by the substrate. Since this must entail some consumption of the substrate, the concern arises that the tungsten deposit may penetrate deeply into the substrate and disturb the underlying device structures. With this in mind, we have used transmission electron microscopy to characterize the interfacial structure of selectively deposited LPCVD tungsten films. Cross-sectional specimens have been employed to reveal the amount of substrate consumed and the degree of lateral encroachment under adjacent SiO_2 layers for different conditions of deposition and surface preparation.

Experimental

The deposition of the tungsten films was carried out in the low pressure (0.5 torr), horizontal flow, chemical vapor deposition (CVD) system described in a previous publication (4). The deposition gases were WF_6 (99.8%), purified H_2 , and Ar (99.9998%). The deposition substrates were 100 mm diam, p-type, 7-21 $\Omega\text{-cm}$, (111) silicon wafers. Three types of substrate coatings were used: patterned SiO_2 , patterned polycrystalline silicon, and patterned polycrystalline aluminum. For the SiO_2 coating, a $0.3 \mu\text{m}$ layer of thermally grown SiO_2 was etched into a repetitive stripe pattern with a pitch of $8 \mu\text{m}$ and a spacing of $4 \mu\text{m}$. The LPCVD polysilicon was defined in the same way on a $0.3 \mu\text{m}$ layer of SiO_2 . The aluminum layer was deposited by E-beam evaporation and patterned in the same way on a $0.45 \mu\text{m}$ layer of SiO_2 . All substrates were cleaned immediately prior to deposition by either a low pressure glow discharge (CF_4 and O_2) treatment or an immersion in dilute HF followed by a rinse in deionized water and spin drying.

The resulting samples were characterized by both scanning and transmission electron microscopy (SEM and TEM). The TEM specimens were prepared in cross section by a procedure involving metallographic sectioning followed by Ar ion beam milling. All TEM micrographs were taken at an accelerating voltage of 120 kV. In some cases, the chemical composition was probed in the TEM by means of an energy dispersive x-ray detector coupled with an electron beam scanning attachment (STEM-EDS).

Results

Hydrogen reduction of WF_6 .—Figure 1 is a cross sectional TEM micrograph of a specimen consisting of tung-

sten deposited onto a silicon substrate partially covered by SiO_2 . The deposition reactant gases were WF_6 and H_2 , and the deposition time and temperature were 20 min and 300°C . After the oxide pattern was formed, the substrate was cleaned just before deposition in a CF_4/O_2 glow discharge. It can be seen that the tungsten layer extends vertically to a depth of $0.1 \mu\text{m}$ and laterally about $0.2 \mu\text{m}$ under the oxide edge. It will be shown later in this section that this lateral encroachment consists mostly of a filamentary structure in the silicon which contains very little tungsten.

The lateral penetration of the bulk of the tungsten layer is only $0.085 \mu\text{m}$. The tungsten extends above the initial silicon surface approximately $0.05 \mu\text{m}$, resulting in a total thickness of $0.15 \mu\text{m}$. The SiO_2 thickness is $0.32 \mu\text{m}$.

The micrograph in Fig. 2 was taken in a thinner region of the specimen and consequently reveals more of the internal structure of the tungsten layer. It can be seen that two layers are involved: an upper layer $0.05 \mu\text{m}$ thick, and a lower layer varying in thickness from 0.02 to $0.1 \mu\text{m}$. The two tungsten layers are separated by a thin interfacial layer, possibly an oxide, approximately 3 nm thick. Note that the W/Si interface is extremely nonuniform. Results similar to those in Fig. 1 and 2 were obtained with polysilicon substrates. Again, a total thickness of $0.15 \mu\text{m}$ was found, and the films exhibited the same double layer structure.

In Fig. 3, the substrate was a $0.7 \mu\text{m}$ layer of polycrystalline aluminum. In this case, again for the same deposition conditions, the resulting tungsten film is thinner, 0.07 - $0.10 \mu\text{m}$. The higher magnification image in the inset

shows only a single-layer structure. Note the irregular shape of the W/Al interface, which suggests that some consumption of Al has taken place.

Substrate reduction of WF₆.—Figure 4a is a SEM micrograph of tungsten selectively deposited onto monocrystalline silicon with only WF₆ and Ar as reactant gases. Again the deposition temperature was 300°C, and the surface was precleaned in a CF₄/O₂ glow discharge. The deposition time, however, was 40 instead of 20 min. Substantial encroachment of the tungsten under the SiO₂ stripe has occurred. The diffuse image of the tungsten edge, which is visible through the oxide, is presumably due to electrons backscattered from the tungsten and rescattered by the SiO₂. The TEM cross section of the same specimen (Fig. 4b) confirms that the lateral encroachment is 0.9 μm and the total layer thickness is 0.17 μm. Note that the tungsten layer is recessed; there is no tungsten formation above the original silicon surface. Also, there is no evidence of a double-layer structure. Higher magnification micrographs (not shown) showed only the presence of a single-layer structure when WF₆ and Ar were the reactant gases. Similar results were obtained with polysilicon substrates.

For the same deposition conditions (300°C, 40 min, WF₆ + Ar), a much thinner deposit was formed on polycrystalline aluminum. The TEM cross section in Fig. 5 reveals only a few grains of tungsten on an oxide layer about 5 nm thick.

Tunnels.—Another example of the filamentary structure in Fig. 1 is shown in detail in Fig. 6 for slightly differ-

ent deposition conditions (300°C, 40 min, WF₆ and H₂). The filaments appear to be individual tunnels in the silicon with diameters ranging from 20 to 40 nm. Each tunnel is constant in diameter over its entire length, and at the end of each tunnel is a particle equal in size to the tunnel diameter. We have analyzed several of the particles with STEM/EDS (4 nm probe beam diameter) and have found in each case a localized tungsten signal. Thus the tunnels appear to be the result of tungsten containing particles “burrowing” into the silicon substrate.

An examination of the tunnels via stereo pair micrographs has revealed many different shapes and lengths. Each particle appears to have had a unique pathway. In Fig. 7, for example, one sees evidence of straight, circular, and spiral trajectories. Note the particle which has reflected from the underside of the SiO₂ layer during its propagation.

In general, the tunnel structures were found at the edges of the tungsten deposits. In cases where the deposition was not uniform (e.g., due to a contaminated surface or a thicker surface oxide layer), the tunnels were observed over most of the tungsten-silicon interface. As the density of the tunnels increased, the tunnel lengths were found to decrease. Figure 8 shows an extreme case, where, owing to an inadequate cleaning procedure, only islands of tungsten were formed. The SEM micrograph (Fig. 8a) shows the isolated tungsten deposits; the TEM micrograph (Fig. 8b) reveals in cross section the underlying tunnel structures.

Fig. 6. Tunnel structures formed at the edge of the oxide stripe. TEM cross-sectional micrograph.

Surface preparation.—The importance of the substrate cleaning procedure is illustrated in Fig. 9a and 9b. The two films were deposited simultaneously under the same conditions ($300^\circ C$, 20 min, $WF_6 + Ar$); only the substrate surface preparation was different. The substrate in Fig. 9a

Fig. 7. Detail showing tunnel deflected by SiO_2 -Si interface

was cleaned prior to deposition in a CF_4/O_2 glow discharge, whereas that in Fig. 9b was immersed for 2 min in a dilute HF solution. The differences in the resulting layer thicknesses and interface smoothness are striking. The layer in Fig. 9a has a total thickness of $0.17 \mu m$, while the layer in Fig. 9b is only $0.02 \mu m$ thick.

This important result has been reported by one of us in a study of the growth kinetics of selectively deposited tungsten (4). It was found that when the silicon surfaces had been exposed to higher temperatures ($425^\circ C$) in the presence of an oxidizing ambient, the tungsten deposit was less uniform and much thicker. This was attributed to the presence of an oxide film of varying thickness which resulted in a nonuniform reduction of WF_6 . Consequently, all of the data in that paper were taken for wafers precleaned in HF.

Discussion

Double-layer vs. single-layer structure.—The tungsten films deposited on silicon were found to consist of two layers when the reactant gases were WF_6 plus H_2 , and one layer when WF_6 plus Ar were used. This can be attributed to the WF_6 reduction mechanisms involved. In the former case, both hydrogen reduction and silicon reduction of WF_6 occur, while in the latter only the silicon reaction takes place. Thus the lower layer is formed by the reaction with the substrate

and the upper layer of the reaction involving hydrogen

Fig. 8. Tunnel structures associated with incomplete coverage of the substrate. (a, left): SEM micrograph showing island growth. (b, right): TEM cross section of an individual "island."

Fig. 9. TEM cross sections of two tungsten layers deposited under the same conditions, but for different substrate cleaning treatments. (a, left): CF_4/O_2 glow discharge clean. (b, right): Immersion in dilute HF.

The very thin, interfacial oxide layer (Fig. 2) may have originated at the original silicon surface. During the formation of the lower tungsten layer, WF_6 would diffuse through this oxide, react with Si to form W, and thus leave the oxide film on the surface of the lower layer. Once the lower layer reaches a thickness sufficient to substantially reduce the transport of WF_6 , the hydrogen reduction of WF_6 would become the dominant deposition reaction. The oxide film would be left behind to mark the transition from tungsten formation at the silicon surface to formation at the tungsten surface.

In the case of an aluminum substrate, the initial layer formed by the aluminum reduction of WF_6

is much thinner, possibly due to the presence of the oxide film seen in Fig. 5. Consequently, the lower layer is not visible in Fig. 3.

Tunnel structures.—The tunnels in Fig. 6, 7, and 8b bear a resemblance to the “channels” reported in studies of the catalytic gasification of graphite (11-14). Metal films (such as Ni or Pt), which have been deposited on cleaved graphite substrates and then heated, have been found to coalesce into droplets and then form pits in the substrate by catalyzing the oxidation or hydrogenation reaction. Using controlled-atmosphere electron microscopy, Baker and co-workers have shown that at certain temperature ranges the metal particles become mobile and actually cut grooves into the graphite surface. The resulting patterns are similar in appearance to the tunnel structures reported here.

Any model of the formation of the tunnels must explain two important experimental results: (i) the tungsten containing particle remains constant in diameter as the tunnel forms. It is neither consumed nor enlarged by the tunneling reaction. (ii) The tunnels are observed in silicon (but not in aluminum), both with and without H_2 in the reaction ambient. Since silicon must be consumed and removed to form the tunnels, and since H_2 is not required in the reaction, it is likely that the gas SiF_4 is a primary reaction product. A possible mechanism then is that silicon is etched by trapped fluorine or some fluorine containing product from the reaction between WF_6 and Si. The selective adsorption of fluorine onto tungsten would bring sufficient concentrations of fluorine in contact with the silicon such that etching could occur.

Thus, analogous to the channels in graphite, the role of the tungsten particle would be that of a reaction catalyst. This is plausible in light of data that F_2 forms an adsorbed film (on tungsten) which is stable to temperatures greater than 2000°C (15).

The location and density of the tunnels is presumably determined by the location and density of the reaction sites. Local inhomogeneities in thickness or structure of a substrate oxide film could lead to preferred nucleation sites of the tungsten deposit. With an increase in the density of the reaction sites, a continuous tungsten layer is formed sooner with less Si consumption, less trapped fluorine, and therefore less tunneling. It follows that the tunnel formation can be eliminated by depositing the tungsten onto either an oxide-free substrate or one whose native oxide layer allows a rapid uniform reaction.

Surface preparation.—As mentioned in Ref. (4), the effects of surface preparation can also be understood in

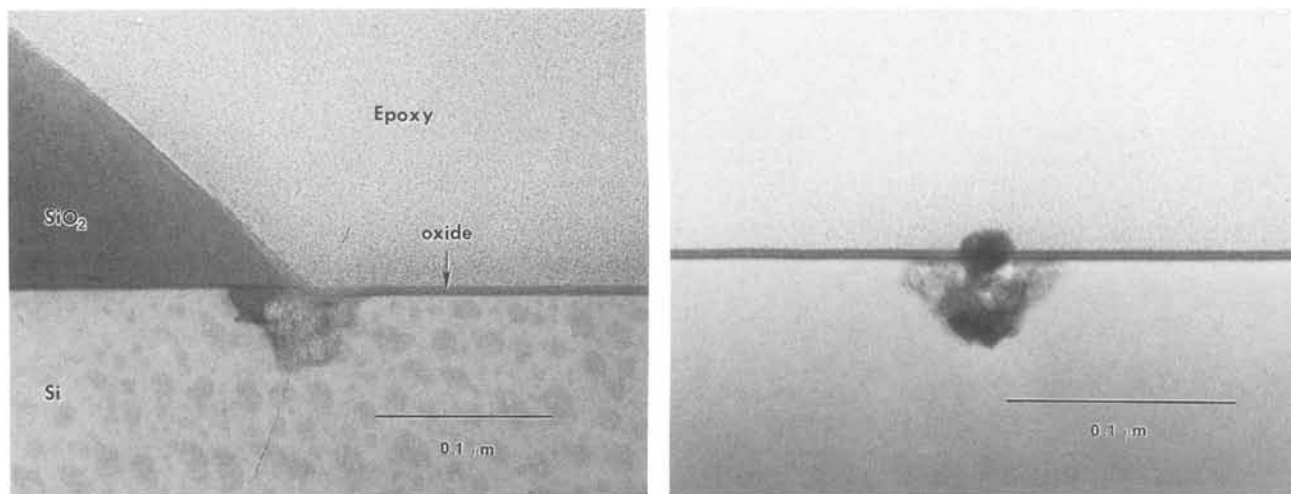

Fig. 10. TEM cross sections showing initial nucleation sites of the tungsten deposit. 300°C , 1 min, $\text{WF}_6 + \text{Ar}$. (a, left): Near the SiO_2 edge. (b, right): Away from the SiO_2 stripe.

terms of oxide films. Cleaning in a CF_4/O_2 glow discharge apparently leaves an oxide layer which results in a nonuniform reaction between WF_6 and the silicon substrate. The HF treatment followed by an unavoidable exposure to atmosphere must also produce a surface oxide layer, but one which is more readily broken up by the substrate reduction reaction.

To add credence to this theory, samples were prepared to reveal the initial tungsten nucleation sites. After a glow discharge surface treatment, a film was deposited at 300°C for only 1 min in $WF_6 + Ar$. Two TEM micrographs of this specimen in cross section are shown in Fig. 10. The micrographs show a surface oxide film as well as two nucleation sites, one near the perimeter and the other within the contact opening area. In contrast, after an HF treatment, we have found that for the same deposition conditions (300°C, 1 min, $WF_6 + Ar$) a continuous, uniform deposit layer is formed. Note that Fig. 10 also demonstrates how the oxide film is left on the surface of the lower tungsten layer as the Si reduction of WF_6 occurs (see above discussion).

Conclusions

The selective deposition of tungsten onto silicon by means of WF_6 and H_2 leads to two layers separated by a thin interfacial oxide. The lower layer is formed by the substrate reduction of WF_6 and is limited in thickness by the rate at which WF_6 reaches the substrate surface. In the case of silicon, the lower layer ranges in thickness from 20 to 150 nm; for aluminum, the lower layer consists of isolated grains of about 20 nm diam. This lower layer accounts for the selectivity of the deposition process and provides a nucleating surface for the subsequent tungsten formation (the upper layer) by the hydrogen reduction of WF_6 .

The important practical conclusion from this study is that the tungsten-silicon interface structure is strongly affected by the surface preparation. A cleaning procedure which results in a thin uniform oxide film (or no oxide film at all) will produce a smooth interface with the least amount of Si consumption. Other procedures, which leave nonuniform surface films, lead to highly irregular interfaces, which in extreme cases include tunnels extending 1 μm or more into the silicon substrate. We suggest that these tunnels are formed by the etching action of trapped fluorine adsorbed onto tungsten particles.

Acknowledgments

E. van de Ven, C. Werkhoven, and J. DeBlasi have provided valuable suggestions and encouragement. We are also grateful to D. Coulman (University of Illinois) for useful discussions of the tunnels and to W. Benzing and C. Ramiller (Applied Materials, Incorporated) for use of the LPCVD W deposition apparatus.

Analysis of Multicomponent LPCVD Processes

Deposition of Pure and *In Situ* Doped Poly-Si

Karl F. Roenigk* and Klavs F. Jensen**

Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, Minnesota 55455

ABSTRACT

A general model has been developed for multicomponent-multireaction systems in the hot-wall multiple-wafers-in-tube LPCVD reactor. The modeling equations describe the coupled convective and diffusive mass fluxes in the annular reactor flow region as well as those between each pair of wafers. Complex reaction mechanisms involving both gas-phase and surface reactions can be included in the model formulation. Multicomponent transport effects in the deposition of pure and doped polycrystalline Si are analyzed. The model predicts experimentally observed growth rates for pure polycrystalline Si quite well. However, because of insufficient data, a comparison of model predictions and experimental growth rates has not been feasible for *in situ* doped Si. The model is also used to predict the performance of a new continuous moving boat LPCVD reactor offering excellent film uniformity and process automation.

Low pressure chemical vapor deposition (LPCVD) is increasingly becoming a preferred method of depositing thin solid films of microelectronic materials because of the many advantages offered by the technique. LPCVD, which is predominantly carried out in tubular hot-wall reactors, allows a large number of wafers to be processed

with excellent film thickness and composition uniformity across each wafer as well as from wafer to wafer (1, 2). The large packing densities that can be realized in LPCVD reactors are possible because at the reduced pressures (~ 0.5 torr) diffusion is rapid so that the chemical reactions at the wafer surface are usually rate-controlling rather than mass-transfer processes. LPCVD is widely used to deposit thin films of polycrystalline Si,

*Electrochemical Society Student Member.

**Electrochemical Society Active Member.

SiO₂, and Si₃N₄ (1, 2). In addition, there is considerable interest in LPCVD of *in situ* doped polycrystalline Si (3, 4) as well as metallization by LPCVD of Al (5) and W (6).

The control and reproducibility of LPCVD reactor performance is crucial in obtaining films that satisfy the stringent demands imposed by modern microelectronic device structures. Nonuniformities in film thickness and composition (and implicitly resistivity) can make it impossible to realize the desired electronic device. LPCVD reactor operation has so far mainly relied on semiempirical design rules and operation regimes selected on the basis of trial and error experimentation. This limits the operation of existing reactors to certain fixed operating ranges and impedes the design of new LPCVD reactors. However, mathematical models incorporating the key physical and chemical process features should prove to be cost and time saving tools in the efficient operation of CVD reactors. In addition, the models should lead to an enhanced understanding of existing processes as well as provide new insight for the design of CVD reactors. In this work, a general mathematical model of LPCVD is presented. As a first application of the model, the deposition of pure and *in situ* doped polycrystalline Si is considered. These processes are suitable for illustrating the manner in which the model may be employed and for providing insight into its application to more complex LPCVD processes such as SiO₂ and Si₃N₄ deposition.

A number of reactor models have been proposed for both the cold-wall, atmospheric pressure CVD reactor and the hot-wall, tubular LPCVD reactor (7). The most complete treatment so far of LPCVD reactors appears to be that of Jensen and Graves (8). Their model, hereafter referred to as model I, combined the diffusive and convective fluxes in the annular flow region between the reactor wall and the wafer edges (cf. Fig. 1) with the diffusion between the wafers and subsequent reactions on the wafer surfaces. However, the change in gas velocity due to temperature variations and hydrogen production was approximated. Nevertheless, the model correctly predicted experimental observations from separate reactor studies of polycrystalline Si growth. Moreover, it allowed the authors to demonstrate the highly uniform deposition rates that were theoretically feasible in a LPCVD reactor with recycle of part of the reactor effluent.

As with previous LPCVD reactor descriptions, model I neglected the coupling of the diffusive fluxes in multicomponent systems through the Stefan-Maxwell relations (9). However, that simplification may lead to inaccurate model predictions for most LPCVD processes of interest (e.g., *in situ* doped polycrystalline Si, SiO₂, and Si₃N₄). Therefore, in this contribution, the original modeling concepts of Model I are extended to encompass multicom-

ponent diffusion effects. The resulting model is applicable to general LPCVD processes given a knowledge of the appropriate homogeneous and heterogeneous kinetics.

The detailed mathematical model is developed in the subsequent section. The model development is followed by an analysis of multicomponent effects in polycrystalline Si deposition including comparisons with predictions of model I. The model is then used to analyze a new continuous LPCVD reactor design where the wafers are conveyed countercurrently to the reactant gases. Finally, the deposition of *in situ* doped polycrystalline Si is discussed, with particular emphasis on the probable kinetics involved in the process.

Model Development

The model is based on the schematic representation of the typical commercial LPCVD reactor illustrated in Fig. 1. The wafers are placed perpendicular to the main direction of flow and concentrically inside the reactor (quartz) tube. The flow in the annular region formed by the tube wall and the wafer edges is laminar for the Reynolds numbers corresponding to typical LPCVD operating conditions. Because of the small wafer spacing relative to the wafer radius and the low pressures, mixing effects near the wafer edges may be neglected. In addition, it may be assumed that there is no imposed flow between the wafers, i.e., multicomponent diffusion and the associated Stefan flow are the dominant modes of transport in the wafer region. Calculations have shown that gas heat up lengths in typical LPCVD reactors are small compared to the reactor lengths. Furthermore, the heats of reaction associated with the growth processes are small because of the slow deposition rates (~100 Å/min). Thus, the temperature profile may be assumed fixed by the furnace settings. This approximation eliminates the need for an energy balance.

The steady-state species mole balance for component *j* has the general form

$$\frac{1}{r} \frac{\partial}{\partial r} (rN_{rj}) + \frac{\partial}{\partial z} N_{zj} = \sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s \quad [1]$$

for both the annular region and the space between the wafers. Here N_{rj} and N_{zj} are the radial and axial molar fluxes, respectively, of the *j*th species. The left-hand side of Eq. [1] represents the production of *j* in n^s independent gas-phase reactions. The α_{ij} 's are the stoichiometric coefficients of the *i*th reaction, \mathcal{R}_i . By convention the α_{ij} 's are positive for products. The boundary conditions on Eq. [1] are for the annular region

$$N_{zj} = v_0 c_0 x_{j0} \text{ at } z = 0 \text{ and } \frac{\partial x_j}{\partial z} = 0 \text{ at } z = L \quad [2a]$$

$$N_{rj} = - \sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s \text{ at } r = R_t$$

and

$$N_{rj} = a \left(\frac{R_t}{R_w} \right) \sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s + N_{rj} \Big|_{R_w} \text{ at } r = R_w \quad [2b]$$

The condition [2a] at $z = 0$ expresses the continuity of fluxes in the axial direction across the reactor inlet. The formulation of the condition at $z = L$ is difficult. The present choice implies that negligible reaction and back diffusion occur downstream of the wafer zone. The first radial condition in Eq. [2b] states that the flux of *j* to the wall equals the amount of *j* consumed in surface reactions on the wall. Similarly, the second condition states that the flux of the *j*th species to the wafer edge is the amount of *j* deposited on the wafer carrier boat plus the flux in between the wafers. The quantity *a* represents the boat area relative to the tube area.

The boundary conditions for the wafer space take the form

Fig. 1. LPCVD reactor

$$N_{zj} = \sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s \text{ at } z = z_k, k = 1, 2, \dots, N_{\text{wafer}} \quad [3a]$$

and

$$N_{zj} = -\sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s \text{ at } z = z_k +$$

$$\Delta x_j \Big|_{R_w^-} = x_j \Big|_{R_w^+} \text{ at } r = R_w, \text{ and } \frac{\partial x_j}{\partial r} = 0 \text{ at } r = 0 \quad [3b]$$

The two conditions on the axial direction express that the flux of material to the wafer surfaces equals that consumed in surface reactions on the wafers. The radial conditions represent continuity of mole fractions from the wafer edge to the annular flow region and symmetry, respectively. Equations [1]-[3] must be combined with appropriate expressions for the fluxes N_{rj} and N_{zj} . In an S component ideal gas, the molar fluxes are related through the Stefan-Maxwell equations (9)

$$\nabla x_i = \sum_{j \neq i}^s \frac{1}{cD_{ij}} (x_i N_j - x_j N_i) \quad [4]$$

Here D_{ij} is the i - j binary diffusivity and N_k represents a vector of the axial and radial components of the fluxes. Since the mole fractions must sum to unity, *i.e.*

$$\sum_{i=1}^s x_i = 1 \quad [5]$$

there are at most $S - 1$ independent Stefan-Maxwell relations.

Equations [1]-[5] combined with appropriate momentum balances form a complex set of partial differential equations which in principle can be solved by a suitable numerical technique. However, it is more useful in this investigation to make some physically reasonable assumptions which reduce the complexity of the model. The same approach was used in deriving model I. First, since the wafer spacing (Δ) is small relative to the wafer radius, the rapid diffusion at LPCVD conditions would be expected to essentially eliminate axial variations within each wafer cell. Therefore, we may average Eq. [1] over the z direction within each cell formed by the wafers. The resulting component balance for the wafer region is then

$$\frac{\Delta}{r} \frac{d}{dr} (rN_{rj}) = \Delta \sum_{i=1}^{n^g} \alpha_{ij}^g \mathcal{R}_i^g + 2 \sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s \quad [6]$$

with boundary conditions of Eq. [3b].

Secondly, the rapid diffusion is also expected to reduce radial variations in gas-phase concentrations in the annulus. Moreover, the time scale associated with deposition is larger than that for diffusion; therefore, perfect radial mixing may be assumed as also done in model I. Then by averaging Eq. [1] over the radial direction, the component balance for the annular flow region takes the form

$$\frac{d}{dz} (N_{zj}) = \frac{2}{(R_i^2 - R_w^2)} \left[R_i(1 + a) \sum_{i=1}^{n^g} \alpha_{ij}^g \mathcal{R}_i^g \right. \\ \left. + R_w N_{rj} \Big|_{R_w^-} \right] + \sum_{i=1}^{n^s} \alpha_{ij}^s \mathcal{R}_i^s \quad [7]$$

with boundary conditions of Eq. [2a]. The flux of species j in between the wafers, *i.e.*, $N_{rj}|_{R_w^-}$ is determined from the solution to Eq. [6].

Equations [6] and [7] with their respective boundary conditions form the general model for the LPCVD reactor. For S chemical species, n^g gas-phase reactions, and n^s surface reactions, there are at most $n^g + n^s \leq S - 1$ independent component balances, Eq. [6] and [7]. These must be solved with the Stefan-Maxwell relations (Eq. [4]) and the constraint (Eq. [5]). The model can be applied to any LPCVD reactor system given the chemical kinetics. To illustrate the use of the modeling approach, the deposition of pure and *in situ* doped polycrystalline Si are considered as examples.

LPCVD of pure and doped polycrystalline Si is usually carried out with SiH_4 and small amounts of dopant (*e.g.*, AsH_3 , PH_3 , or B_2H_6). The kinetics of polycrystalline Si deposition from SiH_4 have received considerable attention (10, 11). However, the detailed kinetics of dopant incorporation are poorly understood, as are the effects of dopants on the Si growth rate. It is known that SiH_4 can decompose in the gas phase to SiH_2 and H_2 and it is possible for SiH_2 to insert itself in both SiH_4 and the dopant gas. However, in view of the low pressures and the limited knowledge of those gas-phase reactions, the surface reactions are assumed to dominate the deposition process. Thus, the model is based on the overall heterogeneous reactions

with reaction rates \mathcal{R}_1 and \mathcal{R}_2 . PH_3 is used as an example, but the model development would be similar for other dopant gases. Because of adsorption/desorption effects it is possible that \mathcal{R}_1 and \mathcal{R}_2 each depend on all the gaseous reactants. The kinetics of these reactions will be discussed in a subsequent section. Since there are no gas-phase reactions and only two surface reactions, the mole balances over SiH_4 (1) and PH_3 (2) take the form for the annulus

$$\frac{dN_{zk}}{dz} = \frac{-2\mathcal{R}_k}{(R_i^2 - R_w^2)} \left[R_i(1 + a) \right. \\ \left. + \frac{R_w^2}{\Delta} \eta_k \right], k = 1, 2 \quad [10]$$

with boundary conditions

$$N_{zk}(z = 0) = v_0 c_0 x_{k0} \\ \text{and } \frac{dx_k}{dz} \Big|_L = 0 \quad k = 1, 2 \quad [10a]$$

where

$$\eta_k = \frac{2 \int_0^{R_w} r \mathcal{R}_k dr}{R_w^2 \mathcal{R}_k \Big|_{R_w}} \quad k = 1, 2 \quad [10b]$$

while for the wafer region

$$\frac{\Delta}{r} \frac{d}{dr} (rN_{rk}) = -2 \mathcal{R}_k \quad k = 1, 2 \quad [11]$$

with boundary conditions

$$\frac{dx_k}{dr} \Big|_0 = 0 \text{ and } x_k(R_w^-) = x_k(R_w^+) \quad [11a]$$

The quantity η_k is defined as the ratio of the average deposition rate on the wafer to that at the wafer edge. Thus, η_1 may be regarded as a measure of film thickness uniformity. When $\eta_1 \dot{=} 1$, η_2 becomes a measure of doping level uniformity. However, if $\eta_1 \neq 1$, it is not feasible to make a simple interpretation of η_2 . If diffusion effects are small, $\eta_1 \dot{=} 1$ and $\eta_2 \dot{=} 1$, whereas they differ from unity when diffusion effects are significant enough to produce nonuniform film thicknesses and doping levels.

The balance over the inert gas (3) gives

$$N_{z3} = v_0 c_0 x_{30} \text{ in the annular region} \quad [12a]$$

$$N_{r3} = 0 \text{ between the wafers} \quad [12b]$$

Because of the coupling of the fluxes and production of H_2 , the constant flux of inert gas does not lead to constant inert mole fractions through the reactor. Finally, the flux of the last component H_2 (4) may be expressed as follows by using the stoichiometry of the reactions [8] and [9]

$$N_{z1} = v_0 c_0 x_{z10} + 2(v_0 c_0 x_{z10} - N_{z1}) + \frac{3}{2}(v_0 c_0 x_{z20} - N_{z2}) \text{ in the annular region} \quad [13a]$$

$$N_{r1} = -2N_{r1} - \frac{3}{2}N_{r2} \text{ in the wafer region} \quad [13b]$$

By combining the modeling Eq. [10]-[13] with Stefan-Maxwell relations [4] for three components and the constraint [5], it is then possible to predict the growth rates and doping levels on each wafer as well as throughout the reactor. If the dopant, component (2), is eliminated, the equations may also be used to predict pure polycrystalline deposition. Both cases are considered below. The nonlinear modeling equations are solved by orthogonal collocation in similar manner to that used for model I (8). However, in the present cases, more than one interior collocation point is used to solve the local wafer deposition equations. Finally, growth rates, average growth rates, and standard deviations in growth rates may be calculated by formulas analogous to those presented in Ref. (8) (cf. Eq. [33]-[35]).

Deposition of Polycrystalline Si

The present model was used to predict reported experimental growth rates. The following rate expression was assumed

$$\mathcal{R} = \frac{kP_{\text{SiH}_4}}{1 + K_{\text{H}}P_{\text{H}_2}^{1/2} + K_{\text{S}}P_{\text{SiH}_4}} \quad [14]$$

This particular rate expression follows from the assumption of adsorption-desorption equilibria of silane and hydrogen and a rate-controlling first-order decomposition of silane on the surface. In addition, it reflects the experimental observations: (i) growth rate is proportional to SiH_4 pressures but saturated at high SiH_4 pressures and (ii) the growth rate is hindered by adsorbed atomic hydrogen. The rate expression [14] and the model were used in nonlinear regression of reported experimental growth rates (1, 10). The kinetic parameters with their 95% confidence intervals were found to be

$$k = (1.6 \pm 0.4) \times 10^9 \exp(-18,500/T) \text{ mol/m}^2/\text{s/atm}$$

$$K_{\text{H}} = (0.6 \pm 0.3) \times 10^2 \text{ atm}^{-1/2}$$

$$K_{\text{S}} = (0.7 \pm 0.1) \times 10^5 \text{ atm}^{-1}$$

The activation energy of k was not determined. Its value is generally agreed upon in previous studies (11). The model with the use of the kinetic parameters in the rate expression [14] correctly predicts both the effect of SiH_4 depletion and H_2 inhibition on the Si deposition rate. Furthermore, as illustrated in Fig. 2, the model predictions span data from two different reactor systems with two orders of magnitude variation in SiH_4 partial pressures. Classen *et al.* proposed that P_{H_2} rather than $P_{\text{H}_2}^{1/2}$ should be included in the rate expression [14]. However, we found significantly better representation of data with $P_{\text{H}_2}^{1/2}$, indicating that dissociatively adsorbed H_2 hinders Si growth. The $-1/2$ power dependence on hydrogen is also supported by experiments of Duchemin *et al.* (12).

The present multicomponent LPCVD reactor model makes it possible to evaluate approximations inherent in Model I (8). Multicomponent effects were neglected in the development of Model I and the conversion of $\text{SiH}_4(\chi)$ was related to the silane mole fraction through a simple algebraic relation (cf., Ref. (8), Eq. [13]). However, this relation is only strictly valid in a well mixed reactor or a plug flow reactor. It is an approximation for LPCVD reactor conditions where both diffusive and convective transport are important. The correct definition of the SiH_4 conversion in the present system is

$$\chi = 1 - \frac{N_{z1}}{N_{z10}} \quad [15]$$

where the flux N_{z1} is composed of diffusive and convective contributions; *i.e.*, $N_{z1} = J_{z1} + x_{z1}c_1v$. Thus, simple algebraic relations between SiH_4 mole fractions and conversion cannot be made without neglecting the diffusive flux, as is done in Model I.

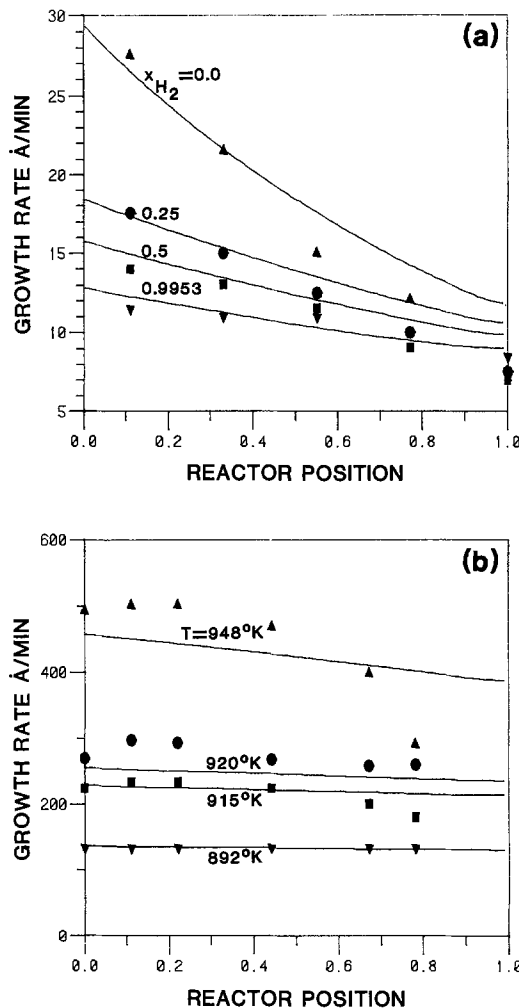

Fig. 2. Model predictions and experimental LPCVD poly-Si growth rates at: (a) various hydrogen feed compositions (10), $Q = 1000$ sccm, $T = 880$ K, 0.47% SiH_4 feed, balance H_2 and N_2 , $P = 0.525$ torr; (b) various temperatures (1), $Q = 650$ sccm, 23% SiH_4 feed in N_2 diluent, $P = 0.5$ torr.

To study the effects of the simplifications in Model I, its predictions for polycrystalline Si deposition from SiH_4 were compared to those obtained with the present multicomponent treatment. The calculations were carried out at varying inlet flow rates for a typical commercial LPCVD reactor and the chemical kinetics given above. Figure 3a shows the maximum and average percent error in growth rates as a function of the Peclet number for the case of pure SiH_4 feed to the reactor. The error is determined as

$$\epsilon = \left[\frac{g(\text{Model I}) - g(\text{new model})}{g(\text{new model})} \right] 100\% \quad [16]$$

The Peclet number, $Pe (= v_0L/D_{\text{SiH}_4, \text{H}_2})$ is a measure of the convective flux relative to the diffusive flux. For high flow rates, Pe is large, and the two models agree as expected since the approximation in Model I holds in the plug flow limit. However, for typical operating conditions, there is approximately 10% difference in the predicted growth rates. Model I consistently predicts higher growth rates than the present model because the velocity in Model I is artificially higher than for the detailed model. Figure 3b illustrates the difference in model predictions in dilute processing. (Here $Pe = v_0L/D_{\text{SiH}_4, \text{N}_2}$.) Again, the models agree at high flow rates, but differ approximately 5% at typical operating conditions.

Although the predictions of Model I differ from those of the detailed multicomponent treatment, Model I is still a useful approximation for simple systems where it is applicable. It is more tractable and gives a simpler picture

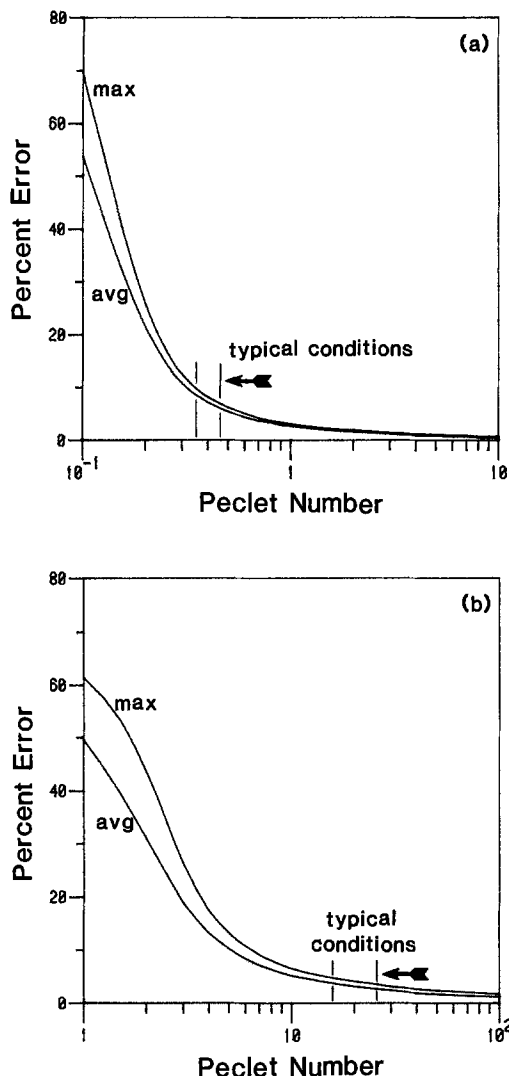

Fig. 3. Error of growth rate and average growth rate between Model I and present formulation for typical LPCVD reactor. $T = 800$ K, $P = 0.6$ torr. (a): Pure SiH_4 feed, $Pe = v_0 L / D_{\text{SiH}_4\text{-H}_2}$. (b): 23% SiH_4 feed in N_2 , $Pe = v_0 L / D_{\text{SiH}_4\text{-N}_2}$.

of LPCVD reactor behavior than the present model. However, for analysis of general LPCVD processes, the present formulation should be preferred.

A Continuous Moving Boat LPCVD Reactor

To further illustrate the utility of the developed LPCVD reactor model, it is employed in reactor design considerations. It is desirable to design and operate LPCVD reactors so that film thickness and composition variations are minimized within each wafer as well as from wafer to wafer. In this spirit, Model I was used to demonstrate the high levels of uniformities feasible with recycle of part of the reactor effluent. Similar results would be predicted by the present model. A continuous LPCVD reactor, where the wafers are conveyed through the reactor countercurrently to the reactant gases, is another attractive alternative to the conventional LPCVD reactor with furnace temperature ramps. Since each wafer would experience the same conditions in its travel through the reactor, each wafer would have identical average film thickness and wafer uniformity. Therefore, the need for adjusting the furnace profile to ensure wafer to wafer uniformity is eliminated and a flat temperature profile may be used. This case is illustrated schematically in Fig. 4. The constant deposition temperature has the advantage of more uniform film morphology and strain (19) than can be achieved in standard LPCVD reactors. This ultimately enhances electronic device uniformity and lessens

Fig. 4. Continuous LPCVD concept. Wafers conveyed countercurrent to gas flow experience reactor growth profile and exit with identical average film thickness and uniformity. $T = 893$ K, $P = 0.5$ torr, $Q(\text{SiH}_4) = 20$ sccm, $\bar{g} = 76$ Å/min, conversion = 0.9, $N_w = 100$.

doping and oxidation concerns in postdeposition process steps.

A continuous LPCVD reactor would have additional advantages associated with process automation. It would enable automatic loading and unloading of wafers and even sequencing with subsequent process steps, thereby decreasing the possibility for contamination. The main difficulty in the design of such a reactor lies in the mechanical handling of the wafers. However, these mechanical problems are beyond the scope of the present work, where process feasibility and performance are the important issues.

The developed model may be used to predict the film thickness and uniformity on the processed wafers by considering the growth rates experienced by any single wafer as it is conveyed through the reactor. If it is assumed that the wafers are stepped through incremental positions in the reactor, then a wafer spends a time Δt at each wafer position in the reactor. The film thickness on the exiting wafer, \bar{d} , would then be the sum of the thickness deposited at each wafer position

$$\bar{d} = \sum_{i=1}^{N_w} g_i \eta_i \Delta t_i \quad [17]$$

Since the wafer spacing is small, the sum may be approximated by an integral over the reactor to obtain

$$\begin{aligned} \bar{d} &= \sum_{i=1}^{N_w} g_i \eta_i \Delta \cdot \frac{\Delta t_i}{\Delta} \\ &= \frac{\Delta t_i}{\Delta} \int_0^L g \eta \, dz = \frac{\Delta t_i}{\Delta} L \bar{g} \end{aligned} \quad [18]$$

The wafer process rate, \dot{w} , is just $(\Delta t_i)^{-1}$ and $N_w = L/\Delta$. Thus, by rearranging Eq. [18], \dot{w} may be expressed as a function of the number of wafers in the boat, the desired average thickness \bar{d} , and the process variables determining the average growth rate, \bar{g}

$$\dot{w} = N_w \left(\frac{\bar{g}}{\bar{d}} \right) \quad [19]$$

Note that each wafer leaves the reactor with the same average thickness \bar{d} given by Eq. [18]. Thus, there is complete wafer-to-wafer uniformity. The in-wafer standard deviation in thickness may be shown to be

$$\begin{aligned} \left(\frac{\sigma}{\bar{d}} \right) &= \left[(\bar{g})^{-2} \int_0^L 2 \left(\frac{r}{R_w} \right) \right. \\ &\quad \left. \left[\frac{1}{L} \int_0^L g(r, z) \, dz \right]^2 d \left(\frac{r}{R_w} \right) - 1 \right]^{1/2} \end{aligned} \quad [20]$$

Fig. 5. Wafer production rate per wafer load for desired thickness and given average growth rate in a continuous LPCVD reactor. Example for $d = 5000\text{Å}$, $g = 80\text{Å/min}$, $NW = 100$, $\dot{w} = 100\text{ wafer/h}$.

By using Eq. [18] and [19], it is possible to construct operating charts, such as Fig. 5, relating the wafer process rate for a desired film thickness to the average growth rate. The model developed is then useful in determining optimal operating conditions where the average growth rate may be obtained with acceptable in-wafer uniformity as given by Eq. [20]. For most polycrystalline Si deposition conditions, the in-wafer film thickness variations are small ($< 2\%$). However, for more complex deposition schemes, such as SiO_2 , it may be necessary to use Eq. [20] to estimate in-wafer film thickness deviations. Extensive calculations indicate that for the poly-Si kinetics the in-wafer film uniformity is always better in the moving LPCVD than the conventional reactor. An additional attractive feature of the moving boat reactor is that essentially complete conversion of the reactant can be achieved.

Deposition of *In Situ* Doped Polycrystalline Si

The presence of dopants has been observed to significantly alter the growth kinetics of Si films (13-15, 19-20). The growth rate is decreased by AsH_3 and PH_3 , whereas it is enhanced by B_2H_6 . Different arguments have been presented to explain the observed effect in the case of n-type dopants. Farrow (14) argued that dopant slowed the Si growth by adsorption on active sites, while Chang (15) proposed that the dopant changed the surface potential so that the Si species were less easily adsorbed. Farrow suggested that B_2H_6 facilitated SiH_4 decomposition on the surface, but Chang again proposed that the change in surface potential due to adsorbed B_2H_6 enhanced adsorption of Si species. Recent surface science experiments by Yu and Meyerson (19) present strong evidence for the site blocking mechanism of rate suppression in *in situ* phosphorous-doped poly-Si deposition. They demonstrate that PH_3 strongly adsorbs on Si and that H_2 desorption from adsorbed PH_3 above 400°C leads to further increases in the phosphorous coverage, effectively blocking the coadsorption of SiH_4 . This is consistent with the appreciable suppression of the Si deposition rate by even small amounts of PH_3 observed experimentally. In addition, the effect has been shown to alter the activation energy of the overall deposition reaction (4, 13, 14, 16). In particular, the experiments by Baudrant and Sacilotti indicate a linearly varying activation energy with PH_3 partial pressure.

The present multicomponent model was used in an attempt to determine the appropriate kinetics of *in situ* P-doped poly-Si. The data of Baudrant and Sacilotti (2) and Kurokawa (3) were used to test proposed kinetic

schemes. However, many reactor parameters and experimental data necessary for simulation were not reported and therefore had to be estimated. It was found that typical Langmuir-Hinshelwood kinetic schemes would not allow satisfactory representation of the reported Si growth rates, although resistivity levels were approximated reasonably well (17). The failure of conventional Langmuir-Hinshelwood kinetics in modeling the data is consistent with Yu and Meyerson's (19) finding of a strong PH_3 adsorption. In fact, preliminary calculations predicted PH_3 surface coverage of approximately unity. Additional more complicated rate expressions were tested including the effect of dopant on the Si deposition activation energy. However, owing to the lack of complete experimental data, it was not possible to conclude about the probable kinetics. Nonlinear regression of *in situ* doping is complicated by the added problem of predicting doping levels. Unfortunately, most studies including that of Baudrant and Sacilotti report resistivities rather than actual solid concentrations. This means that a reliable correlation between resistivity and solid dopant concentration is needed. Nevertheless, the reasonable trends obtained with limited data (17) show good promise for future studies with a larger data base. The gas-phase chemistry of the $\text{SiH}_4/\text{PH}_3/\text{H}_2$ system will likely have to be included in these studies to provide a complete understanding of rate depression and nonuniformities observed in deposition of *in situ* doped polycrystalline Si.

Conclusion

A general model for multicomponent-multireaction LPCVD reactor systems has been developed and applied to specific examples. The model details the multicomponent transport processes in the annular flow region as well as those between the wafers. Complex kinetic schemes involving both gas-phase and surface reactions can readily be included in the model formulation. The multicomponent treatment was used to evaluate approximations made in an earlier model (8) for polycrystalline deposition from SiH_4 .

The utility of the model was further illustrated by the analysis of a countercurrent moving boat LPCVD reactor. This reactor gave excellent uniformity and had the additional advantage of process automation. However, the mechanical aspects of such a reactor need to be resolved.

Because of the lack of detailed kinetic data for *in situ* doped polycrystalline Si, it was not possible to verify the model to the same extent as done for pure polycrystalline Si deposition. In fact, the general scarcity of reliable kinetic mechanisms and rate constants constitutes a major problem in CVD reactor modeling. The good predictions of pure Si deposition and the additional process insights resulting from the LPCVD reactor model should serve as incentives for future combined kinetic and reactor modeling studies of more complex CVD systems, such as SiO_2 and Si_3N_4 . This is currently under investigation.

Vaporization Behavior, Phase Equilibria, and Thermodynamic Stabilities of Nickel Phosphides¹

Clifford E. Myers* and Thomas J. Conti

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13901

ABSTRACT

The equilibrium vaporization reactions $12\text{Ni}_2\text{P}(s) = 2\text{Ni}_{12}\text{P}_5(s) + \text{P}_2(g)$ and $6.8\text{Ni}_{12}\text{P}_5(s) = 32\text{Ni}_{2.55}\text{P}(s) + \text{P}_2(g)$ have been studied by mass-loss effusion in the temperature range 1237–1401 K. The results were combined with published calorimetric data for nickel-rich samples and static phosphorus-dissociation pressure data for phosphorus-rich samples, with consideration of the requirements of the published phase diagram, to obtain enthalpies of formation (from red P), $\Delta H_f^\circ/R$, and enthalpies of atomization, $\Delta H_{at}^\circ/R$, respectively, in kilokelvins at 298.15 K: $1/4 \text{Ni}_3\text{P}(s)$, -5.94 ± 0.5 , 54.8; $1/3.55 \text{Ni}_{2.55}\text{P}(s)$, -6.65 ± 0.5 , 55.2; $1/17 \text{Ni}_{12}\text{P}_5(s)$, -6.73 ± 0.5 , 55.1; $1/3 \text{Ni}_2\text{P}(s)$, -6.87 ± 0.5 , 54.8; $1/9 \text{Ni}_2\text{P}_4(s)$, -6.39 ± 0.5 , 53.0; $1/2.22 \text{Ni}_{1.22}\text{P}(s)$, -6.32 ± 0.5 , 52.9; $1/2 \text{NiP}(s)$, -6.09 ± 0.5 , 52.1; $1/3 \text{NiP}_2(s)$, -5.38 ± 0.5 , 49.4; $1/4 \text{NiP}_3(s)$, -4.52 ± 0.5 , 47.6.

The nickel-phosphorus phase diagram has been well established in the definitive work of Larsson (1), but published data do not permit a complete working out of the thermodynamics of the system. Weibke and Schrag (2) measured directly the heat of reaction of nickel and phosphorus at about 630°C, but their studies were limited to metal-rich compositions. Biltz and Heimbrecht (3) measured dissociation pressures of phosphorus over phosphorus-rich samples, but the static method they employed did not allow an overlap in composition with the calorimetric study (2). Hence, a Knudsen effusion study of phosphorus-dissociation pressures was initiated for the central portion of the phase diagram.

The compositions of the intermediate phases and their temperature ranges of stability were taken from Larsson's study (1); the phase diagram is given in Fig. 1. In terms of this diagram, the reactions studied by Weibke and Schrag (2) are

Similarly, the reactions studied by Biltz and Heimbrecht (3) are

The effusion study reported here considered the reactions

which provide a link between the two previous studies.

Experimental

The effusion apparatus used in this study, together with calibration and operation procedures, has been described previously (4). It consists of a vacuum system, induction heater, temperature controller, and recording vacuum balance. The channel-orifice effusion cells were fabricated from 0.95 cm high-density graphite rod. The effective orifice areas were determined by direct measurement as previously described (4). The phosphide samples were prepared by direct combination of the elements in evacuated and sealed "Vycor" glass ampuls, using the procedures and precautions described earlier (4). The products of the preparations, as well as residues from the effusion runs, were characterized by x-ray powder diffraction (5-7). Observed intensity and d spacing data were compared with published data for Ni_2P (5), Ni_{12}P_5 (7), and $\text{Ni}_{2.55}\text{P}$ (6).

Results

The primary data were the temperature, corrected for thermocouple calibration, and the rate of mass loss, cor-

rected for nonorifice effusion (4) (less than 20%), obtained from the recording vacuum balance. Tables I and II list the results for the Ni_2P - Ni_{12}P_5 and Ni_{12}P_5 - $\text{Ni}_{2.55}\text{P}$ two-phase regions, respectively. The vaporization was found to be severely retarded, and long channels were required to reduce the effective orifice areas sufficiently to achieve equilibrium. Additionally, the measurements were greatly complicated by sintering of the samples which resulted in a decrease in the rate of effusion as the run progressed, even though two solid phases were still present. In order to cope with this difficulty, the sample was removed after every second or third point for re-grinding. While this procedure appeared to overcome the difficulty, the very low rates of mass loss, particularly at lower temperatures, made detection of a decrease in the rate very difficult. The slopes of the mass-time records could be measured with a reproducibility of about $\pm 10\%$. The total mass losses in runs A, B, and C were 3.3, 7.6, and 2.1 mg, respectively, which may be compared with the ~ 16 mg loss needed to cross the Ni_2P - Ni_{12}P_5 two-phase region. For run D, the total loss was 2.3 mg, with about 3 mg loss needed to cross the Ni_{12}P_5 - $\text{Ni}_{2.55}\text{P}$ two-phase region. Pressures of P_2 were calculated, assuming P_2 and P_4 to be in equilibrium in the vapor, with the modification of the effusion equation derived earlier (4)

$$P(\text{P}_2) = \frac{K}{2\sqrt{2}} \left\{ \left[1 + \frac{8m}{aK} \left(\frac{\pi RT}{M} \right)^{1/2} \right]^{1/2} - 1 \right\} \quad [8]$$

$$= \frac{K}{2\sqrt{2}} \left\{ \left[1 + \frac{Cm}{aK} \left(\frac{T}{M} \right)^{1/2} \right]^{1/2} - 1 \right\}$$

where K is the equilibrium constant (8) for $\text{P}_4(g) = 2\text{P}_2(g)$

and M is the molecular weight of P_2 . When $P(P_2)$ is given in atmospheres, m (the rate of mass loss) in mg/min, T as Kelvin temperature, and a (the effective orifice area) in cm^2 , the constant is $C = 2.127 \times 10^{-6}$. Because the calculated pressures do not show any apparent variation with effective orifice area, all the data were assumed to represent equilibrium conditions. There are no entropy nor high-temperature heat-capacity data for the nickel phosphides in the literature, and it was necessary to estimate these. The procedure used earlier (4), based on published data on transition metal silicides (9-13), was used to generate the estimates given in Table III. The value for the entropy of NiP was adjusted upward by 5% in order to obtain results consistent with the observed diagram (1).

Third-law enthalpy changes for reactions [6] and [7] were calculated using free-energy functions, $\Phi' = -(G_r^\circ - H_{298.15}^\circ)/T$, based on the entropy and heat capacity estimates. The second-law enthalpy change for reaction [6] was calculated to be 58.8 kK at 298.15 K, which is in poor agreement with the mean third-law value. The second-law value was rejected in favor of the third-law result. This choice was based on two considerations. First, the very low rates of mass loss at lower temperatures made detection of curvature in the mass vs. time record extremely difficult, and thus, the observed slopes in this range may be too small due to kinetic effects brought on by sintering of the sample. Second, attempts to force agreement of the second-law and third-law results would require increasing $\Delta\Phi'/R$ for reaction [6] by 13.9. It is unlikely that the entropy estimates for $Ni_{12}P_5$ and Ni_2P are in error by an amount sufficient to produce this difference, because similar estimates for other systems (4, 14) have produced acceptable agreement. Hence, the mean third-law value was used in subsequent calculations. The available temperature range for the study of reaction [7] was too small to permit determination of a meaningful second-law enthalpy change; hence, the mean third-law result was carried forward into subsequent calculations. Free-energy functions based on the estimates in Table III were used to obtain third-law enthalpy changes for reactions [3], [4], and [5] from the data of Blitz and Heimbrecht (3). The enthalpies reported by Weibke and Schrag (2) were corrected to 298.15 K by means of the heat capacity estimates in Table III. Enthalpies of reaction at 298.15 K are summarized in Table IV. The appropriate combination of these with the enthalpies of formation (8) of $P_2(g)$ and $P_4(g)$

yields enthalpies of formation

$$\Delta H_1 = \Delta H_f(Ni_3P)$$

$$\Delta H_2 = \Delta H_f(Ni_{2.55}P)$$

$$\Delta H_{13} = \Delta H_f(Ni_{12}P_5) = \frac{1}{6.8} (\Delta H_9 + 32\Delta H_2 - \Delta H_7)$$

$$\Delta H_{14} = \Delta H_f(Ni_2P) = \frac{1}{12} (\Delta H_9 + 2\Delta H_{13} - \Delta H_6)$$

$$\Delta H_{15} = \Delta H_f(Ni_5P_4) = \frac{3}{8} (\Delta H_{10} + \frac{20}{3} \Delta H_{14} - \Delta H_5)$$

$$\Delta H_{16} = \Delta H_f(NiP_2) = \frac{3}{10} (\Delta H_{10} + \frac{2}{3} \Delta H_{15} - \Delta H_4)$$

$$\Delta H_{17} = \Delta H_f(NiP_3) = \frac{1}{4} (\Delta H_{10} + 4\Delta H_{16} - \Delta H_3)$$

which are tabulated, together with enthalpies of atomization, in Table V. In this series of calculations, it is assumed that ΔH° , ΔS° , and ΔC° of phase formation are essentially constant across the Ni_2P single-phase region.

The enthalpies of formation of NiP and $Ni_{1.22}P$ may be deduced from data in Table V and consideration of the phase diagram (1). Because NiP(s) is formed spontaneously from Ni_5P_4 and NiP₂ above (but not below) about 850°C (1123 K), its formation from these compounds must proceed with positive changes in both enthalpy and en-

trophy at that temperature, and $\Delta H_{11}^\circ = T\Delta S_{11}^\circ$ at 1123 K. Use of the estimated entropy and heat-capacity data in Table III leads to the enthalpy of reaction recorded in Table IV and the enthalpies of formation and atomization of NiP(s) given in Table V. According to the phase diagram (1), $Ni_{1.22}P$ is stable with respect to Ni_5P_4 and NiP₂ only between about 770°C (1043 K) and 825°C (1098 K). This requires not only that $\Delta H_{12}^\circ = T\Delta S_{12}^\circ$ at both these temperatures, but also that both ΔH_{12}° and ΔS_{12}° be posi-

Table V. Enthalpies of formation (from red P) and atomization (kK) at 298.15 K

	$\Delta H_f^\circ/R$	$\Delta H_{at}^\circ/R$
$\frac{1}{4} Ni_3P(s)$	5.94 ± 0.5	54.8
$\frac{1}{3.55} Ni_{2.55}P(s)$	6.65 ± 0.5	55.2
$\frac{1}{17} Ni_{12}P_5(s)$	6.73 ± 0.5	55.1
$\frac{1}{3} Ni_2P(s)$	6.87 ± 0.5	54.8
$\frac{1}{9} Ni_5P_4(s)$	6.39 ± 0.5	53.0
$\frac{1}{2.22} Ni_{1.22}P(s)$	6.32 ± 0.5	52.9
$\frac{1}{2} NiP(s)$	6.09 ± 0.5	52.1

$\frac{1}{4} NiP_3(s)$	4.52 ± 0.5	47.6

tive at the lower temperature and negative at the higher temperature. These considerations, together with the estimated entropy and heat-capacity data in Table III, were used to deduce the value for ΔH_{12} in Table IV and the enthalpies of formation and atomization of $\text{Ni}_{1.22}\text{P(s)}$ given in Table V. Uncertainty limits were assigned in the manner described earlier (14).

It has been pointed out (14) that the atomization enthalpies per gram atom of the nickel phosphides are, at corresponding compositions, very nearly the same as those for the phosphides of iron (15) and cobalt (4); but, when valence-state energies (16) of the metal atom are taken into account (14), the atomization enthalpies to valence-state atoms per mole of monophosphides show a regular decrease in the series CrP(145.3 kK) (17), MnP(141.3 kK) (14), FeP(130.0 kK) (15), CoP(119.1 kK) (4), and NiP(104.2 kK). This decrease parallels the decrease in the number of bonding electrons per metal atom from six in CrP to two in NiP and suggests that chemical bonding is similar in this series of compounds.

Properties of LPCVD Aluminum Films Produced by Disproportionation of Aluminum Monochloride

R. A. Levy,* P. K. Gallagher, R. Contolini,*¹ and F. Schrey

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

This study describes the properties of LPCVD Al deposited by the disproportionation of AlCl_3 on Si and SiO_2 substrates. In contrast to the organometallic LPCVD Al processes, this deposition technique offers the advantages of a lower hazard potential and, possibly, the ability of simultaneously incorporating desired dopants such as Cu and/or Si. The Al deposits are shown to be chemically pure, as well as adherent, and to exhibit the normal structural and electrical properties of Al. Furthermore, the films exhibit, in local areas, signs of specularly reflecting the absence of the rough topographical structure typical of organometallic LPCVD Al processes. However, the difficulties associated with proper activation of the substrate surface remain, at the present, a significant problem in the viability of this metallization technology.

Aluminum and aluminum-alloy films are widely used in the metallization of integrated circuits. Such films have normally been deposited by electron-beam (E-Gun[®]) or RF induction-source evaporation (In-Source[®]), although recently the use of magnetron sputtering has become more prominent. All of these line-of-sight deposition techniques suffer, however, from poor step coverage, which often results in formation of microcracks and discontinuities at corners of deep steps. With the current growth in emphasis on multilevel structures for vertical integration, coupled with the incessant interest in devices with high packing densities and horizontally reduced dimensions, the need for deposition processes providing conformal step coverage now becomes essential. Recently, several studies pertaining to the characterization of aluminum films deposited by an LPCVD process using tri-isobutyl aluminum (TIBAL) as a source have been reported (1-4). The results show that this particular process does indeed provide conformal step coverage, exhibits excellent film properties in terms of chemical pu-

rity, adhesion, and electrical resistivity, is compatible with current VLSI processing, and appears to have no adverse effects on overall device performance. However, in a comparison with In-Source Al-0.5% Cu films (1, 5), differences for LPCVD Al were noted with respect to its surface roughness, fine grain size, and inferior electromigration resistance. Furthermore, the safety hazard associated with the use or disposal of TIBAL, a highly toxic and pyrophoric material, was emphasized as being of concern. In view of these recognized limitations, a study was undertaken to assess the feasibility of using alternate and safe Al sources. In this paper, we describe the properties of LPCVD Al films deposited by the disproportionation reaction

We shall demonstrate that, with the use of this process, the deposits exhibit a high degree of chemical purity, a randomly textured structure, the expected electrical properties of Al films, and, in select areas, evidence of a significant degree of optical reflectivity. However, as typical of other LPCVD metal processes, it was found

that the development of a reliable procedure for activating the substrate surface to insure reproducible uniformity in nucleation and growth of the film is essential. Although attempts were made to develop such an activation process, discussions pertaining to this particular topic will not be included in this paper.

Physical properties and plating chemistry of AlCl_3 .—CVD methods based upon the transport of inorganic chlorides have been used in a wide variety of applications (6). As a CVD source, aluminum trichloride (7) is a colorless, crystalline solid with a melting point of 192.4°C , a sublimation point of 180°C at 1 atm, and a density of 2.44 g/cm^3 . The vapor pressure of solid AlCl_3 between 420 K and the melting point 467 K, is given by $\log p_{\text{cm}} = 15.115 - 6000/T$. For the liquid, between 467 and 482 K, $\log p_{\text{cm}} = 6.678 - 2070/T$. Despite its satisfactory vaporization characteristics, AlCl_3 does not readily decompose by a pyrolytic, displacement, or reduction reaction to yield metallic aluminum. However, it can partially react at high temperatures with molten Al ($>660^\circ\text{C}$) to form AlCl as follows.

This equilibrium equation may be viewed as the sum of two equations, namely

and

where standard free energy data (8) is available, in this case, for each. For Eq. [2]

$$\Delta G^\circ (\text{cal/mol}) = 140,000 - 2.5T \log T - 7.05 T$$

and for Eq. [3]

$$\Delta G^\circ (\text{cal/mol}) = \frac{3}{2} (-25,860 + 11.8T \log T - 71.9T)$$

yielding for the sum a value for

$$\Delta G^\circ (\text{cal/mol}) = 101,210 + 15.2T \log T - 114.9T$$

A computer plot for the standard free energy corresponding to Eq. [1] is shown in Fig. 1. Examination of the re-

Fig. 1. Standard free-energy change (ΔG°) as a function of temperature for the reaction $\text{AlCl}_3 + 2\text{Al} \rightleftharpoons 3\text{AlCl}$.

Fig. 2. Schematic diagram of the Al LPCVD reactor used in this project

sults indicates that the equilibrium in Eq. [1] is indeed displaced toward the right with increasing temperature, but the free energy does not become negative till above 1200°C . At lower temperatures, this equilibrium shifts back to the left, and the AlCl reverts to Al and AlCl_3 . For instance, at 1250 K and 0.5 torr of AlCl_3 , approximately 11% of this AlCl_3 vapor in contact with Al would be converted to AlCl at equilibrium. Upon cooling to 500 K , virtually all of this AlCl would disproportionate to Al and gaseous AlCl_3 , which may be recovered and recycled if desired.

Rather than contend with the problems and inconvenience of handling, vaporizing, and preventing the upstream condensation of AlCl_3 , the simpler and controllable process of introducing HCl into the carrier gas stream,

Fig. 3. Representative sampling of SEM photographs showing LPCVD Al films deposited under various experimental conditions: a) AlCl_3 source at 100°C , Al at 900°C , substrate at 400°C ; b) HCl source, Al at 900°C , substrate predipped in 1% H_2WO_4 solution, substrate temperature 220°C , cross-sectional view; c) same as b, but top view; d) AlCl_3 source at 100°C , Al at 975°C , predipped in 1% H_2WO_4 solution, substrate temperature 450°C ; e) AlCl_3 source at 100°C , Al at 900°C , substrate predipped in 100:1 HF, followed by 1% organosilane solution, substrate temperature 515°C ; f) HCl source, Al at 900°C , substrate at 600°C .

e.g., H₂ or Ar, to form AlCl₃ *in situ* by reaction with molten Al was tried in this study and found to be successful. Two simultaneous equilibrium reactions are believed to account for the transport, namely

and

For such a transport mechanism, we found it advisable to limit the flow of HCl so that it could be totally consumed in the hot zone and not be available downstream to etch the Al deposit. It is interesting to note that this AlCl disproportionation process is an atypical CVD method in the sense that instead of having, under normal conditions, the cool reactant gases decompose on a hot substrate surface, we have in this particular case hot reactant gases decomposing on a cool substrate surface. We believe that despite this difference, the conformality in step coverage is still to be expected of this process.

Experimental Procedure

A schematic representation of the apparatus used in the present investigation is shown in Fig. 2. In cases where AlCl₃ was used as a source material, it was heated in Furnace 1 over the temperature range of 120°-160°C. The molten aluminum was heated in Furnace 2 over the temperature range of 900°-1000°C. The samples were placed in the steep temperature gradient at the downstream end of the furnace, with their respective positions determining their temperature. In addition to the thermocouples used for monitoring the temperature of the AlCl₃ source and the molten Al, three others straddled the samples to establish the deposition temperature range. In all cases, the thermocouples were external to the reaction tube, due to the corrosive nature of the ambient. The 2.5 in. id of the quartz tube allowed for samples with approximately 3 cm² areas to be stacked one behind the other 1-2 cm apart or for long narrow strips to be exposed side-by-side so that the entire temperature gradient (150°-550°C) was achieved along a single sample. A small conventional mechanical pump was used to provide the modest vacuum requirements. A total operating pressure of 1 torr was used for most experiments. The base pressure achieved without the intentional addition of gases ranged from 0.02 to 0.05 torr. When HCl was used in the gas stream, there was no AlCl₃ present and, hence, no need for Furnace 1. This in turn simplified the experimental procedure and allowed, through measurement of flow rates, strict control on the composition of reactant gases. In some of the experiments where HCl was used, a small Alundum boat with Ti metal was added in hot zone just ahead of the other Alundum boat containing the Al. The Ti presumably served to getter the gas stream, particularly for O₂ and H₂O, and served to activate the substrate surface as reported in the case of LPCVD Al deposited from organometallics. Although numerous runs have been made using this disproportionation process with a wide range of experimental variables, Al films consistent with the standards required of device fabrication have not been reproducibly achieved. A representative sampling of SEM photographs, shown in Fig. 3, for the films deposited under various experimental conditions is useful here in illustrating the problems associated with improper nucleation and growth of the substrate and the effect on the structure of deposits. This investigation will, thus, solely focus on characterization of the best films produced to date with this process. Such films were deposited both on Si and SiO₂ substrates with HCl accounting for the transport (*i.e.*, no direct addition of AlCl₃). The temperature of Al and Ti (used for gettering) was controlled at 900°C, and the deposition temperature of the samples was monitored at ~400°C. The operational sequence of deposition normally proceeded as follows. Starting with a base pressure of 45 mtorr, H₂ was introduced at room temperature, raising the pressure to 800 mtorr, Furnace 2 was

then heated to 900°C, at which point HCl was added to raise the total pressure to 1 torr. The HCl flow was maintained for 45 min, and then both the flow of HCl and the power to the furnace were shut off and the reactor was allowed to cool at its own rate in the flow of H₂ at 800 mtorr. Approximately 0.6 of the 127.6g of Al was transported during such a run, whereas the loss from the 10.2g of Ti was >0.1g. Some attack of the quartz tube was obvious in the hot zone surrounding the Al. Controlled experiments with the HCl shut off, but all other conditions maintained the same, including pressure adjustment to 1 torr with H₂, failed reproducibly to produce Al deposits on the wafer, thus confirming the chloride transport nature of this process. The contributory effect of Al evaporation onto deposits was considered, but was dismissed in view of the exceedingly low vapor pressure of Al (4.7 × 10⁻⁴ torr at 1000°C) and the lack of material transport noted in the controlled experiments.

Fig. 4. SEM photographs taken at several magnifications of best LPCVD Al deposits.

Film Characterization

The topography, the chemical composition, the adherence, and the structural, electrical, and optical properties of LPCVD Al deposited on blank wafers by disproportionation of AlCl₃ have been characterized. Each of these properties will now be described.

Topography.—In contrast to the cloudy appearance characteristic of LPCVD Al deposited from a TIBAL source (1-3), LPCVD Al produced by disproportionation of AlCl₃ exhibit in localized areas across the sample a significant degree of optical reflectivity. Typical SEM photographs of such areas, shown at several magnifications in Fig. 4, reveal a continuous network of grooved grains, with an average grain size of $\sim 4 \mu\text{m}$ and a rather uniform size distribution. The lack of steep peaks and valleys, which generally account for poor reflectance of a surface, is in this case clearly evident. The extent of these areas is observed, however, to be spatially limited to ≤ 1 cm, with the borders being marked, as seen in Fig. 5, by the presence of voids across the rest of the film. The grooving observed at the grain boundaries is presumably due to preferential etching of the boundary surface by chlorine ions in the gas stream, while the holes scattered through the imperfect regions of the film are believed to be, as previously noted, the result of improper activation of the substrate surface. Evidently, the concentration of nuclei on the substrate surface was not in this case ade-

Fig. 6. Vertical SEM cross section across a coherent region of the LPCVD Al film.

quately uniform to insure proper growth and coalescence of the film. The vertical SEM cross section across a coherent region of the film, shown in Fig. 6, illustrates the smoothness, uniformity, and continuity of the Al deposit.

Chemical composition.—The purity of the Al deposit was investigated through the use of x-ray fluorescence (XRF), energy dispersive x-ray analysis (EDX), and Auger electron spectroscopy (AES).

The fluorescence data was gathered in an x-ray Milliprobe unit interfaced to a Li-drifted Si detector and a PGT-3 analyzing system. A Cr target operated at 50 kV and 3 mA provided the source of radiation. The sample was placed in a chamber flushed with He to minimize absorption of the emitted x-rays. A 0.75 mm aperture and 4.8 mm beam stop were used for enhancing count-rate efficiency. In cases where extraneous diffraction peaks were observed, the sample was reoriented to lessen their interference effect. The x-ray fluorescence spectra for

Fig. 7. X-ray fluorescence (XRF) spectra for Al deposited by a) disproportionation of AlCl₃ and by b) In-Source evaporation.

LPCVD Al deposited by disproportionation of AlCl and for In-Source Al-0.5% Cu, used here for control purposes, are shown in Fig. 7a and 7b, respectively. Besides the common occurrence of the characteristic K_{α} and K_{β} lines of the Cr target tube at 5.41 and 5.95 keV and the Cr K_{α} escape peak at 3.67 keV, the relevant K_{α} lines in both samples appear to be due to Al (1.49 keV) and, as a result of the SiO₂ substrate, Si (1.74 keV). In the case of the LPCVD Al sample, traces of Cl were noted while, for the In-Source Al-0.5% Cu film, the presence of the Cu K_{α} line at 8.05 keV is clearly evident.

Fig. 8. Energy dispersive x-ray (EDX) spectra of a) LPCVD Al at 10 keV, b) LPCVD and In-Source Al at 20 keV in the energy range of 0.80-3.36 keV, and c) same as b, but in an extension of the energy range to 10.96 keV.

While topographical information was being gathered in the SEM, the EDX attachment (KeveX-7000) on the system provided a compositional analysis of areas of interest. Accelerating potentials of 10 or 20 keV were used for the purpose of varying the penetration depth of the electron beam. For the LPCVD Al sample, an EDX spectrum taken at 10 keV over the range of 0.16-5.28 keV reveals in Fig. 8a a unique line at 1.49 keV attributed to the K_{α} transition of Al. At the higher accelerating potential of 20 keV, in the range of 0.80-3.36 keV, the spectra of Fig. 8b representing a superposition of LPCVD Al (dotted lines) and In-Source Al-0.5% Cu (solid lines) reveal in both cases the emergence of the Si K_{α} signal from the substrate at 1.74 keV. The higher intensity peak of Al and lower intensity peak of Si measured for LPCVD Al is a reflection of the thickness of the deposit, which in this case is $\sim 2.4 \mu\text{m}$ vs. $\sim 1 \mu\text{m}$ for the In-Source Al-0.5% Cu film. An extension of the energy scale to 10.96 keV is seen in Fig. 8c to yield the Cu K_{α} peak at 8.05 keV for the In-Source sample. The absence of extraneous peaks over this wide energy range is direct evidence of the compositional purity of both deposits. It is worthwhile noting at this point that one of the advantages of using electrons rather than x-rays in exciting the sample is that peaks generated from the target tube (i.e., Cr K_{α} and K_{β} , as well as other escape peaks) are eliminated, thus simplifying significantly the interpretation of results.

Using Auger electron spectroscopy, additional information about impurity elements below those of Na ($Z = 11$) was gathered for the surface, as well as for the bulk of the Al film. Figure 9 shows an elemental AES survey of the surface, which exhibits signals of aluminum, oxygen, chlorine, carbon, and sulfur. The tendency of aluminum to combine readily with oxygen in the environment to form a thin corrosion-resistant film of Al₂O₃ accounts for the presence of the oxygen in the spectrum. The weak chlorine peak at 181 eV reflects the adsorption of this specie during the final stage of Al deposition, whereas the carbon and sulfur are considered here to be surface contaminants.

A depth profile analysis achieved by ion-beam sputtering with Ne reveals in Fig. 10 the rapid decrease in the oxygen concentration below the surface level and the increase and subsequent stabilization of the pure Al signal within the bulk of the film. A second elemental survey taken at a depth of $\sim 3000 \text{ \AA}$ exhibits (Fig. 11), in addition to the expected aluminum and neon peaks, low levels of oxygen and, as shown on an expanded scale in Fig. 12, silicon. Both these signals are attributed to the SiO₂ substrate exposed to the incident electron beam in the incoherent regions of the films. By focusing the beam to within a single grain and using the undifferentiated energy distribution function $N(E)$, the oxygen and Si signals

Fig. 9. Elemental Auger electron spectroscopy (AES) survey of surface of LPCVD Al deposit.

Fig. 10. AES depth profile of LPCVD Al deposit achieved by ion-beam sputtering with Ne.

are seen in Fig. 13 to vanish, and the only pertinent peaks remaining are those attributed to Al and Ne. In view of the recognized sensitivity of the AES technique to all elements above hydrogen, the impurity level within the film is conservatively established to be less than 0.5%, thus establishing an estimate of the Al purity of these deposits of better than 99.5%.

Adherence.—Several attempts to peel the Al film from the Si or SiO₂ substrate with the aid of scotch tape reproducibly yielded negative results. This method, however rudimentary, is helpful in illustrating the bonding quality of the present deposits. Regardless of the deposition technique, Al has generally been known to exhibit excellent adhesive qualities to SiO₂ because of its competition with silicon for oxygen (the heat of formation of Al₂O₃ is high than that of SiO₂, which results in formation of a strong chemical bond).

Structural properties.—The microscopic structure of the Al films deposited with the present process was inferred from x-ray diffraction measurements. The x-ray diffraction data were gathered in a Phillips Model APD 3600 using CuK_α radiation generated by a power supply operating at 45 kV and 30 mA. A diffraction pattern of an Al film deposited on a thermally oxidized Si wafer is shown in Fig. 14 along with the standard Al pattern from the JCPDS file. Besides the Si <400> and <200> K_α reflections detected at 69.17° and 33.09°, respectively, as

Fig. 11. Elemental AES survey at a depth of ~3000Å in the LPCVD Al film.

Fig. 12. Expanded scale of AES spectrum at a depth of ~3000Å in the LPCVD Al film showing Si.

well as the weak <400> K_β reflection detected at 61.73°, all other peaks of the x-ray pattern were attributed to Al. The relative intensities of all Al peaks followed closely the ratio predicted in the JCPDS card (4-787), establishing a random orientation for the microcrystalline structure of this Al deposit. Those results are in contrast to the microstructure of In-Source (5), E-Gun (9), and the other reported LPCVD Al films which generally show a highly textured <111> structure (1, 2).

Electrical properties.—The electrical resistivity of the deposited Al was determined from the calculated product of the sheet resistance and film thickness. The sheet resistance measurement was carried out with a square array of probes set 150 μm apart at each side. The geometry and spacing of the probes were dictated by the inherent nonuniformity in film thickness. A standard In-Source Al film was used for calibration purposes. A 50 mA constant current was fed through two of the probes, and the voltage was recorded with a microvoltmeter across the other two probes. The film thickness was determined with the aid of a Dektak[®] stylus at a step wet-etched in the vicinity of where the sheet resistance data were gathered. Values of the resistivity ranged from 3.4 to 3.7 μΩ-cm. That is higher than the ideal 2.7 μΩ-cm bulk resistivity value for pure Al, but it is in close agreement with values reported for sputtered (10) and other LPCVD Al deposits (1, 2).

Fig. 13. Undifferentiated AES spectrum taken within a single grain of the LPCVD Al film.

Fig. 14. X-ray diffraction pattern of LPCVD Al deposited on SiO₂.

Optical properties.—In order to investigate the optical properties of LPCVD Al deposited by disproportionation of AlCl₃, reflectance measurements were gathered at a fixed wavelength of 5145Å using a 200 μm wide focused Ar⁺ laser beam. The beam was adjusted to be incident on the sample at a 10° angle from the surface normal. The intensity of both the incident and reflected beams was determined using a Coherent Radiation Model 210 power meter. The reflectance was determined from the ratio of those two measurements. Three Al films were examined for comparison purposes: a sputtered pure Al film deposited in a Varian 3180 magnetron unit, an LPCVD Al film, deposited by decomposition of TIBAL, and the Al film under present investigation. As expected from visual inspection, the sputtered Al film exhibited the highest reflectance, with a value close to 86%, while the LPCVD Al film deposited by TIBAL decomposition showed the poorest, with a value close to 1%. In the shiny regions of the Al film under present investigation, the reflectance was recorded at close to 5%, with most of the light scattering being contributed by the receding grain boundaries and surface pits. Thus, elimination of these surface defects promised to lead to significant enhancement in the specularity of these Al deposits.

Conclusions

Our results have established that the use of an inorganic LPCVD process based upon the disproportionation

of AlCl₃ results in the deposition of Al films on Si or SiO₂ substrates. This deposition technique offers advantages: a lower hazard potential and, possibly, the ability to simultaneously incorporate desired dopants such as Cu and/or Si. The Al deposits have been shown to be chemically pure, as well as adherent, and to exhibit a randomly textured structure, as well as the expected electrical properties of Al thin films. Furthermore, in certain regions, the films exhibited a significant degree of optical reflectivity, pointing to the absence of the rough topographical structure typical of organometallic LPCVD Al processes. However, the difficulties associated with proper activation of the substrate surface still remain a problem in the viability of this metallization technology.

Electrical Conductivities of Er₂O₃ Stabilized HfO₂ Solid Solutions

G. W. Jordan and M. F. Berard

Ames Laboratory,¹ Department of Materials Science and Engineering, Iowa State University, Ames, Iowa 50011

ABSTRACT

The electrical properties of fluorite-structure solid solutions of HfO₂ fully stabilized by doping with Er₂O₃ were studied. The dependence of the total ac electrical conductivity and ionic transference number upon composition (10-50 mole percent (m/o) Er₂O₃), temperature (520°-1070°C), and oxygen partial pressure (1-10⁻¹⁹ atm) were investigated. Bulk electrical conductivities of polycrystalline specimens were separated from other polarizations by a complex impedance technique and were compared to conductivities of single crystals. The electrical conductivity generally decreased as the dopant level increased, although plateaus indicative of possible defect ordering were observed over the composition range of 20-35 m/o Er₂O₃. The effects of surface finish, aspect ratio, and porosity of the specimens were negligible. All Er₂O₃ stabilized HfO₂ compositions were shown to be electrolytic conductors below 1070°C for oxygen partial pressures less than 1 atm. Oxygen diffusion coefficients were calculated using the Nernst-Einstein equation.

Hafnium oxide fully stabilized by additions of alkaline-earth or rare-earth oxides presents many possibilities for exploitation because of its refractory, electrolytic, neutron-absorption, and chemical-inertness characteristics. Uses and studies of stabilized hafnia have been limited because of high cost. Even though hafnium is a moderately abundant element (1), and is present in zirconium containing minerals, typically at a level of 1.5-3.0 weight percent (w/o) hafnium referred to zirconium content (2), the chemical properties of Hf and Zr compounds are nearly identical, making separation of Hf difficult and costly.

Stabilized HfO₂ has several advantages over stabilized ZrO₂ because of superior physical properties, and it has been recommended for use in solid electrolyte oxygen probes in molten metals (3) and for use as high-temperature electrodes and low-temperature current leadouts for magnetohydrodynamic generators (4). Progressive decomposition into two phases caused by repeated cycling through the monoclinic/tetragonal polymorphic transformation temperature occurs at much higher temperatures in stabilized HfO₂ than in ZrO₂, and the volume change associated with the transformation is smaller. The driving force for this destabilization is smaller for rare-earth oxide stabilizing dopants than it is for alkaline-earth oxides, primarily because the rare-earth cations are larger and more electropositive (2).

The purpose of this investigation was to determine the bulk electrical transport properties of Er₂O₃ stabilized HfO₂ (ErSH) over wide ranges of composition (10-50 mole percent [m/o] Er₂O₃), temperature (520°-1070°C), and oxygen partial pressure (1-10⁻¹⁹ atm). This work was to establish a foundation for investigations of fluorite-structure solid solutions in the ternary HfO₂-Er₂O₃-Ta₂O₅ system.

Literature Review

Electrical conductivity investigations of HfO₂ containing systems have been relatively limited, although they were recently surveyed (5). In contrast, such investigations of stabilized ZrO₂ have been numerous and have been frequently reviewed (6-11). Binary systems of HfO₂ with oxides of all the alkaline-earth metals except radium have been studied (12); systems containing CaO [e.g., Ref. (13)] and MgO [e.g., Ref. (14) and (15)] have been most often investigated.

Binary systems containing HfO₂ and oxides of all rare-earth elements of the cerium subgroup, except promethium, have been studied. The most extensively studied components of this group have been La₂O₃ [e.g., Ref. (16)] and PrO_x [e.g., Ref. (17) and (18)]. Fewer investigations of binary systems containing oxides of rare-earth elements of the yttrium subgroup have been conducted. Only Y₂O₃ [e.g., Ref. (19)], Tb₂O₃ [e.g., Ref. (17)], and Er₂O₃ [e.g., Ref. (20)] have been employed as second components from this subgroup. Details of these investigations and several

additional citations of literature pertaining to HfO₂ containing systems can be found in Ref. (5).

Johnstone (20) has made the only previous investigation of electrical transport properties of an extensive range of compositions in the HfO₂-Er₂O₃ system (8.6-90 m/o Er₂O₃), although Marchant (21) has measured the dc electrical conductivity of one high Er₂O₃ content composition in air to 1300°C. Johnstone determined ac electrical conductivities at a fixed frequency of 1592 Hz over a narrow temperature range (800-1000°C) and a fairly wide range of oxygen partial pressures (1-10⁻¹⁴ atm). Ionic transference numbers were determined using the open-circuit emf method, employing Cu-Cu₂O vs. Ni-NiO reversible coexistence electrodes. Predominantly ionic conductivity was exhibited by compositions within the fluorite domain. Evidence of possible ordering within the fluorite single-phase region was also observed.

Transport properties of cations in the HfO₂-Er₂O₃ system have been investigated by Berard and his co-workers in a series of diffusion studies (22-26). Only two of these, those of Tesch (25) and Tesch *et al.* (26), involved the HfO₂ rich fluorite solid solutions; the other studies involved Er₂O₃ rich compositions having the rare-earth oxide type-C structure.

Three investigations of phase equilibria in the HfO₂-Er₂O₃ system have been reported (20, 27, 28) and reviewed previously (29). In all three studies, the phase boundaries of the single-phase fluorite solid-solution region, which is of interest in this study, agreed fairly closely (Fig. 1), except Duran *et al.* (28) reported an ordered phase within the fluorite domain below 1500°C based on the hexagonal compound Er₃Hf₃O₁₂. The ordering process for the formation of the ι -phase² was reported to be very sluggish. Indeed, efforts to replicate these results did not produce any evidence of ordering (29).

The defect structure of ErSH fluorite solid solutions is consistent with an anion vacancy defect model, as was first shown by Johnstone (20). Recently, Tesch (25) presented a very detailed analysis of the defect chemistry in ErSH (which is strictly applicable only in the case of unassociated point defects). The predominating defects (using Kröger-Vink notation) are Er_{Hf}' and V_O°, as is shown by the incorporation reaction

Theoretical density is predicted by

$$\rho_{\text{true}} = \frac{4}{a_0^3 N_A} \left[\frac{(1-x)(MW_{\text{HfO}_2}) + x(MW_{\text{Er}_2\text{O}_3})}{1+x} \right] \quad [2]$$

where a_0 is the lattice parameter of a fluorite solid solution containing x mol fraction Er₂O₃, MW refers to molecular weight of the oxides subscripted, and N_A is Avogadro's number.

²This is the usual designation for the M₃O₁₂ phase; see, e.g., Ref. (30). Duran *et al.* (28) designated this the δ phase, which usually refers to an M₁₁O₂₀ phase (30).

Experimental Procedure

Raw materials.—Impurity analyses of the Er₂O₃³ used throughout this investigation and of the reactor grade HfO₂⁴ used in the preparation of single crystals are shown in Table I. Qualitative emission spectrographic analysis of the reactor grade hafnium oxychloride⁴ used to prepare polycrystalline specimens indicated faint traces of Ba, Ca, Fe, Mg, and Ti.

Powder processing and specimen preparation.—Ten compositions in the HfO₂-Er₂O₃ system were prepared for polycrystalline specimens. Er₂O₃ contents ranged from 10-50 m/o Er₂O₃ in 5 m/o increments and also included the 33 1/3 m/o Er₂O₃ composition. Powders were prepared by calcination of coprecipitated hydroxide precursors. Precipitation was accomplished by adding aqueous ammonia

(2.5N) to blends of cation stock solutions. The stock solutions were prepared by dissolving HfOCl₂·8H₂O in distilled water (50g HfO₂/l) and Er₂O₃ in 2.35N HNO₃ (50g Er₂O₃/l). Final pH during precipitation ranged between 9 and 10.5. The gelatinous hydroxide precursors were de-watered using a series of organic washes to improve the sinterability of the powders (31, 32) and were then calcined at 1100°C in air for 2h.

Small cylindrical specimens were formed without binder, first using uniaxial pressing in a double acting die to approximately 42 MPa (6 ksi), followed by isostatic pressing to 207 MPa (30 ksi).⁵ Two sintering treatments were employed: vacuum sintering at 1880°C for 1h or air sintering at 1706°C for 1h. During sintering, temperatures were measured with an automatic optical pyrometer corrected for sight glass absorption. Specimens were contained in covered erbia crucibles; the air sintering treatments were performed inside an alumina muffle tube inserted into a natural gas-air furnace. After vacuum sintering, all specimens were heated in air for 2h at 1100°C to correct for small deviations from stoichiometry.

Specimen bulk densities were determined by standard water-immersion procedures and have been previously reported and discussed (32). The faces of the cylindrical specimens were generally polished through Linde A (0.3 μm), although some specimens were polished to a lesser degree or even not at all to evaluate the effect of surface finish on conductivity values.

Single-crystal specimens were sectioned from crystals of 10 and 25 m/o ErSH⁶ produced using a skull melting technique.⁷ Faces were polished through Linde A. X-ray diffraction was employed to verify that all compositions were single-phase and fluorite-structure.

Electrical Measurements.—For ac electrical conductivity measurements, porous platinum electrodes were painted onto the specimen faces and baked at 1000°C to create a strong ceramic-metal bond (33); multiple coats were applied until the resistance between any two points on the surface was less than 0.1Ω. The measurement cell, which consisted of one or often two specimens to replicate results, was mounted on an alumina pedestal inside two muffle tubes inserted into a noninductively wound electric furnace; this configuration has been described in detail by Schieltz (34). The outer muffle tube and the lead wires were shielded to eliminate induced EMF's.

Equivalent series resistance and capacitance were measured using the instrumentation shown schematically in Fig. 2(a). A microcomputer⁸ controlled data acquisition by the microprocessor-based bridge⁹ at numerous frequencies between 240 Hz and 20 kHz. Some measurements were made with an LCR meter¹⁰ at higher frequencies ranging from 10 kHz to 1 MHz. Temperature was measured with Pt-Pt10Rh thermocouples using the digital multimeter and was varied from 1070° to 520°C. Oxygen partial pressures ranging from 1 to 10⁻¹⁹ atm were established by a gas mixing and purification train similar to that described by Basler (35) and were verified with an oxygen analyzer.

The bulk (lattice) and interfacial contributions to the total conductances were separated by complex impedance spectroscopy¹¹ (37, 38), even though this generally accepted model has many parameters for which physical interpretations cannot be proven (39). An idealized complex impedance spectrum and equivalent circuit for an ionic conductor are shown in Fig. 3. The three semicircular arcs represent dispersions at low, medium, and high

⁵Typical green densities before and after isostatic pressing were 35 and 44% of theoretical density, respectively.

⁶These are nominal compositions. Wet chemical analyses indicated actual compositions of 10.54 and 23.73 m/o Er₂O₃.

frequencies caused by electrode interfacial polarization, grain boundary polarization, and the bulk specimen, respectively. (Frequency f increases in the direction indicated: the capacitance corresponding to each dispersion can be calculated from the maximum reactance on each arc.) R_b is the bulk ionic resistance; C_g is the geometric capacitance; and R_{gb} , C_{gb} , R_e , and C_e are the lumped resistances and capacitances associated with the grain boundary and electrode interfaces. R_p , the resistance of a parallel electronic conduction path, is very large for an electrolytic

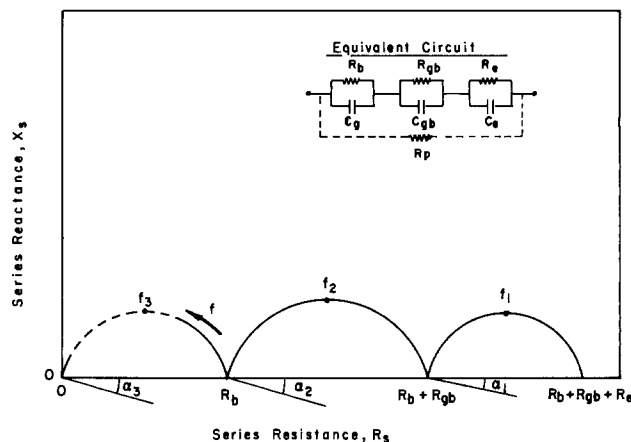

Fig. 3. Idealized complex impedance diagram and corresponding equivalent circuit model (insert).

conductor and can often be neglected for mixed conductors exhibiting high ionic transference numbers. The center of each dispersion arc is depressed by some angle α which is commonly attributed to the distribution of relaxation times associated with each polarization. Only portions of this idealized spectrum were observed at any one time, depending upon temperature and frequency. As would be expected for heavily doped compositions prepared from high purity raw materials, no dispersions due to grain boundary polarization were evident in this investigation. This was verified using the single-crystal specimens.

Transference numbers were determined utilizing duplicate cells and the instrumentation shown in Fig. 2(b). Reversible coexistence electrodes were fabricated from 10:1 mixtures of transition metals (Cu, Co, and Fe) and their oxides. Typical oxygen partial pressures established thus at various temperatures by the Cu-Cu₂O, Co-CoO, and Fe-FeO electrodes employed in this study are listed in Table II. These P_{O_2} values and theoretical EMF's for the various electrode pairs were calculated using the thermodynamic data of Wicks and Block (40). The potentiometer¹² and null detector¹³ measured the actual open-circuit EMF. Temperatures investigated ranged from 720° to 1020°C and were measured as described before.

Results and Discussion

Effects of composition and temperature.—Bulk electrical conductivities determined for various ErSH compositions between 521° and 1063°C in air are shown in Fig. 4. Total electrical conductivity generally decreased as dopant level increased at all temperatures investigated, but a plateau was observed over the composition range of 20-35 m/o Er₂O₃. This decrease in conductivity with increase in dopant is consistent with the immobilization of defects by ordering or clustering in the increasingly defective solid solutions. The plateaus were more pronounced at the lower temperatures and may be indicative of defect ordering in the neighborhood of the pyrochlore composition or one of the other ordered substructures known in some anion deficient fluorite systems (30).

Decreases in electrical conductivities as the defect concentration (dopant level) increases are typical for heavily

Fig. 4. Bulk electrical conductivities of ErSH solid solutions at various temperatures.

doped fluorite and defective fluorite-structure solid solutions. Several different types of defect-structure models involving clustering have been proposed for stabilized ZrO₂. Butler *et al.* (41) employed computer simulations to show that formation of clusters between low-valence dopants and charge compensating anion vacancies was energetically more favorable than formation of ordered microdomains, even though such microdomains consisting of fluorite-related compounds are commonly observed microstructural features (10). Early attempts to rationalize the decrease in conductivity with increasing anion vacancy concentration in stabilized ZrO₂ (and other defective fluorite structure compositions) have been reviewed several times (42, 43, 11) and generally have involved the introduction of configurational constraints to the motion of vacancies due to their mutual coulombic repulsion. Subbarao and Ramakrishnan (42) extended the earlier statistical models (for ThO₂ and ZrO₂ doped with CaO and YO_{1.5}) to include both anion vacancy trapping at lattice sites occupied by cation dopants and vacancy-vacancy repulsions. They assumed that only "free" vacancies (*i.e.*, those with no dopant ions as nearest neighbors) contribute to electrical conductivity, and they obtained better qualitative agreement than the earlier models. However, the conductivity reduction calculated with this model did not decrease as rapidly with increasing dopant level has been experimentally determined—presumably due to influences of long-range coulombic forces and formation of ordered phases. As Norwick (11) has indicated, the problem with a theory of conduction by only "free" vacancies is that, at high defect concentrations, connected paths of such "free" vacancies no longer exist. Nakamura and Wagner (43) considered contributions to electrical conductivity from anion vacancies which were adjacent to dopant ions (in CaO-stabilized ZrO₂). They obtained excellent quantitative agreement with experimental results by postulating that conduction proceeds by a multimode mechanism involving various degrees of association between dopant cations and oxygen vacancies and by assuming that the coordination number of the dopant cations (Ca_{Zr}²⁺) to each 24 second-nearest-neighbor anion site is 1/3.

Electrical conductivities determined in this study for various compositions are compared with those of other investigators at 1000°C in air for related rare-earth oxide (RE₂O₃)-HfO₂(ZrO₂) systems in Fig. 5. Only Johnstone, who also studied the HfO₂-Er₂O₃ system, observed a plateau in the conductivity *vs.* dopant concentration curve at such high temperatures. (Comparable data for related systems at lower temperatures where the plateaus are more pronounced are not available.) The reported conductivities of single-phase fluorite solid solutions containing between approximately 10 and 50 mol/o RE₂O₃ agree within about half an order of magnitude regardless of dopant or host and despite the different measurement techniques

Fig. 5. Electrical conductivities of RE₂O₃-HfO₂(ZrO₂) compositions according to various investigators.

employed (complex impedance analysis was employed in this work; the other studies reported ac conductivities measured at different fixed frequencies). The variation in the electrical conductivities may possibly be due to differences in the reported sintered densities of the specimens on which the measurements were made; although, as is discussed below, the degradation of electrical conductivity due to porosity is much less than might be expected.

The activation energy for conduction increased as the dopant concentration was increased (Fig. 6). Thus, the conductivity values tended to converge at high temperatures, although not nearly as rapidly as Hohnke (46) has suggested for Y₂O₃ stabilized ZrO₂ and other materials. (Log σT has been plotted *vs.* reciprocal absolute temperature in Fig. 6 to determine the activation energy of conduction ΔH , as suggested by absolute reaction-rate theory, even though it is common practice to determine an activation energy we shall call Q from Arrhenius plots of log σ *vs.* $1/T$. Values of ΔH are approximately 0.09 eV higher than values of Q in this temperature range.¹⁴ Com-

¹⁴Schieltz *et al.* (19) have shown that $\Delta G^\ddagger = Q + C$, where $C = -R[d \ln T/d(1/T)]$.

Fig. 6. Log σT vs. $1/T$ plot for selected ErSH compositions

Fig. 7. Activation energies of $\text{RE}_2\text{O}_3\text{-HfO}_2(\text{ZrO}_2)$ compositions according to various investigators.

comparisons with other RE_2O_3 stabilized $\text{HfO}_2(\text{ZrO}_2)$ systems (Fig. 7) also indicate a general trend toward increased activation energies (Q) as the dopant level is increased. However, activation energy plateaus similar to the conductivity plateaus discussed previously (Fig. 5) are observed over the range of 20-35 m/o dopant for all these systems.

Effect of oxygen partial pressure.—Bulk electrical conductivities were found to be independent of P_{O_2} over the range of $1\text{-}10^{-19}$ atm for all temperatures (Fig. 8a) and nearly all compositions (Fig. 8b) investigated. This is usually an indication of predominantly ionic conduction. The 10 m/o single-crystal and 50 m/o polycrystalline ErSH compositions (*i.e.*, those near the fluorite single-phase limits) evidenced slight increases in conductivity above oxygen partial pressures of 10^{-3} atm, which may indicate the onset of p-type electronic conductivity.

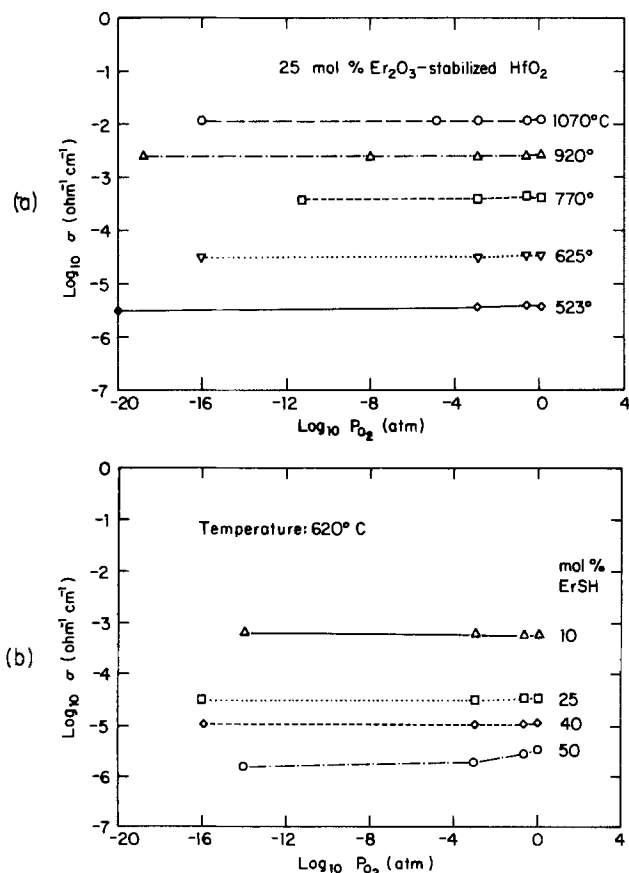

Fig. 8. P_{O_2} dependence of bulk electrical conductivities: (a) 25 m/o ErSH at various temperatures; (b) selected ErSH compositions at 620°C .

Fig. 9. Comparison of thermodynamic EMFs for various coexistence electrode pairs; measured open-circuit EMFs for selected ErSH compositions.

Open-circuit EMF results for 10, 25, 45, and 50 m/o ErSH are summarized in Fig. 9. The ionic transference numbers of these materials were confirmed to be near unity, because the measured open-circuit EMF values fell very near or even slightly above the dotted and dashed lines which represent the thermodynamic EMFs established by the indicated pairs of reversible coexistence electrodes. In particular, 10, 25, and 50 m/o ErSH are shown to be electrolytic conductors between 720° and 1020°C over the P_{O_2} range established by Cu-Cu₂O and Co-CoO electrodes (refer to Table II). Similarly, 45 m/o ErSH is shown to be an electrolytic conductor between 720° and 820°C at the lower oxygen partial pressures established by Co-CoO and Fe-FeO electrodes.

Oxygen self-diffusion coefficients (D_{Ox}) were calculated using the Nernst-Einstein equation

$$t_i k T \sigma = N z^2 e^2 D_{\text{Ox}} \quad [3]$$

where t_i is the ionic transference number (unity for a solid oxide electrolyte), k is Boltzmann's constant, T is absolute temperature, σ represents electrical conductivity, z is the valence of the diffusing species, and e signifies elementary charge. For ErSH, the concentration of oxygen ions, N , was computed from the relation

$$N = 2(x + 2) / [a_0^3(x + 1)] \quad [4]$$

where a_0 , the lattice parameter of a composition containing x mol fraction Er_2O_3 was estimated using the empirical equation¹⁵

$$a_0 \text{ (nm)} = 2.590x + 50.986 \quad [5]$$

Typical values of D_{Ox} for the ranges of temperature and ErSH compositions studied in this investigation are shown in Table III. These values for anion diffusion are

¹⁵Calculated from precision lattice parameter data measured by C. D. Wirkus, Ames Laboratory, Ames, Iowa.

Table III. Values of D_{Ox} in Er_2O_3 stabilized HfO_2

Mole fraction Er_2O_3	$D_{\text{Ox}}, \text{cm}^2 \text{s}^{-1}$		
	550°C	800°C	1050°C
0.10	1.28×10^{-9}	4.50×10^{-8}	3.88×10^{-7}
0.25	2.63×10^{-11}	2.99×10^{-9}	6.26×10^{-8}
0.40	9.52×10^{-12}	1.33×10^{-9}	2.81×10^{-8}
0.50	9.10×10^{-13}	2.40×10^{-10}	9.62×10^{-9}

approximately twenty orders of magnitude greater than estimates of cation diffusivities extrapolated from data obtained by Tesch *et al.* (25, 26), at higher temperatures.

Effects of porosity, surface finish, and aspect ratio.—Total bulk electrical conductivities (determined from complex impedance analysis) of polycrystalline specimens were virtually identical to those obtained for single crystals. Figure 10 includes data for single-crystal and polycrystalline 10 and 25 m/o ErSH of 83%-96% theoretical density, and shows that the expected degradation effect of porosity (47) was negligible. Casselton (48) has also observed virtually identical electrical conductivities for (Y₂O₃ stabilized ZrO₂) single crystals and polycrystals of 92%-95% theoretical density; this agreement was attributed to insignificant grain boundary conductivity in the polycrystals—the effect of porosity was not addressed. A number of tests were performed to determine whether surface finish or aspect ratio (*A/L*) of the specimens could have approximately offset the expected conductance degradation due to porosity. Bulk electrical conductivities were found to be the same regardless of whether electrodes were applied to unpolished (as-sintered) specimen faces or to faces polished through Linde A [Fig. 11(a)]; *i.e.*, the electrode/specimen contact area and effective *A/L* were not changed significantly by polishing. Similarly, electrical conductivities determined for 10 m/o ErSH single-crystal specimens with aspect ratios varying by up to a factor of eighteen were identical [Fig. 11(b)]; neither gas phase nor surface conduction was a problem.

Recently, Brailsford and Hohnke (36) presented an alternative to the usual equivalent circuit method of analysis and showed that intragranular pores should dilute the contribution to impedance arising from the high-conductivity bulk material, whereas intergranular porosity should augment the blocking effect of the high-impedance grain boundary regions. Because complex impedance spectroscopy separates the bulk and grain boundary contributions to the electrical conductivity, and because most porosity in the specimens used in this study appeared to be present intergranularly, it is not surprising that the electrical conductivities of porous polycrystalline and single-crystal specimens were virtually identical.

Conclusions

Erbia-stabilized hafnia (ErSH) exhibits high ionic conductivity similar to other fluorite-structure rare-earth oxide-stabilized HfO₂(ZrO₂) compositions. It is, in fact, an electrolytic conductor (*t_i* > 0.99) over wide ranges of composition, temperature, and oxygen partial pressures. The bulk electrical conductivities determined from complex impedance analysis for polycrystalline specimens are the same as those measured for single crystals; therefore, grain boundary and porosity effects are negligible. The effects of surface finish and aspect ratio of the specimens are also negligible. The electrical conductivity generally

Fig. 10. Bulk electrical conductivities for single-crystal and polycrystalline specimens of two ErSH compositions.

Fig. 11. Effect of specimen variables on bulk electrical conductivities: (a) surface finish; (b) aspect ratio.

decreases, and the activation energy for ionic conduction generally increases as the dopant level increases, although plateaus are observed over the composition range of 20-35 m/o Er₂O₃. (Values of electrical conductivities measured in this investigation ranged from approximately $1.2 \times 10^{-1} \Omega^{-1} \text{cm}^{-1}$ at 1070°C for 10 m/o ErSH to $2.6 \times 10^{-7} \Omega^{-1} \text{cm}^{-1}$ at 520°C for 50 m/o ErSH. Activation energies (ΔH) ranged from 1.14 eV for 10 m/o ErSH to 1.60 eV for 50 m/o ErSH.)

ABSTRACT

A two-dimensional model for the coupled effects of heat transfer and capillarity in a liquid encapsulated Czochralski growth system is analyzed by solving the full free-boundary problem describing the temperature field in each phase, the shapes of the melt/solid and fluid/fluid interfaces, and the radius of a steadily growing crystal. Solutions are based on a finite element analysis with Newton iteration for all the variables. Heat transfer in the melt is taken to be dominated by conduction, and radiation to a uniform ambient is included for a transparent encapsulant. Calculations for a model GaAs system give reasonable predictions of crystal size and axial temperature gradient. The results are most sensitive to radiation through the encapsulant.

The liquid encapsulated Czochralski (LEC) method for growing single crystals of semiconductor materials with high vapor pressure has become an important method for producing GaAs, InP, and other semiconductor materials (1-3). Here a cylindrical crystal is pulled from the surface of a melt pool through a layer of liquid encapsulant, usually boric oxide B₂O₃, which prevents the escape of the vapor. Empirical advances in the technology of LEC growth have led to the production of moderate diameter boules of these materials with low dislocation densities (4-6); however, little progress has been made in the quantitative understanding of the transport processes important in LEC growth. The focus of this research is the de-

*Electrochemical Society Active Member.

velopment of a detailed model for the heat transport and capillarity in LEC growth of GaAs that will become the basis for both design calculations and the development of rational control algorithms.

In LEC and other free-meniscus crystal-growth techniques, the shape of the crystal and the temperature field in the melt, crystal, and encapsulant are controlled by the coupled effects of heat transfer throughout the growth system and the shapes of the melt/encapsulant and encapsulant/gas interfaces. Capillarity and the wetting of the crystal by its melt set the position and shape of the menisci. The mathematical description of this system is an extremely complicated free-boundary problem for the temperature field and the location of the fluid/fluid and

melt/crystal interfaces; the calculations of Ettouney *et al.* (7, 8) for edge-defined film-fed growth of thin silicon sheets are the only similar calculations for an entire free-meniscus crystal growth system. In this paper, we present a finite-element/Newton numerical method for simulating LEC crystal growth. The numerical scheme is modeled after the Isotherm/Newton finite-element method developed by Ettouney and Brown (9); the method was found to be the most efficient of several techniques tested in that report. The Isotherm/Newton method combines the flexibility of finite-element approximations for handling irregularly shaped domains with the efficiency of Newton's method for solving large sets of nonlinear algebraic equations.

The calculations are based on a simplified but realistic model for the growth of GaAs by LEC where heat transfer in the melt and B_2O_3 are dominated by conduction. Convective heat transfer in the melt caused by buoyancy forces and crystal rotation is insignificant on a macroscopic scale for low Prandtl number melts and even moderately intense flows, as pointed out by the hydrodynamic calculations of Langlois (10) and others (11, 12). Indeed, conduction-dominated models have been the basis for other simulations of the interaction of the crystal with a Czochralski melt pool in two-dimensional (13-16) and one-dimensional (17-19) heat-transfer models. The one-dimensional models were based on fin-type approximations to the temperature field which are strictly valid only when the temperature varies slowly across the radius of the crystal. As shown in this paper, this assumption is not met near the contact of melt, crystal, and encapsulant, and the results of these models predict unrealistic behavior for Czochralski growth systems. Neglecting convection in the B_2O_3 also seems justified because the velocity field there is mainly azimuthal, driven by crystal and crucible rotation, and has no influence on vertical and radial heat transfer.

The dependence of the crystal thickness on the pull rate for stable crystal growth was the most important feature of Czochralski growth estimated from these simplified models. The most often used result was derived by Billig (17) and is based on one-dimensional heat transfer to uniform surroundings from a growing crystal coupled to a melt which is just thermally supercooled at the solidification front moving at the solidification velocity. These assumptions lead to the result that the crystal radius is inversely proportional to the square of the pull rate. We will compare this estimate to the results from our detailed model.

Appropriate accounting of radiative heat transfer between the melt, crystal, encapsulant, and the surrounding furnace and modeling of the heat transfer through the surrounding crucible are crucial for quantitative prediction of the crystal shape and temperature fields. In the model presented here, we assume that the B_2O_3 is totally transparent to radiation emitted at the crystal and melt surfaces, and that these surfaces radiate to an average ambient temperature. While this is a considerable simplification of each of these radiative fluxes, particularly when the melt level is low and the hot crucible wall radiates to the crystal, meaningful insight into the response of the system to changes in heat-transfer conditions is obtained. The view factors along the surfaces appropriate for a particular furnace [e.g., see Ref. (18)] can be incorporated into our computational scheme; this work is currently underway. Meanwhile, the validity of the transparent model used here can only be estimated by comparison of the computed values of the axial and radial temperature gradients with the gradients measured recently in a similar liquid-encapsulated Czochralski system during the growth of InP (5). The 530 K difference in melting point between InP and GaAs and the idealized furnace configuration studied here make our comparison only approximate.

The shapes of the melt/encapsulant and encapsulant/gas menisci are determined by balancing surface tension and hydrostatic pressure, as given by the Young-

Laplace equation and by the wetting conditions at the crystal and crucible surfaces. Static meniscus shapes for different radii crystals in a Czochralski system have been calculated both exactly (20, 21) and approximately (22, 23). Heat transfer in the entire growth system determines which of these interfaces are attainable and connects the shape and stability of the crystal grown with the pull rate and thermal operating conditions of the furnace. Only the two-dimensional analysis of Crowley (16) has attempted to link the crystal radius with heat transfer through the shape of the meniscus in a conventional Czochralski system. Crowley solved a time-dependent heat-transfer model, similar in spirit to the one proposed in this paper's next section, in the regions of melt and crystal adjacent to the melt/solid interface. Heat transfer and crystal radius were linked through an approximate solution of the equation of capillary statics. Our analysis differs from the one in Ref. (16) in that the entire melt, crystal, and encapsulant for LEC growth are accounted for so that thermal boundary conditions used in the analysis can be determined from external inputs only.

Our heat-transfer model for LEC growth is described in the following section, and the finite-element method for calculating solutions to it is presented following that section. Sample calculations for the growth of GaAs in a small-scale LEC system are described in the "Results" section. The numerical method is equally applicable for modeling conventional Czochralski growth when the encapsulant layer is removed.

Thermal-Capillary Model for LEC Growth

We model the steady-state growth of a cylindrical boule of GaAs with radius R from a melt of volume \tilde{V}_m encapsulated with B_2O_3 of volume \tilde{V}_e in a crucible of inner radius R_c . The crystal is pulled continuously from the melt at a rate V_p . We imagine a quasi steady-state process in which the melt depth in the crucible, and hence the volume of the melt, changes much slower than the thermal transients in the system. Then it is valid to reconstruct the time history of a LEC growth run from a sequence of steady-state calculations with decreasing melt depths.

Our prototype LEC system is shown schematically in Fig. 1 with the notation needed to represent the melt (D_1), encapsulant (D_2), and the crystal (D_3). Each of these regions is characterized by a set of constant thermophysical properties. Segments of the boundary have been labeled as ∂D_i , where the value of i corresponds to the parts shown in Fig. 1. The energy balances and boundary conditions are put in dimensionless form by scaling lengths with the radius of the crucible, R_c , and temperature with the equilibrium melting point of the crystal, $\theta(r, z) = T(r, z)/T_i$. The dimensionless radius, melt volume, and encapsulant volume are defined by $R = R/R_c$, $V_m \equiv \tilde{V}_m/R_c^3$, and $V_e \equiv \tilde{V}_e/R_c^3$, respectively. All variables discussed below are given in dimensionless form, unless explicitly stated otherwise. The temperature field and the shapes of the melt/crystal [$H_0(r)$], melt/ B_2O_3 [$H_1(r)$], and B_2O_3 /gas [$H_2(r)$] interfaces are represented in the dimensionless cylindrical coordinate system (r, z) centered at the bottom of the crucible.

The energy balances in each of the phases are

$$K_1 \nabla^2 \theta = 0, \text{ in } D_1 \quad [1]$$

$$K_2 \nabla^2 \theta = 0, \text{ in } D_2 \quad [2]$$

$$\nabla^2 \theta - \text{Pe}(e_z \cdot \nabla \theta) = 0, \text{ in } D_3 \quad [3]$$

where $\nabla = e_r(\partial/\partial r) + e_z(\partial/\partial z)$ is the gradient operator in cylindrical coordinates and e_r and e_z are the unit vectors. In the equations above, K_i denotes thermal conductivity ratios and Pe represents the Peclet number, a dimensionless form of the steady-state growth rate; see the List of Symbols for a precise definition.

The conditions on the boundaries between melt, crystal, and B_2O_3 guarantee that temperature is continuous and that energy is conserved along each interface. At the melt/crystal interface (∂D_0), the interfacial energy balance is

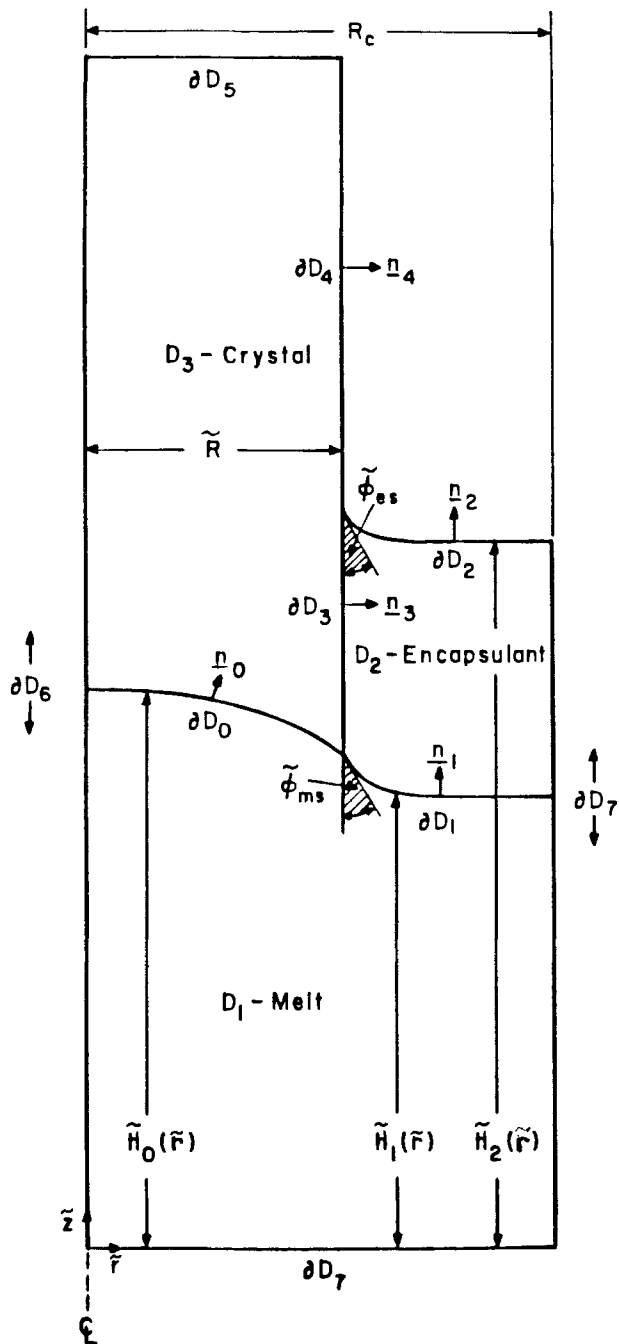

Fig. 1. Schematic of model for LEC system

$$K_1(\mathbf{n}_0 \cdot \nabla \theta)_m - (\mathbf{n}_0 \cdot \nabla \theta)_s = \text{Pe}S(\mathbf{n}_0 \cdot \mathbf{e}_z) \quad [4]$$

where the Stefan number S measures the latent heat of the phase transformation. The subscripts m and s refer to quantities evaluated in the melt and solid crystal, respectively, and \mathbf{n}_0 is the outward pointing normal along the melt/crystal interface (∂D_0) as detailed in Fig. 1.

At the melt/ B_2O_3 interface (∂D_1), the conductive fluxes between the two phases are balanced against the radiative heat loss through the glass to the surroundings. We model the B_2O_3 as being perfectly transparent so that energy radiates directly from this interface to a distant surface at temperature $\theta_a \equiv T_a/T_f$ representative of the furnace ambient. The dimensionless form of the energy balance on the segment ∂D_1 is

$$-K_1(\mathbf{n}_1 \cdot \nabla \theta) = Ra_1(\theta^4 - \theta_a^4) \quad [5]$$

where Ra_1 is the radiation number for this surface.

The energy balance along the crystal/encapsulant surface (∂D_3) also assumes the B_2O_3 to be totally transparent and nonreflective so that the condition is written as

$$-\mathbf{n}_3 \cdot \nabla \theta = Ra_3(\theta^4 - \theta_a^4) \quad [6]$$

where Ra_3 is the radiation number based on the emissivity of this surface. Heat transfer from the interfaces to the ambient include both radiation and convection as

$$-K_2(\mathbf{n}_2 \cdot \nabla \theta) = \text{Bi}_2(\theta - \theta_a) + Ra_2(\theta^4 - \theta_a^4) \quad [7]$$

$$-\mathbf{n}_4 \cdot \nabla \theta = \text{Bi}_4(\theta - \theta_a) + Ra_4(\theta^4 - \theta_a^4) \quad [8]$$

where Bi_j is the Biot number based on the heat-transfer coefficient for each surface; $j = 2$ for the encapsulant/gas interface (∂D_2) and $j = 4$ for the crystal/gas surface (∂D_4). The top of the crystal ∂D_5 is assumed adiabatic

$$\mathbf{e}_z \cdot \nabla \theta = 0 \quad [9]$$

where the length of the crystal is long enough so that the crystal has reached thermal equilibrium with the ambient.

Along the crucible wall (∂D_7) the temperature is set as

$$\theta(r, z)|_{\text{wall}} = \theta_c \quad [10]$$

where $\theta_c \equiv T_c/T_f$. In the calculation presented here, θ_c is taken to be constant, although the numerical methods generalize easily to either specified temperature or flux distributions. As is discussed below, proper accounting of the varying heat transfer through the bottom and sides of a crucible in a real crystal growth system is crucial for accurate prediction of interface shapes. The centerline of the system (∂D_6) is specified as a symmetry axis by

$$\mathbf{e}_r \cdot \nabla \theta = 0 \quad [11]$$

The boundaries of the phases are determined by the shapes of the three interfaces and the radius of the crystal. These are determined by a set of interface and contact conditions which must be satisfied simultaneously with the energy balances, Eq. [1]-[11]. The melt/solid interface shape is determined as the melting point isotherm for GaAs written as

$$\theta(r, H_0(r)) = 1 \quad [12]$$

in terms of the dimensionless location of this interface $H_0(r)$.

The melt/encapsulant and encapsulant/gas interfaces are determined from the Young-Laplace equations for each surface

$$2\mathcal{H}_i = \text{Bo}_i(H_i - \lambda_i), \quad i = 1, 2 \quad [13]$$

where \mathcal{H}_i is the mean curvature of the interface, defined as

$$2\mathcal{H}_i = \frac{\frac{d^2 H_i}{dr^2}}{\left[1 + \left(\frac{dH_i}{dr}\right)^2\right]^{3/2}} + \frac{\frac{dH_i}{dr}}{r \left[1 + \left(\frac{dH_i}{dr}\right)^2\right]^{1/2}} \quad [14]$$

where Bo_i is the Bond number and λ_i is an unknown reference pressure difference for the i th interface. The Bond number measures the relative importance of gravity and surface tension in setting the shapes of these surfaces. For the LEC GaAs system, gravity dominates the interface shape, and surface tension is important only within a small range of several millimeters from the crystal and crucible. Equation [14] has been derived assuming that the dynamic viscous and pressure forces caused by fluid motion in the encapsulant and melt are small with respect to surface-tension forces. The viscous tractions associated with the melt are certainly much smaller than those created by any motion in the B_2O_3 , where the viscosity is 300 times larger and the largest errors associated with our assumption of a hydrostatic interface originate.

The pressure differences arise because no datum location exists along either surface where the curvature is precisely zero. Thus, ambient pressure cannot be directly related to the pressures in the encapsulant and melt. The unknowns λ_i are determined by specifying the volumes of

melt and encapsulant as in other capillary problems (24). These volume constraints are for λ_1

$$\int_0^R H_0(r)rdr + \int_R^1 H_1(r)rdr = V_m/2\pi \quad [15]$$

and for λ_2

$$\int_R^1 (H_2(r) - H_1(r))rdr = V_e/2\pi \quad [16]$$

where V_m and V_e are the dimensionless volumes of melt and encapsulant, respectively.

Equations [13]-[16] are solved with edge conditions on both interfaces which specify the wetting angle ϕ of melt and encapsulant against the crystal and crucible. The B_2O_3 is taken to wet the crystal ($\phi_{es} = 5^\circ$), but not the crucible ($\phi_{ec} = 90^\circ$)

$$\left. \frac{dH_2}{dr} \right|_R = \tan(\bar{\phi}_{es} - 90^\circ) \quad [17]$$

$$\left. \frac{dH_2}{dr} \right|_1 = 0 \quad [18]$$

This last condition is incorrect because the encapsulant does wet the crucible; however, this assumption has no effect on the predictions pertaining to the growing crystal and considerably simplifies the calculations by preventing interfaces from becoming very steep at the crucible. At the three-phase contact between melt, encapsulant, and crucible, the angle is set to 90° , as for the encapsulant/gas interface, *i.e.*

$$\left. \frac{dH_1}{dr} \right|_1 = 0 \quad [19]$$

Along the melt/crystal/ B_2O_3 contact curve, the melt/solid and melt/ B_2O_3 interfaces join

$$H_0(R) = H_1(R) \quad [20]$$

and the wetting angle $\bar{\phi}_{ms}$ for equilibrium crystal growth is met

$$\left. \frac{dH_1}{dr} \right|_R = \tan(\bar{\phi}_{ms} - 90^\circ) \quad [21]$$

For GaAs, $\bar{\phi}_{ms}$ is approximately 15° (25). This last constraint, Eq. [21], overspecifies the melt/encapsulant interface meniscus unless the crystal radius is determined simultaneously. We use Eq. [21] as the condition for determining R .

Finite-Element Analysis

Equations [1]-[21] define a complex nonlinear free-boundary problem which taxes previously developed numerical methods for solution. We have developed a finite-element/Newton method based on the techniques described in Ref. (9) for simultaneously computing the interface shapes and temperature field in each phase.

The regions of melt, crystal, and encapsulant are divided into quadrilateral elements as shown in Fig. 2 for approximate locations of the three interfaces and the crystal radius. The finite-element mesh is defined so that the unknown interfaces always fall along rows of nodes. As the correct solution is approached, the mesh deforms to follow the interfaces. A continuous temperature field is defined over the regions of the system (D_1, D_2, D_3) using polynomial basis functions $\{\Phi^i(\tau, z)\}$ as follows

$$\theta(\tau, z) = \sum_{i=1}^N \alpha_i \Phi^i(\tau, z) \quad [22]$$

where the coefficients α_i are a subset of the solution vector.

Within each element, the basis functions are isoparametrically mapped into a square "unit element" defined in a coordinate system (ξ, η) where $(-1 \leq \xi \leq 1,$

$-1 \leq \eta \leq 1)$. The coordinate system (ξ, η) is related to the cylindrical coordinate system of the element by

$$r = \sum_{i=1}^9 r_i \phi^i(\xi, \eta) \quad [23]$$

$$z = \sum_{i=1}^9 z_i \phi^i(\xi, \eta) \quad [24]$$

The elemental basis functions $\{\phi^i(\xi, \eta)\}$ are standard nine-constant biquadratic Lagrangian polynomials (26), and (r_i, z_i) are the locations of the element nodes. Note that (r_i, z_i) are determined by the positions of the interfaces.

The shapes of the three unknown interfaces are interpolated by one-dimensional quadratic finite-element bases $\{\Psi^i(\tau)\}$ as

$$H_i(\tau) = \sum_{j=1}^{N_i} \beta_{ij} \Psi^j(\tau) \quad [25]$$

with N_i as the number of nodes along the i th surface, and the coefficients $\{\beta_{ij}\}$, $i = 0, 1, 2$, are determined along with R as part of the solution. As with the temperature equations, the interface equations are mapped to a one-dimensional unit element in the radial direction. The elemental quadratic polynomials $\{\psi^i(\xi)\}$ are expressed in the transformed coordinate ξ , where $-1 \leq \xi \leq 1$.

The energy balances in each phase are discretized by the Galerkin finite-element method following the formalism of the isotherm method developed in Ref. (9). This reduces the field equations and the energy balances along boundaries, Eq. [1]-[11], to a set algebraic equations in terms of the coefficients for temperature and interface shape. These equations are

$$\begin{aligned} & - \int_{D_j} K_j \nabla \Phi^i \cdot \nabla \theta \, dV - \int_{D_3} \text{Pe} \Phi^i \frac{\partial \theta}{\partial z} \, dV \\ & + \int_{\partial D_0} \text{Pe} S \Phi^i (n_0 \cdot e_z) \, dS - \int_{\partial D_1} R \alpha_1 \Phi^i (\theta^4 - \theta_a^4) \, dS \\ & - \int_{\partial D_2} [\text{Bi}_2 \Phi^i (\theta - \theta_a) + R \alpha_2 \Phi^i (\theta^4 - \theta_a^4)] \, dS \\ & - \int_{\partial D_3} R \alpha_3 \Phi^i (\theta^4 - \theta_a^4) \, dS - \int_{\partial D_4} [\text{Bi}_4 \Phi^i (\theta - \theta_a) \\ & + R \alpha_4 \Phi^i (\theta^4 - \theta_a^4)] \, dS = 0, \quad i = 1, \dots, N \end{aligned} \quad [26]$$

They are nonlinear because of the term θ^4 in the radiation condition and because of the implicit dependence of the basis functions and the Galerkin integrals on the interface shapes. We represent these equations more compactly as

$$\hat{R}_i(x) = 0, \quad i = 1, \dots, N \quad [27]$$

with \hat{R}_i representing the set of residual equations for the temperature unknowns $x_i = \alpha_i$, for $i = 1, \dots, N$.

The interface shapes are determined from the Galerkin integrals of Eq. [12] and [14], which incorporate all the wetting angle conditions except Eq. [21]. These equations are

$$\int_0^R \Psi^i [\theta(\tau, H_0(\tau)) - 1] \tau d\tau = 0 \quad [28]$$

$$- \int_R^1 \left\{ \frac{\frac{d\Psi^i}{dr} \frac{dH_1}{dr}}{\left[1 + \left(\frac{dH_1}{dr}\right)^2\right]^{1/2}} + \text{Bo}_1 \Psi^i(H_1 + \lambda_1) \right\} \tau d\tau = 0 \quad [29]$$

$$- \int_R^1 \left\{ \frac{\frac{d\Psi^i}{dr} \frac{dH_2}{dr}}{\left[1 + \left(\frac{dH_2}{dr}\right)^2\right]^{1/2}} + \text{Bo}_2 \Psi^i(H_2 + \lambda_2) \right\} \tau d\tau$$

$$- \frac{\Psi^i \tan(\bar{\phi}_{es} - 90^\circ) R}{[1 + \tan^2(\bar{\phi}_{es} - 90^\circ)]^{1/2}} = 0 \quad [30]$$

or more compactly

Fig. 2. Sample finite element mesh. Mesh contains 320 elements and 1361 nodes. There are a total of 1415 unknowns for this system.

$$\hat{R}_i(x) = 0, \quad i = N + 1, \dots, N_t \quad [31]$$

where x_i represent the interface unknowns $\{\beta_{ij}\}$ of Eq. [25]. The remaining volume constraints, Eq. [15] and [16], and the condition for the equilibrium growth angle, Eq. [21], form the remaining residual conditions denoted as \hat{R}_{N_t+i} , $i = 1, 2, 3$, respectively.

The complete set of nonlinear residual equations is

$$\hat{R}(x) = \hat{R}(\alpha, \beta, R, \lambda_1, \lambda_2) = 0 \quad [32]$$

where the entire vector of unknowns is $x^T = (\alpha^T, \beta^T, R, \lambda_1, \lambda_2)$. In this form, the coupling between the temperature field and the shapes of the phases is obvious, as is the

Table I. Operating parameters

difficulty with convergence that one would expect with any iterative method for the solution of Eq. [32] which tries to satisfy the equations successively. The Newton method implemented here iterates simultaneously for the entire solution vector x .

At each iteration, the solution vector is updated according to the formula

$$x^{k+1} = x^k + \delta \quad [33]$$

where x^{k+1} is the new solution vector, x^k is the approximation to the solution vector from the previous iteration, and the correction vector δ is computed by solution of the matrix problem

$$\mathbf{J}\delta = -\hat{\mathbf{R}} \quad [34]$$

The Jacobian matrix \mathbf{J} has components $J_{ij} = \partial \hat{R}_i / \partial x_j$ which

Fig. 3. Isotherms and interface shapes for reference case (parameters listed in Table I). The finite element mesh used in this calculation is shown in Fig. 2. Isotherms for all plots are incremented by 23K ($\Delta\theta = 1.5 \times 10^{-2}$).

represent the sensitivity of the residuals vector to perturbations in the solution vector and are obtained by analytical differentiation of the residual equations.

The sensitivity of the residual equation to the locations of the three interfaces includes the effects on the basis functions of displacing the finite-element mesh; these terms are computed by the isoparametric mapping technique suggested by Saito and Scriven (27) and used by others (28, 29). The evaluation of these terms is carried out in the transformed coordinates (ξ, η) where the dependence of the basis functions on the element shape is explicitly given by the mapping equations [23] and [24]. The derivatives are evaluated in closed form because the relationships between the position of the nodes (r_i, z_i) and the interface shapes and crystal radius are known. The equations for mesh construction allow the finite-element mesh to be preferentially refined near the crystal and melt/solid interfaces.

The dependence of the residual equations on the unknowns gives \mathbf{J} the "arrow" matrix structure typical of free-boundary problems (9, 27). We solve the equation set Eq. [34] by Gaussian elimination using a computer code for banded matrices with the arrow structure. For the discretization shown in Fig. 2, a mesh of 320 elements (a maximum of 16 in the radial direction and 24 in the axial dimension), the equation set had 1415 unknowns, and each iteration required 110 cpu seconds on the Cray-1 computer at Bell Laboratories; over 90% of the cpu time was used in the Gaussian elimination for this large system of equations. For all calculations reported, quadratic convergence of the residuals to the solution was observed, as is expected for Newton's method. The convergence of a particular calculation is displayed in Fig. 6 below.

Results

Calculations were carried out for a prototype of a small-scale GaAs experimental system using the 320-element mesh shown in Fig. 2. A crucible of 5 cm radius was used for all calculations; crucible and ambient temperatures were 1.1 and 0.85 times the melting point of GaAs, respectively; the reference-case pull rate was 2.3 cm/h. The dimensionless groups appropriate for modeling GaAs growth were based on our best estimates for thermophysical data and are listed in Table I. Isotherms

and interfaces for the reference case are shown in Fig. 3. The crystal filled almost half the radius of the crucible, and the melt/crystal interface was concave upward into the crystal. The elevation of the melt/encapsulant "shoulder" was approximately 0.45 cm, and the deflection stretched less than 1 cm away from the crystal surface. In the region of the three-phase contact at the edge of the crystal, the isotherms in all three phases were very curved. The existence of pronounced radial temperature gradients in this region casts doubt upon the validity of one-dimensional heat-transfer models. Radiation from the submerged surfaces through the encapsulant is an important heat-transfer mechanism. This radiative flux acts as a heat sink along the interfaces and is noted by the change in sign of the temperature gradient across the melt/encapsulant and crystal/encapsulant boundaries.

The accuracy of the finite-element calculations was estimated by repeating the calculation of the reference case for several finite-element meshes smaller than the one pictured in Fig. 2. These results are shown in Table II and show the reliability of finite-element approximations constructed with even coarser element discretizations. For example, the crystal radius predicted using a mesh with only 80 elements (391 unknowns) gave a prediction for radius that differed only 2% from the result for the 320 element mesh.

The response of the heat-transfer model to various operating and thermophysical input data was determined by varying parameters about the reference case shown in Fig. 3. These results are discussed in the subsections below for variations of pull rate (Peclet number) and radiative heat loss (radiation number).

Varying pull rate.—Increasing the pull rate increased the amount of heat liberated per unit area of the melt/solid interface and caused it to become more concave with respect to the crystal. The rearrangement of the temperature field necessary to accommodate the extra latent heat drove the melt/solid interface higher. The need to dissipate the greater release of latent heat, coupled with surface tension acting through the melt/encapsulant interface, then decreased the radius of the crystal. Results for varying the pull rate between the reference of 2.3 cm/h ($Pe = 0.1$) and 18.7 cm/h ($Pe = 0.8$) are shown in Fig. 4 as plots of the isotherms in the melt, crystal, and encapsulant. The configurations of the finite-element mesh for

* Numbers in parentheses are relative differences between results for smaller meshes and mesh III, computed as $|(I) - (III)|(III)$.

Fig. 4. Changes in isotherms and interface shapes with increasing pull rate. All other parameters are held fixed at those listed in Table I

these different pull rates are shown in Fig. 5. The convergence sequences with Newton iteration of the calculations for each growth velocity are shown in Fig. 6 for calculations with the same first guess. Each iteration displayed quadratic convergence, *i.e.*, its slope between at least the last two iterates was less than -2 .

The axial temperature profiles along the centerline ($r = 0$) and the crystal edge ($r = R$) are presented in Fig. 7. Increasing the pull rate was expected to increase the temperature gradient in the crystal and decrease the gradient in the melt at the solidification front. As seen in Fig. 7, these trends were evident at the crystal center, but not at the edge. Radiative and conductive heat transfer from the perimeter of the crystal to the surroundings was intense enough to counterbalance the local increase in heat flux caused by higher pull rates. At the pull rate of 2.3 cm/h, the gradient in the crystal at the centerline is -85.5 K/cm, a value which is reasonable for growth of GaAs. Although

the interfacial temperature gradient measured from the melt decreased with increasing Pe , it did not reach zero, even at the highest pull rate; for $Pe = 0.8$, the dimensional temperature gradient was -2.4 K/cm. Thermal supercooling must occur at a yet higher pull rate.

Over the range of pull rates, 2.3–18.7 cm/h, the crystal radius decreased from 2.73 to 1.70 cm, as shown separately in Fig. 8. The proposed relation between crystal radius and pull rate for Czochralski growth derived by Billig (17) predicted that the crystal radius was proportional to the inverse square of the pull rate, or in dimensionless form, $R \propto 1/Pe^2$. Fitting this form to the results of the model leads to the equation

$$R = 0.0776/Pe^2 \quad [35]$$

Kim *et al.* (30) suggested that the radius and pull rate of a Czochralski crystal be correlated as $R = A/(Pe + B)$, where A and B are constants set by the heat transfer in the fur-

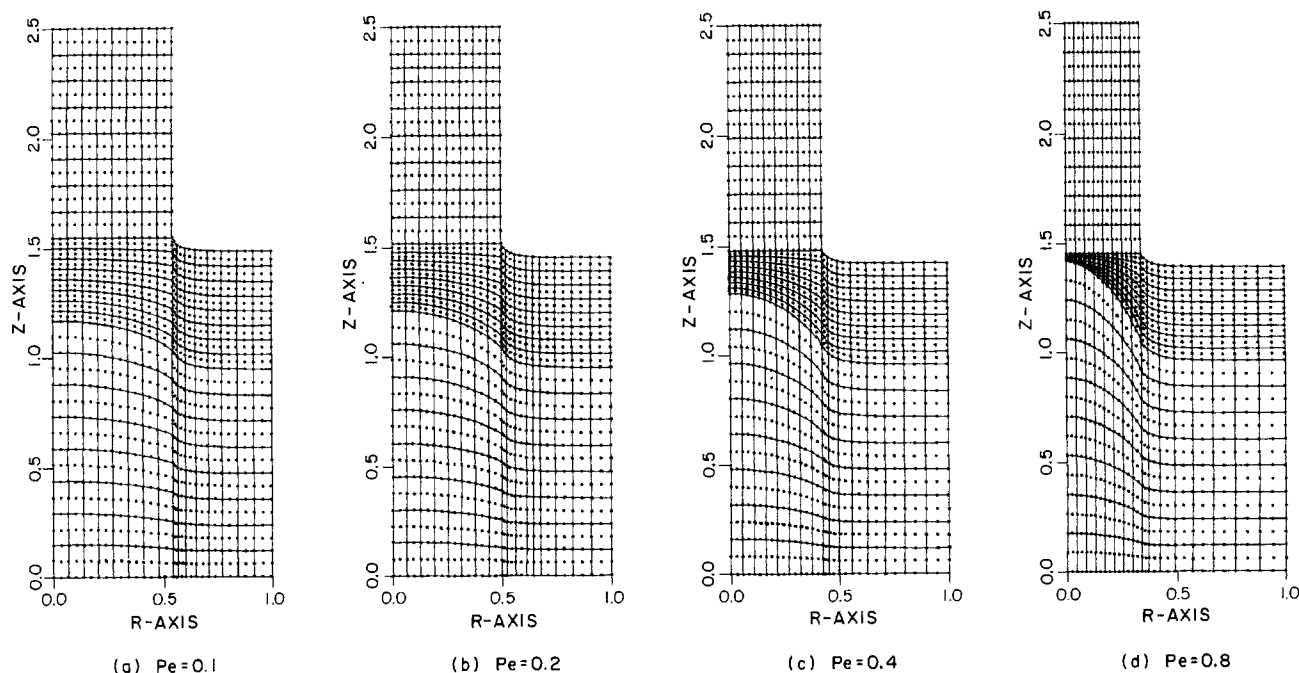

Fig. 5. Finite element meshes for the isotherms and interface shapes shown in Fig. 4

Fig. 6. Convergence of finite element solution with Newton iterations for calculations shown in Fig. 4.

nance. Fitting the data for $Pe = 0.1$ and $Pe = 0.2$ to determine A and B yields

$$R = 0.568/(Pe + 0.941) \quad [36]$$

Both of these relations are plotted, along with the finite-element results, in Fig. 8 for the entire range of growth rates. The agreement with the correlation of Kim *et al.* is excellent (the correlation coefficient was 1.0000), whereas the derivation of Billig does not fit the finite-element results at all (correlation coefficient was 0.68). This is not surprising, because Billig's assumptions of a thermally supercooled melt next to the melt/solid interface and a one-dimensional crystal temperature field in this region were not met by the results of the two-dimensional thermal-capillary model used here.

Varying volume of encapsulant.—The effect of increasing the volume of the encapsulant on the temperature field and the crystal radius was complicated by geometrical interaction of the depth of the B_2O_3 with the size of the crystal. The variation of this depth for the same volume of B_2O_3 and different growth rates is seen in Fig. 4. The depth of the layer measured at the crucible wall varied from 2.27 to 2.1 cm as the pull rate was changed from 2.3 to 18.7 cm/h.

Calculations were carried out for four volumes of encapsulant with all other operating parameters held fixed at the values for the base case; the isotherms and interfaces for these calculations are shown in Fig. 9. The calculations for $V_c = 0$ were for a system without the encapsulant layer and with radiation and convection directly from the now melt/gas meniscus to the ambient. As expected, increasing the amount of the low-conductivity encapsulant inhibited heat transfer from the melt and crystal and resulted in smaller crystals for a given pull rate (2.3 cm/h). Several other features of these calculations were much less obvious.

The melt/crystal interface was more concave with deeper encapsulant. Increasing the depth of the B_2O_3 caused a greater portion of the heat transfer from the melt to occur by conduction through the crystal. The increased heat flux into the crystal near the melt/crystal/ B_2O_3 contact caused the temperature field to be more two-dimensional there; however, the axial temperature gradient at the melt/crystal interface changed little with increasing depth of encapsulant. The magnitude of the radial temperature gradient was proportional to the curvature of the melt/crystal interface.

The axial temperature profiles along the centerline and perimeter of the crystal are shown in Fig. 10 for the base case and three different depths of B_2O_3 . The axially averaged radial temperature differences decreased with in-

creasing encapsulant depth, but the relative deflection of the melt/solid interface did not decrease because of the increased distortion of the temperature field there.

Varying radiative heat transfer.—The importance of the description of radiation through the encapsulant and to the environment was verified by the sensitivity of the results to changes in the emissivities along the surfaces. Isotherms and interface shapes are shown in Fig. 11 for two different sets of radiation numbers. The first corresponded to a factor-of-two decrease in ϵ along all radiating boundaries ($Ra_i = 0.4$), whereas the second was performed with lower emissivities on only the surfaces with the encapsulant, *i.e.*, $Ra_{1,3} = 0.4$ and $Ra_{2,4} = 0.8$. Halving the radiative flux along all the surfaces drastically decreased the radius of the crystal to $\bar{R} = 0.61$ cm [see Fig. 11(b)], flattened the melt/crystal interface, and increased the temperature gradient next to the solidification front. The added resistance to radiation along both menisci inhibited radiation through the B_2O_3 to the extent that the temperature gradients on either side of the boundaries with the encapsulant had the same sign.

Specifying the emissivity along interfaces with the B_2O_3 to be lower than along surfaces with the gas lowered the influence of radiation, but did not eliminate it, as is seen by examining the temperature gradients along the internal surfaces in Fig. 11(c). Here the crystal radius was decreased to 1.29 cm, compared to 2.73 cm for the reference case. The interface shape was flattened and the axial temperature gradient was increased. The largest value of the gradient along the center of the crystal still appeared at the solidification interface; however, the gradient was more uniform near the melt/crystal surface than in the reference case.

Discussion

The two-dimensional model for liquid-encapsulated Czochralski growth presented here is the first to give simultaneous predictions of the crystal shape and temperature field in this system. The accuracy of the calculations depends on the accuracy of the heat-transfer model used in each phase and across phase boundaries, and it depends on the reliability of the thermophysical properties used in the model. The calculations for the prototype of a small-scale growth system given in the "Results" section above predict reasonable dependence of the crystal radius on growth rate and reasonable axial temperature gradients. Müller *et al.* (5) have recently measured temperature gradients in an InP crystal growing in a LEC system. They report temperature gradients near 80 K/cm at the interface and higher gradients as the crystal is pulled through the B_2O_3 . The melt/crystal interface was convex to the crystal in all the experiments reported in Ref. (5). In our calculations, the maximum axial temperature gradient occurred at the solidification front and the interface was concave. The qualitative discrepancies between our results and these experiments may be linked to the method used by Müller *et al.* for measuring axial temperature profiles. In their experiment, the thermocouple was moved upward through the melt and incorporated into the growing crystal during seeding at the initial stages of growth. Enough crystal had not been grown, so the assumption of a uniform radius protruding from the encapsulant was not satisfied. Under these conditions, heat transfer to the ambient changes continuously with time, so the experiments can only be simulated using a transient analysis which accounts for the variations of the radius with time.

Also, the heat transfer through the crucible sides and bottom also plays an important role in setting the magnitude and curvature of the radial temperature gradients and the interface shape in a LEC system. Heat losses through the usually unheated bottom of the crucible cause the temperature at the center of the crucible to be lower than at the sides and can result in interfaces that are convex to the solid at the centerline and result in the formation of solid on the bottom of the crucible. Radiation from the wall of the bare crucible to the crystal also

Fig. 7. Variations of axial temperature profiles along centerline ($r = 0$) and at the crystal radius ($r = R$) for pull rates of Fig. 4.

increases the temperature along the edge of the boule and makes the interface more convex. These effects may be responsible for the differences between the experimental results in Ref. (5) and our calculations, as will be discussed in another communication where the crucible is included in the calculations (31).

The simple model used for radiation through the B_2O_3 to the surroundings is a major source of error in the

finite-element modeling of LEC growth. The limited calculations on the sensitivity to the parameters in the radiation model suggest that small changes in the emissivities can make large differences in the crystal radius and in the temperature distribution in the crystal. A more complete model of radiation along these surfaces is probably needed before computations can be compared quantitatively with experiments. The most serious limitation of

Fig. 8. Variation of crystal radius as a function of pull rate. All other parameters were held fixed at reference values. The dashed curves represent the relations of Billig, Eq. [35], and Kim et al., Eq. [36].

any modeling of LEC growth may be the lack of information on radiation through the B_2O_3 . The assumption of total transparency of this molten glass is undoubtedly poor, especially when even a small amount of water is present in the encapsulant layer (32). More complex heat-transfer models that account for absorption in the B_2O_3 and for reflected radiation are probably not justified without better experimental data on the radiation properties of B_2O_3 .

Even with the simple radiation model, the complete calculation of operating states for a LEC system is a powerful tool for understanding the interactions of various heat-transfer mechanisms and capillarity. Moreover, the numerical method described in the "Finite-Element Analysis" section above is the basis for studies of stability of the entire growth process, for the determination of transfer functions for control algorithms, and for complete simulation of transients in the process that occurs during

seeding of the melt. Each of these extensions is made feasible because of the use of the Newton iteration scheme. The Jacobian matrix used at each step in this iterative procedure is needed in computer-aided algorithms for the calculation of parametric sensitivity and stability (8, 33, 34) and in fully-implicit methods for time integration of the dynamic problem (35). Previous stability analyses for the Czochralski process and other meniscus-defined growth systems have either neglected the interactions of heat transfer with capillarity (19, 36) or have used entirely empirical expressions for the effects of heat transfer (37, 38). The stability analysis based on the entire two-dimensional model used here will give an accurate assessment of the importance of the thermal-capillary coupling in the control of conventional and liquid encapsulated Czochralski growth systems.

ABSTRACT

Infrared, Raman, and x-ray diffraction measurements were used to study films obtained by chemical vapor deposition from SiH₄ and N₂O gases. A wide range of N₂O/SiH₄ ratios (γ) were used to examine the existing phases inside the film, oxidation states of the oxide phases, and crystallite growth of the silicon phase on subsequent heat-treatment. The as-deposited films were composed of an amorphous genuine silicon phase and an oxide phase SiO_x, with x values from 1.38 to 1.63 for γ from 0.5 to 24. Reconstruction of both phases occurred by subsequent heat-treatment in N₂ atmosphere. The sizes of the silicon crystallites formed in the silicon phase by subsequent heat-treatment were related to oxygen content of the film. Comparing reported electric and optical properties with results obtained in this study, we proposed a new model of the films, in which the silicon and oxide phases formed a complicated three-dimensional network. The model consistently explained all the observed film properties.

Much interest has been directed towards chemical vapor deposited silicon oxide films, obtained from SiH₄ and N₂O gases, which can be used for passivation (1-2), nonvolatile memory devices (3), and heterojunction transistors (4). Such films are commonly referred to by the acronym SIPOS (semi-insulating polycrystalline silicon), or silicon-rich silicon dioxide. Through investigations using transmission electron microscopy (TEM) (5, 6), reflection high-energy electron diffraction (RHEED) (7), x-ray photoelectron spectroscopy (XPS) (6, 8), Raman (9), infrared (IR) (10), and IR-visible absorption (11) measurements, the structural image of the films has become clear to a certain extent. However, interesting points still remain regarding oxidation state of the films, morphology of the silicon phase, and structural arrangement of silicon and oxide phases when both are present in the films.

In this paper, accurate determinations of film oxygen content were made by radioactivation analysis. These results formed the basis for evaluation of film oxidation state and existing phases in the as-deposited film. Changes in oxidation state of the oxide phase and morphology of the silicon on subsequent heat-treatment of specimens in a N₂ atmosphere were examined through IR absorption, Raman, and x-ray diffraction measurements. A model was proposed to explain the electrical and optical properties of the films.

Experimental

Film deposition.—An ordinary chemical vapor deposition reactor was used to deposit the films at atmospheric pressure by reactive decomposition of silane (SiH₄) and nitrous oxide (N₂O) diluted in N₂ gas. The deposition tem-

perature was 650°C. In order to obtain a range of oxygen contents in the films, the reactant gas flow ratios N₂O/SiH₄ (designated γ) were varied from 0 to 24. As a matter of convenience for radioactivation analysis of oxygen, the film thickness was varied from 0.22 to 0.75 μ m. High purity (111) FZ silicon plates (oxygen content <10¹⁷ at./cm³) with thicknesses of 300 μ m and 1 mm were used as film substrates for radioactivation analysis and IR absorption measurements, respectively; 1 mm thick fused silica was used as a substrate for the Raman and x-ray diffraction measurements.

Radioactivation analysis.—For accurate determination of film oxygen content, a radioanalytical method using activation by the ¹⁶O(³He, p)¹⁶F reaction was employed. Steam oxidized silicon dioxide film 1.05 μ m thick and having a density of 2.12 \pm 0.02 g/cm³ was used as a reference. Details for activation analysis are given in the literature (12). The maximum error in the oxygen content (atomic percent [a/o]) was estimated to be within 10%.

Infrared measurements.—The IR spectra were recorded from 4000 to 400 cm⁻¹ by a Hitachi spectrometer (EPI-G3), with the reference being the same as the specimen (1 mm thick silicon plate).

Raman measurements.—For the Raman measurements, an argon ion laser line of 514.5 nm wavelength with 100-300 mW power was used as an incident beam with a spot diameter of about 10 μ m. The spectrometer was a JRS-400D (JEOL). The maximum spectral resolution was about 1.0 cm⁻¹, and the tracking error in the wave number was 0.3 cm⁻¹. The Raman scattering was measured with a backscattering configuration.

X-ray diffraction measurements.—In order to investigate sizes of the silicon crystallites in the film, x-ray diffraction patterns were taken of the film. The diffractometer was a Rigaku Geigerflex RAD-rA, and the incident x-ray line was $\text{CuK}\alpha$.

Results

Oxygen content as a function of gas flow ratio γ .—Oxygen content of the as-deposited films as obtained by radioactivation analysis are summarized in Table I. The film thickness measured by Taylor Hobson Talystep I are also given in the same table. The oxygen content increased with the gas flow ratio γ . The relationship between oxygen content α (atomic percent) and γ was approximately given by $\alpha = \beta \log \gamma + \epsilon$, where β and ϵ were about 11 and 20, respectively. This expression differed slightly from that given by Mochizuki *et al.* (2), probably owing to differences in the reactors employed. The oxygen content at $\gamma = 0$ was not zero, owing to oxygen contamination of the reactor walls and gas transfer tube.

Infrared spectra.—The IR absorption spectra for as-deposited films are shown in Fig. 1. The peaks located between $1000\text{--}1100\text{ cm}^{-1}$ shifted slightly to higher wave number with increasing γ , while the 875 cm^{-1} peak remained constant. The 800 cm^{-1} peak was scarcely observable for the $\gamma = 24$ specimen. As shown in Fig. 2, when there was no internal stress in a homogeneous oxide film SiO_x , there was a simple relation between x and the main peak position (between $980\text{--}1082\text{ cm}^{-1}$) (13). Comparing Fig. 1 with Fig. 2, the x values were from 1.38 to 1.63 for the films prepared from $\gamma = 0.5\text{--}24$, which were in good agreement with the $x = 1.4$ value obtained by XPS (5). Assuming that the whole film was composed of a homogeneous oxide, the oxygen contents were accordingly given from 58 to 62 a/o. These values were significantly different from those given in Table I, suggesting that the films were not composed simply of a homogeneous oxide phase.

X-ray, electron diffractions, and Raman spectra.—In order to investigate the phase (or phases) of the films, x-ray and electron diffraction patterns and Raman spectra of the films were measured. The x-ray and electron diffraction patterns indicated that the constituent phase (or phases) of all the films was amorphous, which was in agreement with the findings of Nagashima and Kubota (14) that the silicon phase was amorphous for chemical vapor deposition from SiH_4 under 650°C . As shown in Fig. 3, a broad but obvious peak was observed around 480 cm^{-1} in the Raman spectra for all the films on both silicon and fused silica substrates. It coincided with that of the amorphous silicon phase in the Si:H film prepared in a hydrogen plasma (15). Accordingly, the peak could be assigned to the amorphous silicon phase. Based on the IR and Raman results, the films were regarded as composed of a genuine silicon phase and a silicon oxide phase SiO_x , with $x = 1.38\text{--}1.63$.

Calculation of oxygen content from IR absorption.—When the films were composed of only genuine silicon and SiO_x phases, their oxygen content could be obtained

Table I. Gas flow ratio, thickness, oxygen content, and volume ratio of SiO_x . Deposition temperature: 650°C

No.	Gas flow ratio (γ)	Thickness (μm)	Oxygen content ^a α (a/o)	Volume ratio of SiO_x ^b (R)

independently of radioactivation analysis by using IR absorption intensities. The IR absorption intensities per unit thickness of integrated optical density between $700\text{--}1400\text{ cm}^{-1}$ for homogeneous oxide SiO_x has already been given as a function of the position (cm^{-1}) of the infrared main peak (13). The intensity ratio relative to SiO_2 is also shown in Fig. 2. From this relation, together with the integrated intensity between $700\text{--}1400\text{ cm}^{-1}$ of the experimental spectra shown in Fig. 1, R , the volume ratio of SiO_x to the entire film, was easily calculated. The values are summarized in Table I. The R values increased with increasing oxygen content. Using this ratio, the oxygen content of the film as an atomic ratio was given by $Rx B_{\text{SiO}_x} / [R(1+x)B_{\text{Si}} \rho_{\text{SiO}_x} + (1-R)(B_{\text{Si}} + x \cdot B_{\text{O}}) \rho_{\text{Si}}]$, where B

and ρ indicated atomic weight and density, respectively, for the subscripted species. Since the actual density of SiO_x in the film was unknown, but differences in density among silicon, SiO, and SiO_2 prepared by heating SiO in air were small [e.g., 2.33 (16), 2.16 (13), and 2.27 (13) g/cm^3 , respectively, the last value coincides with that for thermal SiO_2 (16)], its value was approximated to be the mean of those for SiO and SiO_2 (e.g., 2.22 g/cm^3). The maximum error in oxygen content due to this approximation was estimated to be within 10%. The IR results are shown in Fig. 4 vs. those from radioactivation analysis. Deviation from 1:1 correspondence was within 15%, indicating that the films were composed of only genuine silicon and SiO_x phases.

Changes in IR spectra by heat-treatment—The films at $\gamma = 0, 1, 4,$ and 8 were heated from 700° to 1100°C for 1 h in an N_2 atmosphere. As shown in Fig. 5 for the $\gamma = 4$ specimen, the wave number of the main peak located between 1000 – 1100 cm^{-1} shifted to the higher wave number side with higher heat-treatment temperatures. The peaks at 875 – 880 cm^{-1} seen for the as-deposited and 700°C heat-treated specimens disappeared for the specimen heated at 800°C . Instead, a new peak appeared at around 800 cm^{-1} , which shifted to 815 cm^{-1} on heating at 1100°C . However,

Fig. 4. Correlation of oxygen content obtained by IR and radioactivation (RA) analysis.

Fig. 5. Changes in the IR absorption spectra for various heat-treatment temperatures ($\gamma = 4$ specimen).

the absorption intensity in the 700 – 1400 cm^{-1} region was hardly changed by increased heat-treatment temperatures. Almost the same feature was seen for the other specimens. Changes in the main peaks are shown in Fig. 6. These results indicated that the oxidation state x of the film oxide phase increased up to SiO_2 when the heat-treatment temperature was increased, and suggested that the concentration of oxygen atom into the oxide phase, or escape of silicon atom from the oxide phase, occurred. Comparing this change of absorption intensity with the intensity ratio shown in Fig. 2, a slight amount of oxygen impurity appeared to be taken into the oxide phase by the

Fig. 6. Changes in main peak position with heat-treatment temperatures.

increased heat-treatment temperatures. The peak positions around 1100 and 800 cm^{-1} for the specimens heated above 1000°C were shifted to higher wave number over those for SiO_2 (e.g., 1082 and 800 cm^{-1} , respectively). These abnormal peak shifts were attributed, not to an increased oxidation state of $x > 2$, but to internal compressive stress in the oxide phase due to differences in thermal expansion coefficients between oxide and silicon substrates. However, since the changes in main peak positions on heating for peaks above 1080 cm^{-1} were smaller than those for peaks under 1080 cm^{-1} , the contribution from internal compressive stress to shifts in the main peak position was estimated to be small as compared to that from the increase in oxidation state x .

Changes in crystalline size of silicon.—Silicon crystallites appeared in the films after heat-treatment. The crystallite size of silicon, D , estimated by the Scherrer equation for x-ray diffraction

$$D = K \lambda / \beta \cos \theta \quad [1]$$

is shown in Fig. 7 vs. heat-treatment temperature, where K is a constant and selected as 0.90, λ is the incident x-ray wavelength, β the full width of the half maximum of the diffraction peak, and θ the Bragg angle. For the $\gamma = 0$ specimen, crystallites of about 10 nm appeared on both silicon and fused silica substrates when the specimen was heated at 700°C. The size remained fairly constant up to 900°C, and then increased rapidly on heating above 1000°C. For the other specimens which contained more oxygen, no crystallites appeared on heating, even at higher temperatures. For the $\gamma = 1$ specimen, a few crystallites, smaller than those for the $\gamma = 0$ specimen, appeared on heating at 900°C. The higher the oxygen content of the film was, the higher the temperature at which crystallites appeared was. The size of a (111) silicon crystallite and averaged size of (220) and (311) crystallites on silica substrate were almost the same. However, the (111) crystallite was easier to grow at lower temperatures than

Fig. 7. Changes in crystallite sizes of silicon with heat-treatment temperatures.

(220) and (311) crystallites. The same features were observed for the specimens on the silicon substrate, although the size of the (111) crystallite was not (Fig. 7). The crystallite size at the nucleation temperature of the crystallite became smaller according to the increased oxygen content in the film. These observations were similar to those reported by Hamasaki *et al.* (5), although the exact sizes of the crystallites differed.

Changes in Raman spectra on heat-treatment.—The Raman spectra for the specimens for $\lambda = 0, 1$, and 4 heated at 700°-1100°C are shown in Fig 8-10, respectively. A sharp peak appeared around 500-520 cm^{-1} on heat-treatment. The intensity scale with the same laser power (about 150 mW) is given in the figures. The temperatures at which the sharp peak appeared coincided with those of the crystallite nucleation described in the preceding subsection. Accordingly, the sharp peak was assigned to the lattice vibration of the silicon crystallite, as demonstrated by Iqbal *et al.* (15) for Si:H prepared by glow discharge. The detection sensitivity for crystallite appearance was greater for Raman measurements than for x-ray diffraction measurements. In all the figures, the crystallite peak grew with the rise in heat-treatment temperatures, and a corresponding decrease in the amorphous peak. As shown by the dotted curves in Fig. 9, the intensity ratio (crystallite to amorphous phase) was separable for specimens on both substrates. Although silicon peaks (amorphous and crystallite) of the film became difficult to observe for the specimens with high oxygen content (thin film), owing to overlapping with the substrate peaks, they could be obtained by subtracting the substrate spectrum from the mixed spectrum. The width of the crystallite peaks for specimens on silica substrate was more than twice as broad as that for those on silicon substrate, although the mean crystallite sizes were the same on both. This must result from inhomogeneity of the crystallite size and the internal stress on the silicon crystallites, the latter of which is described below.

Raman peak position and crystallite size.—Accurate positions of the Raman peaks were observed. The relation-

Fig. 8. Raman spectral changes with heat-treatment for $\gamma = 0$ specimens. The values in the figure indicate intensity scale for the same incident laser power.

Fig. 9. Raman spectral changes with heat-treatment for $\gamma = 1$ specimens. The values in the figure indicate intensity scale for the same incident laser power.

ships between Raman peak positions and mean sizes of (111), (220), and (311) silicon crystallites, as obtained by x-ray diffraction, are summarized in Fig. 11. Correlations differed between specimens on silicon substrate and those on fused silica. The peak position (wave number)

for specimens on silicon substrate increased with increased crystallite size, and reached that of a single crystal of silicon (520.5 cm^{-1}) when crystallite size was more than 150 nm. This tendency was the same for Si:H as predicted by the slab model (17). However, the peak positions for specimens on silica substrate had a maximum of about 508 cm^{-1} at crystallite sizes around 11 nm, and decreased gradually with larger crystallites. The difference between both correlations could be attributed to the internal stress subjected to the silicon phase. When the thermal expansion coefficient of a substrate material is smaller than that of a film material, the film material is subjected to a tensile stress at room temperature after heating the specimen at high temperatures, and vice versa, as often seen for silicon on insulator (18). Since the thermal coefficient of the fused silica is much smaller than that of silicon crystal, the silicon crystallites should be subjected to a large tensile stress at room temperature after heat-treatments of the specimen; the higher the treatment temperature, the larger the tensile stress. The difference in peak positions on both substrates was explained by this effect. When the silicon crystallite is subjected to hydrostatic pressure τ , τ can be estimated by the shift $\Delta\nu$ of the Raman peak (F_{2g}) of the stressed crystal from that of an unstressed crystal (19) as

$$\tau (\text{N/m}^2) = -2.09 \times 10^8 \Delta\nu (\text{cm}^{-1}) \quad [2]$$

In derivation of Eq. [2], the values of elastic constants given by Kittel (20) and the parameters (p and q) given by Chandraseker *et al.* (21) were used. Since the silicon crystallites on the silicon substrate were subjected to no stress, the stress for the specimens on the silica substrate was given by the difference in peak positions for specimens on both substrates. Anomalous internal tensile stresses of $2.1 \pm 0.6 \times 10^9 \text{ N/m}^2$ for 5-10 nm size crystallites and $3.1 \pm 0.8 \times 10^9 \text{ N/m}^2$ for 15-20 nm size crystallites on fused silica were obtained. The decrease in peak wave number for increasing crystallite sizes over 11 nm was explained by the fact that the specimens which included large crystallites experienced higher temperatures than those which included small crystallites.

Discussion

Oxidation state of the oxide phase.—A number of opinions have been put forward regarding the oxidation state of films, especially for as-deposited amorphous specimens. Knolle and Maxwell (10) stated that the as-deposited film was composed of a homogeneous oxide phase, and the shift of the main IR peak located at $1000\text{--}1100 \text{ cm}^{-1}$ on changes in oxygen content of the film deposited at low pressure (LP SIPOS) occurred from mixing of SiO_2 character (mixture model). However, they used Philipp's statistical model (random bonding model) (22) for the films deposited at atmospheric pressure (AP SIPOS). There are some points to resolve in their discussion. First, the films are not composed of a homogeneous phase, but are heterogeneous phases of silicon oxide (SiO_x) and genuine silicon as demonstrated in this paper and Hartstein *et al.* (9). Second, the mixture model and random bonding model contradict each other; only one model must be employed to explain the oxide phase in the film. As for the oxidation state of the oxide phase, there has been proposed a model (6, 8) in which the oxide is composed of a mixture of the stoichiometric species of Si, Si_2O , SiO , Si_2O_3 , and SiO_2 (mixture model) as based on the chemical shifts observed in XPS studies. However, the stoichiometric intermediate phase between Si and SiO_2 is uncertain. The 875 cm^{-1} peak seen in Fig. 1 and assigned by Ritter (23) as the vibrational mode of Si_2O_3 , could be assigned to a vibrational mode from a structural combination of the species of silicon tetrahedra $\text{Si}(\text{O}_y\text{Si}_{4-y})$ (13) ($y = 2, 3, \text{ and } 4$) given by Philipp's bonding model (22). In the IR spectra, we could not observe any evidence for an intermediate phase between the Si and SiO_2 phases. In XPS studies, we can only observe the bonding character such as Si^0 , Si^+ , ..., Si^{4+} , which suggests no intermediate oxide phase. Accordingly, only Si

Fig. 10. Raman spectral changes with heat-treatment for $\gamma = 4$ specimens. The values in the figure indicate intensity scale for the same incident laser power.

Fig. 11. Peak position of the Raman band vs. crystallite size for specimens on silicon and fused silica substrates.

and SiO_2 stoichiometric species remain in the mixture model. When the oxide is a mixture of Si and amorphous SiO_2 , we can always observe IR absorption peaks at around 1080, 800, and 450 cm^{-1} due to the SiO_2 phase, although peak shifts of several tens of cm^{-1} sometimes occur, owing to internal stress and porosity of the oxide (24). As seen from Fig. 1, we could not observe any evidence that the oxide was composed of Si and SiO_2 phases. Accordingly, the mixture model is inadequate to explain the oxidation state of our films. On the other hand, the shift of the main peak to higher wave number side and the disappearance and appearance of the 875 and 800 cm^{-1} peaks, respectively, according to increases in the oxidation state, could be reasonably explained with Philipp's bonding model. When the value x in oxide SiO_x is given, the probability P_y of each bonding type $\text{Si}(\text{O}_y\text{Si}_{4-y})$ ($y = 0, 1, \dots, 4$) is given by

$$P_y = N_y (1 - 0.5x)^{4-y} (0.5x)^y \quad [3]$$

where N_y indicates the number of possible arrangements in each type. Using Eq. [3], the mean probabilities for SiO_x character of the oxide phase of our as-deposited films were found to be from 0.22 to 0.47 for γ values from 0.5 to 24; these results were quite different from those of Knolle and Maxwell (10). Thus, the oxide phase in the films must be understood as SiO_x whose chemical bonds are given by the Philipp's bonding types $\text{Si}(\text{O}_y\text{Si}_{4-y})$. The chemical shifts seen in the XPS studies (6, 8) are reasonably explained by the random bonding model.

Microstructure of the film.—On the basis of TEM and x-ray diffraction observations of films, Hamasaki *et al* (5) proposed a microstructure film model; the grains of the oxide phase were separately embedded on the silicon phase (separate grain model). However, the question remains whether this simple model can consistently explain the electric and optical properties of the film and the crystal growth in the silicon phase. The large changes in resistivity (2) and bandgap (25) with change in oxygen content suggested that interruption of the electron current by the oxide phase was more influential than expected by the separate grain model.

Kwark and Swanson (11) observed absorption coefficients between 0.5–2.5 eV for films prepared with γ values

from 0.62 to 3.2. Comparing Table I, the volume ratios of silicon phase in their films could be estimated to be located from 0.77 ($\gamma = 0.5$) to 0.62 ($\gamma = 4$). From the data given by Kwark and Swanson [Fig. 1 in Ref. (11)], it could be found that a small amount of volume decrease of the silicon phase gave rise to a large decrease in the absorption coefficients at the energy region (1.5–2.3 eV) where absorption was mainly brought about by bulk silicon. This suggested that the interface between silicon and oxide phase was arranged so that the surface areas of both phases were much larger than those estimated by the separate grain model.

The fact that the crystallite sizes hardly grew with increasing heat-treatment temperatures up to 1000°C indicated that the crystal growth of the silicon phase was more restricted by the oxide phase than could be predicted by the separate grain model. From the viewpoint of the film growth kinetics, it was reasonable for each phase to grow continuously, in the growth direction, in the forms of columns or veins, as for Si:H (26). These columns or veins had branchings due to fluctuations in surface temperatures and reactant gas flows; they intersected each other at certain points.

From these considerations, we can imagine a model in which a considerable part of the surface of both phases is surrounded by the other phases in a manner such that both penetrate each other. However, one phase is not completely enclosed by the other. Accordingly, each phase forms a three-dimensional network with thinner and thicker parts within the mesh. We call our model the three-dimensional network model. With this model, we can consistently explain the electric and optical properties, the silicon crystallite growth, and the ease of reconstruction of both phases in the film on heat-treatment. The semi-insulating property of the film can be attributed to the interruption of electric currents at the thinner parts of the silicon veins enclosed by oxide phase. The increase in silicon crystallite size on heat-treatment over 1000°C must originate in a breakdown of the thinner part of the oxide network, and subsequent union of the silicon phase. The mean mesh sizes of the silicon phase for as-deposited specimens must be almost the same as the crystallite sizes of silicon at the nucleation temperatures.

Conclusion

Films obtained by chemical vapor deposition from SiH_4 and N_2O gases were studied. Infrared, Raman, and x-ray diffraction measurements were employed to evaluate the existing phases inside the film, the oxidation states of the oxide phase, and crystallite growth of the silicon phase on heat-treatment. The conclusions are as follows.

1. The as-deposited films were composed of an amorphous genuine silicon phase and an oxide phase SiO_x , with $x = 1.38\text{--}1.63$ for flow ratios ($\text{N}_2\text{O}/\text{SiH}_4$) = 0.5–24.
2. The oxidation state of the oxide phase increased with increasing heat-treatment temperatures in a N_2 atmosphere; the reconstruction of both phases occurred.
3. On heating the specimens in N_2 atmosphere, silicon crystallites grew inside the silicon phase. The sizes of the crystallites and the nucleation temperatures were closely related to the oxygen content of the films; the higher the oxygen content, the smaller the crystallites were, and the higher the nucleation temperatures.
4. The peak position of the Raman band due to silicon crystallites was closely related to the crystallite sizes and internal stress experienced by the film. When crystallite sizes were known, the stress could be estimated by the difference in Raman peak positions between stressed and unstressed films.
5. The silicon crystallites on silica substrate were subjected to a large tensile stress, *i.e.*, about $2.1\text{--}3.1 \times 10^9 \text{ N/m}^2$.
5. The oxidation states of the oxide phase could be analyzed by Philipp's bonding model. From this model, peak shifts in the infrared absorption and the chemical shifts in the XPS of the oxide phase were consistently explained as changes in the oxidation state x .

6. The silicon and oxide phases in the film formed a complicated three-dimensional network (network model). From this model, electric, optical properties, and crystallite growth of silicon from the amorphous silicon phase were consistently explained.

High Field Phenomena in Thermal SiO₂

C. Glenn Shirley¹

Motorola, Incorporated, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

ABSTRACT

High field phenomena in thermally grown SiO₂ have been investigated by a combination of three techniques: (i) current-voltage characterization, (ii) CV measurements, and (iii) forced-current voltage-time characteristics. Comparison with theoretical Fowler-Nordheim predictions was used in the current-voltage technique. Four oxide thicknesses were studied: 160, 345, 652, and 1452Å. All structures were nonrecessed Al/SiO₂/Si capacitors of various areas. The substrate was n-type silicon. Interface trap formation and charging with electrons near the cathode during injection from Si was observed for all oxides. Creation of immobile holes in the oxide valence band by impact ionization was observed for the thicker oxides, but not the thinnest. Bulk trapping was significant when electrons were injected from Al into the thicker oxides. The Al/SiO₂ interface was considerably leakier in thicker oxides than predicted by the Fowler-Nordheim theory. It is important to consider these high field phenomena in reliability questions because they constitute a true wear-out mechanism for intrinsic (*i.e.*, with no defects) thermal oxides. As oxides become thinner in devices, high field phenomena become a more practical concern.

As integrated circuits shrink, thinner thermal oxides of silicon are required to withstand higher electric fields. This is beginning to change the situation with regard to oxide reliability. Historically, oxide reliability has been limited by defects which have early breakdown characteristics. Much has been done to predict and minimize defect-related failure rates. Statistical methods have played a large role in this. A common procedure is to screen devices by applying a high voltage during an accelerated test. The surviving population has a large reduction in early failure rate at the cost of a small loss in manufacturing yield. This rationale does not apply if oxides fail by a true wear-out mechanism. This is because accelerated stress weakens the entire population. The thin oxides used in VLSI processing must be more nearly defect-free because they must withstand higher fields. Thus, increasingly, reliability is being limited not by defects but by the intrinsic high field processes we shall be examining in this report. The main problem is not that devices will suffer wear-out in operation, but that the likelihood of stressing devices into wear-out during the accelerated testing used to screen devices. Hence the importance of studying the high field behavior of thermal oxides.

The purpose of this paper is to review intrinsic high field phenomena in thermal oxides and to demonstrate

how they may be observed. With this report as a guide, we are in a good position to characterize quickly the high field behavior of any gate oxide system (silicides, etc.).

In this study, three kinds of data were acquired: (i) IV data, (ii) CV data, and (iii) the *V-t* characteristics obtained when a constant current is forced through the MOS capacitor. All three types of data were gathered as function of capacitor area and oxide thickness. No area dependence beyond simple scaling of current and capacitance with area was found. That is, edge effects were negligible. The study was carried out on the Al/SiO₂/n-type Si system.

Theoretical Background

Figure 1 shows a schematic of the well-known (1, 2) band structure of the Al/SiO₂/Si MOS diode. Electrons in Si or Al have high potential barriers at the interface to surmount before they can enter the SiO₂. As the potential difference across the oxide is increased, the barrier at the negative (electron injecting) electrode becomes sharply triangular. When the barrier thickness, *d*, at the Fermi level of the injecting electrode becomes of the order of 50Å, appreciable numbers of electrons can enter the oxide conduction band by quantum tunneling through the interfacial barrier. By simple trigonometry, this occurs at an electric field of about $\phi_{si}/d \approx 3.0 \text{ eV}/50 \times 10^{-8} \text{ cm} \approx 6 \times$

¹Present address: Intel Corporation, Chandler, Arizona 85224.

Fig. 1. Band diagram of Si/SiO₂/Al system shown with aluminum biased positive relative to silicon.

10⁶ V/cm. The barrier height for electrons at the Si/SiO₂ interface is denoted by ϕ_{Si} . Once in the conduction band of the oxide, the electrons have high mobility [20-40 cm²/V-s, Ref. (1)] and move rapidly to the anode. Some electrons may fall into the fairly numerous traps at about 2 eV below the oxide conduction band, but they will immediately tunnel out of them at the high electric fields necessary to cause injection from the cathode. Holes injected from the anode have a much higher barrier (4-5 eV) to surmount than electrons, and holes are known to have a very low mobility in the oxide [2 × 10⁻⁵ cm²/V-s, Ref. (1)]. The low hole mobility is probably due to the large number of shallow hole traps just above the valence band of SiO₂ due to strained Si-O bonds. Hence, the number of injected holes and their influence on conduction is negligible in our experiments. Hot holes can be injected into SiO₂ by avalanche injection from n-type silicon driven into deep depletion, but this condition does not occur in our experiments.

When a constant current is forced into a MOS capacitor, the leakage current-voltage-time characteristic appears as shown schematically in Fig. 2. The leakage current is the forced current less the displacement current. The displacement current can be calculated from $I(\text{disp}) = C(dV/dt)$ where C is the capacitance of the MOS capacitor and dV/dt is the instantaneous rate of increase in voltage. The IV characteristic of the oxide is shown as a projec-

Fig. 2. Schematic of leakage current-voltage-time characteristic. At high fields, the IV characteristic changes with time as charge builds up in the oxide. The time-dependent deviation from the ideal Fowler-Nordheim law at high fields depends on oxide thickness.

tion on the IV plane, while the V-t characteristic obtained when a constant current is forced is shown as a projection on the V-t plane. Figure 2 summarizes the various regimes of importance in the electrical behavior of thermal oxide. At low electric fields, no charge is injected from the electrodes, but electrons will be ejected from shallow traps and will flow to the anode. This is the origin of the flat part of the IV curve labeled "trap emptying." We will not be examining this regime in this report, but we indicate in passing that techniques measuring trap filling and emptying transients at low fields can be used to gauge oxide quality. At higher electric fields, quantum tunneling at the electron injecting electrode (cathode) becomes dominant and the IV characteristic follows the Fowler-Nordheim (FN) law (3-5) (labeled "FN conduction" in Fig. 2). The FN characteristic can be extended to lower fields by maintaining a bias in the trap emptying regime to drain the shallow traps before taking the FN trace. This "uncovers" the FN characteristic at lower fields (4). At high fields, just prior to breakdown, the IV characteristic deviates from the FN law in a time-dependent fashion (4-6) labeled "high-field prebreakdown" in Fig. 2. It is important to realize that the measured injected current depends on the local electric field in the oxide at the cathode. This is the same as the average field across the oxide only if there is no charge in the dielectric. The average field is what is experimentally measured. Therefore, the high field deviations from the FN law are due to charging in the oxide. The charges take time to build up. Hence, the high field deviations from the FN law are time dependent. These charges are intimately related to the intrinsic (that is, nondefect-related) breakdown mechanism. This report is about the FN conduction regime, and the high field prebreakdown regime and the time dependence of the latter. This report does not consider the yield issues associated with defect-caused breakdowns. While this is of great importance, our focus is on the intrinsic properties of the oxide.

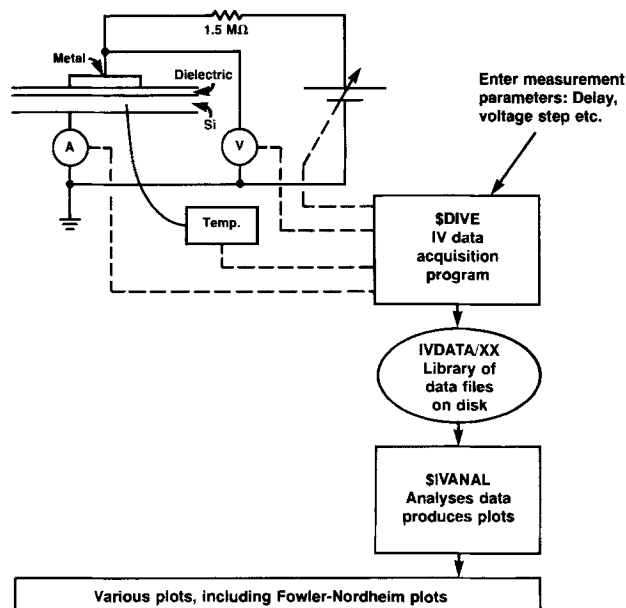

Fig. 3. Computer-automated IV data acquisition and analysis system

Sample Preparation

Four $\langle 100 \rangle$ n-type phosphorous-doped wafers with $N \approx 5 \times 10^{14} \text{ cm}^{-3}$ were separately thermally oxidized using a standard HCl cycle. Only the time in the growth part of the cycle was varied to change the thicknesses of the oxides. The oxide thicknesses were measured using an IBM Film Thickness Analyzer (FTA). The thicknesses obtained are shown in Table I. We shall see later that better agreement between theory and experiment for the IV data of wafer 5 was obtained if the thickness of the thinnest oxide is taken to be 160\AA rather than the 144\AA given by the IBM FTA. Much of the data analysis will use 160\AA instead of 144\AA . This is a reasonable correction, since the IBM FTA gives estimates consistently lower than other thickness measurement techniques such as ellipsometry, CV, etc. Next, 1000\AA of aluminum was deposited on the wafers and then patterned into arrays of rectangular capacitors of various areas. The wafers were then annealed at 450°C for 30 min in forming gas. Finally, the oxide was stripped from the backs of the wafers using an HF fume. All wafers were processed identically except for the growth part of the oxidation cycle.

Electrical Measurements

Current-voltage measurements.—Current-voltage characteristics were measured using the system shown in Fig. 3. A Tektronix 4051 computer controls a Kepco BOP500M bipolar power supply with 500V range. The current flowing from the chuck to ground is monitored by a Keithley 616 electrometer and transmitted to the computer by a

custom interface built in our laboratory. The voltage on the probe is measured by a Fluke 8502A digital multimeter and transmitted to the computer via the general purpose interface bus (GPIB). There is also provision for heating or cooling the sample under computer control, but this was not used in these experiments. All measurements were done at room temperature. The program \$DIVE controls the instruments and acquires the data. The voltage applied to a MOS capacitor was increased in approximately 1V steps until electrical breakdown of the oxide occurred. A 4s delay after each voltage step allowed displacement current transients to decay. IV characteristics were obtained in this way on 25 and 625 mil^2 capacitors in both positive and negative polarities. Each characteristic was obtained on a virgin capacitor, and measurements for any given set of conditions were repeated on virgin capacitors to ensure reproducibility.

Once the data were acquired, they were saved in a library of data files, IVDATA (Fig. 3), on a floppy disk reserved for data. Also saved are an identifying string, the area of the capacitor and the thickness of the oxide. These files can be read by the program \$IVANAL and various types of plots can be generated. Of particular importance in this study are Fowler-Nordheim (FN) plots: $\log J/E^2$ vs. $1/E$, where J is the current density and E is the average field across the dielectric (i.e., $E = \text{total voltage drop/oxide thickness}$). The FN plots for 25 mil^2 capacitors for four oxide thicknesses in both polarities are shown in Fig. 4 and 5. The plotting program ignores the sign of the voltage drop across the oxide except that data taken with

Bottom left: Wafer 7, 652\AA . Bottom right: Wafer 8, 1453\AA .

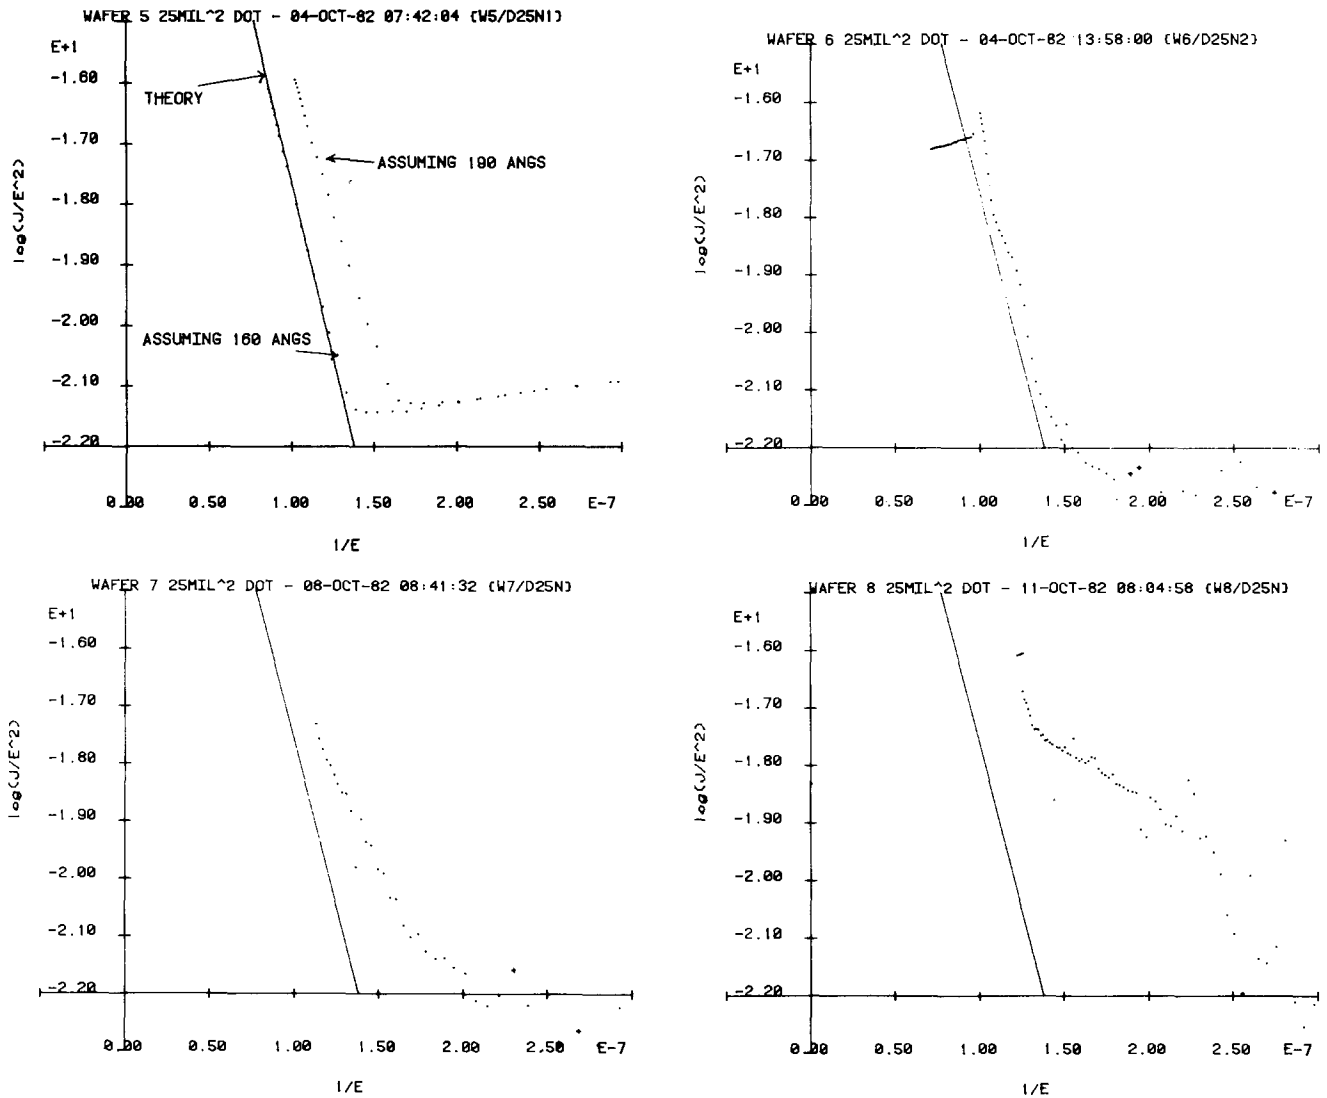

Fig. 5. Fowler-Nordheim plots for injection from aluminum for various thicknesses of thermal SiO₂. Theory shown as solid lines. Top left: Wafer 5 assuming $t_{ox} = 160\text{\AA}$ and $t_{ox} = 190\text{\AA}$. Best agreement with theory for $t_{ox} = 160\text{\AA}$. Top right: Wafer 6, 345Å. Bottom left: Wafer 7, 652Å. Bottom right: Wafer 8, 1453Å.

Al biased positive is plotted with “+” signs, while data with the opposite polarity is plotted with dots. Note also that many of the computer-generated plots have “E + 1” near the end of the x- or y-axis. This means that the appropriate scale numbers are to be multiplied by 10. In general $E + n$ means multiplication by 10^{+n} . The IV characteristic was taken to breakdown so that the smallest value of $1/E$ on a plot is taken as a measure of (the reciprocal of) the breakdown field, E_b . The same kind of data was obtained for 625 mil² capacitors and identical curves were obtained, except that E_b tended to be lower.

It is valuable to compare our experimental data with theoretical expectations. Fowler-Nordheim tunneling has received considerable attention in the literature over the years (3-5), so that there is now a good consensus of opinion regarding the J - E characteristic for various electrode materials. This is summarized in a recent paper by Weinberg (5). The FN characteristic is

$$J/E_c^2 = C \exp(-\beta/E_c) \tag{1}$$

where E_c is the cathode field, where

$$C = q^3 m / (16\pi^2 \hbar m_{ox} \phi_0) = 1.54 \times 10^{-6} (m/m_{ox}) / \phi_0 \text{ A/V}^2 \tag{2}$$

and

$$\beta = (4/3)(2m_{ox}\phi_0^3)^{1/2} / (q\hbar) = 6.83 \times 10^7 (m_{ox}/m)^{1/2} \phi_0^{3/2} \text{ V/cm} \tag{3}$$

In Eq. [2] and [3], q is the electronic charge, m is the elec-

tron rest mass, m_{ox} is the electron effective mass in the oxide, \hbar is Planck's constant divided by 2π , and ϕ_0 is the height above the electrode conduction band in electron volts of the barrier at the cathode. It is important to understand that it is the electric field at the electron injecting interface, the cathode, which governs the current density. In Fig. 1, the cathode electric field in the oxide is represented by the slope of the oxide energy bands at the cathode. A consensus of the literature (5) is that $m_{ox} = 0.5m$, $\phi_{Al} = 3.13 \text{ eV}$, and $\phi_{Si}(100) = 2.96 \text{ eV}$. The aluminum barrier height is to be used in Eq. [2] and [3] for injection from aluminum, i.e., aluminum biased negative relative to the substrate, while ϕ_{Si} is to be used for aluminum biased positive relative to the substrate. If we assume negligible charge in the oxide, then the cathode field, E_c , equals the average field and we may use Eq. [1] with the consensus parameters to compare the theoretical predictions with our data. This is done by superimposing the theoretical J - E relationship, shown as the solid straight lines, over our data in the FN plots in Fig. 4 and 5.

Corrections were applied to the raw IV data before plotting it in Fig. 4 and 5. The corrections caused an appreciable change from the raw data only for the thinnest oxide; nonetheless, the corrections were applied to all of the data. The measured voltage drop across the MOS diode should be corrected for band bending at the silicon surface and the metal-semiconductor work function difference to give the actual potential drop across the oxide (8). For Al negative, voltage was increased slowly enough that the inversion layer in the silicon always had time to

Fig. 6. Breakdown electric field for injection from aluminum. Thermal oxides on n-type silicon (Y58).

form. This means that the usual equilibrium theory (9) may be used to compute these corrections. The corrections amount to about a volt (a bandgap) in inversion, and less in accumulation. This can be an appreciable correction for thin oxides. Specifically, the total potential, V_{TOT} , of aluminum relative to bulk silicon is related to the voltage drop across the oxide, V_{ox} , by

$$V_{TOT} = \phi_{MS} + V_{ox} + \Psi_s(E_s) \quad [4]$$

where $\Psi_s(E_s)$ is the semiconductor surface potential relative to the bulk as a function of the field E_s at the semiconductor surface. E_s is related to V_{ox} by

$$E_s = (K_{ox}/K_s)(V_{ox}/t_{ox}) \quad [5]$$

Equation [4] assumes that there is no charge in the oxide. In strong inversion (9) ($V_{ox} < 0$), we have

$$\Psi_s = -(kT/q) \ln [(E_s^2 K_s \epsilon_0 n) / (2kT n_i^2)] \quad [6]$$

while in accumulation ($V_{ox} > 0$)

$$\Psi_s = (kT/q) \ln [(E_s^2 K_s \epsilon_0) / (2kT n)] \quad [7]$$

where ϵ_0 is the permittivity of the vacuum, k is

Boltzmann's constant, q is the electronic charge, T is the absolute temperature, K_{ox} is the oxide dielectric constant, n_i is the intrinsic electron concentration, and n is the bulk electron density. The Eq. [4]-[7] give a relationship between V_{TOT} and V_{ox} . When parameters appropriate to the substrate and metal used in this experiment ($\phi_{MS} = -0.33V$, $n = 5 \times 10^{14} \text{ cm}^{-3}$) are substituted into the equations we find that over the range of voltages for which FN conduction occurs, the difference between V_{ox} and V_{TOT} is practically constant. In accumulation (fortuitously), $V_{TOT} = V_{ox}$, while in inversion $V_{TOT} = V_{ox} \times 1.26V$. This holds for all four oxides tested. Thus, in practice only the data for injection from aluminum was corrected. Even with this correction, the thinnest oxide FN data deviated appreciably from theory. It was possible to adjust the assumed thickness of the thinnest oxide upwards by 16 to 160Å and get excellent agreement with the FN theory simultaneously for injection from Si and from Al². It is known that the IBM FTA tends to underestimate the thickness of thin oxides, so careful ellipsometer measurements were made. With the refractive index forced to $n = 1.465$ (He-Ne laser), a thickness of 190Å was found. The ellipsometer data were definitely inconsistent with 160Å and, *a fortiori*, 144Å, provided $n = 1.465$. On the other hand, 190Å is inconsistent with the "consensus" parameters in the FN theory, as can be seen in Fig. 4 and 5. Thickness estimates from CV measurements agreed with the ellipsometer estimates. There are several possible explanations for these discrepancies: (i) the refractive index of the oxide is different from the $n = 1.465$ assumed in the

²It is worth noting that simultaneous agreement with theory for both polarities is not possible for any thickness unless the band bending and work-function difference corrections are applied.

ellipsometer calculations. If the refractive index is not forced to a value, then the ellipsometer data give $t_{\text{ox}} = 160\text{\AA}$ and $n = 1.8$. (ii) The oxide has a complicated graded optical structure. (iii) The thin oxide has a lower interfacial barrier than the thicker oxides. Adjustment of the barrier heights to give agreement with theory for both polarities assuming $t_{\text{ox}} = 190\text{\AA}$ gives $\phi = 2.67\text{ eV}$. (iv) The electronic effective mass is different for thin oxides or (v) some other reason. We are unable to resolve this discrepancy, but it seems that the IBM FTA reading is definitely low. We shall take 160\AA as the thickness of the thinnest oxide for much of the discussion which follows. The thicker oxides have good agreement with FN theory without any of these corrections. Nonetheless, the band bending and work-function difference corrections were applied to the data for the thicker oxides. This discussion shows that detailed interpretation of thin oxide FN data is considerably more complicated than for thicker oxides.

Several observations can be made from the FN plots in Fig. 4 and 5 and their deviations from theory.

1. For injection from Si, the IV data agree well with FN theory except at high fields just below breakdown. The nature of the deviation at high fields depends on oxide thickness. For the 1453\AA oxide, the data deviate from the FN theory to higher current densities. For the thinnest (160\AA) oxide, the deviation from the FN theory is to lower current densities. For intermediate oxide thicknesses, deviation is first to the high side of the FN curve and then lower as E increases.

2. For injection from aluminum, the current-voltage data agree well with the FN theory only for the thinnest oxide. As the oxides become thicker, the deviation from the FN theory increases, all in the direction of higher current densities. That is, the films are "leakier" than predicted by the FN theory. As the electric field increases,

the IV characteristic for the thicker films approaches the FN curve.

3. The electric field at breakdown as determined from all of the IV data taken is shown as a function of oxide thickness in Fig. 6 and 7. Two main trends are apparent: (i) the well-known increase in breakdown field for decreasing oxide thickness (10), and (ii) the breakdown field for smaller capacitors tends to be higher than for larger capacitors, especially for thinner oxides. The IV characteristics for the large and small area capacitors are in excellent agreement when scaled according to area, but for the larger area capacitors the current density does not reach quite as high a value before breakdown occurs. It is difficult to interpret the area dependence of E_b without sampling a large number of dots to obtain statistical data.

Capacitance-conductance-voltage measurements.—Because the IV data were so reproducible, it was feasible to carry out ac capacitance-conductance-voltage (CGV) measurements on virgin capacitors using stresses comparable with those used in the IV measurements. The CGV data give information on charging and interface state generation which occurs during the conduction process. Two types of CGV data are acquired: (i) data as a function of stress level held for fixed times at each level, and (ii) data as a function of time at a fixed stress.

Isochronal CV data with varying stresses.—The IV traces were examined and a series of stresses extending into the prebreakdown region, but avoiding breakdown, was chosen. The electric fields ranged from 5 MV/cm to 9 or 10 MV/cm in 1 MV/cm steps. An initial CGV trace was taken on a virgin capacitor. Then, an alternating series of stress and trace was carried out with increasing electric field stress but exactly the same trace conditions. Each stress level was held for 10s at room temperature. Fig. 9. CV data for injection from Si, i.e., Al was biased positive. Traces were taken at 10 kHz and 25°C. Trace 1 is for the virgin capacitor. Subsequent traces were made after successively higher electric field stresses starting at 5 MV/cm and increasing in steps of 1 MV/cm. Each stress was held for 10s at 25°C.

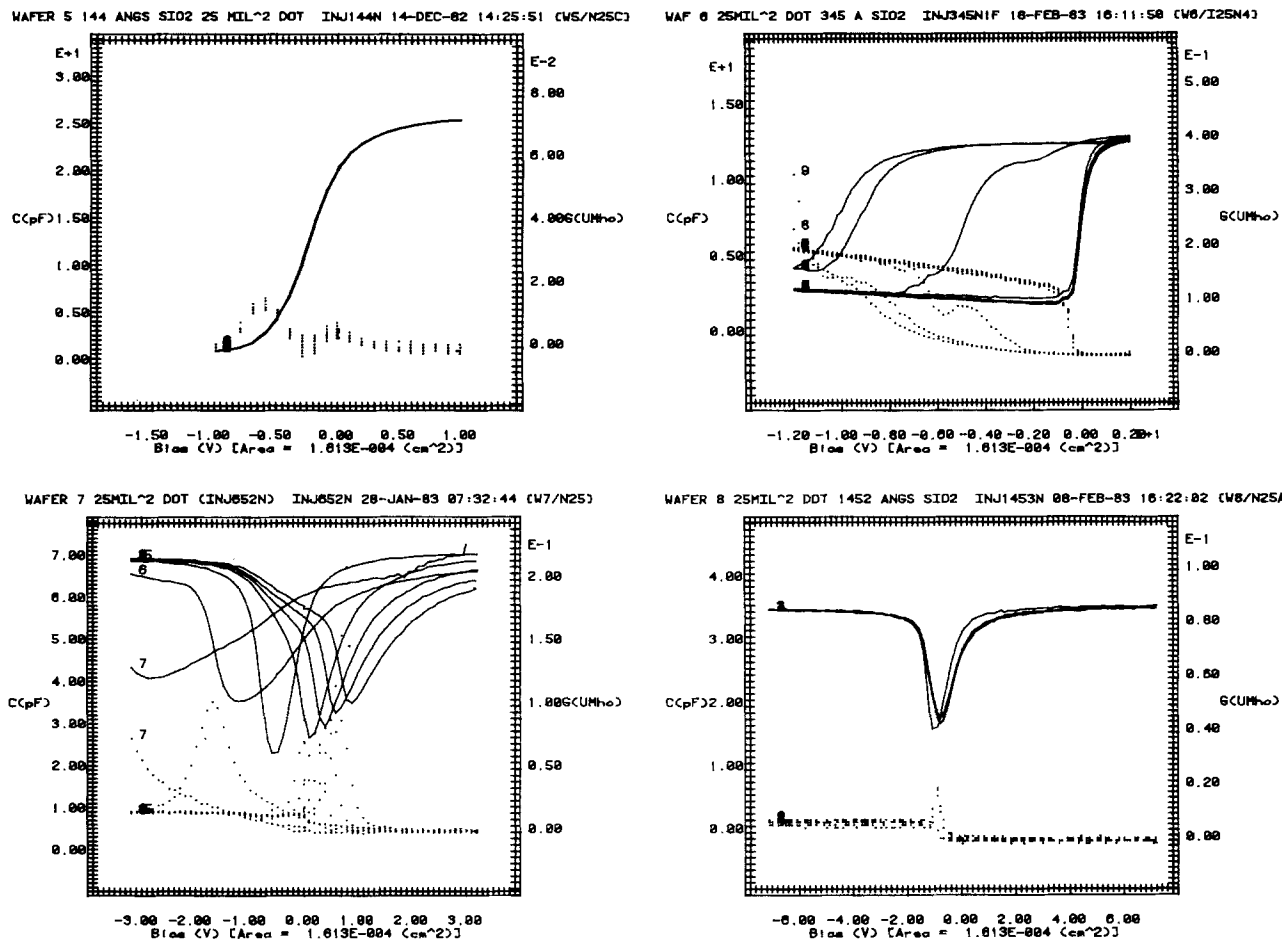

Fig. 10. CV data for injection from Al, i.e., Al was biased negative. Traces were taken at 10 kHz and 25°C. Trace 1 is for the virgin capacitor. Subsequent traces were made after successively higher electric field stress starting at 5 MV/cm and increasing in steps of 1 MV/cm. Each stress was held for 10s at 25°C.

was done in both polarities. There was insufficient bias capability in our CGV measurement equipment to stress the 1453Å oxide into the prebreakdown region. The automatic CV system in our laboratory is well suited to this

type of measurement because a complicated sequence may be set up off line and then executed whenever a measurement is needed. The system is described in detail elsewhere (11). A typical procedure definition is shown in Fig. 8.

Fig. 11. Cumulative flatband voltage shifts after stress at successively higher electric fields. For injection from silicon. Taken from CV data in Fig. 9. Trace 1 is after 5 MV/cm stress for 10s, trace 2 is after 6 MV/cm stress for 10s, etc. Top: all data. Bottom: Expanded voltage scale.

Fig. 12. Cumulative flatband voltage shifts after stress at successively higher electric fields. For injection from aluminum. Taken from CV data in Fig. 10. Trace 1 is after 5 MV/cm stress for 10s, trace 2 is after 6 MV/cm stress 10s, etc. Top: All data. Bottom: Expanded voltage scale.

CGV data obtained in this way were quite reproducible. Typical sets of traces are shown in Fig. 9 and 10. Figure 9 shows data for injection from silicon, while Fig. 10 shows data for injection from aluminum. The shifts of the flatband voltage from the flatband voltage of the first trace were obtained from the data of Fig. 9 and 10 and plotted vs. stress level in Fig. 11 for injection from Si and in Fig. 12 for injection from Al. This was done automatically, using a CV analysis utility in the CGV data acquisition system (11). In Fig. 11 and 12, a positive ΔV_{FB} corresponds to a rightward shift of the CV trace and a negative change in the oxide film. Quantitatively, the relation between ΔV_{FB} and charge induced in the film is

$$\Delta V_{FB} = -\bar{x}Q_{tot}/(\epsilon_0 K_{ox})$$

where Q_{tot} is the total charge induced in the film by the stress which caused the shift and \bar{x} is the location of the centroid of the distribution of the induced charge, measured from the Al/SiO₂ interface. In the following discussion, a flatband shift is interpreted qualitatively as charge in the film, but it must be kept in mind that the magnitude of the shift depends on the position of the charge as well as its magnitude. The data in Fig. 9-12 may be interpreted as follows.

Wafer 5, $t_{ox} = 160\text{\AA}$.—No flatband shifts occur for either polarity, so no charge was induced in the film, except, possibly, close to the Al/SiO₂ interface. For injection from Al no change occurs in the traces. But for injection from Si, the traces become more and more distorted (but unshifted) as the stress increases. The slight shifts shown in

Fig. 11 are just a reflection of the distortion of the traces in Fig. 9, rather than true shifts. Note particularly the large increase in the conductance peak (G) after the final 10 MV/cm pulse. This will be examined in more detail below.

Wafer 6, $t_{ox} = 345\text{\AA}$.—For injection from Si, lower field strengths induce small positive charges until the 9 and 10 MV/cm pulses induce large positive charges. For injection from Al, lower field pulses induce small negative charges, but eventually the 10, 11, and 12 MV/cm produce large positive charges which swamp the earlier-induced negative charge.

Wafer 7, $t_{ox} = 652\text{\AA}$.—Flatband shifts of either polarity were relatively easy to induce. For injection from Si, increasing stress levels induced moderate positive charges until a 9 MV/cm stress caused a large amount of positive charge. For injection from Al, increasing strength pulses cause increasing amounts of negative charge until the 9 and 10 MV/cm pulses reduce the net charge, and even begin to make it positive.

Wafer 8, $t_{ox} = 1453\text{\AA}$.—Slight negative charging occurred for injection from Al, and slight positive charging was seen for injection from Si. High fields could not be obtained because of the limits of our equipment.

CV data as a function of time at a fixed stress level.—A series of CGV measurements was undertaken to measure the accumulated change due to a given stress held for increasing accumulated time. This gives an idea of the times required to produce charging, etc. A trace (or

traces) which characterize the oxide were alternated with stresses of fixed duration and voltage. All traces and stresses were done at room temperature.

Wafer 5, $t_{ox} = 160\text{\AA}$.—The changes in the thinnest oxide due to high field stresses show up as distortions in the CGV traces, Fig. 9 and 10 upper left, rather than as flatband shifts. We therefore decided to take a series of traces at different frequencies to display the effect of fast states being created at the injecting interface. In Fig. 13, we show frequency series CGV data. At the top left is the data for a virgin capacitor. After 10s at 10 MV/cm with injection from Al (top right, Fig. 13), there is no discernable change in the CGV characteristics. This capacitor was then stressed for 10s at 10 MV/cm with injection from Si (bottom left, Fig. 13) and distortion of the CV traces at low frequency was seen. Also, the conductance is seen to have a peak in the depletion region of the CGV plots. A further pulse of 10s at 10 MV/cm with injection from Si caused further distortion in the CV plots and further growth of the peak in G (bottom right, Fig. 13). This was repeated with injection from Si four additional times. The distortion of the low frequency C plot increased, as did the peak in G. The conductance data in Fig. 13 are replotted in Fig. 14 as $G/2\pi f$ vs. $\log f$ (f = frequency) with bias as a parameter. The density of interface traps, N_{it} , is proportional to $G/2\pi f$ (12). An increase in N_{it} causes a proportional increase in $G/2\pi f$. We have taken the height of the envelope of curves at 100 kHz in Fig. 14 as a measure of N_{it} in arbitrary units. In Fig. 15, we have plotted N_{it} in these arbitrary units after each of the pulses described above. It is clear from Fig. 15 that injection from Al causes no increase in the fast states at the Si/SiO₂ interface. However, injection from Si causes increases in N_{it}

which are beginning to saturate after about 60s of accumulated injection at 10 MV/cm. Another measurement was made in which a positive 10s, 10 MV/cm pulse was the first stress on a virgin capacitor. The increase in N_{it} due to this is also shown in Fig. 15. This demonstrates reproducibility and that injection from Al in the first series had no effect on subsequent developments, owing to injection from Si.

Wafer 6, $t_{ox} = 345\text{\AA}$ and wafer 7, $t_{ox} = 652\text{\AA}$.—For these wafers, the main effect of the stress in the prebreakdown region is to shift the flatband voltages. For both wafers, single 10 kHz CGV traces alternated with room temperature stresses. Each stress was held for 2s. The electric field was 10 MV/cm for wafer 6 and 9 MV/cm for wafer 7 since 10 MV/cm caused breakdown of the oxide on wafer 7. The results are shown in Fig. 16. Careful comparison reveals that the results of Fig. 16 are consistent with those of Fig. 11 and 12. We could not produce fields in the prebreakdown region of wafer 8 with our CV equipment. Therefore, there are no data for the time dependence of the flatband voltage for the thickest oxide.

For wafer 6, positive charge generation reaches a limit after 6s of injection from Si at 10 MV/cm. The time to reach the steady-state flatband shift is considerably slower (10s) for wafer 6 when injection is from Al, but the final flatband shift is the same whichever electrode is injecting.

An electric field of 9 MV/cm for injection from Al on wafer 7 does not seem to be enough to create any positive charge, but it does seem to be sufficient to detrapp any electrons (negative charge) trapped at lower fields. This seems to be true for all the oxides because all of the curves in Fig. 12 cross the X-axis near 9 MV/cm. Figure

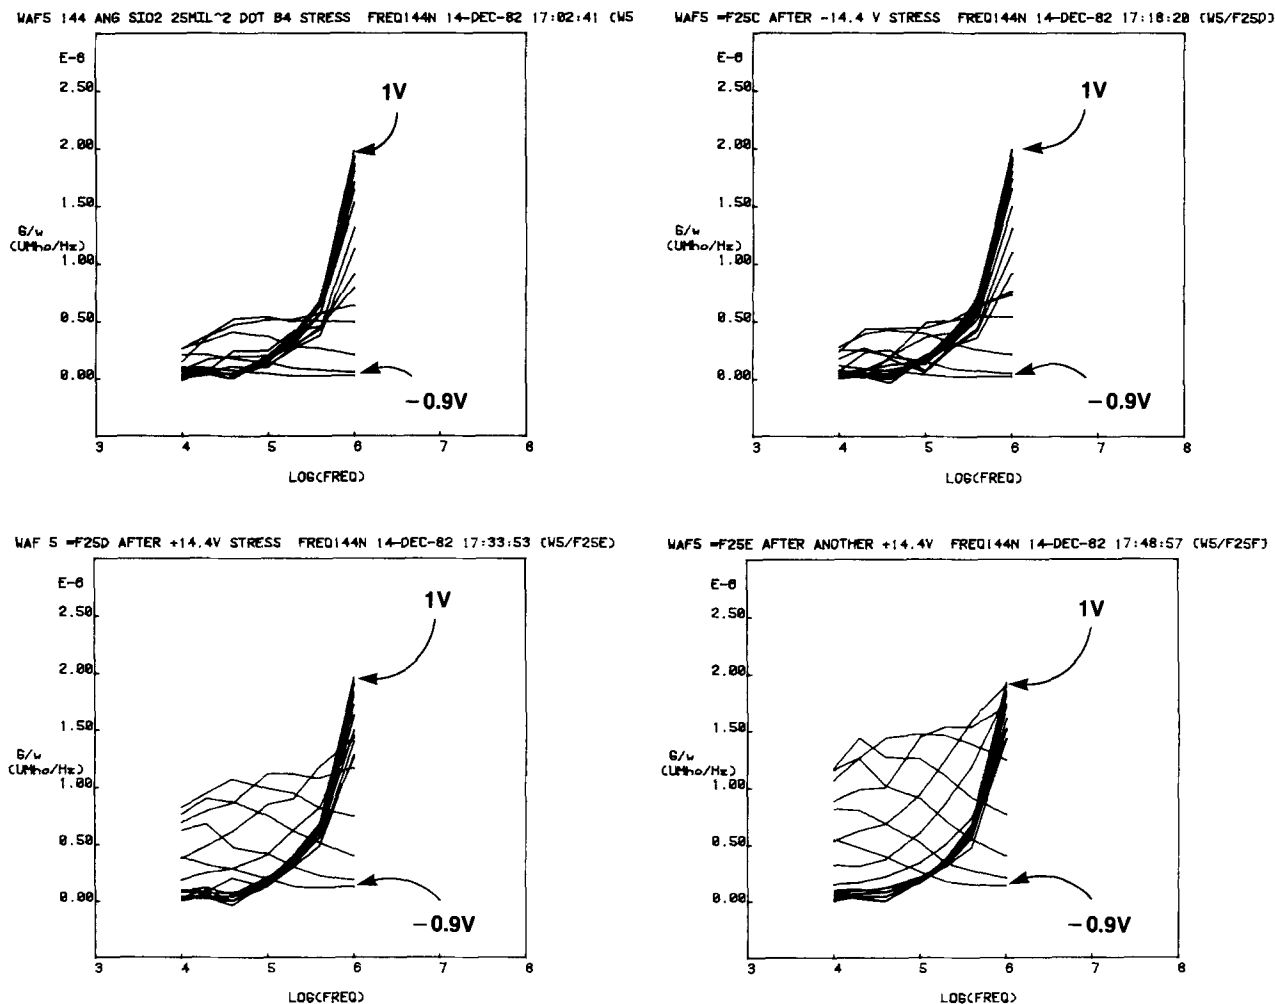

Fig. 14. GV data from Fig. 13 replotted as $G/2\pi f$ vs. $\log f$ (f = frequency) with bias as a parameter. The curves are plotted at 0.1V intervals for biases ranging from -1 to 1V.

Fig. 15. The effect of high electric-field charge injection on N_{it} . For wafer 5: n-type (Y58), $t_{ox} = 160\text{\AA}$, capacitor area = 25 mil^2 . Pulse width = 10s, pulse height = 10 MV/cm.

16, bottom, shows that this condition can be maintained as a steady state. Injection from Si induces positive charges at lower fields than injection from Al, as can be seen from Fig. 11 and 12. Thus, for wafer 7, injection from Si at 9 MV/cm caused considerable positive charging within 2s, whereas injection from Al at the same field caused none (Fig. 16, bottom). The cause of the slow relaxation in the flatband voltage after 2s in Fig. 16, bottom, is not known.

Constant-current V-t characteristics.—The last set of data obtained was the voltage-time characteristic of a virgin test capacitor into which a constant current was forced. The characteristic is obtained by simultaneously unshorting the capacitor, redirecting a current from a constant-current supply onto the capacitor, triggering a high speed DVM, and monitoring the voltage across the capacitor as a function of time. At first, the voltage increase is linear with time as the test capacitor (and stray capacitance) charges. Eventually, conduction through the dielectric becomes appreciable, and the voltage is determined by the IV characteristic of the capacitor and by the current being forced. The voltage in this condition is constant if the IV characteristic of the capacitor does not change. However, space-charge buildup in the dielectric changes the IV characteristic and hence V, so the shape of the V-t characteristic in the conduction regime gives information on charging of the dielectric. This type of information, coupled with simultaneous flatband shift measurements, has been used by Meyer and Crook (16) to characterize trapping in thin oxides. We studied only injection from Si since this maintains the substrate in accumulation, thus avoiding the problem of accounting for the voltage drop across the depletion layer.

Examples of the data obtained for three thicknesses and three current densities are shown in Fig. 17. Several observations can be made: (i) the thicker oxides have an initial peak, whereas this is absent in the thinnest oxide, (ii) the initial peak, when it occurs, is sharper for higher current densities, (iii) all oxide thicknesses show a slow increase in voltage; this occurs after the initial peak for the thicker oxides, but starts immediately for the thinnest oxide, (iv) the slow increase in V is more rapid at higher current densities, and (v) not shown in Fig. 17 is the considerable scatter in time to breakdown, making generalization about times to breakdown difficult without better statistics. Still, the thinnest oxide seemed to have longer times to failure than the thicker oxides.

Discussion

The electrical results described in the previous section can be interpreted in terms of the band diagrams in Fig. 18. These diagrams incorporate the ideas of Harari (6, 7), Solomon (15), Shatzkes and Av-Ron (8), and DiStefano

Fig. 16. Accumulated flatband voltage shifts vs. accumulated time at stress for wafer 6 ($t_{ox} = 345\text{\AA}$) and wafer 7 ($t_{ox} = 652\text{\AA}$). Stress was 10 MV/cm for wafer 6 and 9 MV/cm for wafer 7.

and Shatzkes (14). The diagrams are drawn for the case of a constant cathode field, that is, when a constant current is forced into the oxide and for high fields near breakdown. The time evolution of these bands is shown for thin oxides (6, 7, 16) and thick oxides (8, 14). Electrons injected from an electrode are accelerated by the internal field in the oxide and are scattered, forming a Poisson-shaped energy distribution which broadens and moves to lower energies as distance from the cathode increases. An electron in a part of this distribution which lies above the ionization threshold can create an electron-hole pair. The ionization threshold is one bandgap potential above the oxide conduction band. This is shown as dotted lines in Fig. 18. For thick oxides or high average fields, the peak in the hot electron distribution rises above the ionization threshold somewhere in the oxide causing ionization. The electrons so formed become part of the hot electron distribution, but the holes have very low mobility and so are practically fixed in position. For thin oxides or low average fields, there is insufficient distance or field strength to accelerate the hot electrons to a kinetic energy above the ionization threshold anywhere in the oxide, so no holes are formed. We shall call an oxide "thin" if a field high enough to cause impact ionization cannot be reached before the oxide breaks down. Thus there are two distinct types of behavior depending on oxide thickness. Oxides thinner than 250-300Å will never show a positive charge buildup due to immobile holes, whereas thicker oxides will.

The band diagrams in Fig. 18 can be used to interpret the V-t characteristics in Fig. 17 for injection from Si. The cathode field, that is, the slope of the bands at the cathode, is fixed by the current density being forced. The forced current density and the cathode field are related by the FN law. For thin oxide, traps near the cathode are generated and filled with electrons (6, 7, 15). This causes a downward bending of the oxide bands to the right of the trapped electrons (see Fig. 18). As trap creation and filling proceeds, this bending continues and causes the voltage difference across the capacitor to increase. This effect is seen for the 160Å oxide in Fig. 17. Eventually, breakdown occurs when the electric field exceeds some

Fig. 17. Forced-current voltage-time characteristics for three oxide thicknesses (columns) and three current densities (rows). All data are for injection from silicon. Horizontal (time) axes are the same for all plots. Voltage range is shown on vertical axes.

critical value somewhere in the oxide, variously estimated as 30 MV/cm (7), 11.2 MV/cm (16), etc. For thick oxide, a relatively rapidly formed positive charge due to holes generated by ionization reduces the voltage drop across the oxide from its initial value (see Fig. 18). This is the origin of the initial peak in the $V-t$ characteristic for the thicker oxides. After this initial formation of positive charge, electron traps are generated and filled near the cathode, just as for the thin oxide, causing a slow rise in the voltage drop across the oxide (see Fig. 17). Both the positive charge and the negative charge build up more rapidly for higher current densities.

The effects of hole formation deep in the oxide and trap formation and filling near the cathode also show up in the IV and CV data. For the moment, our discussion is confined to injection from Si. The IV and CV data were taken under forced voltage, not forced current, conditions so the illustration in Fig. 18 does not strictly apply. For the thinnest oxide, the buildup of negative trapped charge at the cathode under fixed voltage conditions reduces the cathode field below the measured average field and hence reduces the injected current. This explains the deviation to lower current densities from the FN law observed in the thinnest oxide (see Fig. 4). However, for the thicker oxides, the rapid buildup of positive charge causes an enhancement of the cathode field above the average field, increasing the current above the FN prediction. Eventually, the slow buildup of trapped negative charge near the cathode tends to reduce the cathode field again bringing current back to the FN prediction, or lower. Thus the same mechanisms explain both the $V-t$ characteristics in Fig. 17 and the deviations from the FN law observed in Fig. 4. The difference is that one characteristic is observed under forced current conditions, while the other is observed under forced voltage conditions.

The CV characteristics for injection from Si, Fig. 11, show only negative flatband shifts. That is, they show

only the positive charge induced in the thicker oxides. In the CV traces for the thinnest oxide, there is no sign of the negative charge which was observed in the IV and $V-t$ characteristics. It seems that the traps created and filled with electrons during stress discharge when the stress is removed to make a CV trace. This means that they must be very close to the injecting interface and are in electrical communication with the bulk Si. Thus, at least some of the traps observed in the IV and $V-t$ data are the interface traps detected in the frequency CV data in Fig. 13-15. The conductance-voltage traces for the thicker oxides (Fig. 9) also show peaks which increase in height with increasing stress, thus showing the formation of interface traps. The CGV data are therefore entirely consistent with the IV and $V-t$ data if the negatively charged traps near the injecting interface are understood to be interface traps which discharge (but do not heal) when stress is removed.

The IV characteristics for injection from aluminum were "leakier" than the FN theory, except for the thinnest oxide (see Fig. 5). This may be due to degradation of the Al/SiO₂ interface by a chemical reaction. The increasing deviation from the FN theory as the oxide thickness increases is not understood. When the cathode field is large enough to cause appreciable charge injection through an ideal triangular barrier by the FN mechanism, the electric fields in the bulk of the oxide are large enough to cause immediate detrapping by tunneling out of the numerous grown-in traps at about 2 eV below the oxide conduction band. Thus, no charging of these grown-in traps will occur. The grown-in traps are distributed uniformly throughout the bulk of the oxide and are to be distinguished from the current-induced interface traps described above. However, if the interface is a more efficient injector than a simple triangular tunneling barrier, then large numbers of electrons will enter the oxide and fill traps at fields low enough that detrapping will not

Fig. 18. Time evolution of bands, electric fields, and charges for thick oxide (top) and thin oxide (bottom). Drawn for constant forced current

occur (20). Thus, the negative charging evidenced by the positive flatband shifts shown in Fig. 12 is probably due to bulk trapping and is consistent with the "leakier" than FN current-voltage characteristics in Fig. 5. Notice that the thinnest oxide, which obeys the FN law, shows no evidence of bulk trapping. As the electric field increases the IV characteristics approach the FN characteristic (Fig. 5), bulk traps are emptied, and impact ionization produces holes which produce negative flatband shifts (Fig. 12).

This discussion has shown that all of the data can be explained in terms of a simple model with the following features: (i) impact ionization produces immobile holes in thicker oxides, (ii) interfacial trap formation and filling near the cathode occur in all of the oxides, and (iii) for "leaky" interfaces, such as the Al/SiO₂ interface in our particular oxides, bulk trapping occurs. These charges distort the bands in the oxide and create internal electric fields which differ from the average electric field. Whenever the electric field somewhere in the oxide exceeds a critical value, breakdown occurs. At a given average electric field, the relative rates of generation of charge formation by the above three mechanisms, especially the first two, determine the time to breakdown. Defects, weak or thin spots in the oxide, etc., will all contribute to a scatter in the times to breakdown. Another factor which determines the time to breakdown is the way in which the oxide is stressed: *viz.*, by forced current or forced voltage, the rate of charge buildup is different for each of these methods.

Conclusions

We have presented a qualitative picture of high field trapping and ionization phenomena in thermal oxides as a function of oxide film thickness. This was done by integrating three types of data: (i) IV data, (ii) CV data,

and (iii) forced-current voltage-time data. Interface trap formation and charging with electrons near the cathode during injection from Si was observed for all oxides. Creation of immobile holes in the oxide valence band by impact ionization was observed for the thicker oxides, but not the thinnest. Bulk trapping was significant when electrons were injected from Al into the thicker oxides. For the thicker oxides, the Al/SiO₂ interface was considerably leakier than predicted by the FN theory. This type of measurement is an important adjunct to long term reliability studies since these phenomena cause wear-out of intrinsic oxides.

There is still considerable controversy as to exactly what mechanisms occur in oxides at highfields (16-19). We have interpreted our data according to what seem to be the most likely mechanisms (7, 8, 15). A partial reason for many of the conflicting observations in the literature must be differences, documented and otherwise, in the processes which produce MOS test capacitors. This shows the importance of setting up the techniques described in this report as a process-development tool as opposed to making the measurements once with the hope of pinning down the mechanisms once and for all. Measurement techniques set up as a process-development tool must be highly automatic both in data acquisition and data analysis in order to facilitate throughput.

Most of the analysis in this report has been qualitative because our purpose has been to review and illustrate rather than to make a detailed quantitative analysis of a particular oxide. Still, it is clear that quantitative analysis such as calculation of cross sections, trapping efficiencies, etc., are quite straightforward since all the data are stored in digital form on floppy disks, and are easily accessible for computer analysis.

The discussion has shown the power of using multiple techniques in unraveling mechanisms. For example, the

CV shifts due to bulk trapping when electron injection was from aluminum would have been difficult to understand without the FN data. It is also worth emphasizing the value of FN data by itself as an analytical tool, especially when comparison is made with theoretical expectations. FN analysis is not as widely recognized as a process development tool as is, say, CV measurement.

The Atomic-Scale Origin of the Strain Enthalpy of Mixing in Zincblende Alloys

J. C. Mikkelsen, Jr.*

Xerox Palo Alto Research Center, Palo Alto, California 94304

ABSTRACT

The atomic-scale structure of Ga_{1-x}In_xAs solid solutions, previously experimentally determined by extended x-ray absorption fine structure, is used to model the strain energy associated with the local distortions in bondlengths and bond angles relative to those in the pure binary compounds. The distortion energy associated with the bondlength change was calculated to be 0.03X(1 - X) eV/cation-anion pair, where X is the InAs mole fraction, and adding the contribution from the bond-angle distortions leads to a total strain energy of 0.11X(1 - X) eV/atom-pair. The composition dependence of the strain energy is the same as the regular solution enthalpy of mixing, α_sX(1 - X), and the calculated value of the solid solution interaction parameter, α_s, is in good agreement with the reported experimental value of 0.13 eV/atom-pair for Ga_{1-x}In_xAs. Similar calculations are made for four other zincblende solid solutions for which the atomic-scale structure has been determined, and the results suggest that local bond strain is the major contribution to the enthalpy of mixing. Generalization of the strain calculations leads to a second-order dependence of the α_s on the normalized difference in endmember lattice constants, with no adjustable parameters, and this result is compared to semiempirical models for α_s.

Ternary and quaternary solid solutions of III-V semiconductors have received much attention as substrates and active layers of optoelectronic devices for applications such as optical communications. In particular, an enormous effort has been expended in determining many of the solid-liquid phase diagrams in order to develop suitable conditions for controlled crystal growth of the desired alloy compositions (1). In an attempt to predict the more complex quaternary phase relations and the ultimate stability of the solid solutions well below the solidus temperatures, various thermodynamic models have been used to parameterize the existing experimental temperature- and compositional-dependent phase equilibria. In an ideal binary solution (2), there is no enthalpy contribution to the solution free energy, and the ideal entropy of mixing is $-R(X_1 \ln X_1 + X_2 \ln X_2)$. The deviations from ideality are small in many III-V ternary systems, and many of the phase diagrams have been successfully modeled by assuming that the solids are regular solutions (1). A regular solution (2) is one in which the free energy of mixing has, in addition to the ideal entropy term, a composition-dependent enthalpy term of the form α_sX₁(1 - X₁), where α_s is the solid solution interaction parameter

(also called Ω) and must be independent of both temperature and composition. In the regular solution models for III-V phase diagrams the α_s's range from zero for Al_{1-x}Ga_xAs to 4.5 kcal/mol (0.195 eV/atom-pair) for GaAs_{1-x}Sb_x (1). Although more complex thermodynamic models have also been used to fit the experimental phase diagrams, the extent of improvement is difficult to assess.

Since the solid solution interaction parameter represents the deviation of zincblende alloys from ideal solid solutions, understanding its atomic-scale origin can improve the ability to predict more complex phase diagrams, the dependence of alloy crystal chemistry on crystal-growth technique, alloy stability against phase separation below the growth temperature, and, possibly, the mechanisms of device degradation. In standard thermodynamic texts, it is postulated that local strain associated with different atomic sizes of the constituents is a major contribution to the enthalpy of mixing in solid solutions. There have been semiempirical correlations of α_s with the difference between the lattice constants of the binary compounds which form the solid solution, Δ = a₁ - a₂. Stringfellow (3) and Brebrick and Panlener (4) have asserted that α_s is reasonably well correlated with square (3) or sixth (4) power dependences of α_s on Δ, respectively.

*Electrochemical Society Active Member.

Although these correlations imply that the deviation from ideality is due to a local lattice mismatch arising from the different "size" of the substituted ions, Stringfellow derived the Δ^2 dependence in the delta-lattice-parameter (DLP) model not on the basis of strain, but on the expected variation of the alloy electronic structure with lattice constant within the context of the dielectric band model of Phillips and Van Vechten (5) which is discussed in detail below.

An estimate of lattice strain energy has been compared to experimental values of α_s for three pseudobinary III-V systems, including $\text{Ga}_{1-x}\text{In}_x\text{As}$, by Foster and Woods (6), and they found that the calculated strain energy led to a calculated interaction parameter which was a factor of 5 too high. In their elastic model, it was assumed that the strain energy was that required to increase the Ga-As distance, and decrease the In-As distance, in order to make both distances equal to the average cation-anion distance defined by the alloy lattice constant. However, recent extended-x-ray-absorption-fine-structure (EXAFS) measurements on $\text{Ga}_{1-x}\text{In}_x\text{As}$ (7) and other III-V alloys (8) indicate this is not a good approximation to the alloy structure. Rather, there is always $\sim 0.13\text{\AA}$ difference between the Ga-As and In-As bondlengths at any given alloy composition. The availability of atomic-scale structural information on solid solutions now permits an examination of the contribution of bond strain to the enthalpy of mixing. We show that the bond distortion energy calculated from the EXAFS structural information for representative ternary zincblende alloys is in good agreement with the thermochemical interaction parameters which model the enthalpy of mixing.

Structural Model for Zincblende Solid Solutions

In the structural discussion which follows, we will compare the equilibrium alloy structure of $\text{Ga}_{1-x}\text{In}_x\text{As}$ as an example zincblende solid solution with two approximations, the deviations from which will provide the basis for the calculation of the bond-distortion energies. The two structural approximations are the virtual crystal approximation (9) (VCA) and what can be called the covalent radius approximation (CRA) after the chemical bond concepts of Pauling and Huggins (10), which suggest that a tetrahedral covalent radius, to first order, is invariant. In the VCA, the substituted and common atoms occupy their respective regular zincblende lattice sites, and at a given composition all cation-anion nearest neighbor (nn) bondlengths are equal to $a_0\sqrt{3}/4$, where a_0 is the alloy lattice constant. Thus, in the VCA description of $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$, all the Ga-As nn bondlengths are stretched and the In-As bondlengths are compressed by 0.087\AA to become equal to 2.535\AA . Since the zincblende crystal structure is strictly retained in the VCA (with random distribution of substituted ions), all interatomic bond angles are at the ideal tetrahedral value of 109.5° . In other words, the VCA is characterized by a zero bond angle distortion at the expense of large changes in the nn bondlengths. This approximation is equivalent to that used in the elastic model of Foster and Woods. Since the EXAFS results indicate that the Ga-As and In-As nn distances change by only 25% of that required to make them equal for any given alloy composition, it is obvious that the Foster-Woods estimate of the strain (which is proportional to the square of the bondlength change) will be much too high. In the CRA, however, local atomic displacements from the zincblende lattice sites are required to produce two different cation-anion nn distances, which correspond to the natural bondlengths in the pure binary endmembers. This condition is satisfied in the zincblende-like chalcopyrite structure (11), where the substituted sublattice can be approximately fcc, and the common sublattice atoms are displaced to accommodate two different cation-anion distances. Atomic displacements from fcc positions result in a deviation of the bond angles from 109.5° . Thus, the CRA is characterized by zero nn bondlength changes at the expense of large bond-angle distortions.

EXAFS measurements (7) indicate that the equilibrium alloy structure of $\text{Ga}_{1-x}\text{In}_x\text{As}$ is closer to the second approximation. The Ga-As nn distance is given by $2.448 + 0.044X_2$ (\AA) and the In-As nn distance by $2.622 - 0.044X_1$ (\AA), where X_1 and X_2 are the mole fractions of GaAs and InAs, respectively. By contrast, in the VCA all of the cation-anion nn distances are given by $2.448 + 0.174X_2$ (\AA). Thus, in $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$, the experimentally-determined Ga-As and In-As nn distances are 2.470 and 2.600\AA , respectively, compared to the VCA average distance of 2.535\AA .

Although the nn Ga-As and In-As distances are known with good accuracy ($\pm 0.005\text{\AA}$), the second neighbor (nnn) distances are less certain, due to both larger experimental error bars ($\pm 0.02\text{\AA}$) and the fact that the (gaussian) width of the alloy nnn pair-correlation functions are of the order of 0.05\AA broader than those in the pure binary compounds. The additional width can arise from both static (statistical distribution of local Ga-In concentrations) and dynamic (thermal vibration) contributions (the latter of which has been minimized by making the EXAFS measurements at 77 K). We cannot calculate an accurate distribution of bond angles from the nnn distance distributions without knowledge of the intermediate-range structure. If we use the mean distance (peak) of the nnn gaussian distributions, the bond angles in $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$ deviate from the ideal 109.5° by a maximum of 3.1° for In-As-In and a minimum of zero for In-As-Ga, with an rms value of 0.5° for all the bond angles. However, the real structure must contain a somewhat different distribution of bond angles which arise from the nnn distances which are either larger or smaller than the peak value of the nnn distributions. Although it would seem reasonable to assume that the shortest Ga-Ga nnn distances are associated with AsGa_4 tetrahedra and the longest In-In distances are associated with AsIn_4 tetrahedra, we have not determined a satisfactory self-consistent bond-angle model which accurately fits all of the EXAFS data.

An alternative estimate of the bond-angle distribution can be calculated for the chalcopyrite-like structural model (7) which gave a good fit to both the nn and nnn EXAFS data for $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$, except that the model cation-cation nnn distributions were too sharp. The change in bond angles for the As atom displacements ranged from 0° for In-As-Ga angle to a maximum of $+4.4^\circ$ for Ga-As-Ga and -4.4° for In-As-In. The rms change in the 12 bond angles associated with a (Ga, In)-As atom-pair is 2.0° , considerably larger than the 0.5 estimated from only the peaks in the EXAFS nnn distributions, but they are the actual bond angles observed in the cubic chalcopyrite compound ZnSnAs_2 , in which the nn and nnn distributions closely approximate those observed for $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$. Regardless of the estimates for the bond-angle displacements, it is obvious that the equilibrium alloy structure is a balance between bondlength and bond-angle distortions, *i.e.*, the two distortions oppose each other. In other words, in the absence of forces which resist changes in bond angles, the minimum energy would be satisfied by a zero bondlength change relative to the binary endmember compounds. The $\text{Ga}_{1-x}\text{In}_x\text{As}$ alloy nn bondlengths determined by EXAFS, along with estimates for the bond-angle contributions, are used below in a simple force constant model to calculate the bonding strain energy, and these results are compared to the thermodynamic analysis of the GaAs-InAs pseudobinary phase diagram.

Estimate of Strain Energy for $\text{Ga}_{1-x}\text{In}_x\text{As}$

Our principal objective is to obtain the excess enthalpy of mixing due to strained bonds, using as the reference state the bondlengths in the endmember binary compounds, *i.e.*, 2.448 and 2.622\AA for Ga-As and In-As, respectively, and ideal tetrahedral angles of 109.5° . If all of the atomic positions in the alloy were known with sufficient accuracy to determine the bond angles, a force constant model (12) could be used to compute the total displacement (strain) energy in terms of changes in bondlengths

and angles relative to the standard states. In the absence of accurate bond-angle information, we take a slightly different approach. We view the local forces as separable into those which resist bondlength changes (central) and the net of all the others, which resist bond-angle changes (noncentral). The strain energy from the former is straightforwardly determined from the isotropic dilation (increase in Ga-As bondlengths) or compression (decrease in In-As bondlength) compared to the reference Ga-As and In-As bondlengths. For example, the strain energy associated with radial changes in the Ga-As bondlength, $U_r(\text{Ga-As})$, is given by $1/2 k_r \Delta r_1^2$, where k_r is the central force constant and has a value of 128 N/m (12) derived from the bulk modulus and Δr_1 is the change in bondlength from 2.448Å. The parabolic dependence of U_r on Δr_1 is shown for a single Ga-As bond by curve (a) in the configuration energy diagram of Fig. 1. If there were no forces resisting the bond-angle distortions [no θ -dependent terms Eq. [1] of Ref. (12)], then the minimum energy would correspond to no change in Ga-As bondlength for any alloy composition, *i.e.*, the CRA model would be satisfied. However, at the experimentally determined Ga-As nn distance in the $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$ alloy, $\Delta r = 0.022\text{Å}$, and $U_r = 0.002$ eV per Ga-As bond (0.007 eV per Ga-As atom-pair). Since $\Delta r_1 = 0.044X_2$, the composition dependence of $U_r(\text{GaAs})$ is given by $0.007 X_2^2$ eV per Ga-As bond. There is a similar energy term from the corresponding decrease of the alloy In-As nn distance, $\Delta r_2(k_{r2} = 108$ N/m), which also contributes 0.002 eV per In-As bond. Since the rate of change in VCA average nn distance, Δr_{VCA} , is approximately four times that observed in Δr_1 or Δr_2 , the strain energy calculated for the virtual crystal structure, which has bondlength changes only, is approximately 16 times higher than that obtained from the experimentally determined alloy bondlength distortions. However, the correct value for the strain associated with only the bondlength distortions is approximately a factor of four smaller than the measured enthalpy of mixing (1, 6). [Fedders and Muller (13) recently obtained a similar result by considering only the changes in alloy bondlengths (7),

but they did not attempt to calculate the strain associated with bond-angle distortions.]

The next step is to estimate the bond-angle, or noncentral, contribution to the bond-strain energy. In the absence of known bond-angle distributions for the alloy, we make a semiempirical estimate of the effective bond-angle strain, U_{eff} , by equating the opposing central and noncentral forces at equilibrium bondlengths which are observed experimentally by EXAFS. In addition, we assume that the reference state for the bond angle is the ideal tetrahedral angle of 109.5° . Since this latter structural condition is satisfied at any alloy composition by the VCA model, we have $U_{\text{eff}}(\text{VCA}) = 0$. The Ga-As bond-angle distortion energy for the $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$ alloy is shown by curve (b) in Fig. 1 which satisfies the two constraints of equal forces at $\Delta r_1 = 0.022\text{Å}$ and zero energy at $\Delta r_{\text{VCA}} = 0.087\text{Å}$. The effective bond-angle distortion energy is 0.005 eV/bond, or 0.023 eV/atom-pair, and the total strain energy is 0.030 eV/(Ga-As) atom-pair in the $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$ alloy. By comparison, for $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$ the total strain energy at CRA, which arises from bond-angle distortions only, is 0.042 eV per atom-pair, whereas the total strain energy at VCA, which arises from bondlength distortions only, is 0.140 eV/atom-pair. Thus, the calculated total strain energy for the equilibrium structure is lower than that of either the VCA or CRA, and it is apparent that most of the strain energy actually arises from the distortion of the bond angles. As a matter of perspective, this strain energy of 0.03 eV/atom pair is certainly small compared with the GaAs cohesive energy of 5.8 eV/atom-pair, or the heat of formation of 0.75 eV/atom-pair (5).

A general form of the bond-angle strain energy is preferred in order to examine the composition dependence of the total strain energy. Curve (b) of Fig. 1 is of the form $U_{\text{eff}}(\text{GaAs}) = 1/2 k_{\text{eff}}(\Delta r_{\text{eff}})^2$, where $\Delta r_{\text{eff}} = \Delta r_{\text{VCA}} - \Delta r_1$. Since the central and effective noncentral forces are equal and opposite at the equilibrium value of Δr_1

$$k_{\text{eff}}/k_r = \Delta r_1/(\Delta r_{\text{VCA}} - \Delta r_1) \quad [1]$$

For later comparison with other zincblende alloy systems, it is useful to express the composition dependence of the bondlengths as $\Delta r_1 = S_1 X_2$ and $\Delta r_{\text{VCA}} = S_{\text{VCA}} X_2$, where S_1 (measured by EXAFS) and S_{VCA} (determined from the alloy lattice constants) equal 0.044 and 0.174Å, respectively, for $\text{Ga}_{1-x}\text{In}_x\text{As}$. Thus, $k_{\text{eff}} = k_r S_1/(S_{\text{VCA}} - S_1)$, and $\Delta r_{\text{eff}} = X_2(S_{\text{VCA}} - S_1)$, and the term in parentheses is independent of composition. Although curve (a) in Fig. 1 universally represents the radial strain energy for Ga-As bonds at any bondlength defined by Δr_1 , the bond-angle contribution is a family of curves like (b) which depend on composition, *i.e.*, which have their minima at the appropriate VCA distance.

Before proceeding with the expression for the composition-dependence of the total strain energy, consider the value of the "effective" angular displacement which is represented by Δr_{eff} and which is on the order of 0.065Å. Since the nn bondlengths are approximately 2.5Å, the effective angular displacements are 1.5° . This value is in better agreement with the above chalcopyrite estimate than that obtained from only the peaks of the EXAFS nnn distributions and at the respective equilibrium nn distances have derivatives equal to those of curve (A). For the sake of comparison, we put the various estimates of the bond-angle displacements in the θ -dependent terms of Eq. [1] in Ref. (12). The largest value of the bond-angle strain (0.020 eV/atom-pair) occurs for the 2.0° rms bond-angle change of the chalcopyrite model, and the smallest value (0.002 eV/atom-pair) occurs for the 0.5° rms displacement calculated from the peak in the EXAFS nnn distributions. It is beyond the scope of this study to make a theoretical analysis of all the terms which comprise the semiempirical parameter k_{eff} ; however, we note that it probably cannot be simply related to the k_θ 's (or to a β/α ratio) of Ref. (12), and that it probably does indirectly include coulombic terms, which may also be minimized at the VCA structure, owing to the periodicity of the lattice.

Addition of the Ga-As bondlength and bond-angle strain energy contributions (multiplied by four bonds per

Fig. 1. Configuration energy diagram for distortions in $\text{Ga}_{1-x}\text{In}_x\text{As}$. Curve (a) is bond-stretching displacement energy per Ga-As bond vs. change in Ga-As nn distance; curve (b) is effective noncentral displacement energy per Ga-As bond in $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$. Arrow indicates the equilibrium Ga-As Δr in $\text{Ga}_{0.5}\text{In}_{0.5}\text{As}$ at 0.022Å.

Table I. Lattice parameter differences, Δ (11), atomic-scale structural parameters, S_1/S_{VCA} (defined in text) from EXAFS (7, 8) and Fukai model (14), central force constants (12), and calculated and experimental (1, 3, 4) regular solution interaction parameters for several zincblende alloys

Alloy	Δ (Å)	S_1/S_{VCA}		k_1	k_2	α_s (calc)	α_s (meas)
		EXAFS	Fukai	(N/m)	(N/m)	(eV/atom-pair)	
(Ga,In)P	0.418	0.204	0.208	147	132	0.11(8)	0.139-0.156
(Ga,In)As	0.382	0.252	0.212	128	108	0.11(4)	0.078-0.130

Ga, As atom-pair) leads to the composition-dependent expression

$$U_{(Ga-As)} = 2k_{r12}S_{VCA}S_1X_2^2 \text{ (eV per Ga-As atom-pair)} \quad [2]$$

A similar expression exists for each In-As atom-pair. In order to compute a strain energy per alloy atom-pair, the Ga-As and In-As contributions are weighted by their respective mole fractions. Although, in principle, S_2 , the rate of change in In-As bondlength with composition, can differ from S_1 , the EXAFS results gave identical values for S_1 and S_2 . Furthermore, since the central force constants are similar (128 and 108 N/m), they can be replaced by an average value, k_{r12} . By combining terms the final approximate strain energy per alloy atom-pair is

$$U_{\text{strain}} = (S_{VCA}S_12k_{r12})X_1X_2 \text{ (eV per atom-pair)} \quad [3]$$

The form of this expression is the same as the regular solution excess enthalpy of mixing, with α_s given by the product of constants, $S_{VCA}S_12k_{r12}$. The calculated value of $S_{VCA}S_12k_{r12}$ is 0.11(4) eV/atom-pair, which is in excellent agreement with the reported value of α_s of 0.130 eV/atom-pair reported by Ilegems and Panish (1), but somewhat higher than the value of 0.087 obtained by Foster and Woods (6). The excess enthalpy of mixing appears to originate from the change in covalent bondlengths and bond angles in the solid solutions. Of course, it is possible to retain the composition dependence of α_s through the use of individual force constants, k_{r1} , rather than their average. In $Ga_{1-x}In_xAs$, for example, α_s varies by 20% from 0.124 to 0.104 eV/atom-pair for values of $x = 0$ and 1, respectively. If the composition dependence of the interaction parameter determined by Foster and Woods is approximated by a linear curve, the change is also a 20% decrease from GaAs to InAs.

Strain Enthalpy of Mixing for Other Zincblende Ternary Alloys

EXAFS measurements have been made on several zincblende solid solutions (8), and the values of S_1 (which were found to be nearly equal S_2) from preliminary data analyses are shown in Table I. The ratio of the observed change in nn distance (S_1) to the change in average nn distance (S_{VCA}) can be taken as a relative measure of the degree of bondlength distortion. This ratio is higher for the more ionic cuprous halides than the covalent III-V systems. Recently, Fukai (14) has applied a force constant model to estimate the bondlength distortions in zincblende solid solutions. He derived an expression for S_1/S_{VCA} (γ in his notation) which is given by $4/3(\beta/\bar{\alpha})/[1 + (\beta/\bar{\alpha})]$, where $\bar{\alpha}$ and $\bar{\beta}$ are the mean short range bond stretching and bond bending force constants given by Martin (12). The agreement between the Fukai model and experimental EXAFS results is very good for $Ga_{1-x}In_xP$ and $GaAs_{1-x}P_x$, and slightly less so for $Ga_{1-x}In_xAs$. However, the predicted trend with ionicity is in the wrong direction. Fukai reasoned that since $\beta/\bar{\alpha}$ decreased with increasing ionicity, S_1/S_{VCA} would therefore decrease with increasing ionicity. The experimental EXAFS data show that the opposite is true: the cuprous halides have much larger S_1/S_{VCA} ratios, and the value for $ZnSe_{1-x}Te_x$ is nearly a factor of two higher than predicted. Qualitatively, the reason why the bondlength distortions do not de-

crease with increasing ionicity is that electrostatic forces resist "ionic" displacements from ideal VCA lattice positions even though the bond-angle restoring force, β , is diminished. In fact, we have observed that S_1/S_{VCA} for alkali halide pseudobinary compounds (in which the ratio β/α approaches zero) is larger than those obtained for the zincblende solid solutions (15). Of course, long-range coulombic contributions are not included in an analysis based on α and β alone. However, all noncentral contributions are included in the above semiempirical determination of k_{eff} from the experimentally measured equilibrium bondlengths.

The calculated strain contributions to the enthalpy of mixing are compared to the (range of) experimentally measured values for the solid solution interaction parameter, α_s , in Table I. The calculated strain enthalpy for $Ga_{1-x}In_xP$ is in good agreement with the lower reported value of the interaction parameter, but those calculated for the $GaP_{1-x}As_x$ and $ZnSe_{1-x}Te_x$ solid solutions are approximately a factor of two higher than the reported values. No enthalpy of mixing has been reported for the $CuBr_{1-x}I_x$ alloy system, but it is interesting to note that the calculated value of 0.066 eV/atom-pair is comparable to the value of 0.081 eV/atom-pair measured for the analogous alkali halide solid solution, $RbBr_{1-x}I_x$ (16). Thermodynamic analysis of EXAFS measurements on alkali halide systems (15), such as $RbBr_{1-x}I_x$, are in progress. Preliminary results indicate that, although the changes in nn bondlengths (S_1) are higher for the alkali halides than the zincblende semiconductors, the smaller values of the bulk moduli lead to comparable values for the enthalpy of mixing.

Discussion

We next examine the similarities between Eq. [3] and the formulation for α_s given by Stringfellow, and then assess the simplifications used to relate the strain energy to experimental thermodynamic parameters. First, since the zincblende nn distance equals $a_0\sqrt{3}/4$, then $S_{VCA} = \sqrt{3}/4 \Delta$. The calculated form of α_s is $3/8 (S_1/S_{VCA})k_{r12}\Delta^2$. In order to generalize this expression to many zincblende solid solutions, note that (i) the values of S_1/S_{VCA} are approximately 1/4 for four of the alloys listed in Table I, and (ii) the values of k_{r12} are 120 ± 20 N/m. Thus, as an approximation $(S_1/S_{VCA})k_{r12}$ is a constant, and $\alpha_s = K\Delta^2$. If K is rewritten as $4.375K/\alpha^{4.5}$ according to Stringfellow's DLP model (3), our calculated values for K determined from the actual parameters for $Ga_{1-x}In_xAs$ and $GaAs_xP_{1-x}$ are 1.06 and 0.96×10^7 cal/mol-Å^{2.5}, respectively, compared to Stringfellow's value of 1.15×10^7 , which was obtained by fitting to the experimental values for 16 systems. Thus, if the strain energy is the major component of the interaction parameter, a second-order dependence of α_s on Δ is expected, in agreement with the correlation proposed by Stringfellow (3). By inspection, since the Δ 's for $Ga_{1-x}In_xAs$, $Ga_{1-x}In_xP$, and $ZnSe_{1-x}Te_x$ are approximately equal, their respective α_s 's should also be nearly equal. Since the Δ for $GaP_{1-x}As_x$ is a factor of two smaller than the other three systems, a factor of four smaller α_s is to be expected.

Although the present strain model and the DLP predict that the regular solution interaction parameters are approximately fit by a universal constant times Δ^2 , the DLP model did not explicitly originate from bond strain. Rather, the DLP model is based on the dielectric band model of Phillips and Van Vechten (5) (PVV). In the PVV model it is assumed that the semiconductor energy gaps are a function of two terms, the homopolar gap energy, E_h , which is proportional to $a_0^{-2.5}$ derived empirically from Si and Ge, and the ionic energy gap, C , which has a more complex dependence on lattice constant, ionicity, and metallization. The PVV model predicts reasonably accurate values of the bandgaps and heats of formation for zincblende compounds. The excess heats of formation of solid solutions relative to physical mixtures of the binary compounds were calculated by Van Vechten (17) and Stringfellow (18). However, the agreement with ex-

perimental values of the interaction parameter was not satisfactory. For example, the calculated value for $\text{Ga}_{1-x}\text{In}_x\text{As}$ was at least a factor of four too low, and the sign was wrong for $\text{Al}_{1-x}\text{Ga}_x\text{As}$ and $\text{Al}_{1-x}\text{In}_x\text{As}$. Stringfellow (3) obtained a significant improvement in the calculated values for the enthalpy of mixing by assuming that the heats of formation (or cohesive energies) have an $\alpha_0^{-2.5}$ dependence and other alloy variations in ionicity and metallization contained in the PVV theory could be ignored. Since the lattice constant of most zincblende pseudobinary solid solutions varies nearly linearly with composition, the composition dependence of the heat of formation (or any other property which varies sublinearly with lattice constant) will also be nonlinear. Since the Taylor series expansion of the alloy exponential term in the DLP model was truncated after the second term (linear term cancels), only the term in Δ^2 would remain for any negative exponent in the expression for ΔH_f dependence on α_0^{-x} (with a different form for the universal constant and a factor in the denominator). Thus, the DLP is only a semiempirical model for the enthalpy of mixing, and has only an indirect relationship to the original PVV dielectric theory. It is unclear what relationship should exist between the bandgap variation with composition and the enthalpy of mixing. The model presented above predicts that the enthalpy of mixing originates from local changes in bondlength and bond angle. However, the electronic band structure of these semiconductors averages the crystal potentials over many atomic sites. In fact, the use of the PVV model, through the dependence of the bandgaps (19) on an average lattice constant, implies the validity of the VCA to describe the atomic separation appropriate for the alloy. However, the EXAFS results indicate that the VCA is a poor description for the atomic-scale structure (7, 8). Elucidation of the correct relationship between the atomic-scale structure and the resultant band structure of alloy semiconductors is beyond the scope of the present work.

Although the major component of the solid solution enthalpy of mixing has been shown to originate from strain inherent in the atomic-scale structure of the solid solutions, it is important to examine some of the thermodynamic simplifications implicit in relating the model to experiment. The experimental values for the enthalpy of mixing were determined by modeling the phase diagrams with a regular solution model for the solid and generally with the simple solution model for the ternary liquids. Thus, as pointed out in Ref. (1), there usually are no unique values for either the liquid or solid interaction parameters, and there is some variation resulting from use of ternary as well as pseudobinary data to obtain a best fit to the model. For example, the values of α_s for $\text{Ga}_{1-x}\text{In}_x\text{As}$ vary by nearly 50% from 0.087 (6) to 0.130 (1).

As pointed out earlier, in the regular solution model, α_s is independent of composition and temperature. However, the strain model presented here has a composition dependence through the variation of the bulk modulus between the two binary compounds. The temperature-dependent interaction parameter obtained by Foster and Woods might be explained on the basis that the variation in α_s is actually a composition dependence through the temperature-composition solidus curve. Since the higher melting point binary compounds also have higher bulk moduli than the lower melting point compounds, this correlation would generally exist in pseudobinary phase diagrams. A temperature dependence to the calculated strain enthalpy is difficult to predict. The EXAFS measurements, upon which the present model is based, were made at 77 K (to reduce thermal vibrations), whereas the thermodynamic liquidus-solidus data were obtained at 1000-1500 K. A small decrease in the strain contribution to the enthalpy of mixing is expected due to the decrease in the bulk modulus at elevated temperature, unless there is a compensating change in S_i . It is possible that the bond strain can be reduced at elevated temperature due to anisotropic (anharmonic) atomic vibrations. This question might be suitably addressed by diffraction experiments at

elevated temperatures. If there is a vibrational contribution to the free energy of mixing, it is generally considered as an excess entropy term and is obviously ignored in the regular solution model. Since the phonon frequencies for III-V alloys do not show appreciable sublinear composition dependence, it might be argued that the vibrational entropy is unlikely to significantly add to the ideal entropy of mixing.

Finally, the regular solution model assumes that the entropy of mixing is ideal. A deviation from random occupation of the substituted sublattice, either through clustering or ordering, will reduce the ideal entropy of mixing term. In the quasichemical models for solutions (2), an excess enthalpy of mixing naturally leads to a deviation from randomness because like bonds are either more or less stable than mixed bonds. However, this model typically assumes that only the differences in chemical energy of just the first-neighbor bonds are important and it does not explicitly treat bond strain. Thus, if the reasoning is extended to second-neighbor interactions in pseudobinary systems because the number of different cation-anion bonds remains unchanged upon alloying, a positive excess enthalpy of mixing in all ternary zincblende solid solutions (except $\text{Al}_{1-x}\text{Ga}_x\text{As}$) means that unlike (Ga-In) bonds are less stable than the mean of like (Ga-Ga and In-In) bonds. This approach ignores the common (As) sublattice altogether. However, it is the As sublattice which undergoes the major displacements from the ideal (VCA) lattice sites to accommodate different Ga-As and In-As bondlengths (7). If the quasichemical model were modified to reflect the additional energy of each near-neighbor bond due to alloying, the approach would be similar to that used above, *i.e.*, the additional individual bond energy arises from changes in bondlengths and bond angles from their ideal values.

Even if the random alloys are not thermodynamically stable at temperatures substantially lower than their formation temperatures, it may not be kinetically possible to order or spinodally decompose the alloys. We have annealed several of the alloy systems below the calculated equilibrium critical temperatures and found no difference in the sublattice occupation using EXAFS. If ordering or clustering is limited by atomic diffusion over dimensions on the order of 10 Å, it means that diffusion coefficients must be less than 10^{-20} cm²s⁻¹. However, solid solutions grown at low temperatures from metal-rich solutions or by CVD methods may produce clustered or ordered alloys. Such experiments are presently underway. However, Stringfellow (20) has calculated that the coherency strain associated with developing critical nuclei from random fluctuations in composition dramatically reduces the critical temperature for alloy spinodal decomposition. For all of the systems included in Table I, the effective critical temperature is reduced to 0 K by this coherency strain. [Feddars and Muller (13) have arrived at a similar conclusion regarding the stability of random alloys once they have formed.] It is interesting to note that thermodynamic analysis of binary metallic alloys, such as Ni-Au (21), indicates both an excess enthalpy and a higher than ideal entropy of mixing in the absence of clustering or chemical ordering. It is presently difficult to assess the importance of the above factors because, since, even under the assumption that the solid solutions are strictly regular, experimental values of α_s for some alloys can vary by a factor of two.

Summary

We have calculated the bond strain associated with the atomic-scale structure as determined by EXAFS measurements for several zincblende solid solutions. It was found that the sum of the strain associated with bondlength and effective bond-angle distortions leads to an expression for the total strain energy which is equal to $\alpha_s X(1 - X)$, which has the same form of the regular solution enthalpy of mixing. The magnitude of the calculated value of α_s is in excellent agreement with experimentally measured values, and a generalization of the expression

leads to a predicted universal dependence of α_s on Δ^2 , in agreement with the semiempirical DLP model.

Technical Notes

A Low Pressure BPSG Deposition Process

Thomas Foster,* Gary Hoeye, and Jon Goldman*

Thermco Systems, Incorporated, Orange, California 92668

Presently, the semiconductor industry uses deposited silicon dioxide glass for insulating layers between conducting polysilicon and metal layers in MOS fabrication (1). It has previously been found that flowing the glass to smooth out the surface before metal deposition tends to alleviate metal step coverage problems (1-3). Phosphosilicate glass (PSG) containing 6-8 weight percent (w/o) phosphorus flows adequately at temperatures of 1000°-1100°C (2). As geometries of integrated circuits decrease in size, it is becoming more important to reduce the flow temperature of the glass to decrease dopant redistribution. A 50°C reduction in flow temperature requires approximately 3 w/o more phosphorus, but too much phosphorus causes problems in IC's, including corrosion of aluminum conductors (1). It is important to lower the flow temperature without increasing phosphorus concentrations above present levels.

Previous work has shown that the addition of boron in making borophosphosilicate glass (BPSG) aids greatly in reducing the flow temperature (1, 2). In addition, BPSG has lower etch rates in buffered HF and has lower intrinsic tensile stress than PSG (2).

In most of the published work on BPSG up to this point, the films were deposited in atmospheric CVD systems employing rotating hot plates, belt drives, etc. (1, 2). The advantages of low-pressure deposition over these types of systems have been well documented. Films deposited at low pressure generally tend to be more uniform, have fewer particles and pinholes, and have better step coverage than their counterparts deposited at atmospheric pressure (4, 5). Recently, some plasma BPSG has been reported (6).

The intent of this work, therefore, was to attempt to develop an LPCVD process for deposition of BPSG.

* Electrochemical Society Active Member.

Experimental

The experiments were performed in a modified Thermco VLTO system utilizing a 145 mm id/151 mm od quartz tube which was approximately 6 ft long. The quartz process tube was enclosed in a resistance-heated furnace element. There were four stainless steel injectors located along the bottom of the tube, along with various mass-flow controllers and a vacuum pump. Two injectors brought oxygen into the deposition zone, and the other injectors brought in the remainder of the gases. A total wafer load of 90 wafers was utilized. Wafers were loaded into five covered boats. Grooves in the covers of the boats were precision cut with a laser and served the function of redirecting the gas flow, improving the film uniformity. B₂H₆ was tried as a boron source, but due to the configuration of the system, it decomposed and deposited inside the injectors. Wafers processed with B₂H₆ were analyzed for boron content, and it was found that they contained less than 1/2 w/o boron. BCl₃ was tried and found effective as a boron source.

Several wafers were analyzed by a commercial laboratory for boron and phosphorus concentrations using a wet chemistry technique. Some samples were analyzed using SIMS to obtain the concentration profile of boron, phosphorus, and chlorine as a function of depth in the film. Film thicknesses were measured with a Nanospec visible light spectrometer.

The BPSG process was run at 425°C and pressures ranging from 175-200 mtorr. The SiH₄/O₂ ratio was kept constant at 0.67 and the O₂ flow rate was constant at 68 sccm. Wafers for the flow tests were processed with approximately 7000Å of BPSG. The polysilicon steps of interest were 0.5 μm thick and 3 μm wide. The wafers were processed with BPSG containing 4 w/o phosphorus and 0.2, and 3.5 w/o boron, respectively. The PH₃ flow rate

Fig. 1. Phosphorus weight percentage as a function of BCl₃ flow rate

was 50 sccm to obtain 0 w/o boron and 4 w/o phosphorus. The PH₃ flow rate was 42 sccm, and the BCl₃ flow rate was 3.6 sccm for 2 w/o boron and 4 w/o phosphorus. The PH₃ flow rate was 32 sccm, and the BCl₃ flow rate was 7.2 sccm for 3.5 w/o boron and 4 w/o phosphorus. A PH₃/N₂ mixture of 15% PH₃ and 85% N₂ was used in the experiments, and the PH₃ flow rates given include N₂. The flow tests were done at 850° and 925°C in steam and at 925°C in N₂ for a duration of 30 min.

Results and Discussion

Deposition rates ranged from 75 to 110 Å/min. The presence of boron and phosphorus in the process did not seem to affect the growth rate as reported in earlier work

Fig. 2. Phosphorus and boron concentration profiles by SIMS

Fig. 3. SEM of as-deposited BPSG (3.5 w/o B, 4.0 w/o P)

(2). The variation in the deposition rate is attributable to differences in pressure caused by changes in the PH₃/N₂ flow rates.

Plotting the phosphorus weight percentage as a function of BCl₃ flow rate yields some interesting facts about this particular process (Fig. 1). It is apparent that as the BCl₃ flow rate is increased along a constant PH₃ flow rate line, the phosphorus incorporation is enhanced, but only up to a point. When the BCl₃ flow rate reaches approximately 7 sccm, the phosphorus incorporation begins to decrease.

A 100 mm wafer was analyzed at 4 points for phosphorus content and at 3 points for boron content. The phosphorus content varied from 4.4 to 4.7 w/o. The boron content varied from 3.3 to 3.6 w/o. From the same run, a wafer from each of the five boats was analyzed for boron and phosphorus concentrations. The phosphorus concentration varied from 4.0 to 4.7 w/o, whereas the boron concentration varied from 3.3 to 3.8 w/o.

The SIMS analysis indicates that the phosphorus and boron concentration profiles are flat, except that there seems to be a depletion of boron and an accumulation of phosphorus in the top 400 Å of film (Fig 2). However, initial charging problems during the SIMS analysis make the surface concentration data unreliable.

SIMS profiles indicate chlorine incorporation in the film varying from 0.3 to 1.0 w/o. Chlorine has been known to cause problems in LPCVD SiO₂ films deposited using SiH₂Cl₂ and N₂O (7). Similar problems have been observed in the present work. Delamination of films containing more than 4.0 w/o boron occurred upon annealing. These films contained the highest chlorine concentrations encountered in these experiments.

Samples composed of 0, 2, and 3.5 w/o boron and 4 w/o phosphorus were etched in 6:1 BOE etchant as-deposited and after annealing (925°C, N₂, 30 min). The as-deposited

Fig. 4. SEM of BPSG annealed in steam at 925°C (2.0 w/o B, 4.0 w/o P)

Fig. 5. SEM of BPSG annealed in steam at 925°C (3.5 w/o B, 4.0 w/o P)

Fig. 6. SEM of BPSG annealed in nitrogen at 925°C (3.5 w/o B, 4.0 w/o P)

etch rates decreased from 105 Å/s (0 w/o B, 4 w/o P) to 35 Å/s (3.5 w/o B, 4 w/o P). The annealed film etch rates decreased from 47 Å/s (0 w/o B, 4 w/o P) to 18 Å/s (3.5 w/o B, 4 w/o P). These etch rate trends agree with previous work (2).

A 76 mm wafer was measured for film thickness at fifteen points spaced equidistant from top to bottom and from left to right. Taking the whole wafer into consideration, the deviation in thickness uniformity was $\pm 2.7\%$. Results on 4 in. wafers are comparable. The deviation in thickness uniformity across all 90 wafers on the paddle was $\pm 6.0\%$.

Figure 3 is a SEM of the as-deposited BPSG with no flow. Figure 4 is a sample containing 2 w/o boron and 4 w/o phosphorus that was annealed in steam at 925°C. A smooth film with gradual tapers is observed. Figure 5 shows a sample containing 3.5 w/o B and 4.0 w/o P annealed at 925°C in steam; it shows excessive flow, approaching planarization. Figure 6 shows a sample containing the same concentrations annealed at 925°C in N₂. The flow is adequate, but not as excessive as that which occurred in steam. Samples containing no boron showed no flow at 925°C. Also, the samples containing 4 w/o P and 3.5 w/o B studied exhibited no flow at 850°C in steam or nitrogen.

There is a difference in degree of flow between atmospheric pressure BPSG (AP BPSG) and low pressure BPSG (LP BPSG). The 2 w/o B, 4 w/o P LP BPSG flows well in steam at 925°C, whereas AP BPSG would require almost double the B concentration to achieve a similar flow (2). This could be due to differences in deposition pressure, reactor geometry, O₂/SiH₄ flow ratios, boron source gases, and deposition rates which lead to a different film chemistry and structure. Still, the exact cause of this difference is not understood.

Summary

Boron and phosphorus are readily incorporated into SiO₂ films at levels required to obtain excellent flow

characteristics at temperatures of 925°C. Increasing the boron concentration results in an increased amount of flow at that temperature, as in previous work. The films flow more in steam than in N₂. For this particular configuration, it was found that phosphorus incorporation was enhanced by the presence of boron until a certain BCl₃ flow rate, where the phosphorus incorporation began to be inhibited. The trends in the etch-rate tests conducted agree with those found in the 1982 paper by Kern *et al.*

The thickness uniformity across the wafer was found to be $\pm 2.7\%$, and uniformity down the boat was found to be $\pm 6\%$.

It appears that LP BPSG has different flow characteristics than AP BPSG. Although the exact reason for this phenomenon is not understood, it could be due to different film chemistry and structure that arises from different deposition parameters.

The incorporation of chlorine in films containing high boron concentrations poses potential problems. It has been observed that blisters formed upon annealing of films containing boron concentrations of greater than 4 w/o.

A New Technique of Forming Thin Free Standing Single-Crystal Films

M. Tanielian, S. Blackstone, and R. Lajos

Gould Research Center, Rolling Meadows, Illinois 60008

The mechanical integrity of vacuum deposited thin films has been the subject of many investigations (1). Two effects that play a vital role in this respect are the adhesion of the thin film to the substrate and the large

stress that may be present in the thin film. Both properties are functions of the deposition conditions, and relate to the nature of the thin film and substrate. The resultant effect of large stresses is the presence of a large number

of defects and, in more severe cases, peeling of the thin film off the substrate. Since large stresses are undesirable (the general trend being that the stress is larger for thicker films), one tries to reduce the stress in thin films by reducing their thickness and improving the adhesion of the thin film to the substrate. Although desirable, this condition cannot often be met. For instance, the adhesion of sputtered films tends to be much better than those of evaporated films, but, at the same time, the stress in sputtered films is usually higher than in evaporated films.

Here, we report on a novel effect in which the large stress present in the thin film is coupled with excellent adhesion and results in the liftoff of the thin film from its substrate together with a layer of the substrate material attached to the thin film. When the thin film material is etched away, one obtains a thin, free standing layer of the substrate. In this particular case, the sputtered thin film material was Nichrome (80Ni/20Cr) and the substrate was a Si or GaAs wafer.

It seems unlikely that this effect is only an isolated incident limited to this specific thin film material and substrates. Since adhesion and stress can be altered by changing the deposition conditions and/or the materials involved, it is quite possible that this process will manifest itself in a variety of thin films and substrates.

Experimental

This investigation was carried out in a small bell jar system fitted with a dc magnetron sputter gun. The target was a Nichrome alloy with a composition of 80Ni/20Cr. The system was pumped typically to a base pressure 5×10^{-7} torr and backfilled with about 3 mtorr of ultrahigh purity argon. The substrates were at ambient temperature and comprised (111), (100), oxidized and unoxidized Si wafers, and in one case a GaAs wafer. The typical sputtering rate was about 100 Å/min. When the thickness of the Nichrome film exceeded about 6-7 μm , the Nichrome

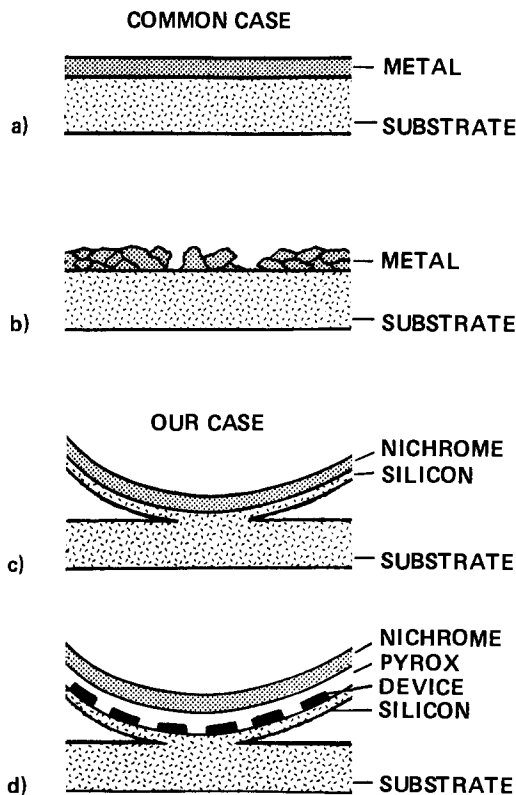

Fig. 1. Schematic representation of the peel-off process: (a) normal case; (b) a "thick" thin film which has large built-in stress thus resulting in cracking and peeling of the thin film; (c) in our case, a "thick" Nichrome film (typically 6-7 μm) which peels off the substrate with a layer of the substrate attached to it, (d) same situation as in (c), but with devices fabricated on the substrate surface.

Fig. 2. Thickness profile of the back (rough) side of a Si wafer after a strip of material was peeled off. The roughness at the bottom of the pit (left by the peeled-off material) is comparable to the roughness of the wafer surface.

film peeled off the substrate together with a layer of Si from the wafer attached to it. The peeled Si thickness was roughly 15-20 μm . An example is shown in Fig. 1. When smaller or well-defined areas of the substrates were to be peeled, we deposited a somewhat thinner film, typically around 5 μm , which produced a stressed wafer but no spontaneous peeling. The areas to be peeled were then photolithographically defined and the excess film was etched away using an aqua regia solution. As soon as the

Fig. 3. Peeled-off Si layers with devices fabricated on them. (a): The whole underlayer of the devices was peeled by depositing a thick Nichrome layer (6-7 μm). (b): A thinner Nichrome layer does not produce enough stress to peel off a whole layer but only individual IC's. The individual IC's have peeled off because of high stress developed along the streets due to the absence of a field oxide.

excess film was etched off, those areas which were still covered by the Nichrome film peeled off on their own. A stylus thickness trace of the peel pits is given in Fig. 2. This spontaneous peeling may often, however, be undesirable. In this case, the deposited film was made somewhat thinner, of the order of $4\ \mu\text{m}$, so that the photodefined areas did not peel off during the etching of the excess Nichrome film. The peeling was instigated in this case by a thermal shock resulting from immersion of the wafer into liquid N_2 or heating the substrate to several hundred degrees centigrade.

Results

Using the above technique, we were able to peel off whole wafer-size layers from 2, 3, and 4 in. wafers and strips of various sizes and shapes. It is interesting to note that the presence of an oxide on the wafer, either thermally grown in the range of 900-4500Å, or deposited using an atmospheric CVD reactor system (Pyrox) with a thickness of 0.5-1.0 μm , did not affect the peeling. Thus whole finished IC's were peeled off a wafer that had a Pyrox layer deposited on top of them (see Fig. 3). Isolated IC's were also peeled off by decreasing the Nichrome thickness and immersing the wafer into liquid N_2 . This was possible because the stresses in a fabricated wafer present a high stress point due to the absence of a field oxide at those areas.

The peeled-off surface appears to be fractured along crystal planes, leaving a faceted texture. A profilometer trace of this surface shows a roughness of about $2\ \mu\text{m}$, which is comparable to the roughness of the back side of a wafer. The uniformity of a peeled off layer is related to the peel-off conditions. On the average it is about 10-20% of the layer thickness. Once a layer of the substrate was peeled off, a second layer could also be peeled following the same procedure. In fact, we observed that, the rougher the substrate surface, the better the adhesion of the Nichrome film to the substrate and the thinner the Nichrome layer needed to induce peeling. Although the peeling action produces a rough surface on the substrate, the peeled-off layers show a small number of defects. This was tested using a Sirtl etch, which showed that

most of the defects were localized along the periphery of the strips.

Discussion

This method of forming thin, low defect, free standing single-crystal silicon wafers could be useful for solar cell applications. It would allow the fabrication of wafers thinner than can be presently sawn, and because all of the starting material is used, the elimination of kerf loss could result in a cost savings. One could even envision skiving a boule to produce large sheets of single-crystal material. The roughened surface of the as-peeled wafers could possibly be optimized as an antireflective coating.

As entirely finished circuits have been peeled from the surface of the wafer, this technique could have applications in silicon-on-insulator technology. Alternatively, on-chip circuits could be isolated by patterning the Nichrome into isolation areas, then by thermal shock, *i.e.*, passing a current through the Nichrome wire, peeling trenches out of the silicon between the circuits. The trench isolation could have similar advantages to etched trenches. Finally, this technique could be useful for TEM sample preparation.

In summary, a method of fabricating thin, low defect, free standing single-crystal films is suggested. It is based on the deposition of a highly stressed film, which, with or without thermal shock, peels off of a substrate, taking a layer of the substrate with it. Although the highly stressed film discussed here is Nichrome, in principle many other thin films could exhibit these peeling phenomena. This technique could have applications in solar cells, in wafer fabrication, and in IC technology.

Precise Evaluation of Oxygen Measurements on Cz-Silicon Wafers

K. Graff

(pp. 1378-1381, Vol. 130, no. 6)

A. Baghdadi:¹ The paper by Graff is primarily concerned with corrections for multiple-reflection effects for optical absorption measurements in thin silicon slices with nonpolished back surfaces. As the author correctly points out, improved accuracy in the infrared absorption measurement of the oxygen content of such silicon wafers is needed in order to allow silicon suppliers to meet modern VLSI processing specifications. However, the methods the author suggests for including the effect of a nonpolished back surface on the intensity of the transmitted light do not adequately take into account losses due to surface roughness.

A better approach, which properly accounts for silicon-air interfaces and for the effects of multiple reflections, would be to start with the following equation²

$$I = \frac{I_0 T_f T_b e^{-\alpha x}}{1 - R_f R_b e^{-2\alpha x}} \quad [1]$$

where I is the intensity of the transmitted light, I_0 is the intensity of the incident light, T is the nonscattered transmittance, α is the sample absorptivity, x is the sample thickness, R is the nonscattered (*i.e.*, specular) reflectance, and the subscripts f and b refer to the front and back surfaces of the silicon slice, respectively. The loss of light due to scattering would result in lower values for both the transmittance and the reflectance of the rough surface as compared to the transmittance and reflectance of a polished surface. Starting from Eq. [1] and assuming that the front surface is polished so that

$$T_f = T \quad \text{and} \quad R_f = R$$

but the back surface is not polished, we can write

$$R_b = sR \quad \text{and} \quad T_b = sT$$

where s is the factor characterizing the scattering from the nonpolished back surface. Then we have

$$I = \frac{I_0 T^2 s e^{-\alpha x}}{1 - R^2 s e^{-2\alpha x}}$$

To put this equation in a form similar to that used by Graff, note that $T = (1 - R)$ and let $s e^{-\alpha x} = e^{-\alpha^* x}$. Then we have

$$\text{Transmittance} \equiv \frac{I}{I_0} = \frac{(1 - R)^2 e^{-\alpha^* x}}{1 - R^2 e^{-\alpha^* x} e^{-\alpha x}} \quad [2]$$

which is not Graff's Eq. [1]. In other words, his method of modifying the classical equation for transmission through a

parallel plate is not adequate, because α^* cannot consistently be substituted for α in both the numerator and the denominator in this equation. In addition, note that both Eq. [2] above and Graff's Eq. [1] would not be useful, because they do not respond properly to a variation in the sample thickness x .

In addition, there are some difficulties with the application of his method, as described in his Eq. [3]-[7]. These equations do not specify which of the reference wafers are designated by the subscripts f , b , and 3 . It appears that a key assumption is that a given back-side treatment, such as grinding or sandblasting, would produce similar results with both Czochralski (Cz) and float-zone (fz) silicon. Unfortunately, because the presence of oxygen in Cz silicon results in a material which is mechanically stronger than low-oxygen float-zone silicon,³ the assumption of equivalent damage in Cz and fz silicon cannot be accepted without experimental support. For example, as Graff points out, the ground Cz wafer transmitted 12% of the incident light, while the ground fz wafer only transmitted 5.6%.

K. Graff:⁴ In measuring the IR transmittance of common silicon wafers with polished front side and more or less rough reverse side, the following experimental facts must be taken into consideration.

According to the reflectance R of the silicon-air interface, the incident beam is reflected at both surfaces of the sample. The reflectance is a constant which depends only on the refractive index of silicon and is independent of the structure of the surface. Whereas the polished surface of the sample reflects the incident beam for perpendicular irradiation in the opposite direction, the rough reverse side does not. Here the radiation is scattered, effecting a divergent reflected beam. For a single-beam transmission (neglecting multiple reflections), this scattering does not affect the transmitted intensity. Therefore, the single-beam approach for thick samples and high absorption remains almost unaffected by rough surfaces.

However, taking into account multiple reflection within the sample to be measured, a considerable difference between a both-sides polished wafer and a common wafer with one rough surface is observed. The divergent reflected beam from the reverse side of the wafer causes a divergent transmitted beam after reflection at the polished surface. Only a small fraction of this divergent beam is monitored by common spectrometers. As a consequence, the absolute transmission is decreased compared to an equal wafer with polished surfaces.

In order to take into account these losses due to surface roughness, we assume an additional fictive absorption α^* within the volume of the wafer, which effects the same loss of intensity in the volume of the sample as scattering does at

¹ National Bureau of Standards, Washington, DC 20234.

² A Baghdadi in "Defects in Silicon," W. M. Bullis and L. C. Kimerling, Editors, p. 293, The Electrochemical Society Softbound Proceedings Series, Pennington, New Jersey (1983).

³ K. Sumino, in "Semiconductor Silicon/1981," H. R. Huff, R. J. Kriegler, and Y. Takeishi, Editors, p. 208, The Electrochemical Society Softbound Proceedings Series, Pennington, New Jersey (1981).

⁴ Telefunken electronic GmbH, D-7100 Heilbronn, Germany.

the rough reverse side. This fictive absorption α^+ can be determined by means of the well-established Eq. [1] using the measured reduced absolute transmittance T .

On the other hand, the proposed statements of Baghdadi

$$R_b = sR \quad T_b = sT \quad T = 1 - R$$

yield

$$T_b = s(1 - R) \quad \text{and} \quad T_b = 1 - R_b = 1 - sR$$

which is contradictory by statement because reflectance R_b and transmittance T_b at the back side are not reduced by the same factor s (for $s \neq 1$). Furthermore, the statement of Baghdadi

$$se^{-\alpha x} = e^{-\alpha^+ x}$$

is not suitable to compare his Eq. [2] with our Eq. [1] because

$$se^{-\alpha x} = e^{-\alpha x + \ln s} \neq e^{-\alpha^+ x}$$

Because the statements of Baghdadi are contradictory, his conclusions must be misleading.

As already discussed in the original paper, a simple reduction of the reflectance R yields no suitable means for evaluating the beam scattering. Besides, by assuming a fictive absorption α^+ , the correction for intensity losses can also be done by assuming a higher fictive sample thickness

d^+ which is performed by the same mathematical formalism. This fictive sample thickness d^+ , however, must be determined using the absolute transmittance of sample at 1105 cm^{-1} where oxygen absorption takes place and not at any other wavelength, because scattering may considerably depend on the wavelength.

In conclusion, our proposed correction method for taking into account intensity losses at rough silicon surfaces has meanwhile been applied in several hundreds of measurements, yielding accurate results. Results obtained on highly scattering wafers with low transmittances approach those obtained by applying the equation for single reflection. On the other hand, results obtained on well-polished wafers approach those obtained by means of the equation for multiple reflection.

Although the mathematical formalism (Eq. [3]-[7]) for developing the rather simple final Eq. [9] seems rather complicated because the usually graphically constructed base line of the reference measurement must be simulated by introducing a further reference measurement on two additional reference samples ref_2 and ref_3 , the application of the final equation is quite simple and fast. The determination of the oxygen content on a single wafer which is composed of two spectra (an absolute air reference and a reference measurement), including evaluation by computer, takes less than 4 min.

INTRODUCTION

During past two decades, the importance of rechargeable lithium cells has been emphasized and a large variety of materials has been discovered and evaluated for use as reversible cathodes and electrolytes. Materials that undergo intercalation or topochemical reactions with lithium have been investigated as candidates for cathodes in nonaqueous secondary lithium cells (1). Recent interest in researching cathode active materials has mainly focussed on crystalline transition metal chalcogenides. On the other hand, electrochemical behaviors of several amorphous materials have been reported, for example MoS_2 , MoS_3 , V_2S_5 (2) and LiV_3O_8 (3). However, no successful cycling behavior has been obtained except for MoS_2 in the amorphous state. This paper reports electrochemical data on rechargeable vanadate glasses in the system V_2O_5 - P_2O_5 .

EXPERIMENTAL

Vanadate glasses in the V_2O_5 - P_2O_5 system with 95 and 90 mole% V_2O_5 were prepared by melting the oxides in platinum crucibles for 1 hr at 750°C followed by quenching at water temperature. X-ray diffraction studies indicated that these vitreous oxides were amorphous to X-ray.

Cathode characteristics of vanadate glasses were examined by using a coin type cell which has a conventional flat cell configuration (23 mm diameter and 2 mm thickness) and a cathode area of 2 cm². The cathode was a mixture of vanadate glass and ketjen black with a small quantity of polytetrafluoroethylene powder. The lithium content in each cell was ca. 200 mAh. The electrolyte used here was 1.5M-LiAsF₆/2-methyltetrahydrofuran. As a separator, Celgard 2402 was used.

*Electrochemical Society Active Member

Key words: Li secondary battery, cathode, vanadate glass.

The cells were assembled in a drybox filled with argon gas. The cell performance was evaluated at a constant current.

RESULTS AND DISCUSSION

Infrared absorption spectra of 95 and 90 mole% V_2O_5 - P_2O_5 glasses are shown in Fig. 1, together with that of V_2O_5 crystal. It should be noted that the absorption of V=O vibration around 1000 cm⁻¹ and V-O vibration around 800,600 cm⁻¹ remain in amorphous state, so similar bonds are present in vanadate glass.

Discharge curves of 95 mole% V_2O_5 - P_2O_5 glass at various currents are shown in Fig. 2. There was no clear appearance of the plateau followed by a slope. This suggests that in the amorphous state there is not any site preference for Li⁺ compared with crystalline V_2O_5 in which there are some energetically different reaction sites depending on crystal structure. Similar discharge behaviors were observed for 90 mole% V_2O_5 - P_2O_5 glass. These vanadate glasses showed high energy density of ca. 900 Wh/kg(glass weight) at 1.5 V cut-off and accommodate 3 Li/vanadate glass.

Typical cycling behavior of 95 mole% V_2O_5 - P_2O_5 glass at 1 Li/mole depth (150 Ah/kg) and 1 mA/cm² rate is given in Fig. 3. After several cycles, the cell showed good reversibility, resulting in a prolonged cycle life of over 145 times. And another deeper cycling test was carried out between 2 V and 3.5 V at 0.5 mA/cm² for the same cell system (Fig. 4). The cell has been cycled over 95 times at a depth of ca. 1.2 Li/mole and is still running.

In crystalline V_2O_5 , further reduction below 2.5 V ($x > 1$ in $Li_xV_2O_5$) leads to eventual breaking of the weak V-O bonds along cleavage plane (010) followed by a major structural reorganization, resulting in further irreversibility (4). To the contrary, although our vanadate glasses have similar V-O bonds to crystalline V_2O_5 as

seen in Fig. 1, the somewhat broad IR spectra are indicative of variations in bond length. This bond length variation seems to act as a structure-stabilizer and to sustain extended cycling without a significant rupture of V-O bonds. Indeed, SEM observation indicated that there was no cleavage in the vanadate glass studied here, in contrast with layer structure crystalline V₂O₅.

We are presently making studies of glass composition dependence and electrolyte effect for cathode properties, and in the course of the study we believe advanced rechargeable Li/vanadate glass cells with improved high energy density and cycle life will be discovered.

Ion Transporting Composite Membranes

I. Nafion-Impregnated Gore-Tex

Reginald M. Penner and Charles R. Martin*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

Nafion is a family of extremely versatile cation transporting polymers (1). While they have many highly desirable chemical and mechanical features (1), the Nafion polymers have a potentially significant disadvantage — they are rather expensive. The high costs of these polymers have prompted an effort to develop membrane materials with the same desirable chemical and mechanical features, but which can be produced more cheaply (2).

It occurred to us that an ionically conductive membrane has two major functions, a structural/mechanical function (i.e., to serve as a chemically inert barrier to prevent bulk mixing of catholyte and anolyte solutions) and a chemical function (i.e., to selectively transport the desired ion from one solution to the other). It seemed likely that a cheaper membrane could be prepared by doping an inexpensive, nonconductive material (which serves the mechanical/structural function) with a small amount of an ion transporting polymer (which allows the membrane to accomplish its chemical function). In an effort to demonstrate the feasibility of this approach, we have impregnated commercially available porous polytetrafluoroethylene membranes (PTFE, Gore-tex) with small quantities of Nafion, to make cation transporting composites. The results of our initial studies of the transport properties of these composites are described here.

Nafion 117 and Gore-tex (0.2 μm mean pore diameter) membranes were donated by E. I. Du Pont and W. L. Gore Associates, respectively. Solutions of Nafion were prepared using the procedure of Martin, et al. (3). The transport properties of the native and Nafion-impregnated Gore-tex (NIGT) membranes were studied electrochemically (4) using wax-impregnated graphite (WIG) rods (5) as the substrate electrodes. Briefly, a section of Gore-tex membrane was stretched over the pretreated (6) WIG electrode surface and held in place by a collar of heat shrinkable Teflon tubing. The Gore-tex was

*Electrochemical Society Active Member.

then Nafion-impregnated by immersing the membrane-covered electrode in Nafion solution (0.7 to 2.5 w/V% in 95% ethanol) and ultrasonically for 30 min. The electrode was removed from the impregnating solution and the solvent was allowed to evaporate (room temperature, 5 hours).

Gore-tex membranes are made of porous PTFE and are available in a variety of porosities. Because of the chemical inertness and mechanical strength of PTFE, Gore-tex seems to be the ideal material for satisfying the mechanical/structural membrane function. Furthermore, Gore-tex is about an order of magnitude cheaper than Nafion. Native Gore-tex membranes are not wetted by water and, therefore, totally insulate a substrate WIG electrode from a contacting aqueous supporting electrolyte solution (Fig. 1, curve A). However, when Nafion-impregnated, the membranes become water swollen and ionically conductive; background cyclic voltammograms (Fig. 1, curve B) similar to those observed at the uncoated WIG electrodes are obtained. The ionic conductivity of NIGT is more dramatically demonstrated by the voltammograms shown in Fig. 2; a NIGT-WIG electrode was immersed in a solution 3 mM in $\text{Ru}(\text{NH}_3)_6^{3+}$ and the potential was scanned over the $\text{Ru}^{\text{III/II}}$ redox wave. A $\text{Ru}(\text{NH}_3)_6^{3+}$ "loading" voltammogram very similar to that obtained at a Nafion-film modified electrode (4) is observed (Fig. 2a).

When $\text{Ru}(\text{NH}_3)_6^{3+}$ loaded NIGT-WIG electrodes are transferred to supporting electrolyte solution, the majority of the $\text{Ru}(\text{NH}_3)_6^{3+}$ is retained by the NIGT membrane (Fig. 2b); this is again, analogous to results obtained with Nafion film-coated electrodes (4). As shown in Fig. 2b, the differences in potential between the anodic and cathodic peaks for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ waves decrease as the quantity of Nafion impregnated increases. This suggests (as might be expected) that the ionic conductivity of NIGT increases with the quantity of

Manuscript submitted Oct. 30, 1984.

Nafion incorporated.

Finally, it is of particular interest to note that preliminary measurements of the apparent diffusion coefficients for $\text{Ru}(\text{NH}_3)_6^{3+}$ and $\text{Ru}(\text{NH}_3)_6^{2+}$ in NIGT membranes containing ca. 15 wt % Nafion have produced values which are over an order of magnitude larger than the corresponding diffusion coefficients in Nafion (4). This suggests that the open porous structure of Gore-tex allows for markedly enhanced ion transport rates. Further studies of these and related composite membranes are in progress.

Activation Energy for the Parabolic Rate Constant during Sequential Si Oxidation

C. J. Han* and C. R. Helms**

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

In this communication we report on an analysis of recent experimental data (1) which clearly shows that transport properties of thermally grown SiO₂ change as a function of temperature. Our analysis is consistent with other observations where the refractive index (2,3), density (3), and interfacial stress (4) in SiO₂ vary with temperature. These changes account for the apparent anomalous effect of temperature on the activation energy for the parabolic rate constant, B, reported by several investigators (5-7). Figure 1 shows this effect in an Arrhenius plot of these data (5-8). The activation energy varies from 0.9 eV at 1150°C to 2.6 eV at 780°C.

Recent experiments by Irene (1) shed considerable light on the mechanism for this change in activation energy. He grew oxides in dry O₂ at 1000°C to 1µm thicknesses, then recorded oxidation rates for subsequent oxidations at lower temperatures. The rates measured at lower temperatures should have therefore exhibited the properties of a "1000°C" oxide, so long as the lower temperature oxidations did not significantly affect their structure.

In a reanalysis of Irene's data, using an improved lag time formulation, we indeed observe this effect (9). The oxidation rates were analyzed using the linear parabolic rate law:

$$\frac{dL}{dt} = \frac{B}{2L+A} \quad [1]$$

where L is the thickness, B is the parabolic rate constant B/A is the linear rate constant, and dL/dt is the growth rate. Since dL/dt and L are measured quantities, B can be determined if A is known; since L>>A for these experiments, the error caused by an uncertainty in A is not significant.

* Electrochemical Society Student Member

** Electrochemical Society Active Member

Key Words: Insulator, diffusion, oxidation

To verify this we evaluated the value for B in two limits. First, the B/A values from Ref. (5) provided one limit; second, B/A → ∞ provided the other limit for the minimum value for B. We plotted these B values for Irene's 800°C, 900°C, and 1000°C oxidation rates in Fig. 1 along with the previously reported B values (5-8). As mentioned above, previous results showed the familiar change in the apparent activation energy as a function of temperature. However, the parabolic rate constants from Irene's sequential experiments at 800°C and 900°C fall along a straight line tangent to the curve of B values at 1000°C with a slope of 1.1 eV! During the second oxidation, the oxide appeared to retain the activation energy and the preexponential factor from the 1000°C oxidation. In the 40 hours Irene oxidized his samples, the 1000°C oxide apparently did not change its form to equilibrate with the lower temperature. It retained a "memory" of the past oxidation process. The direction of the change to lower activation energy for higher temperature oxides is also not surprising since the lower density and the stress relaxation for higher temperature oxides would promote the lower activation energy.

There is also evidence that the linear rate constant exhibits a "memory effect" as well. Hamasaki (10) observed enhanced oxidation rates for thinner oxides in a sequential higher temperature/lower temperature oxidation sequence. In that case, however, the enhancement in oxidation rate decreased with oxidation time. This may not be surprising since the linear rate constant, being an interface property, may equilibrate rapidly at the new growth temperature.

Electrochemical Degradation of Polyacetylene Molecular Structure

Fritz G. Will*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

While the structural effects of thermal and oxidative treatments of polyacetylene have been the subject of a number of studies (1-3), the electrochemical stability of polyacetylene has not been similarly addressed. Evidently, the effect of repetitive charge and discharge and that of deep discharge and overcharge on the structural integrity of polyacetylene are significant for the potential use of polyacetylene electrodes in rechargeable cells or batteries (4). This communication presents results on the effect of deep discharge and heavy charge on the molecular structure of p-doped polyacetylene. Fourier-transformed photoacoustic infrared spectroscopy (PAS) is employed to evaluate structural changes in the polyacetylene resulting from the electrochemical treatment.

Polyacetylene film of 68 μ thickness had been prepared by the Rohm and Haas Company, using the standard Shirakawa technique (5). Details regarding the preparation have been published elsewhere (6). The film had an apparent density of 0.56 g/cm³ or 48% of theoretical and a specific surface area of 40 m²/g. Circular electrodes of 1.2 cm² area were provided on one side with a 1000 Å Au film and an Au wire, attached with Au-epoxy cement. Experiments were carried out in a PTFE cell using a Li counter and reference electrode. The electrolyte was a 10% b.w. solution of LiBF₄ in sulfolane. Handling, experimentation and transfer of samples were performed in dry, inert gas environment. To obtain good PAS data, electrode films were shredded after removal of the Au film. This enhanced the signal strength by improving the acoustic coupling. The PAS equipment employed has been described elsewhere (6).

Electrode 1 was charged with 0.24 mA/cm² for 1 h, corresponding to a BF₄ dopant level of 3 mole%. It was then left on open circuit for 1 h and discharged with 0.08 mA/cm² to 1.5V versus Li reference; 0.9 mole% dopant remained in the structure. The relevant potential-time curves are shown in Fig. 1. After an open circuit stand of 15 h, the

potential was 2.5V and the electrode was removed for IR-spectroscopy.

Electrode 2 was charged with 0.24 mA/cm² for 1 h, left on open circuit for 1 h and then cathodically polarized with 0.24 mA/cm² for 15 h. Only the first 3 h of discharge are shown in Fig. 1. Above about 1.2 V, p-dopant is removed and below 1.2 V n-doping of polyacetylene with Li occurs; n-doping was performed for 14 h to a level of 42 mole%. Subsequent anodic polarization with 0.24 mA/cm² for 9 h leads to the potential-time curve shown in Fig. 2; 13.5 mole% n-dopant, Li, is removed during the first 4.5 h and 13.5 mole% p-dopant, BF₄, incorporated during the next 4.5 h. After an open circuit stand of 15h, a potential of 3.4V was attained and the electrode was removed for IR spectroscopy.

Photoacoustic spectra of pristine polyacetylene film (6) and of electrodes 1 and 2 are shown in Fig. 3(a), (b) and (c), respectively. The wavenumbers of the major absorption bands are given in Table 1. Spectrum (a) is characteristic for undoped film comprising a mixture of the cis- and trans- isomer (6). Spectrum (b) for electrode 1, p-doped to 3 mole% and undoped to 0.9 mole% once, shows the characteristic polyacetylene features much reduced and the cis bands less pronounced than the trans-bands. These two effects are due to the strong free charge-carrier absorption and dopant-induced cis- to trans- isomerization (5,7). The dominating features of spectrum (b) are the strong bands at 1405 and 1295 cm⁻¹ which are not present in spectrum (a) for pristine polyacetylene. Two similar bands have been observed in gas phase-doped polyacetylene by others (8-10) and have been ascribed (8) to dopant-activation of Raman modes in the IR corresponding to C-C and C=C stretching.

Spectrum (c) for electrode 2, p-doped to 3 mole% followed by n-doping to 13.5 mole% and p-doping to 13.5%, shows the weak features of trans-polyacetylene similar to electrode 2. The dopant-activated bands at 1415 and 1297 cm⁻¹ are stronger, corresponding to the higher dopant level. The most significant features, however, are the two strong bands at 2920 and 2852 cm⁻¹ which were not present in the spec-

*Electrochemical Society Active Member

Key Words: Polymers, Electrode, Infrared

tra of pristine polyacetylene or of electrode 1. These bands are typical for the asymmetrical and symmetrical C-H stretching modes of methylene groups in long-chain aliphatic hydrocarbons. In agreement with this interpretation, the complex band structure between 1200 and 900 cm^{-1} can also be ascribed to C-C stretching modes in long-chain hydrocarbons.

Thus, we find clear evidence that a single overdischarge, resulting in 13.5 mole% n-doping, followed by heavy p-doping or charging to 13.5% mole% leads to irreversible attack on the molecular backbone of the polyacetylene structure. The nature of the attack is the breaking of the double bonds in the conjugated bond system $=\text{CH}-\text{CH}=\text{CH}-$ and the concurrent formation of long-chain aliphatic hydrocarbons $-\text{CH}_2-\text{CH}_2-\text{CH}_2-$.

Table I. Photoacoustic Spectra of Polyacetylene Films

A Two-Photoelectrode Solid-State Photoelectrochemical Cell

Anthony F. Sammells* and Sharon K. Schmidt

Eltron Research Incorporated, Naperville, Illinois 60540

The use of solid-electrolyte based photoelectrochemical (PEC) cells provides a unique approach for the PEC conversion and storage of selected redox species incorporated within the proximity of the semiconductor/solid electrolyte interface. For such interfaces, however, the efficient recombination of photogenerated carriers appears to be greatest when both polycrystalline semiconductor and solid electrolyte materials are present at the junction. As a consequence, PEC cells fabricated which contain such interfaces, frequently possess little or no effective photoactivity. To minimize such high populations of surface states, single crystal photoelectrodes in contact with solid polymer based electrolytes have been used. We have previously reported on the two photoelectrode cell p-InP/PEO·NaSCN, Na₂S, S/n-CdS where the sodium ion conducting solid polymer electrolyte (SPE) poly(ethylene oxide) PEO was used.¹ Upon illumination, this cell gave photopotentials up to 540mV, however current densities of less than 1 μA/cm² could only be achieved even under both biased and illuminated conditions. This was in part a consequence of the high resistivity of the SPE material used. PEO had earlier been used in the solid-state PEC cell n-Si/PEO, KI, I₂/SnO₂ glass, where the n-Si photoanode was initially coated with platinum and subsequently protected from photoanodic corrosion effects by a sequential layer of platinum and polypyrrole.² For PEO based PEC cells, small interelectrode spacings are desirable for not only minimizing cell IR losses but also for improving light transmission to the solid-state junction of interest. Achieving small well defined interelectrode spacings can, however, often be logistically somewhat difficult and can frequently lead to cell shorting.

If we wish to introduce some faradaic storage capacity into a solid-state PEC cell, it will be necessary to provide for effective separation of the oxidant and reductant species which reside close to the appropriate photoelectrode. While this, in principle, could be achieved using PEO, the preparation of an interelectrode spacing with clearly

defined oxidant, separator and reductant regions can be expected to provide a formidable task. This problem has been addressed here by the use of the perfluorinated cation exchange membrane Nafion,³ as the SPE in a solid-state PEC cell containing potential storage capacity. The PEC activity of semiconductors incorporated onto Nafion in contact with aqueous solutions has been previously reported on, directed towards the photoelectrolysis of water.⁴

As is well known, this material has found extensive application in a variety of electrochemical cells. In addition, redox species such as (bpy)₃Ru²⁺ have been shown to be irreversibly coordinated into Nafion's polymeric matrix where they have exhibited electrochemical reversibility.⁵⁻⁸

Here it appears that the mobile conducting cations are exchanged by the introduced redox species. When such redox containing polymers are attached to an electrode, redox electrochemistry can take place via an electron self-exchange reaction involving the introduced redox species.⁹⁻¹¹ This SPE material can consist of essentially two phases¹² which contain respectively a bulk polymer and a lower density ionic cluster phase. It is in the lower density phase that introduced redox complexes appear to reside. In addition, the higher oxidation states of such complexes appear to be less strongly held than do their lower oxidation states.¹³

We wish to report on the cell

where the respective redox species are initially introduced in a Nafion 117 solution which is subsequently applied onto the surface of a sodium exchange Nafion 117 membrane. The materials and procedures followed for preparation of this cell will now be discussed.

Single crystal n-CdS was obtained from Cleveland Crystal. Ohmic contact to this

material was made by initially etching with H_2SO_4 and after rinsing with distilled water and drying, contacted with a gallium-indium eutectic. Current collection was achieved to this area via a nickel wire and silver epoxy, and the whole electrode assembly cured at $150^\circ C$ for one hour.

The p-InP single crystal was obtained from CrystaComm Inc. (Zn doped $\approx 10^{17} \text{ cm}^{-3}$). The $\langle 111 \rangle$ face was used. After etching the surface with bromine/isopropanol solution, ohmic contact was achieved by the sequential vacuum thermal evaporation of a Au/Zn/Au layer followed by an anneal under H_2 for one hour at $400^\circ C$. The cell was prepared by introducing a drop of a 5% Nafion 117 present in a mixture of lower aliphatic alcohols containing 0.005M iron (III) meso-tetraphenyl porphine chloride ($C_{44}H_{28}ClFeN_4$) and 0.01NaCl onto both the surface of an appropriately etched p-InP and a Na^+ exchanged Nafion 117 membrane. After both halves were allowed to nominally dry under ambient conditions for about one hour, they could be directly contacted by lightly pressing. A similar procedure was followed for the photoanode side where a 5% Nafion solution containing 0.01M $(byp)_3RuCl_2$ and 0.01M NaCl, was introduced onto both the Nafion 117 membrane and n-CdS single crystal before finally being contacted together. A schematic diagram of the finally assembled cell is shown in Figure 1. The simultaneous illumination of both the n-CdS and p-InP redox solid electrolyte junctions was achieved from the n-CdS photoanode side.

Selection of this two photoelectrode cell was preceded by a preliminary investigation of various redox species introduced into the SPE using cells of the configuration photoelectrode/redox, Nafion117/SnO₂ Cond. Glass. For the cells n-CdS/ $(byp)_3RuCl_2$ + Nafion 117/SnO₂ conducting glass, and p-InP/Tetraphenyl Fe^{3+} Porphine + Nafion 117/SnO₂ conducting glass, illumination through the conducting glass (100 mW/cm^2 quartz-iodine) to the photoelectrode/SPE interface of interest, photopotentials of respectively -750 mV and $+420 \text{ mV}$ were realized from each cell. In addition, upon potentiostatting each of these cells respectively 0.4 V cathodic or anodic of their illuminated rest potential, current densities in the 3 to $20 \text{ } \mu\text{A/cm}^2$ range were obtained.

The two photoelectrode cell
 p-InP/ $C_{44}H_{28}N_4Fe^{3+}$ /Nafion/ $(byp)_3Ru^{2+}$ /n-CdS
 Porphine 117 +
 + Nafion 117
 Nafion 117

approximately one hour after fabrication possessed a dark open circuit potential of 380 mV .

Upon illumination of this cell, an initial photopotential of 1130 mV was realized. The photopotential-time characteristics of this cell are shown in Figure 2A. The photo-current-voltage scan for this cell is shown in Figure 2B. Here the total cell potential is reported where cell charge is occurring over the voltage range shown. PEC charge currents up to $30 \text{ } \mu\text{A/cm}^2$ were realized upon cell bias. The half-cell reactions during cell charge will correspond to $TPPFe^{3+} + e^- \rightarrow TPPFe^{2+}$ at the p-InP photocathode and $(byp)_3Ru^{2+} + h^+ \rightarrow (byp)_3Ru^{3+}$ at the n-CdS photoanode. The photocurrent wavelength response of this cell was performed using a Rudolph Instruments Monochromator Model #681A31. The light source used was a Sylvania 300W ELH bulb. These cell characteristics are shown in Figure 3. The peak photocurrent occurs at $\approx 550 \text{ nm}$ or 2.25 eV , which is approximately 300 mV below the n-CdS band-gap. This may be a consequence of the ruthenium doped SPE sensitizing the n-CdS photoanode to larger wavelengths. This might be a result of the $(byp)_3Ru^{2+}/(byp)_3Ru^{3+}$ couple being somewhat positive of the n-CdS flat-band potential.¹⁴

In conclusion, we have identified a two photoelectrode solid-state PEC cell which is able to produce photopotentials in excess of one voltage and possesses some inherent storage capacity. This storage capacity is, of course, presently limited by the low concentration and thin SPE redox layers used between the photoelectrode and the SPE membrane. It is expected that this cell will be of potential value as not only a specialized storage device, but for specific detector applications.

The n-CdSe Photoelectrochemical Cell: Wavelength-Dependent Photostability

Holly-Dee Rubin, Douglas J. Arent, and Andrew B. Bocarsly*

Department of Chemistry, Princeton University, Princeton, New Jersey 08544

Much recent work has focused on $\text{Fe}(\text{CN})_6^{4-/3-}$ as a stabilizing electrolyte for n-CdX (X=S, Se) based photoelectrochemical cells (1-5). Prior studies performed in this laboratory (6) showed that irradiation of n-CdS in an electrolyte containing $\text{Fe}(\text{CN})_6^{4-/3-}$ can lead to formation of a surface layer of $[\text{Cd}^{\text{II/III}}\text{Fe}^{\text{II/III}}(\text{CN})_6]^{2-/1-}$. In the presence of the appropriate cations, this layer was associated with improved cell output parameters. These studies have now been extended to include the n-CdSe system. In this letter we wish to report an unprecedented wavelength dependence of the n-CdSe photoelectrochemical cell.

Figure 1 illustrates the dependence of the cell photocurrent stability on incident irradiation wavelength. Light intensity was adjusted so that similar current densities were obtained at the two wavelengths employed since some absorption by solution species occurs at 488nm. When the 488nm line of an Ar^+ laser is used, stable photocurrent output is achieved for periods in excess of several hours (7). However, when excitation is at 633nm (He-Ne laser) the photocurrent decreases with time. The extent to which this is observed is found to be concentration dependent. At high concentrations ($>0.5\text{M}$) of $\text{K}_4\text{Fe}(\text{CN})_6$, photostability at 633nm increases, so that the difference in stability between 488nm and 633nm is decreased but still evident.

Further experiments performed on both single crystal [(0001) face], and polycrystalline n-CdSe using a 2500W Xe lamp and a Schoeffel monochromator indicate that the onset of stability occurs at energies higher than about 550nm. All wavelengths studied are capable of exciting the band gap transition of CdSe ($E_{\text{BG}}=1.7\text{eV}$). Furthermore, it is found that if a sample is initially irradiated at 488nm and then later exposed to 633nm light, the resulting photocurrent is stable.

We believe that a $\text{Cd}^{\text{II}}\text{Fe}^{\text{II/III}}(\text{CN})_6$ surface layer is responsible for this behavior. In support of this conclusion diffuse reflectance FTIR spectroscopy of irradiated electrodes yields data which coincide with those obtained from authentic samples of $\text{K}_2[\text{Cd}^{\text{II}}\text{Fe}^{\text{II}}(\text{CN})_6]$.

Although it has been previously suggested that the corrosive formation of a selenium surface layer is the source of n-CdSe photostability in $\text{Fe}(\text{CN})_6^{4-/3-}$ electrolyte (5), such an overlayer cannot be invoked to explain the observed behavior. A selenium layer, were one to form, would be anticipated to develop at all wavelengths studied. This layer would be expected to exhibit the same behavior at a given wavelength, irregardless of irradiation pretreatment, i.e. preirradiation at 488nm should not affect electrode stability at 633nm, in contrast to the observed behavior.

Although a selenium overlayer may be present, the cation dependence of the systems under study also tends to rule out such a layer as responsible for either the electrode photostability or the wavelength dependent behavior. It has been suggested that addition of salts to the $\text{CdX}/\text{Fe}(\text{CN})_6^{3-/4-}$ solution should result in competitive adsorption (3) (i.e. the salt is able to displace adsorbed ferro-ferricyanide) with a concomitant decrease in cell output. Addition of Cs^+ salt to the n-CdSe cell does lead to instability. However, as previously reported (6), addition of CsNO_3 to the CdS/ferro-ferricyanide cell improves stability, in marked contrast to the results obtained at n-CdSe and to those predicted by the competitive adsorption model. These results are consistent with the hypothesis advanced previously that the role of the alkali cation is to influence the redox potential of the surface species, enhancing communication between this species and the semiconductor valence band (6). These observations also tend to support the conclusion that a selenium corrosion layer cannot be responsible for the wavelength dependence - selenium would not be expected to induce cation

*Electrochemical Society Active Member.

Key words: semiconductor, films, photoelectricity, energy conversion

dependent behavior.

Since a $[\text{CdII/III}(\text{CN})_6]^{1-/2-}$ layer appears to form at all wavelengths studied, it is logical to ascribe the wavelength dependence to the photochemical properties of the surface species. Alternately, solution based photochemistry might be considered as the source of the wavelength dependence. However, it is highly improbable that solution photochemistry could produce the wavelength dependence, since there is no observable change in the solution redox potential as measured before and after irradiation, and absorbance at these wavelengths is exceedingly low. If solution photochemistry is occurring, the concentration of products would be too low to have a major effect. Therefore, we propose that at $\lambda < 550\text{nm}$ the surface attached material undergoes a photochemical reaction leading to a product responsible for the improved output characteristics of the n-CdSe ferro-ferricyanide photoelectrochemical cell.

The wavelength dependence suggests ligand loss as the most likely process (8). Several possible outcomes resulting from ligand loss can be envisioned, all of which provide a mechanism for stabilizing the interface. Aquation could occur. The resulting aquated surface species would be expected to have a different film morphology than the parent complex. $\text{MFe}(\text{CN})_6$ species are known to possess a zeolitic structure (9); aquation could lead to a change in pore size. Were the pore size to increase, solution contact with the surface film could be enhanced. Since one function of the film is to mediate charge transfer from the semiconductor to the solution redox couple (6), increased solution contact could facilitate this process, thus providing a more stable interface. A second outcome of ligand loss could be that the iron centers are able to come in close proximity, again enhancing the charge transfer properties of the film. Finally, the introduction of an empty coordination site on the Fe center provides the possibility of direct Se-Fe bonding from a surface Se site. This bonding could promote charge transfer from the semiconductor to the surface attached species via an inner sphere mechanism.

In conclusion, a $\text{CdFe}^{\text{II/III}}(\text{CN})_6$ surface layer on n-CdSe not only enhances photostability, but also induces wavelength dependent behavior in the photoelectrochemical cell composed of n-CdSe/ $\text{Fe}(\text{CN})_6^{4-/3-}$. The wavelength dependence appears to be due to a photochemical reaction which changes the properties of the surface film. Such changes appear capable of enhancing charge transfer

rates at the semiconductor interface, thus decreasing the relative importance of the photodecomposition pathway. The surface film can be prepared at 488nm with subsequent irradiation at much lower energy resulting in a stabilized photoelectrochemical cell.

ABSTRACT

Mechanistic studies of the reactions in Li-SOCl₂ cells have been undertaken to improve understanding of the safety problems of these cells. The electrochemical reduction of 1.5M LiAlCl₄/SOCl₂ has been investigated using gas chromatography, electron spin resonance spectroscopy, and infrared spectroscopy. Cl₂ and S₂Cl₂ have been identified as intermediates in the reduction of SOCl₂, along with a radical species ($g_{xx} = 2.004$, $g_{yy} = 2.016$, $g_{zz} = 2.008$) and the proposed triplet ground-state dimer of this radical. SO₂ and sulfur have been identified as products. Based upon these findings, a mechanism for the electrochemical reduction of 1.5M LiAlCl₄/SOCl₂ has been proposed, and its implications for safety of Li-SOCl₂ cells during discharge to +0.5V at 25°-30°C are discussed.

There has been great interest in the lithium thionyl chloride battery system because of its high energy density. The solvent, thionyl chloride (SOCl₂), is also the cathode active material, so this cell has the potential for high rate discharge. Despite much progress in the areas of design and optimization of cells and elimination of voltage delay, safety problems still hinder the application of the cells. The cells pose a safety problem because they have been found to vent (expel internal liquids and gases) or explode (1). Many explanations have been offered to account for the venting and explosion phenomena.

One general explanation for the observed unsafe behavior of Li-SOCl₂ cells is the production, and violent decomposition, of intermediates formed during the discharge of the cell. The concentration of the metastable compounds increases to the point that their decomposition causes venting or an explosion, or produces sufficient heat to trigger the direct Li-liquid cathode reaction. Although the overall cell chemistry, Eq. [1], is generally accepted, there is disagreement over intermediates formed during discharge and the discharge reaction mechanism

Several intermediates have been proposed in the reduction of SOCl₂, such as SO, (SO)_n, S₂O, and S₂Cl₂ (2-6). Of these intermediates, S₂O has been identified by infrared spectroscopy (5), and S₂Cl₂ has been identified by gas chromatography (6). A method for overcoming the possible "chemical" safety problem is to identify the intermediates which are formed during cell discharge and to establish the reaction mechanism of discharge. With this fundamental understanding of the cell chemistry, it should be possible to establish safe discharge conditions, such as voltage limits, or to modify the cell chemistry to eliminate the unsafe behavior due to hazardous intermediates. This paper presents the results to date of our efforts to achieve this goal for Li-SOCl₂ cells discharged at 25°-30°C to a voltage of +0.5V.

Experimental

All cell components for chemical studies were handled under an argon atmosphere in a Vacuum Atmospheres dry box (<10 ppm O₂). SOCl₂ was obtained from Aldrich and purified by distillation from triphenylphosphite (7). LiCl was obtained from Alfa and dried in vacuo for 24h at 130°C before use. AlCl₃ was obtained from Fluka AG,

* Electrochemical Society Active Member.

Chemische Fabrik (puriss.), and used without additional purification. 1.5M LiAlCl₄/SOCl₂ electrolyte solutions were used in all the experiments, and the reduction experiments were carried out at 25°-30°C.

Gas chromatography (GC) experiments were carried out with a Hewlett-Packard Model 5880 GC, with a 6 ft-1/4 in. glass column packed with 10% QF-1 on 80/100 chromasorb G column. The temperatures of the injector port and column were kept below 130°C to prevent reaction between S and SOCl₂ (8). Samples for the GC experiments were prepared by reduction of the electrolyte solution at the carbon electrode of a Li-SOCl₂ cell at 10 mA/cm² and 25°-30°C. Aliquots were removed and the samples transported to the GC in sealed reactivials. Electron spin resonance (ESR) spectra were recorded at 77 K on a Varian E-line Century Series spectrometer operating at X-band frequency (9.1 to 9.5 GHz) employing 100 kHz field modulation. Samples for the ESR experiments were prepared by rapidly reducing the electrolyte solution at gold or carbon electrodes at 25°-30°C and quickly freezing the samples. Infrared (IR) spectra were recorded at room temperature with a Digilab FTS-15C spectrometer. Samples for IR analysis were prepared *in situ* by reduction of the electrolyte solution at a gold grid electrode, at voltages of 3.6 to +0.5V_{Li}, 0.1 to 0.5 mA/cm², and at 25°-30°C (9).

Results and Discussion

In order to understand what hazardous compounds might be formed during discharge of a Li-SOCl₂ cell, and their implication for cell safety, it is important to establish the mechanism for the electrochemical reduction of SOCl₂. Two mechanisms have previously been reported for this reduction process (Fig. 1). Bowden and Dey (4) have proposed reducing SOCl₂ to yield SO, which could form the polymer (SO)_n. This polymer is proposed to be hazardous. Blomgren *et al.* (6) have proposed reducing SOCl₂ to yield SOCl, which in subsequent reactions yields SCl₂ and S₂Cl₂. Our work has focused on identifying the intermediates of the electrochemical reduction of SOCl₂, employing a variety of complementary techniques. Because of the complexity of the chemistry, it is important to have the corroborating evidence of complementary techniques to provide convincing evidence for a mechanism of the reduction of SOCl₂ in Li-SOCl₂ cells.

The GC results for fresh and discharged 1.5M LiAlCl₄/SOCl₂ solutions have been obtained (Fig. 2). For the fresh samples, the major peak is SOCl₂, but some SO₂ and S₂Cl₂

I. BOWDEN AND DEY (4)

II. BLOMGREN, ET AL (6)

Fig. 1. Postulated mechanisms for reduction of SOCl_2 in Li-SOCl_2 cells.

are present. After discharge, the amounts of Cl_2 , SO_2 , and S_2Cl_2 have significantly increased. These results strongly suggest that S_2Cl_2 and Cl_2 are intermediates in the reduction of SOCl_2 and are possibly formed by the disproportionation of SCl_2 . However, SCl_2 is not positively identified in the chromatograms, but it does seem reasonable to propose SCl_2 as an intermediate in the reduction of SOCl_2 .

Most of the ESR samples were prepared by reduction of $1.5\text{M LiAlCl}_4/\text{SOCl}_2$ at a gold electrode because doing so gives clean samples at voltages of 3.6 to $+0.5\text{V}_{\text{Li}}$ and current densities as high as 0.1 to 0.5 mA/cm^2 . The samples prepared should mimic the Li-SOCl_2 cell chemistry during discharge. In particular, these experimental conditions should mimic cell chemistry at the beginning of discharge, when excess electrolyte is present, because only a small amount of SOCl_2 is utilized. It is not clear if these current densities approximate 10 mA/cm^2 on a Teflon-bonded carbon electrode. Samples are also prepared using a carbon fiber electrode, but there is a problem with the structural integrity of the carbon electrode, since carbon particles are found in the samples. These carbon particles provide a large ESR signal due to the graphitic carbon radical which dominates part of the spectrum obtained with these samples, but the remainder of the spectrum is essentially the same as that observed for samples prepared at the gold electrode. This is an important point because it supports application of the results obtained on gold electrodes to real cell chemistry in which the reduction occurs on carbon electrodes.

The overall ESR spectrum of discharged $1.5\text{M LiAlCl}_4/\text{SOCl}_2$ is shown in Fig. 3. The spectrum is very complicated and covers about 5000G . This is most unusual because most ESR spectra of radicals cover a region of a few hundred gauss. A great deal of interpretation has been necessary to assign most of the features of this spectrum. Figure 4, curve A, shows the region around $g = 2$,

Fig. 2. Gas chromatograms of $1.5\text{M LiAlCl}_4/\text{SOCl}_2$

i.e., 3200G , expanded, and curve B shows the second derivative of the spectrum. The major points made by Fig. 4 are that the three g values are observed for the three principal axis, x , y , and z , because the sample is frozen. For each g value, a quartet is observed due to hyperfine splitting, the nuclear spin interaction with the electron spin angular momentum. Because of the quartet for each g value, it is concluded that the radical electron is localized on a nucleus of spin $3/2$. The most likely candidate for the nucleus is chlorine.

Table I summarizes the results from Fig. 4, along with presenting literature data of similar compounds. It is clear from Table I that these 19 valence electron molecules have similar g values. With these triatomic molecules, the unpaired electron should be largely localized on the central atom (10). As seen for OSCl , which was prepared by γ radiation of a frozen glass of SOCl_2 , there is very little hyperfine splitting because the radical electron is largely localized on sulfur (11). In ClO_2 , the radical electron is largely localized on chlorine, and a quartet is observed for each g value, with large hyperfine constants (12). The hyperfine constants for ClO_2 and the unknown are very similar and, thus, we conclude that the unknown

Fig. 3. ESR spectrum of discharge electrolyte at 77 K

Fig. 4. ESR spectrum of discharged electrolyte at 77 K: curve A = first derivative; curve B = second derivative.

is OCIS, with chlorine being the central atom. OCIS should have chemistry similar to ClO₂, which is a known hazardous compound when present at a partial pressure greater than 50 torr (13). If OCIS is present in significant concentration in a cell, it could be a safety hazard.

The most reasonable explanation for the ESR spectrum covering 5000G is the existence (assumed) of a molecule with large zero-field splitting. In this case, two OCIS monomers come together, and the two radical electrons interact, in the strong field case, to yield a dimer with a triplet ground state. For this dimer, there should be four forms: two isomeric forms of planar conformation; and two isomeric forms of skewed conformation (see Fig. 5). The planar forms are D_{2h} symmetry in the highest reasonable case, assuming O and S are similar (14). The planar forms should have three unique axes. In the ESR spectrum then, two transitions should be observed for each unique axis, and a total of six transitions should thus be observed. Because there are two isomeric forms of the planar conformation, a perturbation on the simple explanation, one would expect each transition, as predicted above, to be split into a doublet, as observed in Fig. 8. Following similar logic, the skewed conformations have a highest reasonable symmetry of D_{2d} (14). There are only two unique axes, since *x* and *y* are degenerate. Thus, four transitions should be observed for this dimer. Again, adding the perturbation of the other isomeric form, one should expect each transition to be split into a doublet. However, the *x* and *y* axes are not actually degenerate, so the transitions in these polarizations are expected to be split again to yield a doublet of doublets. These transitions are also observed in Fig. 6.

To date, the only reasonable way to account for the ten transitions shown in Fig. 6 is with a triplet ground-state dimer of the OCIS monomer. Supporting further these assignments, when the temperature of the frozen sample is warmed, the above peaks move closer to *g* = 2.0 and decrease in intensity. This is expected because the electron-electron repulsion should separate the monomeric units at higher temperatures, reducing the zero-field splitting and the concentration of dimer species. These assignments of the dimer are also supported by calculations (9).

Fig. 5. Proposed structures of (OCIS) dimers

To obtain initial data on the lifetimes of the radical intermediates and to observe ESR active compounds formed later in the reduction sequence of SOCl₂, warming experiments were initiated. In these experiments, ESR samples were warmed for a specific length of time at a specific temperature, then cooled to 77 K to obtain the spectrum. Although these experiments have not been completed, one can estimate that the half-lives of OCIS and its triplet dimer are on the order of 4-10s at 25°-30°C. Much more research is required to accurately determine these half-lives. One other ESR active compound, which is formed later in the reduction sequence of SOCl₂, has been identified. Its spectrum, shown in Fig. 7, is always the last spectrum obtained in these warming experiments. The data from this spectrum are summarized in Table II, along with literature data for oligomeric sulfur (15). As can be seen, the data are in good agreement, and we are confident that the final product observed in the reduction of SOCl₂ is sulfur. This assignment is consistent with the established overall cell chemistry for Li-SOCl₂ cells, and it lends support to the claim that the chemistry of the laboratory cell is similar to that occurring in Li-SOCl₂ hardware cells.

Spectra from the IR investigations of 1.5M LiAlCl₄/SOCl₂ reduced *in situ* have shown that SO₂ (1330 cm⁻¹) and SO₂Cl₂ (1410 cm⁻¹) are present in the reduced solution. These results are reasonable because SO₂ has been observed in discharged solutions by GC, and SO₂ is generally accepted to be a product of the reduction of SOCl₂. With Cl₂ having also been detected in discharged solutions by GC, SO₂Cl₂ is probably formed by the well-known reaction of SO₂ and Cl₂ to yield SO₂Cl₂.

Based upon these results, the following mechanism, shown in Fig. 8, for the reduction of SOCl₂ is proposed. A one-electron reduction of SOCl₂ to yield OSCl, which we have not observed, is proposed as the first step. OSCl isomerizes to OCIS, which should have chemistry similar to ClO₂, a known hazardous compound. OCIS can "dimerize," *i.e.*, at least form a weakly bonded dimer, which should decompose to yield SO₂ and SCl₂. SCl₂ has not yet been identified as an intermediate, but because Cl₂ and S₂Cl₂ have been observed, the known

Fig. 6. ESR spectrum of (OCIS) dimers

Fig. 7. ESR spectrum of discharged electrolyte heated to 228 K for 5 min, then cooled to 77 K.

disproportionation reaction of SOCl_2 to yield S_2Cl_2 and Cl_2 is the most plausible explanation for the occurrence of the latter compounds in the cell chemistry. Because SO_2 and Cl_2 are both present in the discharged solution, it is expected that SO_2Cl_2 will be present; this has been confirmed by IR. The remainder of the details of the reduction of SOCl_2 to yield the known final cell products, S, SO_2 , and Cl^- , have not yet been established. The subsequent overall reduction reactions of SOCl_2 , S_2Cl_2 , Cl_2 , and SO_2Cl_2 to yield S, SO_2 , and Cl^- are only listed for completeness, not because their mechanisms have been established. Since no evidence for other intermediates has been obtained, no additional reactions are included.

Even though this mechanism is not complete or fully proven, it is reasonable to speculate on its implications for safety of Li-SOCl₂ cells during discharge to +0.5V at 25°-30°C using 1.5M LiAlCl₄/SOCl₂. Although OCIS could be a hazardous intermediate, by analogy with the chemistry of ClO₂, if it is present in sufficiently high concentration, the lack of delay in formation of SO₂, observed by Istone and Brodd (5), and the relatively short lifetime of OCIS and (OCIS)₂ suggest that the concentration OCIS never gets high. Thus, it appears that there are no safety hazards due to intermediates formed during discharge of

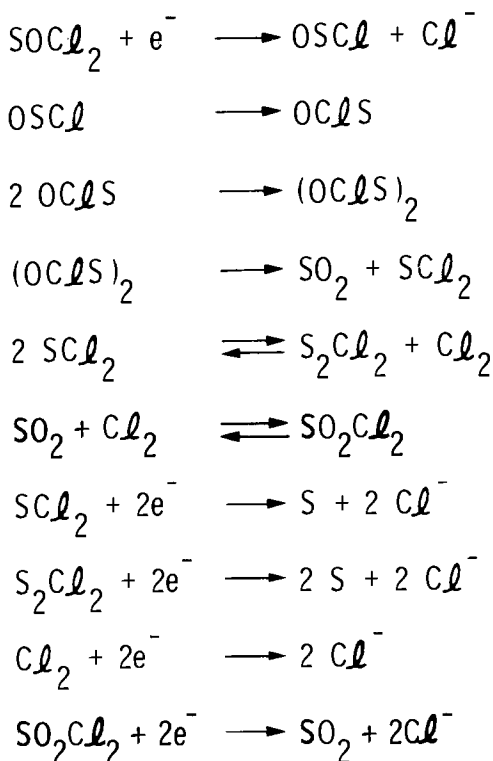

Fig. 8. Proposed mechanism

Table II. ESR parameters

RADICAL	g-VALUE

S_n^+ OPEN CHAIN (17)			2.025

Li-SOCl₂ under these conditions. However, if under other operating conditions, such as low temperature operation, SO₂ delay is observed in a cell, OCIS might form in concentrations sufficiently high to account for unsafe behavior of Li-SOCl₂ cells. Also, the mechanism has not been completed, so other hazardous intermediates may still be identified.

Clearly, more work is needed to fully understand the processes which govern the safety of Li-SOCl₂ cells. Both the identification of possible hazardous compounds (such as OCIS) formed during the discharge of a Li-SOCl₂ cell and the proposed mechanism for reduction SOCl₂ provide the basis for a fundamental understanding of the reactions which can cause venting or explosions. Although additional research is needed, this research also provides the basis for investigating the reactions which occur during voltage reversal, a hazardous condition for some Li-SOCl₂ cells, and it provides the foundation for modifying the chemistry of Li-SOCl₂ cells to improve cell safety.

ABSTRACT

Lithium hexafluoroarsenate/2-methyl tetrahydrofuran electrolytes have been prepared, purified, and evaluated using half-cell galvanostatic lithium cycling, cyclic voltammetry, plus colorimetric, gas chromatographic, and UV absorption techniques. Superior electrolytes have been prepared yielding reproducible cycling efficiencies in excess of 97%. Static aging trials at ambient temperature clearly demonstrate deterioration in cycling performance with time. This decline in performance is related to electrolyte degradation, possibly arising from the formation of peroxides. However, studies of various battery testing regimes on 1M LiAsF₆/2Me-THF electrolyte support the system's battery potential with respect to both rate capability and shelf-life characteristics.

The reversibility of the lithium electrode in aprotic solvent-based electrolytes has improved substantially in the last five years, increasing from cycling efficiencies of approximately 80% in 1976 to efficiencies approaching approximately 98% in 1983. These aprotic, or more specifically "ether," solvents have been studied because of both their stability to alkali metals and their low temperature characteristics: namely, freezing point, solvating power, and viscosity. It has been established that ether solvent stability is not thermodynamic, but kinetic in origin (1). Recent evidence indicates that some ethers are chemically reactive towards lithium metal and, therefore, rely on the formation of insoluble, passivating films for lithium reversibility (2). These films would be beneficial, if they were conductive to lithium ions. However, the film generating reactions in electrochemical cells, in general, result in excessive consumption of electrodeposited lithium, and, ultimately, cell failure occurs.

The ether-based aprotic electrolyte systems that have demonstrated potential for secondary lithium battery development are molar solutions of lithium hexafluoroarsenate (LiAsF₆), lithium perchlorate (LiClO₄), and lithium bromide (LiBr) in propylene carbonate (PC) (3, 4), tetrahydrofuran (THF) (5), 1,3-dioxolane (6), 2-methyl tetrahydrofuran (2Me-THF) (7), and diethyl ether (DEE) (2). For example, the 2Me-THF and DEE based electrolytes have yielded cycling efficiencies greater than 96% and 98%, respectively (7, 2).

The improvements in lithium cycling efficiency for the systems cited above have been due, in large part, to the close attention that has been paid to the "quality" of electrolyte and electrode materials, in terms of purity, handling in "nonreactive" environments, and dryness (moisture free).

Our studies, conducted over the past four years on solvents such as PC, THF, and 2 Me-THF, have focused on the choice of superior solute/solvent combinations with emphasis on determining those factors influencing lithium reversibility as related to electrolyte preparation procedures and to the use of drying and purifying agents (8). This paper examines the LiAsF₆/2Me-THF electrolyte couple for: (i) static stability, (ii) purity, and (iii) lithium cycling in an effort to improve performance and further understand lithium anode behavior.

Experimental

General.—Electrolyte purification procedures and the electrochemical experiments were conducted at ambient temperature under an argon atmosphere in a Vacuum Atmospheres dry lab equipped with a Model HE-493 Dri Train. An additional activated carbon/molecular sieve recirculating chamber further purified the dry box atmo-

sphere. The atmosphere was checked with a bare light bulb filament, which operated continuously for at least 30 days in the box. Solvents and other electrolyte materials (e.g., solutes) were transferred to the box under vacuum through the use of a glass vacuum line and related accessories.

Ultraviolet (UV) spectra were recorded on a Beckman 25 Spectrophotometer. Gas chromatograms (GC) were obtained with a Varian 6000 GC equipped with a flame ionization detector (FID) (sensitivity approximately 10⁻¹¹ A/mV) and a Spectra Physics SP4100 Integrator. A 182 × 0.3175 cm Porapak QS column was used. Colorimetry results were obtained with a Spectronics 20. A Bascom Turner eight-channel X-Y or Y-t recorder was used for data acquisition. Conductivities were obtained with a Model 31 Yellow Springs Instrument Conductivity Bridge and a microcell having a cell constant of 1.0/cm.

Materials.—Lithium hexafluoroarsenate (LiAsF₆) (USS Agri-Chemicals) and lithium trifluoromethane sulfonate (LiCF₃SO₃) (Alfa Ventron) were used as received. Lithium foil (5, 15, 38 mil) was obtained from Foote Mineral Company sealed under Ar. Lithium hexafluorophosphate (LiPF₆) (Ozark Mahoning) was recrystallized from specially purified and dried acetonitrile (MeCN;BDH) prior to use (10). MeCN was purified by the method of Walter and Ramaley (11), followed by successive distillations from treated molecular sieve 3A. Neutral alumina (Fisher) and molecular sieve 3A (Davison Chemical) were treated under vacuum at 300°-350°C for 24h prior to use.

2Me-THF (Aldrich) was refluxed over CaH₂ and then distilled under Ar from a Nester Faust Auto Annular Still. The reflux ratio was generally 20:1. The actual fraction for collection was determined either by an impurity-free GC scan (e.g., 2Mefuran (2Me-F) and peroxide impurity levels to < 10 ppm) or by a minimum UV absorbance at 218 nm. The 2Me-THF was then vacuum distilled two times over treated molecular sieve 3A followed by transfer to the dry box.

Electrolyte preparation and purifications.—Molar solutions of electrolyte were prepared by adding the appropriate Li salt to the purified solvent at room temperature. These solutions were further treated by passage through an alumina column. The first 10-20% fraction was discarded and the electrolyte was stored in glass vials (Reacti Flasks; Pierce) in the presence of Li foil. Teflon (TUF-TAINER; Pierce) and polyethylene (NALGENE) vials were also used. Pre-electrolysis procedures for 2Me-THF-based electrolyte followed those carried out by Koch *et al.* (5).

Aging trials.—Aging experiments are defined as static electrolytes stored in glass, polyethylene, or Teflon vials at ambient temperatures. The vials were not protected

* Electrochemical Society Active Member.

from light unless specified otherwise. Old vials are those which had been used previously to store electrolyte. Comparative tests were run with and without Li foil present in the storage vials.

Cells and electrodes.—Glass rectangular cells [$1 \times 1 \times 4$ cm (full cell), $1 \times 0.5 \times 4$ cm (half-cell), $0.5 \times 0.5 \times 4$ cm (quarter cell), all constructed in house] or UV cuvettes were used for the galvanostatic cycling of Li in a half-cell configuration. In general, the working electrode was a 1×4 cm Ni sheet 0.127 mm thick (Alfa Ventron, m4N8). The auxiliary electrode was cut from Li ribbon foil to meet the cell dimensions. The reference electrode was a Li wire placed in a Pasteur pipette and held in place by a machined Teflon top. Exactly 1 ml of electrolyte was added to the cell, thereby defining the working and auxiliary electrodes as 1×1 cm and 1 cm apart. Solvent evaporation was minimized by sealing the top with Parafilm.

Chronopotentiometric plating and stripping of lithium was conducted using a constant current power supply, a controller relay for polarity reversal, a microprocessor (MOS technology) for timing control, and various monitoring equipment (all constructed in house).

The following procedure, similar to that described by Koch *et al.* (2), was used to determine Li cycling efficiencies: a known charge of Li, 2.9 C/cm^2 , was plated onto the Ni substrate working electrode. A smaller charge (1.3 C/cm^2) was then stripped and plated from this electrode. The excess amount of Li charge, 1.6 C/cm^2 , was then slowly consumed by the $< 100\%$ efficient stripping cycle. Prior to exhaustion of the excess Li and reaching the Ni substrate, many "100%" cycles can be achieved. Therefore, the average efficiency per cycle, \bar{E} can be calculated by Eq. [1], where Q_s is the charge of Li stripped, Q_{ex} is the amount of excess Li, and n is the number of 100% cycles. All cycling tests in this study are based on a 5 mA/cm^2 plating and stripping current density unless otherwise specified

$$\bar{E} = \frac{Q_s - \frac{Q_{ex}}{n}}{Q_s} \quad [1]$$

Results and Discussion

General.—The data presented below are based on different batches of $1\text{M LiAsF}_6/2\text{Me-THF}$ electrolytes. Therefore, cycling efficiencies vary as a result of changes in electrolyte quality during the test program.

Aging trials.— $1\text{M LiAsF}_6/2\text{Me-THF}$ electrolytes were aged in vials at room temperature, and their cycling performances were monitored with time. Li foil was found to have no effect on the cycling performance. The results obtained are illustrated for the case of "old" glass vials in Fig. 1a, "new" glass vials in Fig. 1b, and Teflon or polyethylene vials in Fig. 2. The best overall cycling efficiencies were observed for the "old" vial case. In all instances, cycling efficiencies peaked with time; this behavior is quite reproducible. The second consistent result is the decrease in 100% cycles with time to values ranging from 60% to 70% of the observed maximum. The old and new glass vials are of borosilicate construction. Consequently, further tests were completed to assess the effect of aging in the presence of borosilicate and Pyrex glass ground to a fine powder. These tests showed no difference within ± 2 cycles.

Pre-electrolyzed $1\text{M LiAsF}_6/2\text{Me-THF}$ electrolytes have shown inferior performance in our studies, and, therefore, the aging of the electrolytes, as seen in Fig. 3, would be expected to show no improvement over non-pre-electrolyzed solutions. Similar cycle peaking and slow decline in efficiency over 70 days were observed.

The effect of light on aging (*e.g.*, a 25W bulb) was also assessed. In Fig. 4, electrolyte aged in light showed improved performance relative to those aged in the dark. This evidence substantiates the positive role of light to both degradation of electrolyte and possibly complementary production of new electrolyte species.

Fig. 2. Aging of $1\text{M LiAsF}_6/2\text{Me-THF}$ in Teflon (a) and polyethylene vials (b).

Fig. 3. Effect of aging $1\text{M LiAsF}_6/2\text{Me-THF}$ electrolyte after pre-electrolysis.

Fig. 4. Aging of $1\text{M LiAsF}_6/2\text{Me-THF}$ in glass vials stored in light (a) and dark (b).

Aging trials were also carried out for a $1.5\text{M LiAsF}_6/2\text{Me-THF}$ electrolyte (see Fig. 5). The cycle peaking phenomena observed for 1M solutions was not observed. The "usual" decline in cycling efficiencies, however, was observed, and the 1.5M electrolyte did not cycle as well as a 1M electrolyte.

Alumina electrolyte treatments were monitored for aging and their influence on cycling efficiency during aging. The $1\text{M LiAsF}_6/2\text{Me-THF}$ electrolyte in Fig. 6 clearly indicates the importance of discarding the first fraction (*e.g.*, Fig. 6c) of an alumina-treated electrolyte. Obviously, the amount of discard can be critical to the electrolyte performance. It is our observation that the best long-term cycling efficiency is obtained for the last fraction collected (*e.g.*, Fig. 6b).

Impurities in 2Me-THF solvent.— 2Me-THF (as received) contains approximately 300 ppm of detectable peroxide and approximately 1000 ppm of 2Me-F . Spinning band distillation under Ar atmosphere is very effective in removing these impurities. GC data (9) have verified that all impurities can be removed to detection limits. The detection limit for 2Me-F , based on standard curves, has been determined to be 10 ppm. Removal of 2Me-F impurities to < 10 ppm in 2Me-THF solvent was carried out to

Fig. 5. Aging of 1.5M LiAsF₆/2Me-THF electrolyteFig. 6. Effect of passing 1M LiAsF₆/2Me-THF electrolyte through a treated alumina column. (a): Fraction 2. (b): Fraction 3. (c): Fraction 1.

establish its effect on electrolyte cycling performance. Therefore, additions of 2Me-F ranging from 0 to 200 ppm to 2Me-THF electrolyte were studied. No adverse effects for 2Me-F addition (see Fig. 7) were noted for the electrolyte tested.

Peroxide impurities were assessed using colorimetric, GC, and UV absorption techniques. A colorimetric redox reaction employing the ferric/ferrous thiocyanate couple [e.g., absorption of the red Fe³⁺ thiocyanate complex at 512 nm (12)] was used to quantitatively detect peroxide. The detection limit of this technique was determined to be approximately 10 ppm. At present, the GC detection limit is also 10 ppm. Exposure of "peroxide-free" 2Me-THF solvent to the atmosphere at any point of transfer prior to introduction to the dry box will result in degradation. For example, a distillate fraction of 2Me-THF under argon was briefly exposed to air. The GC chromatograms of this solvent taken several weeks later showed additional peaks, which we have attributed to peroxide formation (9).

Both 2Me-THF solvent and 1M LiAsF₆/2Me-THF electrolyte absorb strongly in the UV at 218 nm. This absorbance is strong for as-received 2Me-THF (9) and falls rapidly with successive distillate fractions. Note that while colorimetric and GC techniques indicate solvent peroxide levels to be < 10 ppm, the UV absorbance of the solvent is strong (see Fig. 8). In one experiment, molecular sieve treatment (see Fig. 8b) marginally decreased the 218 nm absorption. Zeolites or molecular sieves have been reported to be efficient agents for removal of peroxides in ether solvent (13). However, whether these agents are effective at the 10 ppm level has not yet been established. Alumina stirred in 2Me-THF solvent showed, in Fig. 8c, an increase in UV absorption. However, we have also shown that successive fractions of electrolyte passed through alumina results in reduction of absorption levels. Alumina is another agent which has been reported to be effective in removing peroxide impurity in cyclic ethers

Fig. 7. 2-Methyl furan addition to 1M LiAsF₆/2Me-THF electrolyte.

(14). It is probable that alumina performs two functions: (i) removal of water, and (ii) removal of peroxide. There is preliminary evidence which correlates cycling performance with UV absorption. The best electrolytes consistently show low absorbance levels. For example, as illustrated in Fig. 9, absorption differences are observed for a 42-cycle electrolyte, a 22-cycle electrolyte, and a pre-electrolyzed electrolyte.

UV absorption for cyclic ether electrolytes has been reported previously. In studies by Koch *et al.* (15) on LiAsF₆/THF electrolyte, an absorption maximum of 260 nm was obtained. No correlation between α -hydroperoxide and the UV absorbance was found. This correlation is expected to be less likely in the 2Me-THF case. However, the source of the 260 nm absorption band could not be ascertained. Nevertheless, LiAsF₆/2Me-THF or THF based electrolytes definitely show increases in UV absorbance with time. The corresponding pure solvents do not exhibit this characteristic. Consequently, Koch *et al.* (15) have speculated, and we concur, that LiAsF₆ or an impurity in the salt may be the source of degradation.

The linkage between the UV absorption band at 218 nm and the presence of peroxide cannot be firmly estab-

Fig. 9. UV spectra of 1M LiAsF₆/2Me-THF electrolyte. (a): 42-cycle electrolyte. (b): 22-cycle electrolyte. (c): Pre-electrolyzed electrolyte.

lished. However, recent preliminary GC data do show additional peaks on solvent degradation, which we have attributed to peroxide formation. Identification of these species is in progress.

Solute studies.—In past studies, lithium hexafluorophosphate (LiPF_6), lithium hexafluoroantimonate (LiSbF_6), and lithium hexafluorotungstate (LiWF_6) were prepared in house, purified, and 1M solutions tested in 2Me-THF solvent (8). Poor cycling performance was observed with these three solutes. Recently, other solute materials were examined.

Lithium trifluoromethanesulfonate, LiCF_3SO_3 , showed limited solubility ($< 0.4\text{M}$) in 2Me-THF, and the prepared electrolyte showed no lithium reversibility. Commercially available LiPF_6 was recrystallized from MeCN and retested. No improvements over material prepared in house were observed.

Cell dependencies.—The relationship of our cell system design to cycling efficiency was assessed. The purpose was to ensure experimental reproducibility. For example, different glass cells, cuvettes, and Ni foil substrate combinations were used under otherwise similar experimental conditions with 1M $\text{LiAsF}_6/2\text{Me-THF}$ electrolyte. These tests established a reproducibility of ± 2 -100% cycles. The lithium reference electrodes, either as a lithium plug in a glass tube or as a lithium wire in a Pasteur pipette, also yielded the same number of cycles. The reference to working electrode potential, however, does change. Pre-treatment of the lithium auxiliary electrode by scraping, anodic prestripping, etc., also showed no influence on cycling efficiency.

Cell geometry has a strong influence on the ratio of electrode surface area to edges. Therefore, the rectangular cell geometry was changed and a one-half cell and a one-quarter cell were tested. Since the cycling efficiency remained invariant (within ± 2 cycles) with changes in cell geometry, edge effects were eliminated as a significant variable for our test conditions.

Electrochemical effects.—Cyclic voltammograms of 1M $\text{LiAsF}_6/2\text{Me-THF}$ electrolyte showed good lithium reversibility (9).

The experimental regime chosen for all comparative studies was a 5 mA/cm^2 stripping/plating sequence. An independent study was performed to determine the influence of variations in the plating and/or stripping current density in 1M $\text{LiAsF}_6/2\text{Me-THF}$ electrolyte. Figure 10 illustrates the behavior of varying the plating current density (e.g., from 0.5 to 5 mA/cm^2) while holding the stripping current density at 5 mA/cm^2 . The lower plating current densities resulted in a significant decrease in cycling efficiency. In a complementary series of tests, the stripping current density was varied from 0.5 to 5 mA/cm^2 while the plating current density was held at 5 mA/cm^2 . As seen in Fig. 11, the same decline in cycling efficiency is observed. For the case where the stripping and plating current densities are kept equal, while the current density is varied from 1 to 10 mA/cm^2 (see Fig. 12), no real effect on cycling efficiency is observed. This result is, therefore, surprising in view of declines observed at < 2.5 mA/cm^2 in Fig. 10 and 11.

The shelf-life characteristics of the 1M $\text{LiAsF}_6/2\text{Me-THF}$ electrolyte systems are important to future battery development. Several experiments assessing this effect through open-circuit stands (OC) were completed. Preliminary results, which reflect both charge retention capabilities and shelf-life characteristics, show minimal differences, if any, in cycling efficiency with increasing OC times. For example, a comparison of the cycling efficiency at 0 OC stand vs. a 10 min OC stand (equivalent to a total open-circuit stand time of approximately 10h during the experiment) shows a decrease of less than 0.25%. It is also clear that further work is indicated.

Optimized cycling behavior.—All the data we have collected on solvent/electrolyte dependencies can be used to advantage. For example, with care in purification procedures and aging conditions, it is possible to prepare elec-

Fig. 10. Plating current effects

Fig. 11. Stripping current effects

Fig. 12. Current density effects

trolytes that exhibit, reproducibly, 40 ± 2 -100% cycles or approximately 97% cycling efficiency at an average 45% depth of discharge in half-cell tests. In one isolated experiment, an optimized electrolyte actually gave 123 cycles or approximately 99% cycling efficiency; the experiment terminated only because of solvent evaporation. Observations at the 50 cycle mark revealed a lithium electrode that was smooth, and silvery gray in appearance. No further observations were made until cell failure, at which time the lithium electrode had turned mossy black.

Stability considerations.—2Me-THF solvent is more stable than THF to chemical breakdown. This has been demonstrated by Koch *et al.* (5) in static and dynamic experiments. In addition, it is known that THF can be easily polymerized in the presence of LiAsF_6 salt, a phenomena not yet observed for 2Me-THF. One argument advocated for this enhanced stability is the inductive effect of a methyl group in the position raising the energy of the lowest unoccupied molecular orbital (LUMO). We have carried out a series of CNDO molecular orbital calculations on these molecules using a program developed by Dobosh (17). LUMO values of 7.01 (THF) and 7.07 eV (2Me-THF) were obtained. These differences are marginal, considering the differences in their reactivity, and would suggest that nonthermodynamic effects play a major role.

Conclusions

Pure, reasonably stable 1M $\text{LiAsF}_6/2\text{Me-THF}$ electrolytes can be prepared. Although this electrolyte deteriorates with time, stable cycling efficiency plateaus can be obtained. Optimized 1M $\text{LiAsF}_6/2\text{Me-THF}$ electrolyte yields reproducible cycling efficiencies in excess of 97%. At present, LiAsF_6 is the best solute material for 2Me-THF solvent. Whether LiAsF_6 or an impurity in this salt is

responsible for electrolyte degradation has yet to be determined. The evidence is consistent for electrolyte degradation being linked to "peroxide" formation.

An Electrochemical Study of the Pit Initiation Resistance of Ferritic Stainless Steels

W. R. Cieslak*

D. J. Duquette

Department of Materials Engineering, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

A variety of electrochemical techniques has been used to study the resistance of ferritic stainless steels to pit initiation in 1M NaCl at 80°C. Critical pitting potentials have been measured by potentiodynamic anodic polarization and by the "scratch" technique. The effectiveness of passivation potential and alloy content to promote formation of a film that is resistant to breakdown has been studied by pit induction time measurements. The ability of the passive surface to adjust to abrupt changes in passivating conditions has been studied by potential stepping experiments. It has been shown that the effect of Cr on passive film properties is disproportionately great with respect to that of Mo for alloys of comparable pitting resistance.

The use of critical pitting potentials measured potentiodynamically to determine pitting resistance has been widely criticized, particularly in the interpretation of polarization diagrams to locate the critical potential(s). A critical potential, V_c , may be defined as that potential noble to which pits, once initiated, will stably grow (1). However, a second critical potential, V_{pp} , may be defined for the reverse potential scan as that potential active to which growing pits cannot be maintained (2). There is no clear agreement as to the criteria required to define a critical potential or as to whether such potentials are theoretically meaningful (3-5). The issue is complicated by the sensitivity of measurements to experimental variables such as rate of polarization and surface treatment. Slow rates have been recommended for the most accurate measurement of V_c (5-8) because with increasing scan rate insufficient induction time for pit initiation is allowed at less noble potentials. However, with too slow a scan rate, the measured V_c shifts in the noble direction, possibly due to development and/or thickening of the passive layer (9). Similarly, a very fast scan may give a more active V_c if

* Electrochemical Society Active Member.

time for film development is not sufficient. The balance between film growth and surface activation may lead to a maximum in the V_c vs. scan rate curve (10) or to variable responses among a group of alloys (1, 11). Although the lack of a shift of V_c to active values as scan rate increases may signify relatively rapid film formation kinetics, it does not appear to be a sufficient criterion for distinguishing more resistant alloys.

Surface treatment affects film formation kinetics and, therefore, may affect V_c measurements (12). For example, 600 grit surfaces yield the most reproducible pitting data for Zr, as compared to chemical polish, electropolish, and air or vacuum anneal (10). Pitting resistance of stainless steels as measured by very rapid scanning also increases with finer grit finishes (13). However, this relationship was observed at slow scan rates only when the availability of pit initiation sites was affected by the surface finish (14).

To determine V_c precisely, in the absence of induction-time complications, the "scratch" technique was developed (15). By eliminating the induction period, this technique should provide better reproducibility than

potentiodynamic methods, for which variations of 100-500 mV are routinely reported (1, 6, 11, 16, 17).

The effect of Mo on the pitting properties of stainless steels is not fully understood. For example, it has been stated that Mo can aid the film's healing capability, but not the basic initiation resistance (18). However, Mo has little effect on V_{rp} and localized corrosion propagation resistance (6, 19), yet it improves crevice corrosion resistance (16, 20-26). To make a reasonable comparison of these results, variations in experimental techniques must be taken into account, as well as the fact that the effectiveness of Mo is not independent of the Cr content of the steel. The aim of the present study is to interpret the responses to different experimental techniques as an aid in understanding the effects of alloy composition and microstructure on pitting resistance. Properties of films formed under the same conditions as used in determining pitting resistance are tested. Electrochemical techniques are used to learn about film stability to provide insight into the nature of the passive film protectivity.

Experimental Procedure

The six heats of high purity ferritic stainless steel, listed in Table I and supplied by the Climax Molybdenum Company, are referred to as 18-0, 18-2, 18-5, 28-0, 28-2, and 28-5, respectively. Rectangular specimens ($13 \times 8 \times 1$ mm) were annealed in vacuum for 10 min at 1040°C and water quenched to produce a fully recrystallized single-phase ferritic microstructure.

Samples were wet ground on all sides on 240 through 600 grit SiC papers. For mounted samples, a stainless-steel wire was percussion welded to the sample, and the joint and the end of a plastic or glass tube shielding the wire were cast in epoxy (Maraglas no. 655 resin with no. 555 hardener, ACME Chemicals & Insulation Company, New Haven, Connecticut 06505). The mounts were cured at 80°C for a minimum of 8h. Immediately prior to use, each sample was again wet ground on 600 grit paper.

The test apparatus was a standard 1-liter six-necked flask. The specimen holder for the sheet samples was a platinum wire platform which created a three-point electrical contact (14). Test solutions were 1M NaCl prepared with distilled, deionized water. Electrolytes were deaerated with prepurified argon for a minimum of 4h before each test, and purging was continued throughout the test. A temperature of $80 \pm 1^\circ\text{C}$ was maintained by a transformer-controlled heating mantle. Potentials were measured against and are referred to a saturated calomel electrode (SCE).

The basic potentiodynamic anodic polarization test was begun by leaving the sample at open circuit for 10 min, during which time the corrosion potential attained a steady value between -500 and -650 mV. To save time, a rapid scan (3.6 V/h) was employed from -600 to -300 mV. This was followed by a slow scan (360 mV/h) from -300 mV until a sharp increase in current occurred, signaling the initiation of pitting. The steels did not exhibit active dissolution in the deaerated NaCl electrolyte. The effect of scan rate on V_c as measured potentiodynamically was investigated for the range 80 mV/h to 21.6 V/h. Critical pitting potentials were also measured by mechanical film rupture (scratch) testing (15), using 20 mV steps and scratches which generated 5-10 μA current spikes. Galvanostatic testing was conducted at an anodic

current density of 1 mA/cm², which was held for 15 min to allow pit growth (17, 18).

Induction times were measured on samples that had been anodically passivated for 2h at potentials of -600, -400, or -200 mV, each of which is active to the critical pitting potential. The potential was then stepped to +25, +100, or +250 mV, and the time, τ , to an abrupt rise in current was recorded.

Current transients following a potential step were measured using a Physical Data Model 514A transient recorder. Samples were left at open circuit for 2 min, held at -650 mV for 2 min, and then stepped to the potential of interest. A Princeton Applied Research Model 173/176 potentiostat/galvanostat was used for all studies.

Results

Critical pitting potentials, V_c .—The results of potentiodynamic testing at 360 mV/h and scratch testing (Table II) do not reveal identical trends of pitting resistance dependency on alloy composition. For example, 18-2 appears more resistant to pitting than 28-0 in the scratch test but no more resistant in scan testing. V_c measured by the scan technique was never active to that measured using the scratch technique. The difference in pitting potentials measured by the two techniques shows no clear dependence on alloy composition. Previously, it was shown that preferential localized attack at microstructural features, e.g., inclusions, is not observed under any of the experimental conditions (27, 28). Rather, the pit initiation resistance is controlled by alloy composition. For pitting at inclusions, the pits do not necessarily nucleate preferentially on the film-free surface created during scratch testing, and the comparison to scan testing is not valid (29, 30).

The critical pitting potentials are not a function of scan rate for rates more rapid than 360 mV/h but shift in the noble direction with decreasing scan rate. The scatter of data, however, is large at slow scan rates. Critical pitting potentials measured at a single scan rate shift in the noble direction and exhibit increased scatter with finer surface finishes. Those conditions producing nobler critical potentials also result in lower pitting densities (number per square centimeter). The influences of alloy composition and surface finish on pitting density were further investigated by galvanostatic testing (Table III). Pitting density was observed to be a function primarily of surface finish; a finer polish produced a surface which was more resistant to pit initiation. Therefore, pitting density cannot provide a basis for differentiating pit susceptibility among the experimental alloys.

Induction times.—The induction time, τ , for film breakdown was measured at several potentials after initial passivation at a less noble potential. The pit initiation potential of +25 mV is approximately 125 mV noble to V_c measured by scratch testing for 28-0; +100 mV provides the same ΔV for 18-2, and +250 mV for both 18-5 and 28-2.

Table II. Comparison of potentiodynamic anodic polarization (360 mV/h) to scratch technique, critical pitting potentials (mV vs. SCE)

Alloy	V_c		Difference scan-scratch
	Scan	Scratch	
18-0	-172	-230	58
18-2	-37	-33	-4
18-5	+142	+126	16
28-0	-40	-104	64
28-2	+274	+98	176
28-5	+985 ^a	—	—

Each V_c is the average of 5-10 tests.

Pooled standard deviation for scan testing = 30.1.

Pooled standard deviation for scratch testing = 26.9.

^a The critical potential was ill-defined due to the onset of transpassive dissolution.

Table III. Galvanostatic testing
1 mA/cm² anodic for 15 min

Alloy	Surface	Oscillation V range (mV vs. SCE)	Pit density (no./cm ²)
18-5	600 grit SiC	+50 to +130	55
18-5	600 grit SiC	+20 to +100	58
28-0	600 grit SiC	-190 to -120	56
28-0	600 grit SiC	-190 to -110	66
18-5	0.3 μm Al ₂ O ₃	0 to +100	20
18-5	0.3 μm Al ₂ O ₃	+20 to +80	—
28-0	0.3 μm Al ₂ O ₃	-180 to -120	24
28-0	0.3 μm Al ₂ O ₃	-190 to -140	—

Passivating the specimens at -600 mV did not provide protection from pit initiation (Table IV), τ being less than 1s in all cases. Better protection was obtained at more noble potentials. The full range of responses is clearly exhibited by 28-0, which is the only alloy whose critical pitting potential is noble to each passivation potential and active to each induction potential.

Those conditions that caused τ to increase also caused the pitting density to decrease. Numerous pits formed on samples passivated at -600 mV, while only one or two pits formed after passivation at -200 mV. The current rose much more steeply upon breakdown of a very protective film than upon breakdown of a less protective film, over a range of a few seconds to a few minutes to reach 1 mA. Similarly for potentiodynamic testing, more rapid scan rates produced larger numbers of smaller pits at a slower rate of increase in current. Tests were conducted to a constant final current; therefore, the amount of charge passed varied inversely with the rate of increase in current.

Potential step responses.—A potential step from -650 mV to -400, -200, or +200 mV was used to evaluate the ability of each alloy to adjust to an abrupt disturbance of the passivating condition. The initial rate of current decay following a potential step is approximately 1.5 decades in the first 10 ms and exhibits a linear relationship between $\log i$ and $\log t$

$$\log i = m \log kt \quad [1]$$

The slope, m , is lower for steps to more noble potentials, and higher currents are generated for larger steps

Table IV. Effect of alloy composition, passivation potential, and induction potential on induction time for pit initiation

28-0	-1.18	-1.07	-0.85
28-2	-1.13	-1.02	-0.87
28-5	-1.05	-1.03	-0.95

Fig. 1. Log i vs. $\log t$ plot for 18-5 at three step potentials

(Fig. 1). The charge passed is calculated by integrating the area under the curve

$$Q = \int_{t_1}^{t_2} i dt = k \int_{t_1}^{t_2} t^m dt \quad [2]$$

$$Q = \frac{k}{(m+1)} \left[t_2^{(m+1)} - t_1^{(m+1)} \right] \quad [3]$$

The calculation was performed from $t_1 = 0.1$ ms to $t_2 = 5$ ms. The slopes and charge densities for the initial current decay curves are presented in Tables V and VI, respectively.

The slopes of the decay transients are steeper for the 28% Cr alloys than for the 18% Cr alloys, at a given step potential. The experimental scatter produced an average difference between the minimum and maximum slopes of 0.06, measured in 2-3 replicates of each experiment. While the addition of Mo does not appear to affect the slope (Table V), it does reduce the amount of charge passed during the initial 5 ms (Table VI). This is shown consistently for the 5% Mo alloys, as compared to the Mo-free alloys, at all step potentials. The increase from 18% to 28% Cr, however, results in a greater decrease in charge density than does the addition of 5% Mo.

Charge density for 60s decays was measured using planimetry on the i - t curves. Just as for the 5 ms time period, the charge density for the 60s time period decreased with increasing Mo or Cr. No linear i - t relationships, even for a logarithmic or a semi-logarithmic plot (Fig. 2) were observed. If the step potential was noble to V_c , an increase in current would occur within this time period. Therefore, the data in Table VII are presented as charge density for those combinations of alloy and step potential resulting in only passive film growth and as the time at which the current began to increase for those conditions causing pitting. The times at which pitting started (current reversal) correlate well with the pitting resistances of the alloys, increasing with more noble V_c .

Discussion

The stability of passive films formed on high purity ferritic stainless steels in a pitting electrolyte has been studied. The time to initiate pits depends upon the stage of development of the passive film and the driving force (pitting overpotential) for breakdown. The kinetics of film development play a major role in determining pitting parameters.

The induction-time experiments indicate that nobler potentials promote the development of more protective passive films. The Mo additions are effective in increasing the pit induction times measured at potentials at least 125 mV noble to potentials for stable pitting. Film self-repair is not a competitive process for the large driving force for breakdown at such noble potentials. Therefore, the ability of Mo to increase induction time must be a consequence of its ability to enhance film resistance to breakdown. In general, increased induction times may be attributed to the existence of more homogeneous films, regardless of thickness (31, 32).

The steeper slope of the current decay curves (Fig. 1) following a potential step for the 28% Cr alloys indicates that the films provide protection more quickly than those on the 18% Cr alloys. As noted in the Results section, this slope is not particularly sensitive to Mo content, although the charge density for this linear region decreases as a result of alloyed Mo. The magnitude of the charge density, a substantial portion of which may be attributable to charging of the electrical double layer, is less than needed for one monolayer of film growth (28). These effects of Mo in stainless steels in NaCl solution are different from those in acids, where Mo increases the charge density for formation (33) and the growth rate (34) of passive films. Additionally, for current decay following abrasion, Mo increases the rate of decay (35,

36). In these and other studies of active dissolution or propagating pits (37-41), the effects of Mo may be attributed to MoO₄²⁻ surface enrichment, which could lower the anodic dissolution kinetics and promote (re)passivation. Under the present conditions, pits are not propagating nor is the surface film-free at any time, yet Mo still affects the electrochemical behavior. A decrease in charge passed indicates better efficiency of protection, whether related to composition, thickness, or structure. Obviously, less charge is needed to grow a Cr-rich film on the 28% Cr alloys than on the 18% Cr alloys, because more Cr is available. However, the smaller charge required for passivation of Mo containing alloys may be related to the defect structure of the film. Passive films on Fe-Cr alloys (of $\geq 19\%$ Cr) are primarily amorphous (42). If this amorphous film is assumed to exhibit short-range order, then the coordination of O²⁻ ions around Cr³⁺ may be somewhat deficient in oxygen because of Fe²⁺ ions in the film. A minimal Cr³⁺/Fe²⁺ ratio in the film is required to produce a protective film containing sufficient oxygen, and this ratio is achieved with lesser charge for alloys of higher Cr content. This model assumes that the O²⁻ defect structure controls the resistance of passive film to breakdown by the Cl⁻ ion. Interaction of Cl⁻ with O²⁻ vacancies has been suggested in a model of pitting corrosion (43), and the interaction has been considered to be the reason that oxygen-deficient (n-type semiconducting) films are pit-susceptible (44, 45). Although it is well known that little Mo is incorporated in the film, the incorporation of a small but significant number of Mo ions in the +6 oxidation state cannot be ruled out. The Mo⁶⁺ ion is expected to reduce the O²⁻ defect concentration of the passive film, resulting in a more protective film. Thus, the Mo⁶⁺/Cr³⁺ ratio of the film would primarily affect the resistance of the film to local breakdown. This could explain the synergistic effect of Mo and Cr for highly alloyed stainless steels.

The hypothesized effect of Mo is similar to that which is expected in the presence of the increasingly oxidizing conditions imposed by increasingly noble passivation potentials. Both a noble passivation potential and a greater Mo content enhance the resistance of the film to breakdown, while affecting the composition, as measured by Auger analysis, very little (28, 46). Therefore, both might act to decrease the susceptibility of film imperfections to breakdown.

Conclusions

1. Mo enhances the passivating capabilities of Cr, but to a lesser extent than is expected based on the effectiveness of Mo to promote pitting resistance.
2. Lower pitting densities are exhibited by passive films that are more resistant to pitting, implying that film sites at which pits initiate are less susceptible and/or less numerous. Film resistance, as measured by induction time, is increased by higher alloy content and by more noble passivation potential.
3. It is suggested that the resistance to pit initiation of passive film imperfections related to insufficient O²⁻ incorporation might be improved by Mo incorporation, much in the same manner as by nobler passivation potential.

A Theory of Perturbation-Initiated Pitting

T. Okada

Industrial Products Research Institute, M.I.T.I., Yatabe, Tsukuba, Ibaraki 305, Japan

ABSTRACT

It is shown that perturbation of the concentration of aggressive ions and also of an electrical field in a corrosive solution can initiate local activation and pitting nucleation in a passive metal. The linear stability theory was applied to the system in which a passive metal is kept at a constant potential in a solution containing aggressive ions. A critical condition was discovered where the possible disturbance in the solution caused the acceleration of local dissolution of the passive film. This process advanced autocatalytically until it reaches pit nucleation. Perturbations were found to grow with time above a critical wavelength. It was demonstrated that a high concentration of aggressive ions, a high electrical field in the solution, and a positive electrode potential promotes pit nucleation. The process was well explained as a probability event.

There is much current debate concerning the initiation step of pitting corrosion (1-5): on which part or in what stage does the nonuniform and localized corrosion process, which leads to film destruction, arise?

One approach is to assume the effects of heterogeneity present on the passive metal (4, 6), and the other is to assume an induced heterogeneity at the interface between a passive metal and corrosive media (1, 7, 8). The former approach is called an *a priori* assumption, because it puts an emphasis on the inherent microscopic defects on the metal surface: inclusions, grain boundaries, scratches, etc. The latter approach is called the *a posteriori* assumption, in that it acknowledges a nonuniformity on the metal surface and its development to the visible dimension, which occurs after a passive metal is placed in a cor-

rosive media. It should be recognized, however, that these assumptions might equally contribute to the occurrence of pitting phenomena.

In connection with *a posteriori* assumptions, the significance of stochastic (9-11) or fluctuation (12) processes have been stressed as the initial step of pitting. This presents the possible occurrence of series of processes initiated by perturbations in corrosive media, which then lead to passive film breakdown and pit initiation. However, very few mechanisms can satisfactorily explain the occurrence of this process. Also, it is necessary to specify the mechanisms which account for the feature of localization and isolation of pits.

In this study, the system of passive metal in a corrosive environment will be examined and its stability discussed,

in which aggressive ions are transported and adsorbed on the passive film with spatial fluctuations. The process of passive film destruction and pit initiation will also be discussed.

Theory

Suppose that a passive metal is kept at a constant potential in a solution containing aggressive ions. At the interface between the metal and the solution, the metal ion passes through a passive film which is in equilibrium between growth and dissolution. The current flows from the anodic part of the passive metal to the counterelectrode or to the cathodic part of the passive film (Fig. 1).

In the initial state, the metal ion dissolves uniformly through the passive film. Current flows through the solution by ionic transport. The halide ion moves by electric migration towards the surface of the passive metal, and this brings about the concentration of halide ions and their adsorption on the surface of the passive film. This further causes the increment of the rate of dissolution reaction of metal ions (5, 7, 13).

If the transport is perturbed, resulting in a concentration of aggressive ions on the passive film surface, the dissolution rate changes locally. This causes nonuniformity in the ion flux. The system becomes unstable and promotes local destruction of the passive film if the perturbation increases with time. If, however, the perturbation decreases, the passive metal dissolves uniformly and no pits appear. Whether the disturbance increases or decreases will determine the possibility of pit nucleation.

The instability of disturbed parameter systems is examined using the linear stability theory (14, 15). The theory has been successfully applied to the problem of convective transport (14), as well as to the problem of morphological instability in electrocrystallization (16, 17).

Parameters to be considered in the system are: (i) transport of ionic species in the solution, (ii) reaction current at the passive film-solution interface, and (iii) the electrical potential profile which governs the ionic current in the solution. The basic relationships for these parameters will be established first, from which perturbation equations around the steady state will be derived, and the instability of the system against infinitesimal perturbations can be examined from the analysis of normal modes (14, 15).

Basic equations.—Reactions which are occurring at the passive film-solution interface are

Fig. 1. Processes occurring in the passive metal-solution system. Broken line indicates perturbed potential profile in the solution. M^{z+} : metal ion. X^- : halide ion.

The current density of each reaction is designated as I_a , I_{c1} , and I_{c2} , respectively. In the present system, the passive film is in equilibrium between formation and dissolution, so that $I_{c1} = 0$. Also, I_{c2} is supposed to be very small compared with I_a : $|I_{c2}| \ll I_a$.

I_a is affected by the concentration of the halide ion X^- at the interface (7, 13). X^- is assumed to be adsorbed on the surface of the passive film following the Temkin-type isotherm, and it forms a complex with the lattice cation M^{z+} by which M^{z+} dissolves, so that it is obtained (Appendix A)

$$I_a = k_M C_X(0)^m \exp \left\{ \frac{\beta F \Delta \Phi_{\text{MO/S}}}{RT} \right\} \quad [2]$$

where $C_X(0)$ is the concentration of X^- at the interface and $\Delta \Phi_{\text{MO/S}}$ is the Galvani potential difference through the interface.

Ionic species move by diffusion and by electric migration in solution. The X-Y plane lies along the surface of the passive film and the Z axis normally extends into the solution. The concentration $C_j(x, y, z, t)$ of ion j at (x, y, z) and at time t is expressed by the following equation (18)

$$\frac{\partial C_j(x, y, z, t)}{\partial t} = -\nabla \cdot J_j \quad [3]$$

where ∇ is the gradient operator and J_j is the flux of ion j. J_j is composed of a diffusion component and a migration component (19)

$$J_j = -D_j \{ \nabla C_j + z_j C_j \nabla (f\Phi) \} \quad [4]$$

Here, $f \equiv F/RT$, D_j and z_j are the diffusion coefficient and the charge of the species j, respectively, and Φ is the electrical potential in the solution measured by a reference electrode. D_j is assumed to be a constant, independent of concentration or location. Equations [3] and [4] give

$$\frac{1}{D_j} \frac{\partial C_j}{\partial t} = \nabla^2 C_j + \nabla C_j \cdot \nabla (z_j f \Phi) + C_j \nabla^2 (z_j f \Phi) \quad [5]$$

For Φ , the Laplace equation is assumed to hold (20) as a first approximation, with no excess charge density in the solution

$$\nabla^2 \Phi = 0 \quad [6]$$

The perturbation equations.—Suppose that the system is subjected to small perturbations. Each parameter of the system can be divided into two parts

$$C_j = \bar{C}_j + c_j \quad [7.1]$$

$$\Phi = \bar{\Phi} + \phi \quad [7.2]$$

where \bar{C}_j and $\bar{\Phi}$ are steady-state components and c_j and ϕ are perturbations. \bar{C}_j and $\bar{\Phi}$ would be uniform in the X and Y directions and are functions only of Z. Ignoring the contributions by reactions other than [1.1] at the interface, Nernst's ionic mobility equation gives (19)

$$\frac{\nu_j}{nF} \bar{I}_a = -D_j \{ \nabla \bar{C}_j + \bar{C}_j \nabla (z_j F \bar{\Phi}) \} \quad [8]$$

Here n and ν_j are the charge transferred and the stoichiometric factors in the reaction [1.1]. In this case $n = z_M = z$, $\nu_M = 1$, and $\nu_{j \neq M} = 0$. It can also be written

$$\nabla^2 \bar{C}_j + \nabla \bar{C}_j \cdot \nabla (z_j F \bar{\Phi}) = 0 \quad [9]$$

$$\nabla^2 \bar{\Phi} = 0 \quad [10]$$

The amplitude describing the perturbation A ($A = c_j, \phi$) can be expanded in the manner (14)

$$A(x, y, z, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} dk_x dk_y A_k(z, t) \exp [i(k_x x + k_y y)] \quad [11]$$

where k_x and k_y are the wave numbers associated with the perturbation $A_k(z,t)$, and can be related to the wavelength λ_x, λ_y of perturbation in the X and Y directions as follows

$$\lambda_x = 2\pi/k_x; \quad \lambda_y = 2\pi/k_y \quad [12]$$

The instability of the system will result from perturbations of even one wave number, so the analysis can be made in terms of two-dimensional periodic waves of an assigned set of wave numbers (k_x, k_y).

The perturbed components c_j and ϕ are described in the form

$$c_j(x,y,z,t) = c_j^\circ(z) \exp[i(k_x x + k_y y) + pt] \quad [13.1]$$

$$\phi(x,y,z,t) = \phi^\circ(z) \exp[i(k_x x + k_y y) + pt] \quad [13.2]$$

where p is a constant for the time variation of perturbations. Substitution of Eq. [7.1], [7.2], [9], [10], [13.1], and [13.2] into Eq. [5] and [6] yields

$$\left[D^2 + \left\{ D \left(\frac{z_j F \bar{\Phi}}{RT} \right) \right\} D - k^2 - \frac{p}{D_j} \right] c_j^\circ(z) + (D \bar{C}_j) D \{ z_j f \phi^\circ(z) \} = 0 \quad [14]$$

$$(D^2 - k^2) \phi^\circ(z) = 0 \quad [15]$$

where $D = d/dz$ and

$$k^2 = k_x^2 + k_y^2 \quad [16]$$

For simplicity, the electric field in the solution is assumed to be constant for the steady-state component¹

$$D(z_j f \bar{\Phi}) \equiv E_j = \text{const.} \quad [17]$$

Of ionic species which move through the solution, the metal ion M^{2+} and the halide ion X^- will be taken into consideration in the following treatment.² From Eq. [8]

$$D \bar{C}_x = - \bar{C}_x E_x \quad [18.1]$$

$$D \bar{C}_M = - \bar{C}_M E_M - \frac{\bar{I}_a}{z F D_M} \quad [18.2]$$

The boundary conditions.—The perturbation diminishes in the bulk of the solution, so that

$$c_j^\circ(z) = 0 \quad (j = M, X) \text{ at } z \rightarrow \infty \quad [19.1]$$

$$\phi^\circ(z) = 0 \quad \text{at } z \rightarrow \infty \quad [19.2]$$

Using Eq. [18.1] and [18.2], the general solutions for Eq. [14] and [15] are obtained as follows, which satisfy the conditions [19.1] and [19.2] (Appendix B)

$$c_X^\circ(z) = X_1 \exp(E_{X1} z) + X_2 \exp(E_{X2} z) \quad [20.1]$$

$$c_M^\circ(z) = M_1 \exp(E_{M1} z) + M_2 \exp(E_{M2} z) \quad [20.2]$$

$$\phi^\circ(z) = S \exp(-kz) \quad [20.3]$$

where³

$$E_{j1} \equiv -\frac{1}{2} E_j - \sqrt{\frac{1}{4} E_j^2 + k^2 + \frac{p}{D_j}} \quad (j = M, X) \quad [20.4]$$

$$E_{j2} \equiv -E_j - k \quad (|E_{M1}| < k) \quad (j = M, X) \quad [20.5]$$

¹Equation [8] together with the uniformity of $\bar{\Phi}$ in the x- and y- directions gives $d\bar{\Phi}/dz = \text{const.}$

²In general, several cationic and anionic species exist in the solution which come from the corrosive materials (HCl, etc.) or from the supporting electrolyte (Na_2SO_4 , etc.). However, perturbations of concentrations other than those of M^{2+} and X^- are disregarded for simplicity.

³ M_2 should be zero if $k < |E_{M1}|$. In the usual corrosive media, however, $|E_{M1}|$ is of the order of 1 so that the wavelength λ of perturbations should be larger than the order of a few centimeters in order for $k < |E_{M1}|$. Such waves will have no physical significance because they will be extinguished, e.g., by convection.

Continuity in terms of flux at the passive film-solution interface requires that

$$D_X \{ D c_X^\circ(z) - \bar{C}_X f D \phi^\circ(z) + c_X^\circ(z) E_X \} = 0 \text{ at } z = 0 \quad [21.1]$$

$$\frac{i_a^\circ}{zF} = -D_M [D c_M^\circ(z) + \bar{C}_M z f D \phi^\circ(z) + c_M^\circ(z) E_M] \text{ at } z = 0 \quad [21.2]$$

here i_a° is the amplitude of a normal mode of i_a , which is a perturbation of the current density I_a caused by perturbations in the solution, i.e.

$$I_a = \bar{I}_a + i_a \quad [22]$$

$$i_a = i_a^\circ \exp[i(k_x x + k_y y) + pt] \quad [23]$$

Using Eq. [2], i_a° can be expressed as follows (Appendix C)

$$i_a^\circ = \frac{\bar{I}_a}{1 + \frac{\beta}{\alpha_t}} \left\{ (\alpha z + m) \frac{c_X^\circ(0)}{\bar{C}_X(0)} - \beta f \phi^\circ(0) \right\} \quad [24]$$

where α_t is the transfer coefficient for conduction in the passive film and decreases with an increase in passive film thickness L ($\alpha_t \propto 1/L$).

Integrating the material balance Eq. [5] over the range of z [0, ∞] and using Eq. [18.1] and [18.2], the following is obtained

$$\begin{aligned} [(D + E_X) c_X^\circ(z)]_0^\infty - \bar{C}_X f \phi^\circ(0) \frac{k E_X}{k + E_X} \\ - \left(k^2 + \frac{p}{D_X} \right) \int_0^\infty c_X^\circ(z) dz = 0 \end{aligned} \quad [25]$$

$$\begin{aligned} [(D + E_M) c_M^\circ(z)]_0^\infty + \left\{ \bar{C}_M(0) E_M + \frac{\bar{I}_a}{z F D_M} \right\} z f \phi^\circ(0) \frac{k}{k + E_M} \\ - \left(k^2 + \frac{p}{D_M} \right) \int_0^\infty c_M^\circ(z) dz = 0 \end{aligned} \quad [26]$$

Applying the condition of electroneutrality to the range of z [0, ∞] where fluctuations of the charge density other than M^{2+} and X^- are assumed to cancel or to be negligible, the following is obtained

$$\int_0^\infty -\zeta F c_X^\circ(z) + z F c_M^\circ(z) dz = 0 \quad [27.1]$$

where

$$\zeta \equiv \frac{z \bar{C}_M(0)}{\bar{C}_X(0)} \quad [27.2]$$

is the factor to correlate the amplitude of perturbations of two ions in the presence of other ions.

Substitution of Eq. [20] into Eq. [21.1], [21.2], [24]-[26], and [27.1] yields

$$(E_X + E_{X1}) X_1 - k X_2 + \bar{C}_X(0) f k S = 0 \quad [28.1]$$

$$\begin{aligned} (\alpha z + m) \bar{K} (X_1 + X_2) + (E_M + E_{M1}) M_1 - k M_2 - \{ \bar{C}_M(0) z f k \\ + \beta f \bar{K} \bar{C}_X(0) \} S = 0 \end{aligned} \quad [28.2]$$

$$\begin{aligned} \left(E_X + E_{X1} - \frac{k^2 p}{E_{X1}} \right) X_1 + \left(-k + \frac{k^2 + \frac{p}{D_X}}{k + E_X} \right) X_2 \\ + \bar{C}_X(0) f \frac{k E_X}{k + E_X} S = 0 \end{aligned} \quad [28.3]$$

$$\begin{aligned} \left(E_M + E_{M1} - \frac{k^2 + \frac{p}{D_M}}{E_{M1}} \right) M_1 + \left(-k + \frac{k^2 + \frac{p}{D_M}}{k + E_M} \right) M_2 \\ - \left\{ \bar{C}_M(0) E_M + \frac{\bar{I}_a}{z F D_M} \right\} z f \frac{k}{k + E_M} S = 0 \end{aligned} \quad [28.4]$$

$$\frac{\zeta}{E_{X1}} X_1 - \frac{\zeta}{E_X + k} X_2 - \frac{z}{E_{M1}} M_1 + \frac{z}{k + E_M} M_2 = 0 \quad [28.5]$$

where

$$\bar{K} \equiv \frac{1}{zFD_M \bar{C}_X(0)} \frac{\bar{I}_a}{1 + \frac{\beta}{\alpha_f}} \quad [28.6]$$

The characteristic equation.—Equations [28] represent a system of linear homogeneous equations for the coefficients X_1 , X_2 , M_1 , M_2 , and S . For a nonzero solution of these equations to exist, the determinant H of the system must vanish (14). It can be shown that p is real and that the principle of the exchange of stabilities is valid in this system (Appendix D). The transition from stable to unstable state occurs via a stationary state, which corresponds to $p = 0$, as seen from Eq. [13.1] and [13.2]. Then H becomes at this marginal state

$$H(p = 0) = H_1 H_2 = 0 \quad [29.1]$$

here

$$H_1 \equiv \frac{k^2 E_X E_M}{E_{X1} E_{M1}} \left(\frac{k}{k + E_X} \right)^2 \frac{1}{k + E_M} \quad [29.2]$$

$$H_2 \equiv z f \left\{ -(\alpha z + m) \bar{K} \bar{C}_X(0) + \beta \bar{K} \bar{C}_X(0) + z k \bar{C}_M(0) \right. \\ \left. (k + E_X) + \zeta \bar{C}_X(0) f k^2 \right. \\ \left. - z^2 f k \left\{ \bar{C}_M(0) E_M + \frac{\bar{I}_a}{z F D_M} \right\} \frac{k + E_X}{k + E_M} \right\} \quad [29.3]$$

Conditions for perturbation to grow.—In order for Eq. [29.1] to be satisfied, at least one of the members H_1 , H_2 , must vanish. For $k > |E_M|$, $H_1 \neq 0$, so that $H_2 = 0$. Rewriting Eq. [29.3] with $E_M = -zE_X$ it is obtained

$$(1 + z) \zeta \omega^2 - h(\omega, W) \omega - (m + \alpha z - \beta) W = 0 \quad [30.1]$$

in which

$$h(\omega, W) \equiv \left\{ m + \alpha z - \beta + z \left(1 + \frac{\beta}{\alpha_f} \right) \frac{\omega + 1}{\omega - z} \right\} W \\ - z \zeta \left(1 + z \frac{\omega + 1}{\omega - z} \right) \quad [30.2]$$

and ω and W are dimensionless parameters

$$\omega \equiv \frac{k}{E_X}; \quad W \equiv \frac{z \bar{K}}{E_X} \quad [30.3]$$

W is expressed as follows, using Eq. [28.6] and [C-9]

$$W = k_a \bar{C}_X(0)^n \exp \left(\frac{\alpha_a F E}{RT} \right) / F D_M E_X \left(1 + \frac{\beta}{\alpha_f} \right) \quad [31]$$

where $n \equiv \{(\beta + m)\alpha_f / (\beta + \alpha_f)\} - 1$, $\alpha_a \equiv \beta \alpha_f / (\beta + \alpha_f)$, and E is the potential of the passive metal. W increases exponentially with the increase in E , so that $h(\omega, W)$ becomes large⁴ and k has a root in the range $k > zE_X$

$$k_c = \frac{E_X}{2(1+z\zeta)} \left\{ h(W) \right. \\ \left. + \sqrt{h(W)^2 + 4(1+z\zeta)(m + \alpha z - \beta)W} \right\} \quad [32]^5$$

The wave number of the perturbation at the marginal state is given by Eq. [32] and when k becomes short of k_c , the perturbation grows with time and the system

⁴In Eq. [30.2], the first term in the right-hand side becomes negative only in the case when the increase in the halide ion concentration at the passive film-solution interface brings about a decrease in the anodic current. This is not plausible for the system under consideration.

⁵ $(\omega + 1)/(\omega - z)$ was put to 1 for large $h(\omega, W)$, which is denoted as $h(W)$.

moves from the stationary to the unstable state (Appendix E). As seen from Eq. [31], the region of k specifying instability expands as the potential of the metal and/or the concentration of halide ion are increased (Fig. 2). For the fixed W in Eq. [31]

$$E = \text{const.} - \frac{nRT}{\alpha_a F} \ln \bar{C}_X(0) \quad [33]$$

which is the relationship between the potential of the metal and the concentration of aggressive ions. This shows a tendency for pitting to occur.

Current distribution and the localized attack.—When dissolution current arises locally at some point on the passive film by perturbation, the surroundings may become cathodic. Then dissolution is suppressed and this results in a localization of pits. This situation can be illustrated as follows.

Take a cylindrical coordinate system (r, ψ, z) with the Z -axis originating from the surface of the passive film normally into the solution. Disturbances c_X and ϕ shall be expressed as follows, by separation of variables

$$c_X(r, z, t) = c(r) c^o(z) \exp(pt) \quad [34.1]$$

$$\phi(r, z, t) = \phi(r) \phi^o(z) \exp(pt) \quad [34.2]$$

where symmetry around the Z -axis is assumed. From Eq. [5], [6], and [17] is obtained

$$(D^2 + E_X D) c^o(z) + \frac{c^o(z)}{c(r)} \nabla_z^2 c(r) - \frac{p}{D_X} \\ - (DC_X) \frac{\phi(r)}{c(r)} D \left\{ f \phi^o(z) \right\} = 0 \quad [35]$$

$$\frac{1}{\phi(r)} \nabla_r^2 \phi(r) = - \frac{1}{\phi^o(z)} D^2 \phi^o(z) \quad [36]$$

where $\nabla_z^2 \equiv \frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr}$. The solution to Eq. [36] which satisfies $\phi = 0$ at $z \rightarrow \infty$ and nonzero at $r = 0$ is

$$\phi^o(z) = P_1 \exp(-kz) \quad [37.1]$$

$$\phi(r) = Z_0(kr) \quad [37.2]$$

where $Z_0(kr)$ is the Bessel function of 0th order. Substitution of Eq. [37.1] and [37.2] into Eq. [35] comes to Eq. [14], if it is put

$$\nabla_z^2 c(r) = -k^2 c(r) \quad [38]$$

then the solution exists in the form

$$c(r) = P_2 Z_0(kr) \quad [39]$$

Fig. 2. Variation of p with k . Units are arbitrary. k_c : critical wave number for instability. $k_c = k_c(W)$, $k'_c = k'_c(W')$, $W' > W$.

Substituting these results into Eq. [24] and [11], the fluctuation of anodic current at the surface of the passive film is obtained

$$i_a(r,t) = \int_{z \in X} \frac{A_k \bar{I}_a}{1 + \frac{\beta}{\alpha_f}} \left\{ \left(\alpha z + m \right) \frac{c^0(0)}{C_X(0)} A_2 + \beta f A_1 \right\} Z_0(kr) \exp(pt) dk \quad [40]$$

In Fig. 3, the radial distribution of $i_a(r,t)$ was illustrated schematically. Because no assumptions were made for the cathodic reactions for this consideration, the case will be allowed where $\bar{I}_a - \bar{I}_{c2} = 0$. This indicates that cathodic current flows at the surroundings and the passivity is protected at these areas so that the pitting nucleation site is localized (21).

Discussion

Origin of localized attack.—There are several kinds of heterogeneities present on the surface of a passive film: inclusions, grain boundaries, dislocations, etc. These are sometimes believed to be related to the pitting nucleation site (5). However, it does not seem likely that pits always nucleate at these sites when the metal is immersed into a corrosive medium.

According to the probability concept of pitting corrosion, some stochastic process should precede pit nucleation (9-11). Fluctuations of the concentration of ionic species or of the electrical field in the solution would thus play a major role at the initial stage of pit nucleation, and if they grow with time, an unstable state results. Once this instability occurs, it would ultimately come to the state where localized concentration of aggressive ions and localized attack at the passive film start. As seen from Eq. [31] and [32], the system is more susceptible to pitting if there are a large halide concentration, a more positive metal potential, or higher electrical field in the solution. A rough estimation of the wavelength of perturbation where instability sets in was made for typical values of parameters (Table I).⁶ It is seen that a borderline exists for the possible occurrence of processes leading to pit nucleation.

The structural defects (4, 5) on the passive film would be favorable in the occurrence of perturbation or in the stimulation of following processes, if these defects "harmonize" the perturbations. The effects of the change in pH should also be significant in some cases, which is considered in Appendix F.

Pit initiation via the halide nuclei formation.—Pitting is expected to initiate when a localized attack by aggressive

⁶The electrical field in the bulk of the solution was adopted, for simplicity, for the calculation instead of the possible strong field at the vicinity of the interface.

λ_c
→ PIT NUCLEATION

sive ions starts by perturbation. However, in order to obtain the condition where aggressive ions break through the passive film of thickness L , the metal should be polarized above a certain critical potential. This potential is referred to as the pit-initiation potential, and often deviates positively from the repassivation potential at which pits stop (22, 23).

A process is assumed in which hemispherical halide nuclei form on the surface of the passive film and grow inwards. Whether the halide nuclei grow continuously or not determined the occurrence of pitting (12, 23).

It should again be noted that the pit initiation process is a probability event, in that it requires the growth of perturbation in the solution and the formation of halide nuclei in the passive film, and that it implies a positive polarization of the passive metal.

Manuscript submitted May 14, 1984; revised manuscript received Oct. 31, 1984. This was Paper 237 presented at the New Orleans, Louisiana, Meeting of the Society, Oct. 7-12, 1984.

Industrial Products Research Institute assisted in meeting the publication costs of this article.

APPENDIX A

The significance of the adsorption process of aggressive ions in the passive film destruction was pointed out by several authors (7, 24, 25). Halide ions are adsorbed on the surface of a passive metal and form a complex with the lattice cation. This complex is then activated to dissolve the metal ion

Suppose that the number of metal ions per unit surface area of the passive film is S_M and that the number of coordination sites of the halide ions for each surface metal ion is N_X . Then the number of adsorption sites for X^{-} per unit surface area of the passive film is $S_M N_X$. Following the reaction [A-2], m halide ions are assumed to jointly adsorb on the surface metal ion ($0 < m < N_X$). The dissolution current density I_a depends on the surface concentration $C(MX_{\text{ad}})$ of the adsorbed complex. Neglecting the reverse rate (19, 26)

$$I_a = k_M' \exp\left(-\frac{\Delta G^{\ddagger}}{RT}\right) C(MX_{\text{ad}}) \exp\left[\frac{\alpha z F (\Delta\Phi_{\text{MO/S}} - \Delta\Phi_{\text{MO/S,rev}})}{RT}\right] \quad [A-3]$$

where k_M' is rate constant, ΔG^{\ddagger} the standard chemical free energy of activation, α the symmetrical factor, and $\Delta\Phi_{\text{MO/S}}$ and $\Delta\Phi_{\text{MO/S,rev}}$ are the Galvani potential difference at the passive film-solution interface and its equilibrium value.

$C(MX_{ad})$ is expressed as follows

$$C(MX_{ad}) = \text{const. } S_M \frac{N_X!}{(N_X - m)!m!} \prod_{i=1}^m \theta_i \quad [\text{A-4}]$$

where θ_i is surface coverage of X^- which come i th in the units of N_X coordination sites. θ_i is assumed to obey the following adsorption isotherm (27, 28)

$$\theta_i = \frac{K_i C_X(0)}{1 + K_i C_X(0)} \quad [\text{A-5}]$$

in which K_i changes with the change in θ_j ($j < i$)

$$K_i = K_0 \exp \left(-r \sum_{j=1}^{i-1} \theta_j / RT \right) \quad [\text{A-6}]$$

$$K_0 \equiv \exp \left(\frac{-\Delta G_{ad}^\circ(0) + F\Phi_1}{RT} \right) \quad [\text{A-7}]$$

here $\Delta G_{ad}^\circ(0)$ is the standard free energy of adsorption at $\theta_i = 0$, and r is the Temkin parameter, *i.e.*, the variation of standard free energy of adsorption with coverage (26, 28). Φ_1 is the potential at the inner plane of the electrical double layer (27)

$$\Phi_1 = \alpha_1 \Delta\Phi_{MO/S}, \quad (0 < \alpha_1 < 1) \quad [\text{A-8}]$$

Since $1/N_X > \theta_1 > \theta_2 > \dots, \theta_i$ in Eq. [A-5] can be approximated as follows

$$\theta_i \propto K_i C_X(0) \quad [\text{A-9}]$$

Only the interaction between adsorbed X^- in the units N_X coordination sites is significant, so that

$$K_i = K_0 \exp \{ r(i-1)/N_X RT \} \quad [\text{A-10}]$$

Substituting Eq. [A-9] and [A-10] into Eq. [A-4] and rewriting Eq. [A-3], Eq. [2] is obtained in which

$$k_M \equiv \text{const. exp} \left\{ \frac{-\Delta G_{ad}^\circ - m \Delta G_{ad}^\circ(0) - \alpha z F \Delta\Phi_{MO/S,rev}}{RT} \right\} \exp \left\{ \frac{m(m-1)r}{2N_X RT} \right\} \quad [\text{A-11}]$$

$$\beta \equiv \alpha z + \alpha_1 m \quad [\text{A-12}]$$

APPENDIX B

Equation [14] becomes using Eq. [17]

$$\frac{(D^2 + E_j D - k^2 - \frac{p}{D_j}) c_j^\circ(z)}{D \bar{C}_j} = D \left\{ \frac{z_j F \phi^\circ(z)}{RT} \right\} \quad [\text{B-1}]$$

from Eq. [17], [18.1], and [18.2]

$$D^2 \bar{C}_j = -E_j D \bar{C}_j \quad [\text{B-2}]$$

$$D^3 \bar{C}_j = E_j^2 D \bar{C}_j \quad [\text{B-3}]$$

Operating $(D^2 - k^2)$ to Eq. [B-1] and using Eq. [15], [B-2], and [B-3]

$$\frac{1}{D \bar{C}_j} (D^2 + 2E_j D - k^2 + E_j) \left(D^2 + E_j D - k^2 - \frac{p}{D_j} \right) c_j^\circ(z) = 0 \quad [\text{B-4}]$$

The general solution to the above equation is

$$c_j^\circ(z) = c_j^{\circ+}(z) + c_j^{\circ-}(z) \quad [\text{B-5}]$$

where

$$c_j^{\circ\pm}(z) \equiv J_1^\pm \exp(E_{j1}^\pm z) + J_2^\pm \exp(E_{j2}^\pm z) \quad [\text{B-6}]$$

$$E_{j1}^\pm \equiv -\frac{1}{2} E_j \pm \sqrt{\frac{1}{4} E_j^2 + k^2 + \frac{p}{D_j}} \quad [\text{B-7}]$$

$$E_{j2}^\pm \equiv -E_j \pm k \quad [\text{B-8}]$$

The general solution to Eq. [15] is

$$\phi^\circ(z) = S^+ \exp(kz) + S^- \exp(-kz) \quad [\text{B-9}]$$

Each member of the right-hand side of Eq. [B-5] makes a pair with those in Eq. [B-9]. In order for the solution [B-9] to satisfy the boundary condition [19.2], S^+ should be zero. Then $c_j^\circ(z) = 0$ in Eq. [B-5], and so $j_1^+ = J_2^+ = 0$. Also it is seen in order for Eq. [19.1] to be satisfied

$$E_{j1}^- < 0 \quad [\text{B-10}]$$

$$E_{j2}^- < 0 \quad [\text{B-11}]$$

Inequality [B-10] is always satisfied. From Inequality [B-11], it is obtained that $-E_j < k$. All these results are used in Eq. [20].

APPENDIX C

Suppose that I_a is subjected to a small change around the steady-state value \bar{I}_a . Substituting Eq. [2] into Eq. [22] and retaining only the first-order derivatives, it is obtained that

$$i_a = \bar{I}_a \left\{ \frac{\partial \ln k_M}{\partial C_X(0)} C_X(0) + m \frac{C_X(0)}{C_X(0)} + \frac{\beta F}{RT} \delta\Delta\Phi_{MO/S} \right\} \quad [\text{C-1}]$$

in which k_M is expressed as follows, according to Eq. [A-11]

$$k_M = \text{const. exp} \left[-\frac{\alpha z F \Delta\Phi_{MO/S,rev}}{RT} \right] \quad [\text{C-2}]$$

and

$$\Delta\Phi_{MO/S,rev} = -\frac{RT}{F} \ln \bar{C}_X(0) + \text{const.} \quad [\text{C-3}]$$

The potential E of the passive metal measured by a reference electrode in the solution is

$$E = \Delta\Phi_{M/MO} + \Delta\Phi_{MO/S} + \Delta\Phi_{sol.} + \text{const.} \quad [\text{C-4}]$$

in which $\Delta\Phi_{M/MO}$ is the potential difference across the passive film and $\Delta\Phi_{sol.}$ is the potential difference in the solution. In the case E is kept constant

$$\delta\Delta\Phi_{MO/S} = -\delta\Delta\Phi_{M/MO} - \delta\Delta\Phi_{sol.} \quad [\text{C-5}]$$

The current density which passes through the passive film is expressed as follows

$$\bar{I}_a = \text{const. exp} \left[\frac{\alpha_f F}{RT} \Delta\Phi_{M/MO} \right] \quad [\text{C-6}]$$

Then

$$i_a = \delta I_a = \frac{\alpha_f F}{RT} \delta\Delta\Phi_{MO/S} \bar{I}_a \quad [\text{C-7}]$$

$\delta\Delta\Phi_{sol.}$ can be equated to the change in electrical potential in the solution by perturbation

$$\delta\Delta\Phi_{sol.} = \phi(z=0) \quad [\text{C-8}]$$

Substituting Eq. [C-2], [C-3], [C-5], [C-7], and [C-8], into Eq. [C-1] and dividing by $\exp [i(k_x x + k_y y) + pt]$, Eq. [24] is obtained, in which \bar{I}_a is written as follows, using Eq. [2] and [C-6]

$$\bar{I}_a = k_a \bar{C}_X(0)^{m'} \exp \left\{ \frac{\alpha_a F \Delta\Phi_{M/S}}{RT} \right\} \quad [\text{C-9}]$$

where

$$m' \equiv \frac{(\beta + m) \alpha_f}{\beta + \alpha_f} \quad [\text{C-10}]$$

$$\alpha_a \equiv \frac{\beta \alpha_f}{\beta + \alpha_f} \quad [\text{C-11}]$$

$$\Delta\Phi_{M/S} \equiv \Delta\Phi_{M/MO} + \Delta\Phi_{MO/S} \quad [\text{C-12}]$$

APPENDIX D

Define $G(z)$ as follows

$$(D^2 + 2E_j D - k^2 + E_j^2) c_j^{\circ}(z) \equiv G(z) \quad [\text{D-1}]$$

It is written from Eq. [B-4]

$$\left(D^2 + E_j D - k^2 - \frac{p}{D_j}\right) G(z) = 0 \quad [\text{D-2}]$$

Multiply the complex conjugate G^* of G on both sides of Eq. [D-2] and integrate over the range of z , thereby using the boundary conditions

$$\begin{aligned} \int_0^{\infty} G^* \left(D^2 + E_j D - k^2 - \frac{p}{D_j}\right) G dz &= -G^*(0) DG(0) \\ &- \int_0^{\infty} |DG|^2 dz - E_j |G(0)|^2 \\ &- \int_0^{\infty} GE_j DG^* dz - \left(k^2 + \frac{p}{D_j}\right) \int_0^{\infty} |G|^2 dz = 0 \end{aligned} \quad [\text{D-3}]$$

Taking the imaginary part of Eq. [D-3]

$$\begin{aligned} im G^*(0) DG(0) + im \int_0^{\infty} GE_j DG^* dz + im \left(\frac{p}{D_j}\right) \\ \int_0^{\infty} |G|^2 dz = 0 \end{aligned} \quad [\text{D-4}]$$

$c_j^{\circ}(z)$ is adopted which takes real values according to Eq. [20], so that $G(z)$ is also real as seen from Eq. [D-1]. Then the first two terms in Eq. [D-4] vanishes and

$$im(p) \int_0^{\infty} |G|^2 dz = 0 \quad [\text{D-5}]$$

Since the integral is positive definite, it is seen that $im(p) = 0$ so that p is real.

APPENDIX E

The variation of p with k is determined by $H(p) = 0$. In the region $-E_M < k$, p passes through the axis $p = 0$ once at $k = k_c$ given by Eq. [32]. The gradient of $p - k$ curve around this point is to be examined. This can be done by noting the direction of shifting p from $p = 0$ when k goes over k_c by small amount.

To simplify the treatment, it would be reasonable to put

$$\int_0^{\infty} \frac{\partial}{\partial t} c_x dz = 0 \quad [\text{E-1}]$$

$$\int_0^{\infty} \frac{\partial}{\partial t} c_M dz = \frac{i_a}{zF} \{1 - \kappa(p)\} \quad (0 < \kappa(p) < 1) \quad [\text{E-2}]$$

$\kappa(p)$ is a function of p , and $\kappa = 1$ at $p = 0$.

The determinant $H(p)$ is then expanded

$$\begin{aligned} H(p) &= k^2 \frac{(E_N + E_{N1} + k)(E_{N1} - k)}{E_{N1}(k + E_N)} \\ &\frac{(E_M + E_{M1} + k)(E_{M1} - k)}{E_{M1}(k + E_M)} \frac{1}{k + E_N} \end{aligned}$$

$$\times \{H_2 + (1 - \kappa)zf(\alpha z + m - \beta) \bar{K} \bar{C}_X(0)(k + E_N)\} = 0 \quad [\text{E-3}]$$

Expanding each element of the above equation with respect to p around $p = 0$ and neglecting the second- and higher-order terms, it is obtained

$$\begin{aligned} H_p \equiv \left\{ \frac{kE_N}{E_{N0}} + \alpha_N(k)p \right\} \left\{ \frac{kE_M}{E_{M0}} + \alpha_M(k)p \right\} \left(\frac{k}{k + E_N} \right)^2 \frac{1}{k + E_M} \\ \times \{H_2 - \kappa_1 zf(\alpha z + m - \beta) \bar{K} \bar{C}_X(0)(k + E_N)p\} = 0 \end{aligned} \quad [\text{E-4}]$$

where

$$E_{X0} \equiv E_{X1}(p = 0), E_{M0} \equiv E_{M1}(p = 0), \kappa_1 \equiv \left(\frac{\partial \kappa}{\partial p} \right)_{p=0}, \text{ and}$$

$$\begin{aligned} \alpha_j(k) &\equiv \frac{1}{\sqrt{E_j^2 + 4k^2} D_j} \\ &\left\{ 1 + \frac{k(k + E_j)}{\frac{1}{2} E_j^2 + k^2 + E_j \sqrt{\frac{1}{4} E_j^2 + k^2}} \right\} \end{aligned} \quad [\text{E-5}]$$

H_p is a function of third order with respect to p

$$H_p = K(k)p^3 + L(k)p^2 + M(k)p + N(k) = 0 \quad [\text{E-6}]$$

$H_p - p$ makes a family of curves with k as a parameter. $N(k)$ is the value of H_p at $p = 0$, i.e., at the intersection of $H_p - p$ curve with the ordinate. At $k = k_c$, $N(k_c) = 0$. It is seen that $H_p - p$ curve goes through the origin for $k = k_c$. Obviously $N(k)$ is equal to $H(p = 0)$ in Eq. [29.1]

$$N(k) = H(p = 0) = H_1 H_2 \quad [\text{E-7}]$$

It is seen from Eq. [29.2] and [29.3] that $H_1 < 0$ and $H_2 > 0$. at $k = k_c + dk$ ($dk > 0$), so that

$$N(k_c + dk) < 0 \quad [\text{E-8}]$$

Whether the gradient of $H_p - p$ curve for $k = k_c + dk$ around $p = 0$ takes positive or negative values determines the sign of p which satisfies Eq. [E-6]. The gradient of $H_p - p$ curve around $p = 0$ will not change very largely if k increases from k_c to $k_c + dk$ by infinitesimal amount

$$\frac{dH_p}{dp}(k = k_c + dk) \approx \frac{dH_p}{dp}(k = k_c) \quad [\text{E-9}]$$

Also from Eq. [E-6]

$$\frac{dH_p}{dp}(k = k_c) = \frac{dH_p}{dp}(p = 0) = M(k_c) \quad [\text{E-10}]$$

Equation [E-4] is expanded and the coefficient $M(k)$ for the first order of p is obtained as follows

$$\begin{aligned} M(k) &= \left\{ \frac{kE_N}{E_{N0}} \alpha_M(k) + \frac{kE_M}{E_{M0}} \alpha_N(k) \right\} \left(\frac{k}{k + E_N} \right)^2 \frac{1}{k + E_M} H_2 \\ &- H_1 \kappa_1 zf(\alpha z + m - \beta) \bar{K} \bar{C}_X(0)(k + E_N) \end{aligned} \quad [\text{E-11}]$$

$H_2(k_c) = 0$, as seen from Eq. [29.1]. It is also seen from Eq. [E-2] that $\kappa_1 < 0$, so that

$$M(k_c) < 0 \quad [\text{E-12}]$$

because $H_1(k_c) < 0$. This shows that $p < 0$, i.e., p becomes negative when k goes over k_c . Then $p - k$ curve has a shape as depicted in Fig. 2.

APPENDIX F

The change in pH of the solution at the interface seems to play a major role on the initiation of pitting (5, 29). The H^+ activity will change by two processes. One is due to the hydrolysis of the dissolved metal ions (5)

The other is due to the change in activity coefficients caused by the increase in the halide ion concentration. These two effects will be considered briefly. The formula for the dissolution current density which includes H^+ activity a_H is

$$I_a = k_M'' C_X(0)^m a_H(0)^n \exp \left[\frac{\beta F \Delta \Phi_{M(OH)}}{RT} \right] \quad [\text{F-2}]$$

H^+ concentration is given by (5)

$$C_H = K_1 C_M / C_{M(OH)} \quad [\text{F-3}]$$

where K_1 is the equilibrium constant of reaction [F-1]. If the change in concentration of $M(OH)^{(z-1)+}$ which is produced by hydrolysis is neglected

$$C_H \propto C_M \quad [F-4]$$

The activity coefficient γ_H of H^+ can be expressed as follows, if it is not in dilute solutions (30)

$$\ln \gamma_H = -K_2 + K_3 C_X \quad [F-5]$$

Then Eq. [F-2] is written as

$$I_a = k_M C_X(0)^m C_M(0)^h \exp \{hK_3 C_X(0)\} \exp \left[\frac{\beta F \Delta \Phi_{M0/S}}{RT} \right] \quad [F-6]$$

For simplicity, the ionic transport equation for H^+ is not considered here except for the contribution of a_H to boundary conditions. In this case, Eq. [28.2] is replaced by the following equation

$$\begin{aligned} & \{(\alpha z + m) \bar{K} + hK_3 \bar{C}_X(0)\} (X_1 + X_2) \\ & + \left\{ E_M + E_{M1} + \bar{K}h \frac{\bar{C}_X(0)}{\bar{C}_M(0)} \right\} B_1 \\ & + \left\{ \bar{K}h \frac{\bar{C}_X(0)}{\bar{C}_M(0)} - k \right\} B_2 - \left\{ C_M(0)zfk + \beta f \bar{K} \bar{C}_X(0) \right\} S = 0 \end{aligned} \quad [F-7]$$

It is rather tedious to solve characteristic equations including Eq. [F-7]. In the special case where reaction [F-1] can be ignored and only the change in γ_H is taken into account, the results can be obtained with little alterations. In this case the critical wave number k_c for the growing perturbation is expressed similarly to Eq. [32], where $h(W)$ is replaced by $h_1(W)$

$$\begin{aligned} h_1(W) \equiv & \left\{ m + \alpha z - \beta + hK_3 \bar{C}_X(0) - z \left(1 + \frac{\beta}{\alpha_f} \right) \right\} W \\ & + z(z-1)\zeta \quad [F-8] \end{aligned}$$

Semiconductor Electrodes

LVI. Principles of Multijunction Electrodes and Photoelectrosynthesis at Texas Instruments' p/n-Si Solar Arrays

James R. White, Fu-Ren F. Fan, and Allen J. Bard*

Department of Chemistry, The University of Texas Austin, Texas 78712

ABSTRACT

In photoelectrochemical (PEC) cells based on single junctions of semiconductors with solutions or metals, photopotentials are rarely above 0.6-0.8V. The higher photovoltages needed to drive more energetic reactions require multijunction cells involving multilayer electrodes or series connection of PEC cells. Such PEC cells are considered, and their behavior is shown to be predicted from the current-potential (i-V) behavior at each interface; the sum of the voltage drops at a given current yields the i-V characteristic of the overall PEC cell. These principles are illustrated with the Texas Instruments arrays based on silicon spheres and Si p/n junctions contacting a solution via a noble metal layer. Reactions considered include generation of Cl_2 with reduction of O_2 or the generation of H_2 , the photobromination of phenol, and the photochlorination of cyclohexene in acetonitrile.

Liquid-junction photoelectrochemical (PEC) cells are of interest in the direct utilization of solar energy to carry out useful chemical reactions (1-4). In most liquid-junction PEC cells, the photopotential arises at the semiconductor/solution interface. The maximum (open-circuit) photopotential, which represents the driving force of the cell chemical reaction, is rarely more than 0.8V, and is often below 0.6V. This rather low driving force limits the

range of possible photoelectrosynthetic reactions which can be carried out in PEC cells without the application of an external bias. Alternatively, the photoactive junction can be at a metal/semiconductor (Schottky barrier) interface with the faradaic reaction occurring at the metal (sometimes bearing an appropriate electrocatalyst). For example, PEC's with the following junctions have been described: Au/n-GaP (5, 6), PtSi/n-Si (7), and Pt/n-GaAs (8). Such cells have the advantage that the semiconductor is protected from the solution environment and show

* Electrochemical Society Active Member.

photopotentials that are independent of the redox potential of solution species. However, again the reported photopotentials are usually below 0.6V. Related PEC's involve photopotentials that arise at a p/n semiconductor junction, again protected from the solution by a metal overlayer. The most highly developed systems of this type are probably the p-Si/n-Si junctions separated from the solution by suitable noble metal overlayers that are used in the Texas Instruments Solar Energy System (TISES) (9-11). The photopotential developed at these junctions is about 0.55V. These latter p-Si/n-Si junctions are clearly related to solid-state photovoltaic cells (e.g., involving single-crystal Si) that are used for electricity production. In the TISES system, these junctions are produced on small (0.2 mm diam) Si spheres that are embedded in glass and backed by a conductive matrix to form arrays in contact with a solution. The relative advantages of these arrays compared to solid-state devices has been discussed (10, 11).

If more energetic reactions are to be driven in PEC cells without an external bias, cells with both photoactive anodes and cathodes can be employed. These two electrodes must be matched carefully to maximize the efficiency, since two photons are used to drive a single electron through the circuit. This strategy is employed in the TISES system, where both n-Si on p-Si spheres (photocathodes) and p-Si on n-Si spheres (photoanodes) are coupled to produce a total open-circuit voltage of 1.1V. These microspheres are coated with noble metal films which act as electrolytic contacts to the solution, stabilize the substrate Si, and catalyze the electrode reactions. The TISES system has been developed specifically for the overall conversion of solar to electrical energy in a system where HBr is decomposed by sunlight to form Br₂ at the photoanode and H₂ at the photocathode. The Br₂ and H₂ are stored and subsequently recombined in a fuel cell to produce electricity.

To form systems with higher output voltages, a number of junctions must be connected in series or the PEC cells must be coupled in a suitable way. Particularly interesting structures would involve multilayer devices with several photoactive junctions, especially if semiconductors with different bandgaps are employed. Structures of this type have been proposed in solid-state photovoltaic devices (tandem or cascade cells) (12), but few examples have been given in photoelectrochemical cells for direct utilization of radiant energy in chemical reactions. In this paper, we consider the principles of semiconductor electrode devices with interior photoactive junctions and the means of coupling PEC cells to increase the available voltage to levels consistent with a particular reaction. In particular, we demonstrate the application of the Texas Instruments solar arrays to electrosynthetic reactions, e.g., in the production of chlorine and oxygen and in the bromination of phenol. The utilization of these arrays in a nonaqueous solvent (MeCN) for the chlorination of cyclohexene is also described.

Principles of Operation

We suggest the following notation for multilayer semiconductor devices

where CM represents the contact metal to the electrode (connected to an external lead), A and B represent other, often semiconductor phases, SM is the surface metal or layer contacting the solution phase, and S is the solution. As usual in electrochemical cells, a slash represents a junction; we represent an ohmic contact by //. For example, the Texas Instruments photoanode (TIA), which is part of the array used in this work, is represented as

where CM is the tantalum back contact, and SM is a surface metal (e.g., Pt or Ir) with a suitable catalyst. The photoactive junction (indicated by the asterisk) is the Si

n/p junction. This can also be denoted as an L₄P₁ electrode, where L represents the number of layers used and P the number of photoactive junctions. The TI photocathode (TIC) is thus

and the array is formed by contacting CM and CM'.

The operation and current-voltage (i-V) curves of a given electrode can be understood by examining the i-V characteristics of each junction and noting that these are connected in series. Operation of the total cell can then be obtained, as is usual for electrochemical devices, by combining the i-V characteristics of each electrode. Consider the TIA shown in Eq. [2]. The electrochemical behavior is described by that of the p/n junction, either in the dark or under irradiation, in series with the SM/S interface (Fig. 1). For the p/n junction the dark behavior (curve A) is given by the Shockley Eq. [4] (13)

$$j = j_s [\exp (eV_j/kt) - 1] \quad [4]$$

where j is the current density, j_s is the saturation current density for the junction as determined by the carrier density, mobility, and diffusion length, and V_j is the voltage drop across this junction. The illuminated p/n junction (curve B) behaves as a constant current source in parallel with the junction and the j - V relationship is given by

$$j = j_s [\exp (eV_j/kT) - 1] - j_L \quad [5]$$

where j_L is the constant current produced by photogeneration of carriers in the junction. The metal/solution junction shows behavior that depends upon the nature of the metal and solution components and is governed by the typical electrochemical thermodynamic, mass-transport, and kinetic considerations (14). A representative curve is given in Fig. 1C, showing the current across this junction as a function of the potential of SM *vs.* a reference electrode, V_{SM} . The j - V behavior of the multilayer structure is given by the summation of the j - V_j and j - V_{SM} curves, assuming a series connection (Fig. 1D). At any current density, j , the voltage drop between CM and the reference electrode, V , is $V_j + V_{SM}$ (plus any iR drops within the phases). Clearly, the light driven photopotential (or the underpotential for the electrode reaction because of the p/n junction), at any value of j , is V_j . The behavior of the TIC shown in Eq. [3] can be obtained in an analogous manner, as shown in Fig. 2. The characteristics of multilayer, multijunction devices, e.g., containing several photoactive junctions, can be obtained in a similar way by adding the j - V characteristics of each junction.

Fig. 1. Representative j - V curves for p on n-Si junction in the dark (A) and in the light (B). Voltage scale for curves A and B represents a voltage drop, ($\Delta V = V_j$) across the p/n junction. (C): j - V curve for a metal/solution junction. (D); j - V curve for total TIA. Potentials are *vs.* a reference electrode.

Fig. 2. Representative j - V curves for n on p-Si junction in the dark (A) and in the light (B). Voltage scale for A and B represents a voltage drop, $\Delta V = V_J$, across the n/p junction. (C): j - V curves for a metal electrode; (D): j - V curve for total TIC. Potentials are vs. a reference electrode.

Single photoelectrode cells.—The behavior of the overall photoelectrosynthetic cell, e.g., TIA/S/M, where M is the conductive counterelectrode, is determined by the i - V curve of the TIA discussed above, the i - V curve of electrode M (in the cathodic region) and any iR drop in solution, under the conditions that the total anodic current at the TIA is equal to the cathodic current at M at any given cell voltage, V_{cell} . Representative curves are given in Fig. 3. The maximum current in the absence of any externally applied voltage would be i_{sc} , the short-circuit current. Clearly, for a spontaneous reaction, good overlap of the anodic and cathodic i - V curves is required. The i - V curve for a variable load resistor, R_L , across the cell, represented by V_{cell} , or with an externally applied voltage, V_{appl} , can also be obtained (Fig. 3). The maximum photocurrent under any conditions [in the absence of current doubling effect (15)] is i_L , governed by the p/n junction characteristics. An analogous treatment applies for the TIC coupled in a cell with a metal anode.

Systems with two photoelectrode (dual-array PEC).—When one photoelectrode is coupled with a metal counterelectrode, the maximum open-circuit photovoltage, V_{oc} , is limited by the potential generated at a single p/n junction, e.g., for a silicon p/n junction, 0.55V. However, if a photoanode is coupled with a photocathode, V_{oc} is the sum of both photoactive junction potentials. Thus, for the cell TIC/S/TIA, $V_{\text{oc}} = 1.1\text{V}$. This allows more energetic reactions to be driven without an external bias. Again, the overall cell behavior can be predicted from the individual i - V curves for the TIA and TIC. This is shown in Fig. 4.

Multiple photoarray system.—To obtain even higher potentials to drive more energetic reactions, two (or more) photocells must be coupled. For example, by suitable coupling of the photocells: TIC/S/TIA and TIC/S'/TIA an open-circuit photovoltage of 2.2V can be obtained across solution S'. In this case, cell 1 would contain a single redox couple (e.g., Br_2/Br^-) and behaves as a photovoltaic cell which provides a bias to cell 2 and adds to the photovoltage developed in cell 2. The mode of connection of these cells and the relevant i - V curves are shown in Fig. 5, where a reaction involving $> 1.1\text{V}$ (e.g., $2\text{HCl} \rightarrow \text{H}_2 + \text{Cl}_2$) is carried out.

The experimental results that follow illustrate i - V curves for several redox couples at TI silicon arrays (TIA, TIC) and demonstrate several photoelectrosynthetic PEC's of the type outlined above.

Experimental

The multilayered semiconductor electrodes used in these experiments were the TISES silicon arrays pro-

Fig. 3. Representative i - V curves for the cell TIA/S/M. Top: curves A and B represent TIA and M, respectively. Potentials are vs. a reference electrode. Bottom: i - V_{cell} behavior when electrodes are coupled through a load resistance, R_L . For $R_L = 0$, $i = i_{\text{sc}}$, and $V = 0$; for $R \rightarrow \infty$, $i = 0$, and $V = V_{\text{oc}}$. V_{out} represents a voltage produced by the cell under illumination. Fig. 5. Schematic representation of dual cell photoarray system. Top: *i-V* curves for cell 1; (A) TIA, (B) TIC. Bottom: *i-V* curves for cell 2. (A) (---): Pt electrode in HCl. (B) (-.-.-): TIA and TIC in HCl under illumination. (C) (—): as in B, under bias from cell 1.

tact was covered with epoxy cement which was insulated from solution with silicone rubber. The exposed front surface geometrical area was 0.25 cm^2 . RuO_2 films were prepared by decomposition of RuO_4 vapor, which was prepared chemically (16), onto ambient temperature substrates. XPS data showed that the binding energies for the Ru $3d_{5/2}$ line from samples prepared in this manner are in agreement with those obtained for anhydrous RuO_2 powder (17).

Voltammetric experiments were performed in a single-compartment Pyrex cell with a volume of 50 ml. All solutions were degassed with prepurified N_2 for 15 min prior to use unless indicated otherwise. Voltammograms were recorded with a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat, a PAR Model 175 Universal Programmer, and a Houston Instruments Model 2000 X-Y Recorder. The illumination source was a tungsten-halogen lamp with a 13 cm water filter.

A dual-compartment Plexiglas cell (40 ml each compartment) was used for experiments involving multiple photoelectrodes immersed in two solutions. For the experiment involving HCl electrolysis, one compartment contained HCl while the other contained the Br^-/Br_2 redox couple. Photoelectrodes were placed as close to the cell wall as possible to minimize absorption of light by the solution.

A Pyrex H-cell was used for the experiments in which Cl_2 was produced by reduction of O_2 (TIA/S/M). A fuel cell electrode (geometrical area, 3.1 cm^2), Teflon/carbon/platinum (donated by TI), was used as a cell divider. One compartment contained $5M$ HCl, and the other was kept dry and pressurized with O_2 .

Power characteristics were evaluated with a series, variable resistance box and a digital voltmeter. Short-circuit measurements were approximated by using a 15Ω resistance and measuring the corresponding voltage drop. All chemicals were reagent grade and were used without further purification. Triply distilled water was used in all

experiments. Acetonitrile was dried over molecular sieves.

Results and Discussion

Half-reactions at TIA's and TIC's.—We considered half-cells composed of a TIA immersed in different solutions (cell [2]) and compared the photoresponse of these to the *i-V* curves at a metal electrode.

Oxidation of chloride.—The voltammetric curves for a TIA in $10.0M$ LiCl are shown in Fig. 6. In the dark, curve A, essentially no current is observed, even at potentials where vigorous Cl_2 production is observed on a bare Pt electrode (curve C). Under illumination, at a light intensity of 170 mW/cm^2 , *j-V* curve B results. The limiting current density, j_L , was 38 mA/cm^2 . The open-circuit photopotential, V_{oc} , was $0.49V$, as measured from the differences between curves B and C. The platinum disk electrode operated near the reversible potential for the Cl/Cl_2 couple at low current densities. The fill factor was 0.42 . The stability of the TIA for Cl_2 evolution was tested by holding it at $\pm 1.0V$ vs. SCE under illumination of 170 mW/cm^2 for 48h; voltammograms taken intermittently during this time period showed no change in j_L or in the *j-V* curve. No apparent changes in the electrode surface were observed.

The effect of thin films of RuO_2 , a known catalyst for chlorine evolution, on the voltammetric response in Cl^- media was also examined. Films about 100\AA thick were deposited by chemical vapor deposition onto ambient temperature substrates. The TIA/ RuO_2 electrode showed a slightly more negative onset for chlorine evolution compared to an unmodified TIA (Fig. 7). The modified TIA also showed a larger cathodic peak on the reverse scan. These results suggest that the kinetics of the Cl^-/Cl_2 couple are somewhat improved by the RuO_2 treatment. The fill factor for the RuO_2 coated anode increased to 0.48 . There was, however, some attenuation of j_L because of light absorption by the RuO_2 layer (25% attenuation in the worst case). The RuO_2 modified TIA's were tested for stability by potential cycling for 1h under illumination. The films showed stable operation for solutions of $pH > 2$; however, for $pH < 1$, the *i-V* curves showed only resistive behavior with poor photoeffects, indicating deterioration of the surface film.

The Br^-/Br_2 couple.—This couple is of interest because photogenerated Br_2 could be employed in brominations of organics and because this couple could be used in a photovoltaic mode in the coupling of two PEC's. Typical *i-V* curves are shown in Fig. 8 for the TIA and TIC electrodes. The data pertaining to this couple are given in Table I.

$Fe(III)/Fe(II)$ couples.—We also investigated the $Fe^{3+/2+}$ couple in $1M$ HCl medium and the $Fe(CN)_6^{3-/4-}$ couple in $0.5M$ Na_2SO_4 for use in the photovoltaic biasing cell. The

results are summarized in Table I. The efficiency with these couples was lower than that found with the Br⁻/Br₂ couple. This can primarily be attributed to lower values of j_i (and, hence, i_{sc}). For the Fe^{3+/2+} couple, this arises because of increased light absorption by the solution, while for the Fe(CN)₆^{3-/4-} couple the relatively low solubility causes j_i to be limited by mass transfer. The latter couple also suffers from some photochemical instability (18).

The O₂/OH⁻ system.—The *i*-*V* curves for the oxidation of hydroxide ion at a TIA are given in Fig. 9. For an unbuffered solution (curve A), the *i*-*V* is drawn out, probably because of pH changes in the vicinity of the electrode during the oxidation as well as sluggish electron-transfer rates at the metal/solution interface. Sharper *i*-*V* curves occur in 1M NaOH (curve B); these show some hysteresis on scan direction which, perhaps, is caused by blockage of electrode surface by oxygen bubbles. We also examined the effect of a chemically vapor deposited layer of RuO₂ on the TIA. While RuO₂ coating had only a small effect in the unbuffered solutions (pH = 8), for the 1M NaOH there was a significant improvement in behavior. The potential for the onset of photocurrent was shifted to more negative values and the current rose more steeply (*i.e.*, the fill factor improved).

Single photoarray cells.—Since the total driving force for a single photoarray cell is small (0.55V), only photo-

electrosynthetic reactions which have both a small positive ΔG° and good kinetics (low overpotential) are possible. An interesting reaction possibility is the photo-production of chlorine via the reaction

At pH = 0, ΔG° is 0.13 eV. This reaction can be accomplished in a cell represented as TIA/S/M, where the metal electrode, M, is a large area (geometric, 3.1 cm²) fuel cell cathode (Pt-C-Teflon) with the *i*-*V* characteristics shown in Fig. 10A; this showed a 0.7V overpotential for O₂ reduction. The TIA *i*-*V* response, Fig. 12A, shows poor overlap with that of M; thus, large photocurrents would not be expected upon coupling the two electrodes. Experimentally, i_{sc} was 0.5 mA/cm² and V_{oc} was 0.15V; these are comparatively low values, in agreement with the prediction based upon individual *i*-*V* characteristics. While the TIA demonstrated characteristic behavior for photo-oxidation of Cl⁻,

the cell was limited primarily because of poor kinetics for O_2 reduction at the metal cathode.

Dual photoarray cells.—The coupling of two photoarrays, TIA/S/TIC, allows the generation of ca. 1.1V during force for synthetic reactions. An example of a reaction in this type of cell is the bromination of phenol (18) at a TIA, coupled with the reduction of H^+ at a TIC. The photo-oxidation of Br^- in 48% HBr, has a V_{onset} shifted ca. 0.55V more negative compared to a Pt electrode (Fig. 11). On the reverse scan, a cathodic peak was observed, indicating at least some of the Br_2 being produced was rereduced. Addition of 1M phenol to the cell suppressed the cathodic wave and shifted V_{onset} about 50 mV more negative (curve C). The cathodic wave was absent even at scan rates of 10 V/s, indicating that the bromination of phenol is an efficient approach to preventing back electron transfer. Experiments performed with only phenol and supporting electrolyte showed no photoanodic current, indicating that the observed behavior was not due to direct oxidation of phenol. i_a for the TIA was attenuated by 20% in the presence of phenol; however, reduction of H^+ at a TIC, curve D, was unchanged by phenol addition. The two photoelectrodes when coupled give a V_{oc} of 0.42V with i_{sc} of 4.5 mA.

Multiple photoarray cells.—In order to drive more energetic reactions, individual photocells must be coupled to obtain larger potentials. The reaction

has a $\Delta G^\circ = 1.36$ eV ($pH = 0$), and would not occur in a cell of the type TIA/S/TIC, since the maximum available

Fig. 11. *i*-*V* behavior in 48% HBr for a TIA (A), TIC (B), and Pt electrode (C). TIA response after addition of 1M phenol (D). Scan rate: 100 mV/s. Light intensity: 80 mW/cm².

Fig. 12. *j*-*V* behavior for TIA (A) and TIC (B) in 5M HCl. Light intensity: 170 mW/cm². Scan rate: 100 mV/s.

photovoltage is only ca. 1.1V. The coupling of two cells, TIA/S/TIC (cell 2) and TIA/S/TIC (cell 1), where cell 1 contains a single redox couple, which provides a bias to cell 2, will produce a photopotential large enough for HCl electrolysis to occur in cell 2. The *i*-*V* curves for both a TIA and a TIC in 5M HCl are given in Fig. 12. The overlap is poor, and coupling these electrodes resulted in no observable short-circuit photocurrent. However, addition of the bias from cell 2 (coupled as in Fig. 5) did result in a net short-circuit photocurrent. For the case of cell 1 containing 1.0M $Br_2/1.0M$ KBr, the observed value of j_{sc} was 7.3 mA/cm² with V_{oc} being 2.0V with illumination intensity of 170 mW/cm². Table II gives values of j_{sc} for various conditions in cells 1 and 2. As predicted from the *i*-*V* characteristics for individual half-cells (Table I), the Br^-/Br_2 couple gave the best behavior. Moreover (see Table II), more acidic conditions favor the reaction, since the proton reduction reaction shifts towards more positive potentials with decreasing pH but the Cl^- oxidation is invariant with pH. Efficiencies for the coupled cell arrangement are also given in Table II. The efficiency, ϕ , is defined as

$$\phi = P_c/I \quad [7]$$

where P_c is the power stored as free energy in the electrolysis products and I is the incident light intensity. P_c was evaluated by assuming the products are consumed in a fuel cell reaction at the same current density as that for their production. Therefore, we take

$$P_c = j_{sc} \times E^\circ \quad [8]$$

where E° is the standard potential for rereaction, $-1.36V$.

Photoarrays in nonaqueous media.—Halogenation in nonaqueous media is possible at the TIA, as demonstrated by the following results for the chlorination of cyclohexene in acetonitrile (MeCN) (19). The photo-oxidation of Cl^- at a TIA occurs with V_{onset} ca. 0.5V vs. SCE (Fig. 13). The cathodic wave indicates that some of

Fig. 13. j - V behavior for a TIA in 0.5M TBACl in MeCN (A) and after addition of 1M cyclohexene (B). Light intensity: 70 mW/cm². Scan rate: 100 mV/s. Potentials vs. SCE.

the Cl₂ produced was reduced on the reverse scan. Addition of 1M cyclohexene completely suppresses the cathodic wave, curve B, but had no effect on $i_{i,c}$, as in the bromination case. The wave was also shifted in a negative direction by 50-100 mV. The direct photo-oxidation of cyclohexene does not occur until ca. 1.6V vs. SCE and, therefore, does not influence the i - V behavior in Fig. 12.

Conclusions

Multilayer semiconductor electrode structures involving several photoactive junctions, such as the Texas Instruments arrays based on Si p/n junctions, can show stable operation and produce sufficient photovoltages to promote energetic reactions, such as the decomposition of HCl to H₂ and Cl₂. The i - V behavior at the interface with the solution is an important component of the cell performance, and metal surfaces can be selected to stabilize the electrode from photodecomposition and to catalyze the desired reactions. The behavior of multijunction devices can be obtained graphically from the i - V characteristics of each junction. Multijunction structures, such as coupled TI arrays, can produce photovoltages in excess of 2V, and can drive energetic reactions. The application of these arrays to nonaqueous solutions was also illustrated.

Anodic Dissolution of Iron in Ammoniacal Ammonium Carbonate Solution

J. W. Lee, K. Osseo-Asare, and H. W. Pickering*

Metallurgy Program, Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

The electrochemical behavior of iron has been characterized in aqueous ammoniacal ammonium carbonate solution. Pure iron anodically polarized in He- or O₂-saturated 2 kmol m⁻³ NH₃ + 1 kmol m⁻³ (NH₄)₂CO₃ solutions exhibits both stable active ($E = -650$ to -400 mV, SHE) and passive ($E = -330$ to 1000 mV) regions. A cathodic loop was observed in the potential range of -380 to 100 mV. It is suggested, on the basis of cathodic polarization curves of a graphite electrode in various concentrations of ammoniacal solution, that the cathodic loop is due to oxygen discharge. The addition of CoCO₃ to the ammoniacal solution has the same effect as oxygen in that it increases the cathodic current and potential range of the cathodic loop and, as such, functions as a strong oxidant.

Low grade oxide ores such as the land-based laterites and the ocean-floor manganese nodules, which contain only about 0.2% cobalt, are important cobalt resources (1, 2). When the reductive-roast ammonia leach process is applied to these materials, cobalt extraction rarely exceeds 50%, whereas nickel and copper recoveries of greater than 90% are attainable (3, 4). In this process, the roasting step produces alloys of Fe, Co, and other metals, which are

then involved in the subsequent leaching step. The low cobalt extraction can be attributed in part to coprecipitation of cobalt with iron and manganese and to the adsorption of cobalt on the oxide leach residues (5, 6). Adsorption experiments with model oxide powders have shown that the hydroxo species play a dominant role in cobalt uptake from aqueous ammoniacal solutions (6, 7). It has also been shown recently that the poor extraction of cobalt may be related to the electrochemical behavior of metallic iron (8). It was found during the anodic dissolu-

* Electrochemical Society Active Member.

tion of sintered iron-cobalt electrodes that cobalt dissolution was inhibited when the electrode potential was increased above 0.5V (SHE), which is in the passive region of the iron electrode in aqueous ammoniacal solutions (8). Additional indications of the possible influence of electrochemical processes are provided by the work of Kasherininov (9), Gong *et al.* (10), and Goeller *et al.* (11).

A detailed study of the electrochemical aspects of cobalt and iron dissolution in ammoniacal ammonium carbonate solutions is needed in order to understand better the behavior of these metals and in order to identify the conditions which would maximize cobalt extraction in ammonia hydrometallurgical systems. In this paper, electrochemical polarization techniques are applied to the study of iron dissolution in ammoniacal ammonium carbonate solutions with a view to laying the foundation for a study of iron-cobalt alloys.

Experimental Procedures

Samples of pure iron (99.7%) were prepared as cold-rolled polished, and annealed specimens, as described previously (8). Electrochemical characterization of the iron electrode was attained by determining (i) the current response to anodic or cathodic polarization under various controlled aqueous-phase conditions and (ii) the time dependence of the open-circuit potential.

Details of the electrochemical equipment and the procedures used for the polarization and open-circuit potential measurements are given elsewhere (8). Reagent-grade chemicals were used throughout, and, when needed, cobalt was introduced into the solution as CoCO_3 , but much of the cobaltous ion was likely converted to cobaltic ion during preparation of the solution (12). Following a period (~30 min) at open circuit, the electrode was swept at 6 mV min^{-1} in the more noble direction from a potential more negative than the open-circuit potential. This rate was slow enough to produce quasistationary values. In order to investigate the origin of the cathodic loop observed in the iron polarization experiment, cathodic polarization curves were measured potentiodynamically on graphite rod electrodes in various ammoniacal solutions, following a 30 min period at the open-circuit potential, after which time a quasistationary mixed potential was obtained. The electrochemical behavior of dissolved cobalt was also studied in this manner using the graphite electrode. All the experiments were conducted at room temperature (~25°C).

Results

Open-circuit potential behavior of iron.—The open-circuit potential of iron was monitored as a function of time (Fig. 1 and 2). The solutions were He- or O_2 -saturated $2 \text{ kmol m}^{-3} \text{ NH}_3 + 1 \text{ kmol m}^{-3} (\text{NH}_4)_2\text{CO}_3$ (pH = 9.90) with and without the addition of CoCO_3 . The values of the open-circuit potential presented in Table I are after 9h in the solutions.

In general, the open-circuit potential was more noble the higher the concentration of CoCO_3 . Another tendency was that the potentials were more positive in O_2 -saturated solution than in He-saturated solution. In the case of iron in the He-saturated cobalt-free (blank) solution, the potential initially decreased to less noble values and then increased in the more noble direction with increase in time. The minimum in the potential occurred at shorter and shorter times with increase in CoCO_3 in the solution, and was absent at the highest concentration (Fig. 1). In the case of the oxygen-saturated solutions (Fig. 2), no minima were observed; the potentials increased steadily with time.

Anodic polarization curves of iron.—The potentiodynamic anodic polarization curves of iron are presented in Fig. 3 to 5. The curves show three general regions of active, passive, and oxygen-evolution in addition to a cathodic loop. These same features were observed for sweeps in the opposite direction.

As the potential was swept in the noble direction, anodic current increased at first, but then

Fig. 1. Open-circuit potential vs. time for iron in He-saturated solution containing $2 \text{ kmol m}^{-3} \text{ NH}_3 + 1 \text{ kmol m}^{-3} (\text{NH}_4)_2\text{CO}_3$ and various concentrations of CoCO_3 .

leveled off, producing a yellow insoluble precipitate identified as a basic ferrous ammonium carbonate, $(\text{NH}_4)_2\text{Fe}_2(\text{OH})_4(\text{CO}_3)_2\text{H}_2\text{O}$ by x-ray diffraction. After that, the current density exhibited irregular oscillations within the range of $0.4\text{--}3.0 \text{ mA cm}^{-2}$ and a loosely adhering mixture of a yellow-and-brown-colored film formed on the corroding surface. As the potential was further increased, the iron electrode surface became covered with a shiny, dark-brown precipitate, which adhered tightly to the surface and could only be removed by application of a strong water spray. With additional increase in potential, a cathodic current was observed and the shiny dark brown film completely disappeared. Thus, the visible film is stable in the presence of high concentrations of ferrous ion (as exist at the surface during active dissolution), but apparently is not at the much lower current in the passive region. Its presence may be a necessary precursor for the passivating reaction. Table II shows the maximum values

Fig. 2. Open-circuit potential vs. time for iron in O_2 -saturated solution containing $2 \text{ kmol m}^{-3} \text{ NH}_3 + 1 \text{ kmol m}^{-3} (\text{NH}_4)_2\text{CO}_3$ and various concentrations of CoCO_3 .

Table I. Open-circuit potentials for iron after 9h in He- or O₂-saturated 2 kmol m⁻³ NH₃ + 1 kmol m⁻³ (NH₄)₂CO₃ solutions

CoCO ₃ (kmol m ⁻³)	Potential (mV, SHE)	
	He-saturated solution	O ₂ -saturated solution
Blank	-140	35
5 × 10 ⁻⁴	-50	80
5 × 10 ⁻³	45	95
5 × 10 ⁻²	140	160

of the cathodic current density and the corresponding potential range in He- or O₂-saturated 2 kmol m⁻³ NH₃ + 1 kmol m⁻³ (NH₄)₂CO₃ solution.

As shown in Fig. 3-5 and Table II, as the concentration of CoCO₃ is increased or O₂ is added, the maximum cathodic current density and the range of potential across which the cathodic loop occurs increase and the maximum anodic current density decreases. The effect of cobalt in the electrolyte is illustrated also on graphite in Fig. 6, which shows a typical polarization curve for the Co(II)/Co(III) couple in ammonia-ammonium carbonate solution. According to this figure, reduction of Co(III) occurs below 45 mV (SHE).

As shown in Fig. 7, the cathodic polarization curves on a graphite electrode are not a strong function of the ammonia-ammoniacal solution composition. However, as O₂ is added to the solution, the cathodic current density in the -800 to 200 mV potential range increases by about an order of magnitude over that in He-saturated solution.

Discussion

General considerations.—The results presented above have shown that, in aqueous ammoniacal solution, the iron electrode exhibits active, passive, and oxygen evolution behavior, in addition to a cathodic loop. The onset of the anodic current in the neighborhood of -650 mV (SHE) is consistent with the thermodynamics of the Fe-

5×10^{-2}	800	-350 to 130	5×10^{-2}	1200	-360 to 150

$\text{NH}_3\text{-CO}_3\text{-H}_2\text{O}$ system. In a solution containing $10^{-4} \text{ kmol m}^{-3} \text{ Fe(II)}$ and $4 \text{ kmol m}^{-3} (\text{NH}_3 + \text{NH}_4^+)$, the $\text{Fe}(\text{NH}_3)_4^{2+}/\text{Fe}$ boundary occurs at $E_h = -780 \text{ mV}$ (8, 13). The maximum anodic current density of 4.3 mA cm^{-2} is much lower than that of 200 mA cm^{-2} obtained for the iron electrode in $1N$ sulfuric acid solution (14); in contrast, in basic solutions containing sodium borate or sodium benzoate, the maximum anodic currents are 10 and $230 \mu\text{A cm}^{-2}$, respectively (15). The decrease in anodic current observed at about -450 mV (SHE) is in qualitative agreement with the thermodynamic data and $E_h\text{-pH}$ diagrams presented in earlier papers (8, 13) which for $\text{pH } 10$, $10^{-4} \text{ kmol m}^{-3} \text{ Fe(II)}$ and $4 \text{ kmol m}^{-3} (\text{NH}_3 + \text{NH}_4^+)$ give the $\text{Fe}(\text{NH}_3)_4^{2+}/\text{FeOOH}$ boundary at $E_h = -380 \text{ mV}$. Characteristics of the surface films which form in this potential region are discussed elsewhere (16).

The cathodic loop.—The potentiodynamically produced anodic polarization curves for iron show a cathodic loop (Fig. 3-5). A few papers have treated the subject of the cathodic loop in the range of passive potentials in acid solutions and have shown that it is strongly related to the solution chemistry (17-22). In the CoCO_3 -free solutions, oxygen reduction may be the source of the loop (Fig. 3), even for the He-saturated solution, since it is difficult to completely eliminate oxygen from solution. Shams El Din *et al.* (23) have shown that NH_4^+ ions can facilitate the O_2 -reduction reaction. The hydrogen discharge reaction is also facilitated by the presence of NH_4^+ (24-26).

The following equation can be used to describe the discharge of hydrogen (13)

$$E_h(\text{V}) = -0.55 + 0.059 \log \frac{[\text{NH}_4^+]}{[\text{NH}_3]} \quad [2]$$

However, the cathodic loop at -380 to 100 mV in Fig. 3-5 cannot be attributed to this reaction since from Eq. [2] the equilibrium potential for reaction [1] is -550 mV for equal concentrations of NH_3 and NH_4^+ .

The oxygen reduction reaction can be written as follows

Fig. 6. Current-potential curve for the redox reaction of soluble Co(II)/Co(III) species at a graphite working electrode in He-saturated solution containing $2 \text{ kmol m}^{-3} \text{ NH}_3 + 1 \text{ kmol m}^{-3} (\text{NH}_4)_2\text{CO}_3 + 0.05 \text{ kmol m}^{-3} \text{ CoCO}_3$.

$$E_h(\text{V}) = 0.956 - 0.0296 \text{ pH} + 0.0296 \log \frac{[\text{NH}_4^+]}{[\text{NH}_3]} \quad [4]$$

The equilibrium potential for the $\text{pH } 9.9$ solution used in these experiments containing equal concentrations of NH_3 and NH_4^+ is 660 mV . Since this potential is more noble than the cathodic loop, it is possible for the oxygen reduction reaction to produce the loop. As shown in Fig. 3 and Tables I and II, with the introduction of oxygen into the solution, the open-circuit potential, the cathodic current at -250 mV (SHE), and the potential range of the loop are all increased. Also, Fig. 7 strongly suggests that oxygen reduction contributes to the cathodic loop; the shapes of the various current waves are almost the same while the introduction of oxygen into the solution substantially increases the cathodic current in the potential range -850 to 200 mV (SHE). Furthermore, it is significant to note that the maximum cathodic currents in the cathodic loops of the iron polarization curves in the He- and O_2 -saturated polarization curves of Fig. 3 are of the same order of magnitude as the respective cathodic polarization curves on a graphite electrode presented in Fig. 7 ($\sim 5 \times 10^{-3}$ for He and $\sim 5 \times 10^{-2} \text{ mA cm}^{-2}$ for O_2).

The effects of Co(II) and Co(III) amines on the polarization and open-circuit behavior of iron.—It is evident from the results presented in Fig. 1, 2, 4, and 5 and Tables

Fig. 7. Cathodic polarization curves on graphite in He- or O_2 -saturated solutions of ammonia-ammonium carbonate.

I and II that the presence of dissolved cobalt has a significant effect on the polarization behavior of iron. It is well known that in the Co-H₂O system, the oxidation of the cobaltous ion to the cobaltic ion is very unfavorable as can be understood from the standard potential (27)

However, the oxidation of Co(II) to Co(III) becomes much more favorable in the presence of a variety of complexing ligands especially ammonia and may even be brought about by atmospheric oxygen (27). This is attributed to the formation of a stable complex of trivalent cobalt with NH₃ (8, 12, 27)

It should be noted that the cobaltic and cobaltous species are indicated in Eq. [7] as hexammine and pentammine species, respectively, since these have been indicated by thermodynamic analysis to be the stable forms under the present experimental conditions (8, 27).

The effect of cobalt addition to the electrolyte on the open-circuit potential (Fig. 1 and 2) and on the anodic polarization curves of Fe (Fig. 4 and 5) can be attributed to the reduction of Co(III) to Co(II); the oxidizing power of Co(III) is greater than that of oxygen based on a comparison of the relevant potential regions and maximum cathodic currents in Fig. 3-5. Comparison of the equilibrium potential of Fe/Fe(NH₃)₄²⁺ ($E_h^\circ = -0.548\text{V}$) with Co(II)/Co(III) ($E_h^\circ = 0.161\text{V}$) or OH⁻/O₂ ($E_h^\circ = 0.66\text{V}$) at equal concentrations of NH₃ and NH₄⁺ shows that spontaneous metal dissolution occurs with either oxidant, in accord with mixed potential theory. Thus, one expects the open-circuit potential to shift in the noble direction with increasing cobalt (or oxygen) content, as was found (Fig. 1 and 2). According to Fig. 6, below 45 mV (SHE), a significant cathodic reaction should be expected on a graphite electrode; at -200 mV, the cathodic current density is of the order of 0.5 mA cm⁻² in a solution containing 5 × 10⁻² kmol m⁻³ of cobalt. Examination of Fig. 4 reveals that the maximum current density of the cathodic loop is of the same magnitude (i.e., ~ 0.5 mA cm⁻²). Thus it appears that the cathodic loop in the CoCO₃ containing, He-saturated solutions is mainly due to the reduction of Co(III) amines. These explanations implicitly assume that during preparation of the solutions, most of the Co(II) added to the solution as CoCO₃ is oxidized to Co(III) by dissolved oxygen, in accord with other observations (12).

The shift of the open-circuit potential of Fe by cobalt addition to the electrolyte (Fig. 1 and 2) takes place wholly within the passive region of Fe (Fig. 3-5) and, therefore, has relatively little impact on the corresponding low corrosion rate of iron in this (passive) potential range. The direction of the potential shift, however, has far-reaching implications for Fe-Co alloys and reduction of roasted ferruginous oxide ores. In particular, a shift in the open-circuit potential of up to 300 mV in the noble direction could include the potential of the active/passive transition for these alloy materials, in which case, the addition of cobalt to the electrolyte would cause a marked decrease in the metal dissolution rate. Available polarization curves of Fe-10%Co and Fe-50%Co, indeed, show that the metal dissolution rate decreases with increasing potential above about -100 mV for the same electrolyte conditions (8). This is a potential range within the observed shift of the open-circuit value with increasing cobalt and/or oxygen concentration (Fig. 1 and 2). Thus, Co(NH₃)₆³⁺, even more so than oxygen, tends to promote the formation of passive films, as well as of bulk solid reaction products, on iron in its role as a strong oxidant, as the following reactions illustrate

Conclusions

1. Iron in ammonia-ammonium carbonate solution exhibits three general regions (active, passive, and oxygen evolution) in addition to a cathodic loop.

2. The cathodic loop is due to the discharge of oxygen. Cobalt additions to the electrolyte significantly increase the cathodic current in the loop. Co, even in a deoxygenated solution, provides a strong oxidizing power to the system.

3. The measured shift of the open-circuit potential in the noble direction by the Co(III) and O₂ reduction reactions is in accord with the mixed potential theory. The shift could have significance for Fe-Co alloy material produced by reductive roasted oxide ores, since the tendency for passivation sharply increases at more noble potentials as has already been found in laboratory tests on Fe-Co alloys.

Solute-Vacancy Interaction Model and the Effect of Minor Alloying Elements on the Initiation of Pitting Corrosion

Mirna Urquidi and Digby D. Macdonald*

SRI International, Chemistry Laboratory, Menlo Park, California 94025

ABSTRACT

A solute-vacancy interaction model (SVIM) is proposed to account for the effects of minor alloying elements (*e.g.*, Mo) on the breakdown of passive films. This model, which is an extension of the point-defect model (15-17) that was previously developed to account for the growth and breakdown of passive films, assumes that highly charged solutes (*e.g.*, Mo⁶⁺) form complexes with negatively charged cation vacancies ($V_{M\chi'}$). This interaction has the effect of reducing the flux of cation vacancies from the film/solution interface to the metal/film interface, and hence of increasing the breakdown voltage (V_c) and the induction time (t_{ind}) for pitting attack. By using experimental data for 18%Cr-1%Mo to calculate values for various parameters, we found that the SVIM accurately predicts the changes in V_c and t_{ind} for higher molybdenum concentrations in these ferritic stainless steels.

It is well known that minor alloying elements can have a profound effect on the susceptibility of a metal or alloy to localized corrosion, including pitting. By far the most important element is molybdenum, which, when added to austenitic and ferritic stainless steels at a concentration of a few percent, causes a significant shift in the breakdown (pitting) potential to more positive values (1-13). However, not all minor alloying elements are beneficial. For example, the addition of sulfur to carbon steels, particularly those containing manganese, increases the susceptibility of the matrix to localized attack (14). This has been attributed to the formation and subsequent electrodisolution of MnS particles in the passive film, but few details of how this occurs are known.

In spite of a considerable amount of work (1-13), no completely acceptable mechanism has been advanced to explain how small additions of elements such as molybdenum have such profound effects on the pitting resistances of metals and alloys. Thus, some workers propose that molybdenum increases the repassivation rate of the alloy and that because pitting occurs at a potential at which the breakdown rate exceeds the repassivation rate, the net effect is to shift the pitting potential in the positive direction. Other workers have advanced the hypothesis that molybdenum stabilizes a salt film (perhaps CrCl₂) on the metal surface, which, in turn, inhibits anodic dissolution of the underlying alloy and hence imparts some protective properties to the system. Still other researchers (8) have proposed that the beneficial effects of molybdenum and tungsten might be due to one, or to a combination of more than one, of the following: (i) thickening of the passive film, (ii) formation of a heteropoly-acid film that is less hydrolyzed and more readily polymerized than the existing passive film, (iii) an impeding of the adsorption of Cl⁻ onto the surface of the steel by increasing the oxygen affinity of the steel, or (iv) formation of an amorphous oxide film with a glassy structure. Bui *et al.* (8) finally attributed the beneficial effect of tungsten to the "formation of insoluble WO₃, which enhances the stability of oxide layers," but provided little experimental evidence that this is indeed the reason.

Over the past three years, we have developed the point-defect model for the growth and breakdown of passive films (15-17). This model has been particularly successful at explaining the growth kinetics of passive films on iron and nickel in aqueous solutions, and has been successful in accounting for chloride-induced breakdown of passive

films, in terms of the dependence of both the breakdown potential and induction time on the chloride activity (16). In this paper, we extend the point-defect model to explain the effects of certain alloying elements on the pitting behavior of metals and alloys. Since the basis for this extension is the interaction between the minor alloying element in the film (*e.g.*, Mo⁶⁺) and cation vacancies, this new model is hereafter referred to as the "solute-vacancy interaction model" (SVIM).

Pitting Characteristics of Metals and Alloys

Before discussing the theoretical basis for the solute/vacancy interaction model, it is advantageous to first summarize the experimental observations that must be explained by any satisfactory mechanism for the localized breakdown of passive films. These observations are as follows (18).

1. A critical pitting potential exists, above which localized attack is sustained, but below which pits spontaneously passivate.

2. In systems containing aggressive anions, such as Cl⁻, Br⁻, and I⁻, the breakdown potential (V_c) depends on the activity of the anion (a_x) according to

$$V_c = V_c^0 - B \log a_x \quad [1]$$

where B is normally greater than the Nernstian gradient of $2.303RT/nF$ (n = number of electrons involved in the dissolution reaction).

3. Breakdown involves an induction time between the point at which the aggressive anion is added to the system and when breakdown is observed. The induction time decreases with increasing pitting overpotential ($V - V_c$, where V is the applied voltage).

4. The addition of an aggressive anion, such as Cl⁻, to a solution in contact with a passive metal causes a "burst" of cations to be released from the oxide surface (19).

5. Little evidence exists that chloride or other aggressive anions penetrate barrier oxide films (18). However, penetration of "upper layer" films, which may form in certain systems as porous deposits on the base layer via dissolution/precipitation processes, may well occur, and this phenomenon probably accounts for the occasional report of chloride penetration into passive films.

6. A relationship appears to exist between the size of the aggressive anion, or its free energy of adsorption onto the passive film, and its ability to cause passivity breakdown.

7. In the case of Fe/Cr/Ni alloys, passivity breakdown coincides roughly with electrodisolution of chromium

* Electrochemical Society Active Member.

Fig. 1. Processes leading to the breakdown of passive films according to the point-defect model.

from the films (20), such that for potentials greater than the breakdown value (V_c) the concentration of Cr as Cr(III) in the film is greatly reduced. As we argue later, electrodisolution of Cr(III) leads to the formation of cation vacancies ($V_{Cr,3'}$) at the film/solution interface.

8. The addition of small amounts of certain alloying elements to the alloy phase, and, by implication, to the passive film, greatly increases the pitting resistance of the alloys. The most effective elements appear to be those that are capable of existing at oxidation states in excess of that for the cations in the host lattice. For example, Mo and W, both of which exist in the +6 state, are effective in protecting alloys (e.g., Fe/Cr) whose host cations in the passive film exist in the +3 state.

9. A synergistic relationship appears to exist between the chromium and molybdenum contents of the alloy, such that molybdenum is more effective at protecting Fe-Cr-Ni authentic stainless steels when the chromium content is high (6).

Any theory developed to account for the pitting characteristics of metals and alloys must explain the generalizations noted above, in addition to accounting for the properties of specific systems. However, the currently available theoretical treatments are either capable only of a semiquantitative explanation of some of the more important observations, or do not address the principal theme of this paper: the role of solutes in the film in determining the breakdown characteristics.

Solute-Vacancy Interaction Model

The solute vacancy interaction model described in this paper was developed to account for the effect of minor alloying elements, such as Mo and W, on the pitting resistance of iron-based alloys. The point-defect model (15-17), upon which the SVIM is based, proposes that passivity breakdown occurs because of an enhanced flux of cation vacancies from the film/solution interface to the metal/film interface, such that the excess vacancies arriving at the interface between the metal and the film cannot be absorbed into the metal at a high enough rate (Fig. 1). Accordingly, the vacancies accumulate to form a vacancy condensate at the metal/film interface, which then grows to a critical size. At this time, the film collapses locally to form a pit that will continue to grow provided that conditions are not conducive to repassivation. The point-defect model has led to the formulation of expressions for the two most important parameters that characterize the onset of pitting attack; the breakdown potential (V_c) and the induction time (t_{ind})

$$V_c = \frac{4.606RT}{\chi F \alpha} \log \left[\frac{J_m}{J_o u^{-\chi/2}} \right] - \frac{2.303RT}{\alpha F} \log [a_{Cl^-}] \quad [2]$$

$$t_{ind} = \xi' \left[\exp \left(\frac{\chi \alpha \Delta V}{2RT} \right) - 1 \right]^{-1} + \tau \quad [3]$$

where

$$\xi' = \xi / J_o u^{-\chi/2} [a_{Cl^-}]^{\chi/2} \exp \left(\frac{\chi F \alpha V_c}{2RT} \right) \quad [4]$$

$$\Delta V = V - V_c \quad [5]$$

and ξ is the critical size of the vacancy condensate, χ is the stoichiometry of the oxide ($MO_{\chi/2}$), and

$$u = \frac{N_v}{\Omega} \exp \left(\frac{\Delta G_{A-1}^0 - F\beta p H - F\phi_{fs}^0}{RT} \right) \quad [6]$$

The parameter J_o is given by

$$J_o = \chi K D_{V_{M^{x'}}} [N_v/\Omega]^{(1+\chi/2)} \exp(-\Delta G_{sp}^0/RT) \quad [7]$$

where

$$K = \epsilon F/RT \quad [8]$$

and $D_{V_{M^{x'}}$ is the diffusivity of cation vacancies, N_v is Avogadro's number, Ω is the molar volume per cation of the film, α is the fraction of the total voltage applied between the metal and the solution that appears across the film/solution interface, F is Faraday's constant, ϵ is the electric field strength, ϕ_{fs}^0 and β are constants, and ΔG_{sp}^0 is the change in standard Gibbs energy for the Schottky pair reaction

The parameter ΔG_{A-1}^0 is the change in standard Gibbs energy for reaction [10]

where $V_{M^{x'}}$ and V_{O} represent cation and anion vacancies, respectively, at the film/solution interface, and Cl_{O} represents a chloride ion (for example) occupying an oxide ion vacancy at the same location.

An enhanced flux of cation vacancies from the film/solution interface to the metal/film interface, which in turn may induce breakdown, can result from any process that gives rise to an increase in the concentration of cation vacancies at the film/solution interface. We identify three such processes below that we believe are of fundamental importance in determining the pitting characteristics of metals and alloys.

Anion adsorption.—Anions, which are comparable in size to oxide ions (e.g., Cl^-), may adsorb into anion vacancies at the film/solution interface according to reaction [10]. Thus, the removal of anion vacancies causes a concomitant increase in the concentration of cation vacancies according to the Schottky-pair reaction (Eq. [9]) and hence to an increase in the flux of these species toward the metal/film interface. Consideration of this process leads directly to Eq. [2] and [3] for V_c and t_{ind} , respectively. We believe that this is the primary process that is responsible for halide-induced breakdown because Eq. [2] and [3] are found to account quantitatively for the pitting of iron and nickel in sodium chloride solutions (16). This mechanism also accounts for the apparent dependence of V_c on the size of the aggressive anion, through the equilibrium constant for reaction [10].

Electrochemical cation dissolution.—In certain systems, cations may be ejected from the film/solution interface provided that the applied potential is high enough. This requires that the cation formed on dissolution exists in a higher oxidation state than it does in the film. An example of this phenomenon is the electrodisolution of chromium from the passive films on austenitic stainless steels

where Cr_{Cr} represents a chromium (III) cation occupying a cation site in the film at the film/solution interface, and $V_{\text{Cr},3'}$ represents the cation vacancy formed by the electrodisolution of that ion. Because this process is a charge-transfer reaction, the concentration of cation vacancies at the film/solution interface will increase dramatically (i.e., exponentially) above a certain voltage, which may be identified with the breakdown potential.

Electrodissolution of inclusions.—Pitting of carbon steels and stainless steels containing high concentrations of manganese sulfide inclusions frequently coincides with the dissolution of this second phase. In this case, pit nucleation probably occurs via the creation of cation vacancies according to reactions of the type

In the first case, the net effect of electrodisolution of the manganese from the sulfide particles is to create cation vacancies, which, in turn, may lead to film breakdown by condensing into voids at the metal/film interface. In the second case, destruction of the manganese sulfide matrix itself occurs, which will result in the formation of a local void. This void may then act as a nucleus for pitting attack.

Examination of Eq. [2]-[7] shows that any phenomenon that leads to a reduction in the diffusivity of the cation vacancies, $D_{V_{\text{Mn}}}$, will increase the breakdown potential (V_c) and induction time t_{ind} . Accordingly, the material should become more resistant to breakdown. In the SVIM, which is outlined below, we propose that complexes form between the mobile vacancies (V_{Mn}') and the immobile highly charged solute ions, such as Mo^{6+} and W^{6+} .

The interaction between cation vacancies (V_{Mn}') and a solute ion (A^{n+}) in a passive film can be represented as a chemical equilibrium

where K_n is the equilibrium constant

$$K_n = [P]/[A][V]^q \quad [15]$$

in which we represent the complex, solute, and vacancy concentrations by [P], [A], and [V], respectively. The condition for breakdown remains unchanged from that stated previously (16)

$$(J_{\text{ca}} - J_{\text{m}})_{\text{m}/f} (t_{\text{ind}} - \tau) > \xi \quad [16]$$

where J_{ca} and J_{m} are the fluxes of cation vacancies in the film and in the metal, respectively, at the metal/film interface, and τ is a relaxation time. The problem is now to compute J_{ca} as a function of solute concentration, recognizing that the concentration of cation vacancies is reduced by complex formation compared with the solute-free case.

Assuming that the complexes are immobile, the flux of cation vacancies in the film at the metal/film interface can be written as

$$(J_{\text{ca}})_{\text{m}/f} = -D_{V_{\text{Mn}}'} \left[\frac{\partial(n_v - q[P])}{\partial x} \right]_{\text{m}/f} - e\chi D_{V_{\text{Mn}}'} \frac{F\epsilon}{RT} (n_v - q[P])_{\text{m}/f} \quad [17]$$

where e is the electronic charge, ϵ is the electric field strength [assumed to be constant and independent of applied voltage (15-17)], and n_v is the concentration of vacancies that would exist if the solute was not present. The concentration of the complex can be obtained by solving Eq. [18], which is itself a restatement of Eq. [15]

$$[P] = K_n \{n_A - [P]\} \{n_v - q[P]\}^q \quad [18]$$

where n_A is the stoichiometric concentration of solute in the film.

Equation [17] can be rearranged to yield

$$(J_{\text{ca}})_{\text{m}/f} = -D \left(\frac{\partial n_v}{\partial x} \right) + D^* K^* (-e\chi) n_v \quad [19]$$

where D^* is the modified diffusivity coefficient and K^* is the modified K value ($K = F\epsilon/RT$). These functions must be calculated for specific values of q , i.e., for

various complex configurations. In this work, only $q = 1$ is considered, in which case

$$K^* = \frac{K \left(1 - \frac{\alpha}{2n_v} \pm \frac{1}{n_v} \left(\frac{\alpha^2}{4} - n_A n_v \right)^{(1/2)} \right)}{\frac{1}{2} \left\{ 1 \pm \left(\frac{\alpha}{2} - n_A \right) / \left(\frac{\alpha^2}{4} - n_A n_v \right)^{(1/2)} \right\}} \quad [20]$$

$$D^* = D \left[\frac{1}{2} \pm \frac{1}{2} \left(\frac{\alpha^2}{4} - n_A n_v \right)^{-1/2} \cdot \left(\frac{\alpha}{2} - n_A \right) \right] \quad [21]$$

where

$$\alpha = n_A + \frac{1}{K_q} + n_v \quad [22]$$

Only the real roots that produce positive values for D^* and ϵ^* are considered.

In order to quantify the effect of the solute on the pitting characteristics of an alloy, it is necessary to compute the change in breakdown potential and induction time as a function of solute (molybdenum) concentration. The appropriate functions are, therefore, given by

$$V_c(X_{\text{Mo}}) - V_c(X_{\text{Mo}} = 0) = \frac{4.606RT}{\chi F \alpha} \log \left[\frac{KD}{K^* D^*} \right] \quad [23]$$

$$\frac{t(X_{\text{Mo}})}{t(X_{\text{Mo}} = 0)} = \frac{\left[\xi + \tau \hat{J}_0 u^{-(\chi/2)} [\text{Cl}^-]^{(\chi/2)} \exp \left(\frac{\chi F \alpha V_c}{2RT} \right) \right] J_0}{\hat{J}_0 \left[\xi + \tau J_0 u^{-(\chi/2)} [\text{Cl}^-]^{(\chi/2)} \exp \left[\frac{\chi F \alpha V_c}{2RT} \right] \right]} \quad [24]$$

where \hat{J}_0 is defined by Eq. [7] with $D_{V_{\text{Mn}}'}$ and K replaced by $D^*_{V_{\text{Mn}}'}$ and K^* , respectively.

This last equation can be simplified for $t \rightarrow 0$ to read

$$\frac{t(X_{\text{Mo}})}{t(X_{\text{Mo}} = 0)} = \frac{KD}{K^* D^*} \quad [25]$$

The simplification $\tau \rightarrow 0$ is considered in this work.

Results and Discussion

Plots of V_c and the induction time ratio are shown in Fig. 2 and 3, respectively, as functions of X_{Mo} . In the first case, two sets of parameters n_v , q , and K_q have been used, and the values of n_v and K_q are such that the calculated values of $V_c(X_{\text{Mo}}) - V_c(X_{\text{Mo}} = 0)$ coincide with the experimental data for the breakdown potential for the 18%Cr-1%Mo alloy. As can be seen, reasonable agreement is obtained between the calculated and experimental data at other molybdenum concentrations, particularly considering the uncertainty in the experimentally determined breakdown potentials ($\pm 0.1V$). This model also predicts that the induction time is increased by complex formation between the solute and cation vacancies, as shown in Fig. 3. Thus, molybdenum not only shifts the breakdown voltage to more positive values, but also increases the induction time at any given breakdown overvoltage.

The point-defect model and the solute/vacancy interaction model discussed above have provided quantitative or semiquantitative explanations for most of the correlations discussed in the previous section. For example, the point-defect model (16) accounts quantitatively for the first six generalizations, and the SVIM developed in this work accounts for the next two, at least semiquantitatively. No explanation is currently available for the last observation (the synergistic relationship between the Cr and Mo contents of the alloy), but we believe that it may be due to the ability of chromium to establish a uniform molybdenum distribution in the film. This question will be addressed in a later paper.

Finally, we note that interactions between solutes (impurities) and charged species (eg. electrons and holes) in semiconductors and between point defects and solutes in crystalline solids have been well characterized in the literature (21). Accordingly, a firm theoretical basis exists for the SVIM developed in this work.

Fluctuation Phenomena Studies in Chemically Sensitive Field Effect Transistors

I. Corrosion of Aluminum

Zheng Kang Li, Johannes M. Reijn, and Jiří Janata*

Department of Bioengineering, University of Utah, Salt Lake City, Utah 84112

ABSTRACT

It is shown that chemically sensitive field effect transistors can be used to study stochastic processes at the solution/solid interface which is not at equilibrium. Auto spectral densities and coherence functions for corrosion of aluminum-silicon alloy at zero-net current conditions have been obtained.

Noise in chemically sensitive field effect transistors (CHEMFET) originates both from the solid-state part of the device and from the electrochemical processes at each interface. In our previous work, we have shown that the analysis of noise of CHEMFET's with various ion selective membranes at chemical equilibrium yields an information about the exchange currents at the solution/membrane interface and about the bulk impedance of the membrane itself (1).

High signal-to-noise ratio, small input capacitance, small surface area of the electrode, and low parasitic impedance are the attractive features of CHEMFET's for the study of stochastic processes in electrochemical systems. Because each chip contains at least two transistors, it is possible to use multichannel analysis methods. These methods can yield a unique additional information about the whole system, and they reduce contributions from the solid-state part of the system.

In the first part of this series, we shall outline the theory of noise analysis in CHEMFET's and describe the experimental arrangement which was used in this and the subsequent studies.

Principle of Operation

The basic operation of CHEMFET's has been described elsewhere (2). The output, drain-to-source current I_D , for a n -channel transistor operated in the nonsaturated region [$V_D < (V_G - V_T)$] is

$$I_D = K \left[(V_G - V_T) - \frac{V_D}{2} \right] V_D \quad [1]$$

and in the saturation region where $V_D > (V_G - V_T)$

$$I_D = K' (V_G - V_T)^2 \quad [2]$$

The constants K and K' are characteristic of the geometry and material properties of the transistor shown in Fig. 1. The transconductance of the transistor is defined as

$$g_m = \left(\frac{\partial I_D}{\partial V_G} \right)_{V_D} \quad [3]$$

Because the magnitude of the solid-state part of the noise depends on the value of the drain current, it is preferable to operate the transistor in so-called feedback mode in which the average drain current is kept constant. In this case, the gate voltage fluctuations $v(t)$ are transformed into the drain current fluctuations $i(t)$ through the relationship

$$i(t) = g_m v(t) \quad [4]$$

Fluctuation Analysis Theory

In this section, a brief review of theory relevant to the present experiments is given. For a fuller account of the theoretical background, the reader is referred to textbooks (3-5). The drain current in the channel $I_D(t)$ of a CHEMFET can be expressed as (1)

$$I_D(t) = \bar{I} + i(t) \quad [5]$$

where \bar{I} is the mean value of the current and $i(t)$ is the fluctuating part of the drain current (noise). In the remaining part of this text, we will consider the fluctuations in the drain current only and for the sake of notation describe drain current fluctuations as $x(t)$ or $y(t)$.

When one is interested in the origin of the fluctuations, characterization of the signal (by means of parameters, for instance) is necessary. Before any meaningful signal characterization can be attempted, the signal has to be qualified.

This qualification can be carried out in the following way: Fig. 2 shows graphically the concept of a probability density function (PDF), which is defined for the signal $x(t)$ as

$$p(x) = \lim_{\Delta x \rightarrow 0} \frac{\text{Prob}[x < x(t) < x + \Delta x]}{\Delta x}$$

In general, $p(x, t)$ is a function of time. If this is not the case, that is when $p(x, t_1) = p(x, t_2)$ for all t_1, t_2 , it is said that the fluctuating signal is stationary. By its definition, the PDF $p(x, t)$ is normalized, i.e., $\int p(x, t) dx = 1$, where the integration is carried out over all values of the signal $x(t)$. For the PDF statistical moments can be calculated in the usual way, e.g., Eq. [6]. A large class of signals is formed by signals with a gaussian PDF, as illustrated in Fig. 2. When a fluctuating signal of this class has "direct" statistical moments defined by

Mean value

$$\langle x(t) \rangle = \lim_{T \rightarrow \infty} \left(\frac{1}{T} \int_0^T x(t) dt \right) \quad [6]$$

Fig. 1. Schematic diagram of the transistor chip (drawing not to scale). D: drain. S: source. I: insulator. M: metal. E: encapsulant. R: reference electrode. SB: substrate. I_D is drain-to-source current, and V_G is the applied gate voltage.

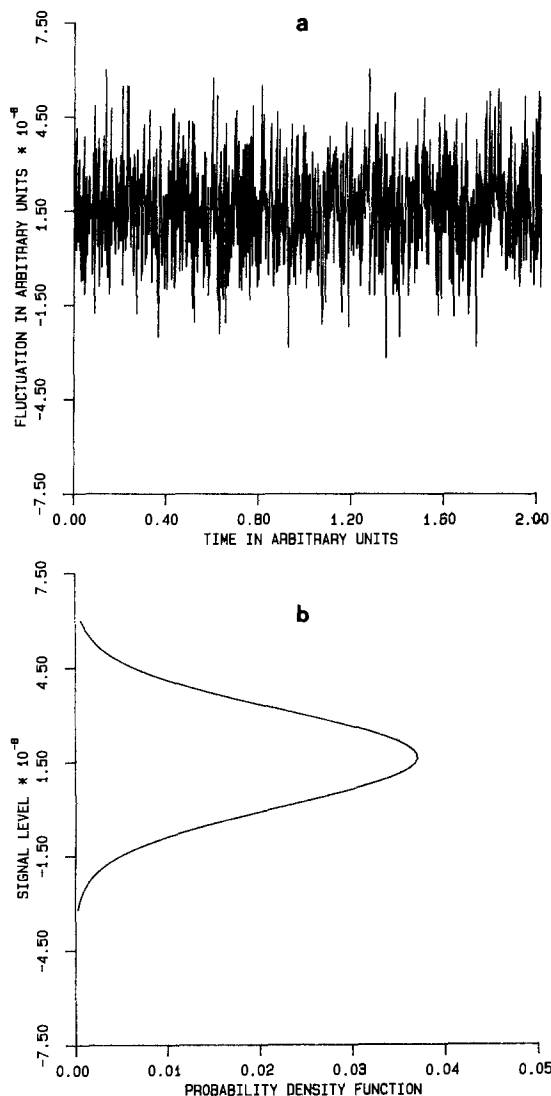

Fig. 2. Illustration of probability density function (PDF) for an arbitrary signal. a: Time record. b: PDF.

Mean value of the square

$$\langle x^2(t) \rangle = \lim_{T \rightarrow \infty} \left(\frac{1}{T} \int_0^T x^2(t) dt \right) \quad [7]$$

Variance

$$\sigma_t^2 = \langle x^2(t) \rangle - \langle x(t) \rangle^2 \quad [8]$$

When the measuring time is taken long enough (usually a limit $T \rightarrow \infty$ is involved) and the above defined moments equal the corresponding moments of the PDF for a stationary fluctuation, the signal is ergodic.

Frequency Domain Analysis

When the signal is stationary and ergodic, its parameters are independent of the observation time. This property allows for analysis of signal parameters from individual time records, e.g., mean and variance or from many different records as, for example, for frequency analysis using sampled portions of the signal of finite length (to be referred to as ensembles).

Suppose that one ensemble is represented by N samples, taken at time intervals Δt ; N is usually an integer power of 2. From the sequence of samples one calculates a discrete Fourier transform (DFT), usually using a fast Fourier transform algorithm (FFT) to save computation time (7). From the Fourier components estimates of spectral densities $G_x(k)$ are calculated as discrete frequencies $k f_s$, unique up to $k = N/2 - 1$. The sequence $G_x(k)$ is a discrete representation of the auto spectral density function for the signal $X(t)$. The true, continuous, signal-continuous, single-sided auto spectral density $G_x(f)$ is defined as

$$G_x(f) = 2 \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T X_k(f, T)^2 dT \quad [9]$$

The random part of the error in the spectral estimates is given by Bendat and Piersol (3) for the case of a signal with a gaussian PDF as a normalized standard error

$$\epsilon_T = \sqrt{2/M} \quad [10]$$

where M equals the number of degrees of freedom in statistical sense (each time record has two degrees of freedom, due to the fact that the spectral estimate has a real and an imaginary component). This implies that the standard deviation in a spectral estimate calculated from one time record is 100%, independent of the length of the record.

The number of degrees of freedom can be increased in two ways: by smoothing of the estimates at the expense of spectral resolution or by segment averaging. The latter technique requires a longer observation time, but preserves the spectral resolution, and is, therefore, adopted in this paper.

The bias part of the error in the spectral estimates is a function of the "shape" of the spectral density function. For flat spectra, $1/f$ noise, and lorentzian spectra this error is negligibly small at the frequencies of interest (3).

From the definition of the spectral density, it follows immediately that if a signal can be considered to be the sum of some stationary, ergodic signals the spectral density of the sum equals the sum of the spectral densities of the individual signals

$$\begin{aligned} x(t) &= \sum x_i(t) \quad i = 1, 2, 3 \dots \\ G_x(f) &= \sum G_{x_i}(f) \quad i = 1, 2, 3 \dots \end{aligned} \quad [11]$$

In a previous paper (1), this property was used by Haemmerli *et al.* to discriminate between noise originating in different parts of the CHEMFET/electrochemical cell system. It is clear from Eq. [11] that as soon as one of the different noise sources is stronger than the others this discrimination becomes impossible. The same conclusion was reached by Haemmerli.

Two-Channel Approach

In order to reduce the device noise in a CHEMFET/electrochemical system, a two-channel approach was developed based on the following reasoning: suppose that two CHEMFETs have an electrochemical noise source in common but that their "solid-state" noise is not correlated. For the fluctuations in the two drain currents, we can write

$$\begin{aligned} x(t) &= d_1(t) + e(t) \\ y(t) &= d_2(t) + e(t) \end{aligned} \quad [12]$$

$d_1(t)$ is the device noise for FET1, $d_2(t)$ is the device noise for FET2, and $e(t)$ is the (electrochemical) noise common to both channels. The true continuous single-side spectral density functions are

$$\begin{aligned} G_x(f) &= [D_1(f) + E(f)][D_1(f) + E(f)]^* \\ G_y(f) &= [D_2(f) + E(f)][D_2(f) + E(f)]^* \\ G_{xy}(f) &= [D_2(f) + E(f)][D_1(f) + E(f)]^* \end{aligned} \quad [13]$$

where (*) denotes a complex conjugate. $D_1(f)$ and $D_2(f)$ are Fourier transforms of signals $d_1(t)$ and $d_2(t)$, and $E(f)$ is the Fourier transform of the noise $e(t)$ common to both channels. If we drop the frequency dependence for convenience of notation, expanded Eq. [13] becomes

$$\begin{aligned} G_x &= D_1 D_1^* + E D_1^* + D_1 E^* + E E^* \\ G_y &= D_2 D_2^* + E D_2^* + D_2 E^* + E E^* \\ G_{xy} &= D_2 D_1^* + D_2 E^* + E D_1^* + E E^* \end{aligned} \quad [14]$$

If d_1 , d_2 , and e are uncorrelated noise sources, all cross-terms in Eq. [14]

$$E D_1^* = D_1 E^* = E D_2^* = D_2 E^* = D_1 D_2^* = D_2 D_1^*$$

are zero and hence

$$\begin{aligned} G_x &= D_1 D_1^* + EE^* \\ G_y &= D_2 D_2^* + EE^* \\ G_{xy} &= EE^* \end{aligned} \quad [15]$$

The cross spectral density function is thus a function of electrochemical noise common to both channels only.

A derived quantity is the coherence function defined as

$$\gamma(f)^2 = \frac{|G_{xy}(f)|^2}{G_x(f) G_y(f)} \quad [16]$$

Theoretically, this function has a range from zero for no coherence to one for complete coherence. It can be viewed as a measure for the amount of signal common to both channels.

The same considerations as above apply to the statistical errors in estimates of the auto spectral density functions obtained by Fourier analysis of time records. Error estimates in the cross power spectral density and in the coherence function are dependent on the amount of coherence between the two signals and are relatively complicated (3, 8). The number of degrees of freedom is important especially at low levels of coherence, as Table I shows.

Experimental

The transistor chips used in this study are identical to those used previously (1). They were mounted on 1.5 mm diam PVC tubing and encapsulated with a high grade epoxy resin (Epon 826 with Jeffamine D230 crosslinker). The two gates used for the cross-correlation measurements are connected as shown in Fig. 1. In this study, we have used 25 μm diam Al-Si (1%) wire, the geometrical area of the metal exposed to the solution was approximately $7 \times 10^{-6} \text{ cm}^2$. During etching experiments, this area was renewed by cutting the sample perpendicularly to the wire axis after each experiment. Unless stated otherwise, the measurements were done at room temperature. The actual temperature at the sensor site was determined by precalibration of one of the MOSFET's available on the transistor chip.

The noise measurements were done under two sets of experimental conditions: in pH 9.0, 0.1M borate buffer (no corrosion) and in etching solution consisting of 1600 ml H_3PO_4 (35% Fisher), 100 ml HNO_3 (69% Fisher), 100 ml acetic acid (glacial, Fisher), and 200 ml of water. This solution was diluted with distilled deionized water for concentration dependence studies as necessary. The solutions were degassed with nitrogen and stored in glass bottles under nitrogen. They were delivered to the transistor under constant pressure using the manifold shown in Fig. 3. The volumetric flow rate was controlled by adjusting the nitrogen pressure. Because of the irregular geometry of the encapsulated sample, the absolute face velocity of the flowing solution at the sample surface could not be determined. The electrical circuits used for monitoring the drain-to-source current are shown for a two-channel operation in Fig. 4b. The output signals were amplified with low noise, variable gain (1-10 K) preamplifiers (Princeton Applied Research, Model PAR 113A) and analyzed using Hewlett-Packard Signal Analyzer (HP 3582A). The accessible frequencies of this measuring setup were between 0.8 Hz and 25 kHz.

Results

In the preliminary experiments, we have used diluted hydrochloric acid (0.1 mM to 0.1M) has the reaction me-

dium. For concentrations above 5 mM HCl, the reaction was too violent, yielding bubbles of hydrogen which created problems in the flow cell. For concentrations below 1 mM, the change of surface pH due to low buffering capacity led to irreproducible results. Nevertheless, the auto spectral densities in these experiments exhibited a pronounced maximum in the region between 1-10 Hz which increased with increasing concentration of the acid from $5 \times 10^{-18} \text{ A}^2 \text{ Hz}^{-1}$ for 0.1 mM HCl to $5 \times 10^{-17} \text{ A}^2 \text{ Hz}^{-1}$ for 0.1M HCl.

In order to control the surface concentrations better a buffered solution normally used for etching aluminum in the integrated circuit fabrication process (9) has been used in various dilutions. For undiluted solutions at room temperature, the typical etching rate is less than $1000 \text{ \AA min}^{-1}$. Therefore, for the duration of our experiment (~ 10 min), the removal of the material has not significantly altered the flow pattern around the sample.

The auto spectral densities for etching solutions of various dilutions are shown in Fig. 5. These are the results of 128 averages. There is a clear evidence of a lorentzian character of the spectrum (slope: -2) for the two highest concentrations. The intensity of the spectrum increases with the increasing concentration of the etching solution, in general agreement with the results obtained with hydrochloric acid.

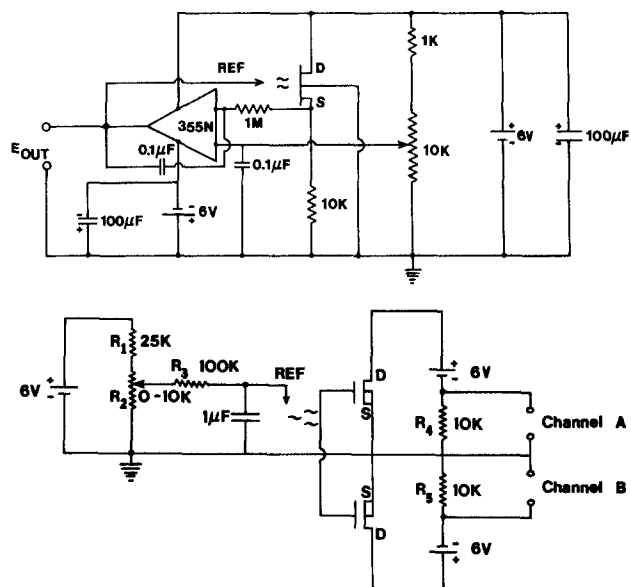

Fig. 4. Circuit used in two-channel measurements. REF: reference electrode. E_{OUT} : output voltage. D: drain. S: source.

Fig. 5. Autospectral density for corrosion of aluminum at three different concentrations of etching solution. Vertical axis current density units are in A^2/Hz .

The coherence function (Eq. [16]) for the data presented in Fig. 5 is shown in Fig. 6. It again shows the expected concentration dependence. In buffer solution where no significant corrosion takes place, its value is 0.025 and independent of frequency up to 1 kHz. The fact that the coherence has a nonzero value indicates the presence of common electrochemical noise, which probably originates from the pseudo-exchange current (nonequilibrium) which takes place at the metal/solution interface. This statement has to be taken within the context of the statistical accuracy of the coherence function (Table D).

Conclusion

In this paper, we have outlined the framework for study of nonequilibrium fluctuation phenomena in chemically sensitive field effect transistors from both the theoretical and the experimental points of view. The corrosion of

Fig. 6. Coherence function obtained in two-channel mode for three different concentrations of etching solution and for buffer solution.

aluminum/silicon alloy is used only as an illustration that this approach is feasible, and no interpretation of the experiments is attempted. The corrosion of metals and semiconductors is commonly studied by conventional electrochemical means in which the important corrosion parameters are derived from current-voltage characteristics which are extrapolated to zero net current conditions. Bertocci (10-12) has introduced the concept of coherence to corrosion measurements. It has allowed him to determine the causal relationship between current and voltage. The fundamental difference in our measurements is that they are performed at zero-net current condition. Thus, the only independent variables are surface concentrations, temperature, and pressure. This approach is possible because the coupling between the electrochemical process and the interface and the observable (fluctuation of the drain-to-source current) is through the electric field. In the following paper, we will show that this mode of operation yields a unique approach to the study of electrochemical reactions of various materials, including insulators.

Fluctuation Phenomena Studies in Chemically Sensitive Field Effect Transistors

II. Corrosion of Silicon Oxynitride

Zheng Kang Li, Johannes M. Reijn, and Jiří Janata*

Department of Bioengineering, University of Utah, Salt Lake City, Utah 84112

ABSTRACT

Drain current fluctuations in a field effect transistor caused by the corrosion of silicon oxynitride have been measured and analyzed. It has been shown that under wet etching conditions the surface of silicon oxynitride becomes conducting. The equivalent electrical circuit corresponding to this situation has been proposed.

Analysis of equilibrium (1) and nonequilibrium noise (2) in CHEMFET's has shown that electrochemical information can be obtained from the solution/membrane (1) or solution/metal (2) interface without external electrical perturbation. The system is allowed to tell its own story, so to speak. The unique feature of CHEMFET lies in the fact that the electrochemical signal is coupled through the electric field directly to the transistor channel. In other words, there is no need for connecting the interface under study to the amplifier through a metal lead, which would introduce a parasitic impedance into the measurement. Under these conditions, any material, conductor, semiconductor, or insulator, deposited directly over the gate of the CHEMFET can be studied by this technique. In this paper, we will describe the study of electrochemical processes which are taking place at the surface of the gate insulator during a wet etching reaction. The theoretical background for this work has been outlined in the first paper of this series (2).

Experimental

Transistors used in this study were of the same type as used previously (2) except for the aluminum layer [Fig. 1 of Ref. (2)] which was not present. The size of the gates was $20 \times 400 \mu\text{m}$, and they were spaced $700 \mu\text{m}$ apart. The area of the chip exposed to the etching solution was typically $0.9\text{--}1.0 \text{ mm}^2$. A slightly different instrumentation approach has been used. The outputs from the two preamplifiers (PAR 113A) are connected to the signal analyzer HP 3582A (Hewlett-Packard) and also to a digitizing oscilloscope (Tektronix 5225). Signals were recorded on an FM tape recorder (Hewlett-Packard Model 3964A). This arrangement allows for on-line spectral analysis using the spectrum analyzer and for off-line analysis using our computer system.

The computer system used is an LSI 11/23-based minicomputer (Digital Equipment) running under an RT-11 5.1 operating system. Storage facilities are a 10 megabyte RL01 hard disk (Digital Equipment) and a dual RX02 floppy disk system (Data Systems Design) mainly used for backup purposes. Standard programming language is FORTRAN IV version 2.6 (Digital Equipment). We developed a Ratfor preprocessor to extend this language (3).

The computer performs a variety of tasks, as follows.

Data acquisition.—A Tektronix 5223 digitizing oscilloscope is connected through an HP-1B instrument interface bus. This arrangement allows for acquisition of two channel time records of 1016 points each, digitized to 10

bits, including sign. During the time needed for data transfer, the sampling is interrupted; thus, a discontinuous time series is obtained. As pointed out in the previous paper, this can be allowed for if the stochastic process is stationary and ergodic. For the nonstationary cases, we are studying alternatives to obtain continuous time series.

Data qualification.—Software is available to inspect time records for stationarity. The main test performs a fit of experimental data to a gaussian PDF. This test enables one to distinguish between "true" signals and unwanted disturbances. Furthermore, spectral analysis of nonstationary data yields results which have to be regarded very critically with respect to their interpretation. Use of the spectrum analyzer yields only averaged spectral estimates, and, therefore, information is lost in this computation. Even if the experimental data are expected to be stationary (for instance in equilibrium noise measurements) it is good practice to subject (part of) the time history of the experiment to statistical tests (4).

Data processing.—Programs are available for spectral analysis yielding estimates of the auto and cross spectral densities and the coherence function. In the time domain, auto and cross correlations can be calculated for individual time records.

Data presentation.—The software supports a HP 7220C digital plotter (Hewlett-Packard) for permanent copies of graphs and a graphical terminal MG8000 (Wicat) for quick visualization of results.

Data modeling.—The main programs in this group perform curve fitting as mentioned above for the PDF. The software is adapted from Bevington (5) and is written using the Marquardt algorithm.

Copies of programs are available upon request.

Solutions used in this study were $0.1M$ pH 7.00 phosphate buffer and etching solution containing 100 ml 85% w/w H_3PO_4 , A.C.S. Certified, Fisher and 5 ml 48-50% w/w HBF_4 , Purified, Fisher. Solutions were handled using the same manifold as described in the first paper of this series (2).

Results

The time records of the noise in buffer solution (equilibrium) and at 55°C in the etching solution (corrosion) are shown in Fig. 1. The temperature for etching of silicon oxynitride under normal processing conditions is 180°C . At that temperature, silicon oxynitride is removed at the rate of $\sim 50 \text{ \AA min}^{-1}$. We have found that the highest temperature under which our noise measurements could be done reproducibly was 55°C . At higher temperatures, the overall fluctuations were too violent and samples were

Fig. 1. Time record of the drain current fluctuations under (a) equilibrium (buffer) and (b) corrosion (55°C etching solution).

destroyed too quickly. The auto spectral density of corroding silicon oxynitride was found to be strongly dependent on temperature (Fig. 2a) and on mass transport (Fig. 3a).

The most surprising result of this work has been the strong correlation between signals from the gate A and the gate B [Fig. 1 of Ref. (2)] during corrosion conditions. As a matter of fact, the cross power spectral density and auto power spectral density calculated for the same corroding sample are almost identical. Consequently, the coherence function, $\gamma^2(\omega)$ has a nonzero value over broad range of frequencies, meaning that there is a strong correlation between these two signals. Thus, coherence is again strongly dependent on temperature (Fig. 2b), and on flow rate (Fig. 3b). The data in Fig. 2 and 3 are presented on different frequency scales in order to highlight the shapes of these frequency-dependent functions.

It has been found that the coherence function measured under mildest etching corrosion conditions (36°-38°C) slowly shifts towards lower frequencies with time. At

temperatures above 45°C, such shifts have not been observed. The time-dependent surface conductivity has been suspected to be the cause of this behavior. In order to verify this hypothesis, the following experimental sequence has been tried. The sample was first placed in the etching solution at 25°C. Under those conditions, no coherence occurs in the frequency range accessible to our measurements (0.8 Hz-25 kHz) (Fig. 4, curve 1). Without interrupting the flow of the etching solution, the heater was turned on and the temperature of the etching solution was raised to 38°C (Fig. 4, curve 2). After 4 min, the coherence has decreased gradually (Fig. 4, curve 3). The heater was then disconnected for 4 min and the coherence at 25°C was again measured; it had returned to near zero value. After 4 min, the temperature was again raised to 38°C. The coherence function has reached lower value than that obtained during the first cycle (Fig. 4, curve 4) and, again, gradually decreased with time. This behavior is consistent with formation (25°C) and removal (38°C) of surface conductive layer which is necessary for the nonzero value of the coherence function. It must be pointed out that zero value of coherence at 25°C does not imply the absence of surface conductive layer. It can mean the absence of the common correlated source of fluctuation, *i.e.*, the corrosion process, or it can mean that the surface resistance is so high that the coherence is shifted to frequencies below 0.8 Hz.

Discussion

There are two significant results of this study: the ability to investigate directly the electrochemical corrosion process taking place at the insulator/solution interface, and the finding that the entire surface of the silicon oxynitride becomes conductive during wet etching. The latter result, unfortunately, makes the interpretation of the fluctuation phenomena difficult at present. The time record of the corrosion process (Fig. 1) reflects the nature of the physical process itself. Each current excursion corresponds to an instantaneous charge imbalance at the gate capacitor. This can be due to random interaction of ions (both positive and negative) with the silicon oxynitride surface, ion exchange, or physical removal of charged material from the surface (etching). Any or all of these processes take place at the entire surface of the transistor chip. The original hypothesis has been that only the interactions taking place directly over the gate area A and B would be contributing to the fluctuations in those respective channels and be uncorrelated. This situation is in direct contrast to the experimental conditions

Fig. 2. The effect of temperature on corrosion of silicon oxynitride. a(left): Auto spectral density. b(right): Coherence function.

for the corrosion study of aluminum (2) in which the electrochemically generated fluctuations were made intentionally correlated to both gates through a common, metallic connection.

The presence of strongly correlated fluctuation source in the case of silicon oxynitride points to the existence of a conducting layer spread over the entire silicon oxynitride surface. Since this surface is laterally homogeneous chemically, it is reasonable to expect that the corrosion and hence the source of fluctuations is distributed uniformly over the entire surface. The process can be, therefore, modeled as a distributed impedance, as shown in Fig. 5a. In this model, the whole surface of the chip is subdivided into elementary complex impedance cells (Fig. 5b). In the first approximation, it is assumed that the conduction takes place in a two-dimensional conducting plane array of the elements Z_{jk} . It is further assumed that the elementary fluctuation sources, S_{jk} , are connected to the center of each impedance element Z_{jk} (Fig. 5b) and that the interconnections between neighboring elements are only orthogonal. Through this two-dimensional network each noise source anywhere on the chip surface contributes to the fluctuations measured in channels A and B.

The experiment described in Fig. 4 allows us to speculate about the nature of the plane conductor. At high tem-

perature ($> 45^\circ\text{C}$), the coherence function has a nonzero value which does not decrease in time. This means that the surface conductor is being formed continuously. At 38°C , the auto spectral density is high, meaning that the corrosion-related fluctuation source is operative but the coherence function gradually shifts to lower frequencies (Fig. 4, curves 2, 4, 5). This is consistent with the increase of the resistance value in the impedance element (Fig. 5b), which would effectively filter out the higher frequencies of the coherence function.

Periods 1, 3, and 6 in Fig. 4 represent time intervals in which the surface conductor can re-form. High values of the coherence function in the intervals 2, 4, and 5 support this hypothesis.

So far, we have been considering only a two-dimensional planar conductor, which is formed chemically. There is other evidence which suggests that this conductor is a three-dimensional layer of finite thickness. In that sense, the observed changes in the resistance as inferred from the time dependence of the coherence function can be due to the changes in the geometry of the layer (thickness) and/or of the volume density of charge carriers in that layer. At present, this question cannot be resolved on the basis of experimental evidence available to us.

The other supporting argument for the existence of the active surface layer comes from the analysis of concentration profiles of silicon oxynitride which has been done by both Auger spectroscopy (6, 7) and by ESCA (8) combined with argon ion sputtering. An oxygen-rich layer approximately 50\AA thick has been found to exist on the surface of silicon nitride. This layer re-forms spontaneously upon exposure to air at room temperature. This process resembles the formation of the passivation layer which is common to most metals and semiconductors.

It is well documented (9) that silicon oxynitride surface exhibits a linear pH sensitivity over a broad range of values (1-13 pH). Some authors have ascribed this sensitivity to ionization of silanol groups located in the surface plane. The linear character of the pH dependence would dictate the existence of at least 30 acid dissociation constants uniformly distributed over this pH range. The more likely explanation of the linear pH sensitivity is the existence of a hydration layer analogous to the one which forms on a glass pH electrode membrane (10).

The hydrated silicon oxynitride interface exhibits a typical nonpolarized behavior (11); it does not respond to adsorption of polyelectrolytes and is insensitive to the

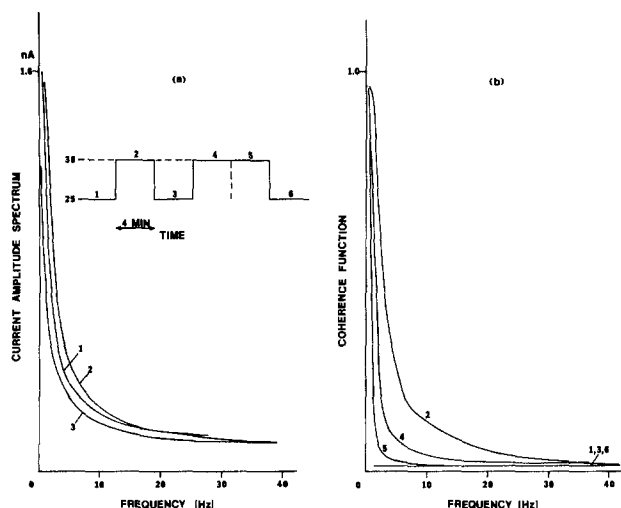

Fig. 4. Time dependence of the current spectrum (a) and coherence (b)

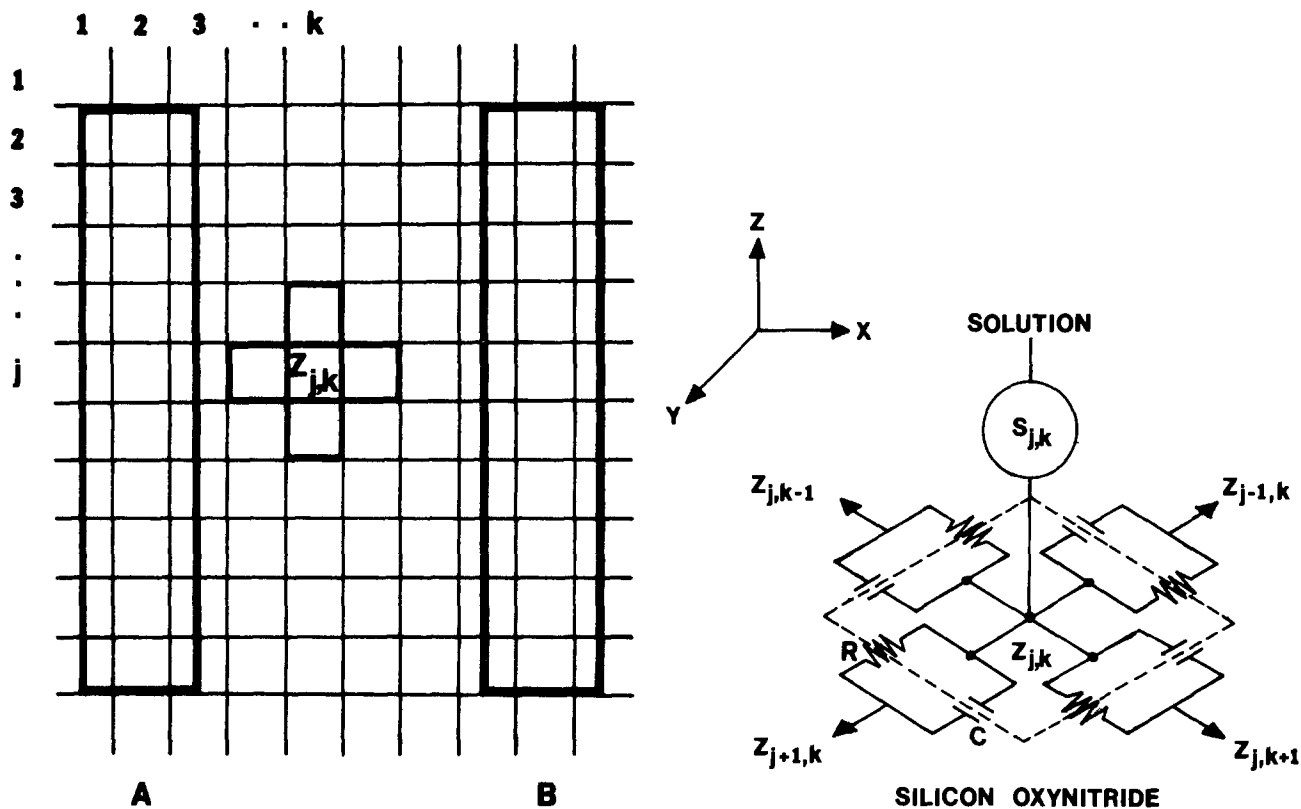

Fig. 5. Model of the transistor chip covered with silicon nitride under corrosion conditions. a(left): Distributed impedance superimposed on channels A and B. b(right): Model of the impedance cell $Z_{j,k}$ with the fluctuation source $S_{j,k}$. The reference point of the cell numbers is arbitrary.

motion of the solution. This is again consistent with the existence of a separate phase (hydrated layer) which has the boundary potential determined by the ion exchange process only.

Finally, our previous study has shown that silicon oxynitride allows migration of charge when exposed to water (12). The conduction properties of silicon nitride have been found to be strongly dependent on the degree of "wetness." While a dry surface would not allow charge migration for several hours, a wet surface dissipates charge from electrically floating transistor gate in a matter of seconds. From the time dependence of this charge migration, the surface resistivity of $10^{16} \Omega \square^{-1}$ has been found for a fully encapsulated transistor chip which has been immersed in water for several days. In contrast, the surface resistivity of the chip under etching conditions at 38°C is only $10^{11} \Omega \square^{-1}$ as estimated from the frequency dependence of the coherence function. The lower frequency roll-off of our experimental setup does not allow us to estimate the surface resistivity of silicon oxynitride under equilibrium conditions. However, the results of this work and of the charge migration studies which were mentioned above, point to a potentially serious problem due to the cross-talk in silicon oxynitride devices which would be used under aqueous conditions. It must be pointed out, however, that silicon oxynitride is a perfect insulator, for CHEMFET applications, in direction perpendicular to the surface as has been confirmed by repeated leakage tests done throughout this study.

ABSTRACT

Thin films of Cu_{2-x}S and Cu_{1+x}S have been electrodeposited at temperatures from 21° to 120°C from propylene glycol solutions of CuNa_2EDTA , elemental sulfur, and KCl. The films were grown on a variety of substrates, including indium tin oxide (ITO) and tin oxide (TO) coated glasses, graphite, nickel, tin and titanium. The stoichiometry of those films grown at room temperature can be controlled through the electrolyte stirring rate which controls the rate of sulfur diffusion toward the cathode. Heterojunction-like double-layer structures of Cu_{2-x}S on Cu_{1+x}S and Cu_{1+x}S on Cu_{2-x}S were electrodeposited by changing the stirring rate midway through a deposition. Those films grown at room temperature had nearly structureless x-ray diffraction spectra, while those grown at high temperatures were polycrystalline. X-ray microanalysis data indicated a continuous copper-sulfur atomic ratio from 2.33 to 1.06. The Cu_{2-x}S -based films were brown to dark-gray, and the Cu_{1+x}S films were blue-green to black. The apparent absorbance edge minimum shifted continuously from 835 to 575 nm as the sulfur content of the films increased, and the apparent indirect or nondirect bandgaps of the least copper-deficient but nearly amorphous Cu_xS films electrodeposited at room temperature were in the 1.25-1.50 eV range.

Electrodeposition has emerged as an inexpensive, low temperature, and relatively simple method of producing thin semiconductor chalcogenide films, such as CdTe (1-14), CdSe (15-21), CuInSe_2 (22), CdS (14, 21, 23, 24), Bi_2S_3 (25), SnSe (26), etc., which are potential photovoltaic materials. Previous work involving the electroplating of copper sulfide-based material can be found in Ref. (21, 27, 28). Major problems with the method include difficulty in producing perfectly stoichiometric material as required for electronic purposes and in achieving large grain sizes.

We report the electrodeposition of thin films of the copper-sulfur system from solutions of ethylenediaminetetraacetic acid-disodium-copper (CuNa_2EDTA) and elemental sulfur dissolved in 1,2-propanediol (propylene glycol). The creation of a Cu_{2-x}S layer by ion displacement, chemical vapor deposition, evaporation, etc. in the fabrication of CdS/ Cu_{2-x}S solar cells is well known, and the successful controlled electrodeposition of Cu_{2-x}S might allow the fabrication of heterojunctions or Schottky barriers with Cu_{2-x}S as the base material. Good reviews of Cu_xS -based solar cells can be found in Ref. (29-32). Major problems with these cells include stability, the formation of Cu_{2-x}S with too large an x value, and electrochemical formation of shorting copper nodules.

Experimental Instrumentation and Procedure

The experimental apparatus included an IBM EC 225 voltammetric analyzer, Hewlett-Packard 7046-B X-Y-t recorder, Pine glassy carbon-glassy carbon ring-disk electrode and rotator, Fisher Thermix 600T stirring hot plate, Fisher Accumet 630 pH, temperature, and millivolt meter, and in-house constructed voltage followers, galvanostats, and potentiostats. The solution was typically 10^{-2}M in CuNa_2EDTA and 10^{-1} - 10^{-2}M in sulfur and contained 200 ml of propylene glycol. Occasionally, KCl or NH_4Cl (0.01-0.1M) was added for conductivity purposes. All chemicals were purchased from Alfa or Fisher and were reagent-grade. The solution and 1.5 in. long Teflon-covered stirring bar were contained in a 1325 ml Pyrex crystallizing dish covered with a polypropylene cover, which contained ports for cathode removal and for the insertion of a Corning double junction Ag/AgCl reference electrode, a Fisher temperature electrode, and a Poco graphite anode with sufficient area to completely "shadow" the 1 in.² cathodes. The cathode substrates were held by a Poco graphite clamp connected with Teflon bolts and nuts.

¹ Present address: University of Missouri at Rolla, Rolla, Missouri 65401.

The IBM EC 225 voltammetric analyzer were normally used as the deposition power supply and was also used for the conduction of occasional voltammetric measurements in conjunction with the rotating electrode system and X-Y-t recorder. A battery-powered, floating OPAMP potentiostat/voltage follower circuit was used to control and measure the ring voltage and current.

A Perkin-Elmer/Hitachi Model 330 optical spectrophotometer was used for the measurement of optical absorbance vs. wavelength for those samples grown on the glass substrates. Conventional x-ray diffraction, x-ray microprobe analysis, and scanning electron microscope instrumentation located at the University of Missouri-Rolla and Arkansas State University were used for these measurements on the Cu_xS films.

Our deposition technique is similar to that developed by Baranski and Fawcett (21, 23, 25, 37, 38) and Roe *et al.* (24). In this technique, the film is formed by the plating of the metal and the subsequent reaction of the metal with the dissolved molecular chalcogen, and/or by the reduction of the chalcogen to a divalent anion and the precipitation of these anions with the metal cations. Baranski and Fawcett were successful in electrodepositing Cu_2S (21), but used hazardous CuCN due to the formation of "undesirable intermediates" when other copper salts were used.

Our copper sulfide films were produced by the electrodeposition of copper metal and subsequent reaction with sulfur at cathode voltages from -0.70 to -5.0V (Ag/AgCl). At -0.70V, the current densities varied from 3-16 $\mu\text{A}/\text{cm}^2$ at room temperature to 30-150 $\mu\text{A}/\text{cm}^2$ at temperatures near 100°C. The angular velocity of the stirring bar ranged from 0 to nearly 600 rpm, as measured with a strobe light or the period of the noise voltage induced in a nearby coil by the changing magnetic field of the stirring system.

The approximately 1 × 1 in. cathode substrates included PPG indium tin oxide (ITO) and tin oxide (TO) coated glasses, Poco graphite, nickel, tin, and titanium. The initial deposition voltage for the glass substrates was usually restricted to greater than -0.9V, owing to eventual electrochemical reduction of the conductive oxides at more negative voltages.

Substrate preparation was found to be critical to the uniformity and adherence of the deposits. After marking the conductive side with a diamond pen so that this side could be placed opposite the anode, the oxide-coated glasses were scrubbed with a test-tube brush and detergent. Graphite substrates were rubbed down to expose new material. Metal substrates were washed and then

etched in HCl or HNO₃. All substrates were rinsed in acetone, thoroughly dried, and handled with plastic forceps.

The finished deposits were carefully removed from the cathode clamp with the forceps and immediately rinsed with acetone, which was superior to water in removing the propylene glycol. The films were then rinsed in distilled/deionized water and dried before storage in sample boxes.

Experimental Results and Discussion

We have successfully electrodeposited Cu_xS films with x ranging from nearly 1 to >2 . The films with Cu/S ratios near unity are green to blue when thin, and dark black when thick and opaque. The films with Cu/S ratios near 2 are brown when thin and gray-brown when thick. Intermediate Cu/S ratios in the films produce either mixtures of brown and green colors on the same substrate or, more commonly, a homogeneous yellow-brown color. It was observed that the green Cu_{1+x}S material was favored near the solution-air interface; often, the brown deposits would yellow and turn green at the top one-third of the submerged substrate.

It was determined that the stoichiometry of the deposits could be controlled by varying the temperature, stirring rate, sulfur concentration, and current as a function of voltage. Evidently, the rate of reaction between the copper and sulfur is determined by the relative rates of mass transport of the sulfur and copper toward the cathode and their temperature-activated reaction rate constant. It is well known that the copper-chalcogen reaction rate is higher than such rates for most other metal-chalcogen reactions and may be up to 10⁴ that for tin and nickel (33). Of special significance is the fact that we were successful in depositing both green and brown films at room temperature, whereas most of the previous work utilizing this technique has been at temperatures greater than 90°C to avoid metal-rich deposits. This was possible because of the complexing nature of the EDTA ion, which allowed typical current densities of only 3-16 $\mu\text{A}/\text{cm}^2$, depending upon the stirring rate, at a deposition voltage near -0.7V vs. Ag/AgCl and because of the large Cu-S reaction rate constant. With sulfur concentrations between 10⁻³ and 10⁻²M, the color and composition could be well controlled through the angular velocity of the approximately 1.5 in. stirring bar. With no or very slow stirring (<50 rpm), the deposits were a rich but transparent brown color, and with rapid stirring were a blue-green color. Sulfur concentrations much less than 10⁻³M resulted in copper-rich deposits and rapid sulfur depletion due to film formation and oxidation of the sulfur at the anode. One disadvantage of the low current, room temperature depositions was that it often took over 12h to obtain reasonably thick deposits. This was especially a problem with the pulsed deposition method to be discussed below.

The fact that x in Cu_xS ranged from 1 to over 2 when there were no Cu⁺ ions deliberately added to the solution is evidence that the compounds are being produced primarily from the chemical reaction of plated copper and dissolved sulfur. If the primary reaction was the precipitation-like reaction of electrochemically produced S⁻ ions and Cu⁺ ions, the deposit would tend to be primarily CuS. This reaction could predominate in the electrodeposition of electronegative metal sulfides such as ZnS or MnS, where the sulfur reduction wave occurs at potentials more positive than the metal Nernst potential.

Those films grown at room temperature were smooth, shiny, and reasonably adherent. Rinses in water tended to produce more cracking of the films than did rinses in acetone. Those films grown on graphite and metal rarely cracked, while those grown on the oxide-coated glasses occasionally cracked and flaked, especially when very thick. A few depositions from a CuSO₄-based bath yielded powdery and nonadherent green-to-brown deposits, especially at high deposition temperatures and current densities greater than 100 $\mu\text{A}/\text{cm}^2$. The powdery nature was probably a consequence of the powdery copper deposition, as often occurs with noncomplexed copper ions.

At a temperature between 90° and 120°C, where the currents typically ranged from 30 to 150 $\mu\text{A}/\text{cm}^2$ at voltages near -0.7V (Ag/AgCl), thick, nearly opaque deposits could be obtained after 1-2h. Deposits grown at these temperatures, especially those grown on metal substrates, had a much more grainy texture than those grown at room temperature. It was difficult to obtain brown deposits at these temperatures because of the rapid reaction of the copper and sulfur, and there was a rapid transition from very copper-rich to green deposits as the sulfur concentration was increased from 10⁻⁴ to 10⁻³M. By using voltages negative of -1.0V , the copper current could be increased enough that the deposits would darken and become Cu_{2-x}S. It is likely that CuS is also directly reduced to Cu₂S at these very negative voltages. The high temperatures tended to change the color of the electrolyte from a bright blue to a dark blue-green when maintained for lengthy periods. Furthermore, a dark precipitate appeared in the crystallizing dish. After this precipitate formed, the subsequent deposits became very copper-like and nonuniform. Also associated with this phenomenon was the onset of a sweet, yeast-like odor from the solution. Although not rigorously investigated, we speculate that the high temperatures promote the in-solution formation of CuS from the reduction of Cu⁺⁺ to copper by the solvent and, thus, the removal of all of the sulfur from solution.

Annealing of the green CuS-based deposits in air at 200°-300°C quickly converted them to dark brown and very adherent Cu_{2-x}S-based deposits, probably with some oxides existing on the outer surface. However, we were unable to detect any oxygen in the microprobe analysis data due to oxygen's low atomic weight. There was always much sulfur remaining, as evidenced by microprobe analysis data, and, thus, Cu₂O formation was minor. We could also produce Cu_{2-x}S from Cu_{1+x}S by inserting the green deposits in a graphite clamp and placing them in a weakly acidic aqueous solution opposite a graphite anode. By generating small quantities of H₂ on the surface of the deposits, the "excess" sulfur reacted with the H₂ to form H₂S or HS⁻ and produced brown Cu_{2-x}S deposits. Large hydrogen currents and associated bubble formation tended to crack the films mechanically.

The solution used for this work was convenient to work with because of the very low toxicity of the propylene glycol and sulfur. Furthermore, the Cu⁺⁺ ions are complexed by the EDTA ions and rendered relatively nontoxic. The boiling point of propylene glycol is 187°C, so high temperatures can be used without boiling and rapid solvent evaporation and the associated flash ignition problems. This also allows for the melting of the submerged sulfur and greatly increases its rate of dissolution. Room temperature evaporation was negligible. A key advantage of this bath is that both the EDTA ions and the propylene glycol molecules complex most other heavy metal ions and strongly hinder or prevent their electrodeposition. Thus, metal impurities in the films are minimized.

Material Data

Table I shows experimental data for representative Cu_xS films. All of the samples in the table were grown from the same bath, which was 10⁻²M in CuNa₂EDTA, 10⁻²M in sulfur, and 10⁻²M in KCl. The films were grown in the same sequence as their sample numbers. The sequence E34-E50 was grown approximately in order of increasing stirring rate with all of the other parameters constant.

Those films grown at room temperature and those grown on the oxide-coated glasses were usually mirror-like and usually lacked definite x-ray diffraction structure because of, in part, the "brightening" effect of the EDTA ion and the very small grain sizes of the oxides on the glass. Figure 1 exhibits x-ray diffraction spectra typical for those films grown at temperatures greater than 90°C on metal substrates. The peaks are still rather weak and broad, consistent with small grain sizes. Sample E79 was grown on a nickel substrate at a temperature of

96°-108°C, a voltage of -1.6V (Ag/AgCl), with a current density of 370 μA/cm² and a stirring rate of 550 rpm (determined from strobe light measurements). The sample was subsequently annealed in air at 213°C for 3h. The

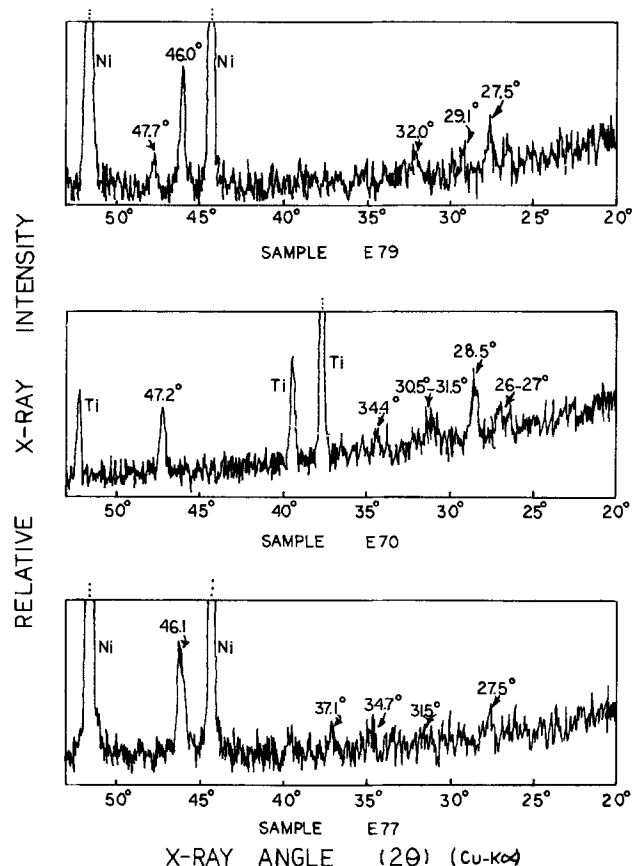

Fig. 1. X-ray diffraction spectra for Cu_xS films electrodeposited at high temperatures on metal substrates. The numbered peaks are possible Cu_xS structures while the substrate peaks are identified by the substrate material.

color of the film after annealing was gray-black. The peaks near 47.7° and 29.1° (2θ, Cu-Kα) are those associated with Cu_{1-x}S (covellite). The peaks near 46.0° and 27.5° are those associated with Cu_{2-x}S. The broad peak near 32.0° may be from either or both materials. Microanalysis data for this sample indicated a gross Cu/S elemental ratio of 1.90, but, evidently, more than one phase exists in the sample.

Sample E70, grown on titanium, exhibits peaks near 47.2° and 28.5°, which are probably characteristic of Cu_{1+x}S. Again, the broad peak near 31° may be due to either Cu_{1+x}S or Cu_{2-x}S. There is some indication of a small peak between 26° and 27°, consistent with anilite (Cu₃S₄). The x-ray microanalysis data for this sample indicated a Cu/S elemental ratio of 1.06. This sample was grown at 97°-98°C, with a deposition voltage of -1.40V (Ag/AgCl), a current density of 341 μA/cm², and a stirring rate of 550 rpm.

Sample E77 yielded peaks near 46.1°, 37.1°, and 27.5°, all characteristic of Cu_{2-x}S, and showed some indication of a peak near 31.5°. Microanalysis data indicated that the sample was Cu_{1.81}S, consistent with the digenite system. The conditions for the deposition of this film were a temperature of 98°-111°C, a deposition voltage of -4.30V (Ag/AgCl), a current density of 1.1 mA/cm², and a stirring rate of 550 rpm.

Figure 2 is a plot of typical graphical microanalysis data that accompanied the numerical printouts containing the elemental percentages. Sample E34 was grown on an indium tin oxide-coated glass substrate and E77 was grown on nickel, consistent with the indium, tin, and nickel peaks in the data. There were never any peaks in the microanalysis data for any film that were not attributable to copper, sulfur, or the substrate.

Although there is some scatter in the data points, Fig. 3 indicates an increase of sulfur content with increasing

Fig. 2. Graphical x-ray microanalysis data for electrodeposited Cu_xS films.

Fig. 3. Relative copper to sulfur atomic ratio vs. approximate stirring rate for electrodeposited Cu_xS samples E34-E49 that appear in Table I. All experimental conditions except the stirring rate were constant.

stirring rate as would be expected from the decreased sulfur diffusion-layer thickness and the increased cathode-surface sulfur concentration. Even with the lowest stirring rate (<50 rpm) and deposition voltages negative of the copper Nernst potential, no great excess of copper was indicated when the sulfur concentration was 10^{-2}M or greater.

Figure 4 shows the optical absorbance spectra for samples E34, E39, E48, E50, and E73. The spectra were compensated for substrate absorbance but not for reflectance. Referring to Table I, one notes that the bandgap absorbance edges, as approximately defined by the wavelength location of the spectra minima, move from 835 to 575 nm with increasing sulfur content. Thus, it should be possible to vary the bandgap of Cu_xS by controlling x with the stirring rate. These minima energies are not necessarily the bandgaps of the materials, as must be determined from various functional plots of the data.

Note that the gross absorbance also increases at the longest wavelengths and that the long wavelength absorbance seems to increase with increasing sulfur content. Rigorous comparison is hindered, however, by the slightly different film thicknesses. This low energy absorbance is probably due to free carrier absorption, but could also be partially due to interface reflectance between the sample and substrate. Most Cu_xS films, especially the green films, were very conductive and probably p-type degenerate with large hole concentrations leading to plasma resonance effects such as are discussed in Ref. (34). Note that the CuS -based samples on indium tin oxide-coated glass could serve as crude optical bandpass filters to the red end of the visible spectrum. The two competing "absorbance" processes make the determination of the actual material bandgap value difficult. Figure 5 plots $[\hbar\nu(A - A_0)]^{0.5}$ vs. $\hbar\nu$ for sample E34 and should yield linear plots if (35, 36)

$$A = A_0 + \frac{C(E - E_g)^2}{E}$$

Fig. 4. Optical absorbance spectra for typical electrodeposited Cu_xS films. The apparent bandedge shifts consistently to shorter wavelengths with a decreasing copper-to-sulfur atomic ratio.

where $E = h\nu$ is the photon energy, E_g is the bandgap energy, and C is a constant. This functional form applies to materials exhibiting indirect or nondirect (amorphous-like) optical transitions. The uncertainty lies in A_0 , a background absorbance due to imperfect substrate compensation, sample reflectance, free carrier and impurity absorption, etc. Two values have been selected for A_0 , 0.0 and 0.34, the minimum absorbance of the sample. For $A_0 = 0.34$, a least squares fit of those points visually appearing linear yields a bandgap estimate of 1.5 eV, and A_0

Fig. 5. Plots of $[\hbar\nu(A - A_0)]^{0.5}$ vs. $\hbar\nu$ for the slightly copper-rich sample E34 for two A_0 values. The extrapolated intercepts of the linear portions of the curves with the horizontal axis are estimates of the bandgap of the nearly amorphous sample.

Fig. 6. Micrographs of Cu_xS samples E37 and E48, both yielding structureless x-ray diffraction spectra.

= 0.0 yields a bandgap estimate of 1.25 eV. We feel that the former estimate is more correct, but the actual E_g value could lie anywhere within this 0.25 eV range, which is consistent with that observed for Cu_{2-x}S produced by other methods (29, 30). Samples E34 and E73 were slightly copper-rich and were probably more nearly Cu₂S (chalcocite) than most of the other brown samples. Most brown samples with Cu/S ratios between 1.6 and 1.8 had absorbance minima occurring between 700 and 750 nm, consistent with the digenite phase. We feel that digenite is the most commonly electrodeposited form of Cu_{2-x}S. However, with more exact "fine tuning" of the experimental conditions, we hope that chalcocite can be consistently produced. A slight excess of copper might be required to achieve chalcocite, however, because djurleite ($x = 1.94-1.97$) is so close in composition and is considerably inferior to low chalcocite (Cu_{2.00}S) in photovoltaic properties. A very slight copper excess would shift the equilibrium toward copper interstitial atoms rather than vacancies and hinder the changes in crystal structure associated with increasing numbers of copper vacancies.

Figure 6 shows micrographs of samples E37 and E48, both grown at room temperature. Note the nodular appearance of the surfaces. The nodules range from 0.1 μm to 0.5 μm in breadth. The nodules for sample E37 exhibit a columnar structure when viewed at higher magnifications. However, the x-ray diffraction spectra for these samples were nearly structureless.

Figure 7 exhibits micrographs for sample E73 grown at 110°C on SnO₂-coated glass using a pulsed deposition technique. The dark green sample was then annealed in air at 213°C for 3h and transformed into a dark brown deposit (Cu_{2.06}S). The x values slightly greater than 2 could be due to a minor amount of Cu_xO formation at the surface of the film with annealing. Any oxygen present was not detected in the microprobe analysis data due to its low atomic weight and, thus, the Cu/S ratio calculated could be slightly in excess of the true x value.

These photographs are for the after-annealing case. Note the sponge-like structure of the deposit as opposed

Fig. 7. Micrographs for sample E73 (Cu_{2.06}S) after annealing. This sample exhibited a weak Cu_{2-x}S x-ray diffraction structure.

to the nodular-like structures of samples E37 and E48. At higher magnifications, a brain-like structure is apparent. The x-ray diffraction spectrum for this sample showed a weak but definite peak between 45.5° and 46.0°, indicative of Cu₂S. Some of the brown samples, such as E45, grown at room temperature, also exhibited a similar structure when observed with magnification near 20,000×.

Figures 8 and 9 show micrographs for samples E66, E70, E77, and E79 grown at temperatures near 100°C on metal substrates. Sample E77 (Cu_{1.81}S) is composed of columnar crystals 0.5-1.0 μm wide and approximately 1.0 μm high. Sample E70 (Cu_{1.06}S) exhibits many needle-like or whisker-like crystals approximately 0.5 μm long and 0.05-0.1 μm wide. Sample E66 (Cu_{1.23}S) and E79 (Cu_{1.90}S) also exhibit these needle-like crystals, which sometimes clump together to form spheroids.

All of the samples viewed with the scanning electron microscope showed one or more of these four basic surface structures: (i) nodular (ii) sponge- or brain-like, (iii) columnar, and (iv) needle- or whisker-like. The nodular structure appears for both Cu_{1+x}S and Cu_{2-x}S and is indicative of nearly amorphous films. The sponge-like and columnar structures appear to arise from Cu_{2-x}S, and the needle-like structures seem to be indicative of Cu_{1+x}S. It is obvious that the high temperature depositions on metal substrates produce much larger crystallites than do the room temperature depositions.

Electrodeposition of Multiple-Layer Structures

We were also successful in plating heterojunction-like structures of Cu_{2-x}S/Cu_{1+x}S and Cu_{1+x}S/Cu_{2-x}S at room temperature simply by increasing or decreasing, respectively, the stirring rate midway through the deposition. By raising the cathode substrate slightly out of the electrolyte at this time, both film colors were visible at the end of the deposition. Thus, it is possible to electrodeposit two chemically similar but different (in band structure) semiconducting compounds with the same substrate and deposition voltage, and approximately the

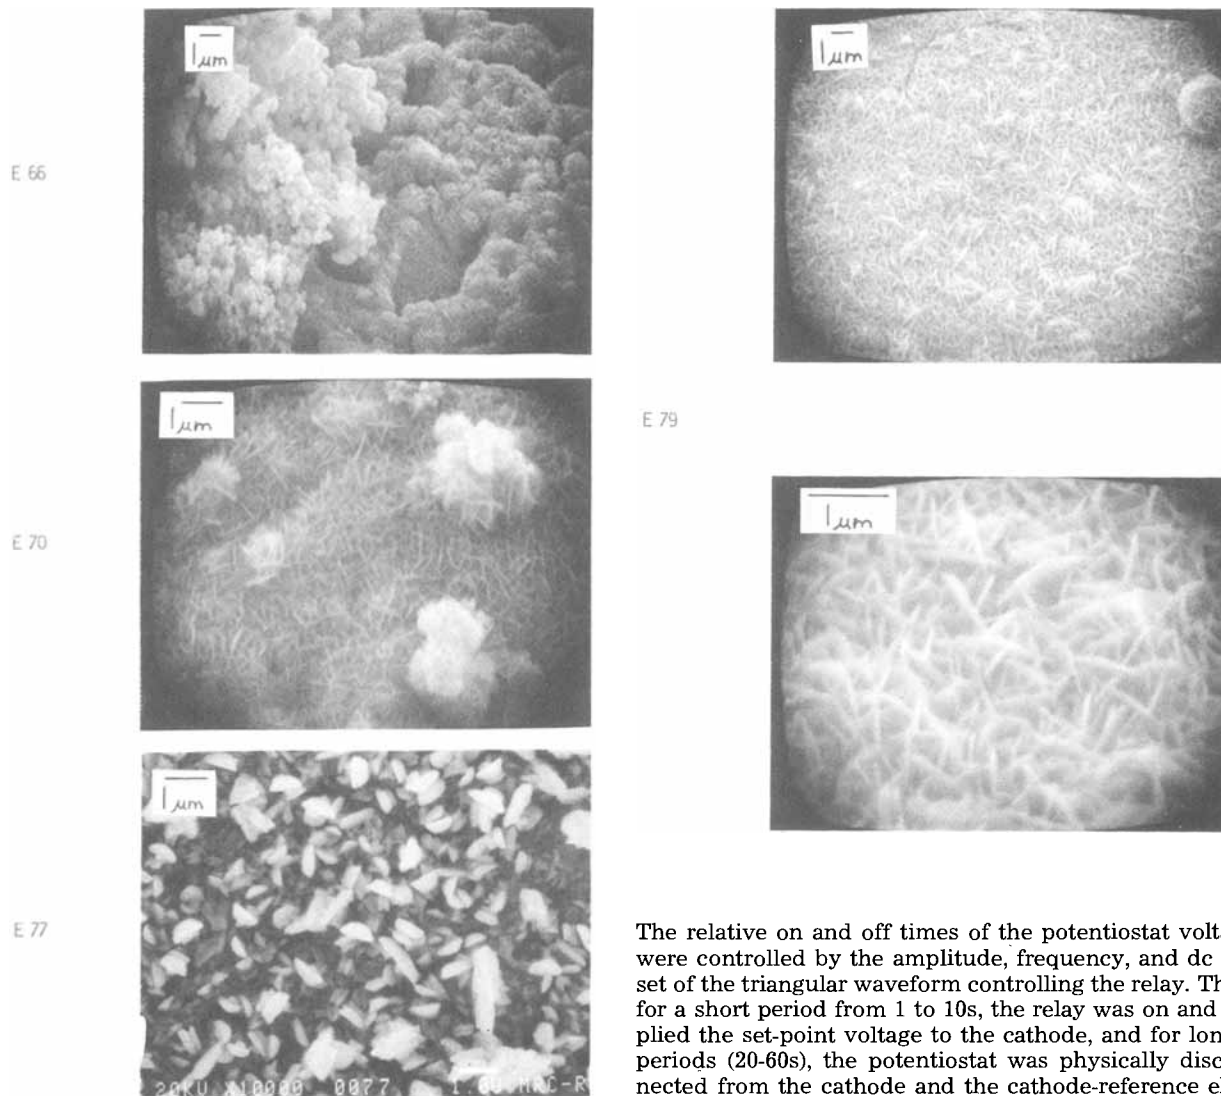

Fig. 8. Micrographs for samples E66, E70, and E77 grown on metal substrates at temperatures near 100°C and exhibiting substantial x-ray diffraction structure.

same current, simply by controlling the mass transport of the sulfur toward the cathode through the stirring rate. Such a technique would have many practical advantages in a commercial process. It would minimize the impurity problems associated with atomic diffusion across a heterojunction formed between two chemically unrelated compounds, and the associated doping of the depletion regions. Other multiple semiconductor compound systems such as the SnSe/SnSe₂ system (26) might be plated by this technique.

Furthermore, the same scheme might be used for depositing two different semiconductor layers and the top contact. Thus, a Cu_{1+x}S/Cu_{2-x}S/Cu device could be deposited through stirring rate variations. The copper layer adjacent to the Cu_{2-x}S would also tend to hinder its possible electrochemical transformation to a lower sulfur-content state under photovoltaic operation.

Pulsed Deposition Method

One fundamental advantage of the described electro-deposition technique is that it is nearly impossible to produce chalcogen-rich deposits, as is a likely possibility with cathodic deposition of the chalcogen from ions as occurs during CdTe electrodeposition. To take advantage of this fact, we developed a pulsed deposition scheme. The output of the potentiostat was connected to a relay. The relay coil was controlled by the triangular waveform of a Tektronix FG-504 low frequency function generator.

The relative on and off times of the potentiostat voltage were controlled by the amplitude, frequency, and dc offset of the triangular waveform controlling the relay. Thus, for a short period from 1 to 10s, the relay was on and applied the set-point voltage to the cathode, and for longer periods (20-60s), the potentiostat was physically disconnected from the cathode and the cathode-reference electrode voltage followed the open-circuit rest potential of the cathode and was sensed by a voltage follower circuit connected to the X-Y-t recorder. During the off portion of the cycle, the open-circuit voltage would nearly instantaneously increase to the quasi-rest potential of the deposited film and then quasi-exponentially increase from the quasi-rest voltage to an equilibrium value between 0.1 and -0.1V (Ag/AgCl), depending upon the experimental conditions. The apparent time constant of the "decay" was from 1 to 5s and resulted from the reaction of the plated copper with the dissolved sulfur, which caused a reduction of the copper activity in the deposit, and the relaxation of the copper ion activity in the Helmholtz layer to the bulk value. The reaction was essentially complete and produced nearly stoichiometric Cu_{1+x}S when the open-circuit potential reached a steady value.

It should also be possible to directly use a pulse generator as the set-point input to the potentiostat and alternately pulse the film anodically and cathodically. However, this would redissolve the Cu_xS during the anodic part of the cycle and slow the rate of deposition, although possibly decreasing the defect density and stress in the deposit. The relay scheme allows the sulfur to react with the deposited copper with no net change in the total copper content of the deposit. If the on times were long, the copper deposit might become too thick to allow sulfur diffusion through the deposit and, thus, complete reaction would be hindered. In this case, the anodic pulse might be beneficial to help remove excess copper which should dissolve at a more negative potential than would Cu_xS.

The pulsed mode is very attractive for the deposition of metal chalcogenide systems with only one compound, such as CdS, but for multiple-compound systems, such as

Cu_xS, would tend to produce the most sulfur-rich compound. The technique should allow the deposition of most metal chalcogenides at room temperature if there is a nonzero rate of reaction between the sulfur and metal. However, the required off time might be prohibitively long. It should be possible to deposit Cu_{2-x}S by closing the relay when the open-circuit potential just reaches the calculated equilibrium rest potential between stoichiometric Cu_xS and the electrolyte. As discussed previously, there is a continuous shift in the absorption edge of the Cu_xS to shorter wavelengths as x goes from 2 to 1. Thus, it might be possible to "tailor" the bandgap of the metastable Cu_xS deposits by switching the relay at the appropriate rest potential value. We are presently investigating this possibility.

Conclusions and Further Work

Both Cu_{2-x}S and Cu_{1+x}S thin films have been electro-deposited at temperatures from room temperature to 120°C from propylene glycol solutions of CuNa₂EDTA and sulfur. The stoichiometry of the films can be varied by controlling the rate of sulfur diffusion toward the cathode via the stirring rate. By changing the stirring rate midway through a signal deposition, both Cu_{2-x}S/Cu_{1+x}S and Cu_{1+x}S/Cu_{2-x}S structures have been deposited on the same substrate. The use of a pulsed deposition scheme allows nearly complete reaction of the copper and sulfur to form Cu_{1+x}S.

Those films grown at room temperature are usually amorphous, while those grown at temperatures near 100°C are polycrystalline. The amorphous films show a nodule-covered surface. Polycrystalline Cu_{1+x}S is composed of needle-like crystals, while polycrystalline Cu_{2-x}S exhibits a sponge-like or columnar surface. X-ray micro-analysis data indicated a continuous Cu/S ratio from 2.33 to 1.06. Furthermore, the optical absorbance edge minimum shifts continuously from 835 to 575 nm as the sulfur content increases. This might allow for bandgap "tailoring" even though the deposits may be metastable or mixtures in some cases. Plots of $[h\nu(A - A_0)]^{0.5}$ vs. $h\nu$ for the slightly copper-rich, amorphous sample E34 indicated an indirect or nondirect bandgap between 1.25 and 1.50 eV.

Future work includes deposition of Cu_xS films with an open-circuit potential controlled pulsed deposition system and a rotating cathode to better characterize the relationship between the stoichiometry and deposition conditions, so that photovoltaic-quality Cu₂S and, ultimately, junction devices can be consistently produced, as determined from structural, composition, optical, and electrical measurements.

Electrochemical Study of the Autocatalytic Deposition of Gold-Copper Alloys

A. Molenaar and B. C. M. Meenderink

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

ABSTRACT

The oxidation of formaldehyde was studied on a range of homogeneous copper-gold mixed crystals made by electroless deposition. The potential of passivation depends on the composition of the alloy. Electrochemical measurements were also performed for the deposition of alloys with a low, an equivalent, and a high gold-copper ratio. The catalytic activity of the gold-copper alloy for the oxidation of formaldehyde, and thus for autocatalytic metal deposition, is different from that of the pure metals. It is suggested that competition between the adsorption of formaldehyde and cyanide on the alloy surfaces at different potentials determines the catalytic properties.

A range of autocatalytic gold-copper alloys can be deposited from alkaline solutions containing $\text{KAu}(\text{CN})_2$, cupric ions complexed with EDTA and formaldehyde as reducing agent (1). Oxidation of formaldehyde does not take place on a gold surface in a wide potential range when cyanide ions are present in solution. It is, therefore, impossible to deposit, autocatalytically, pure gold from an electroless solution based on $\text{KAu}(\text{CN})_2$ and formaldehyde. However, cyanide has very little effect on the oxidation of formaldehyde on copper. In Ref. (1), we suggested that the copper acts as a catalyst for the oxidation and the electrons released at the copper or copper alloy surface can reduce both gold and copper ions. We have shown (1) that both copper- and gold-rich alloys can be deposited in this way. One of the surprising aspects of this work was that each gold-copper alloy, deposited from a stable electroless solution, has a characteristic lattice constant. A linear relationship was found between lattice constant and the alloy composition [Ref. (1), Fig. 7]. We must conclude that the gold-copper layers deposited from autocatalytic solutions are homogeneous mixed crystals in contrast to electroplated layers (2). Recent papers in the field of catalysis show that a metal in an alloy very often has catalytic properties similar to those of the bulk metal (3). De Jong (4) demonstrated that the catalytic properties of smaller stable metal particles can be studied in an alloy. Because we found that oxidation of formaldehyde in the presence of cyanide ions takes place on pure copper but not on pure gold, we tried to determine if, in the copper-gold alloy, only the copper atoms act as catalyst supplying the electrons for the reduction of the metal ions.

Experimental

Glass slides, roughened with silicon carbide and treated with 4% by weight hydrogen fluoride solution, were used as substrate. These were activated with stannous chloride-hydrochloric acid and palladium chloride-hydrochloric acid solution. The plating solutions had the following composition: copper sulfate 0.04M, tetrasodium salt of ethylenediaminetetraacetic acid 0.072M, gold(I) cyanide 10^{-2} - 10^{-4} M, potassium cyanide 10^{-3} M, sodium hydroxide 0.12M, and formaldehyde 0.10M. All solutions were prepared from analytical-grade chemicals. The experiments were carried out at 50°C. Plating rates were determined by weighing the deposits. The amount of hydrogen liberated during electroless metallization was measured with a gas burette. The copper/gold ratio was measured by low energy electron induced x-ray spectroscopy (LEEIXS) and in some cases by wet chemical analysis. Electrochemical measurements were carried out with the metallized glass slides. The working electrode was completely surrounded by a platinum sheet as counterelectrode. A saturated calomel electrode (SCE) was used as reference in combination with a Luggin capillary. The potential of the working electrode, given in V vs. SCE, was varied continuously with the aid of a Wenking ST 72 standard potentiostat and a Wenking VSG 72 voltage scan generator. The

scan rate was 1 mV/s in all cases. The current was recorded using a Philips PM 8141 X-Y recorder, and a Philips PM 2443 digital dc voltmeter was used to measure the potential.

Results

Using autocatalytic plating solutions at 50°C, we obtained a range of gold-copper alloys by changing the gold-cyanide concentration in the solution from $1.8 \cdot 10^{-4}$ to $1.4 \cdot 10^{-2}$ M. The metal content of the alloys and the lattice constants are given in Table I.

The potentials measured during plating (E_{pl}) shift to less negative values as the gold content is increased. We measured the plating rate and calculated the values as a current density (i_{pl}) using the measured copper/gold ratio (Fig. 1) in the layer and assuming that two electrons are required to form one copper atom and one electron for gold. The calculated current decreases as the gold content is increased.

The voltammograms for the oxidation of formaldehyde using a plating solution without metal ions are shown in Fig. 2 for the different alloys. When more gold is present in the alloy, not only is the current lowered in a wide potential range, but also the passivation of the alloy surface is also shifted to less negative values. Passivation is not observed on many alloys at potentials at which pure copper is oxidized. The plating potentials for the alloys with a copper content of less than 5% lies in this range. A reasonable agreement is found when the measured anodic current (i_M in Fig. 2) at the plating potential (E_{pl}) is compared with the currents (i_{pl}) deduced from the plating rate (Fig. 1 and Table I).

In Fig. 3-5, both the anodic and cathodic partial current-potential curves are given for alloy layers with 2.5, 49, and 98.5 atom percent (a/o) gold. The plating potentials (E_{pl}) are shown in the figures. The differences in the plating potential are not determined by the cathodic current, but correspond to the degree of inhibition of the oxidation of the formaldehyde. The overall cathodic current (Fig. 3-5)

is not significantly changed when different alloy layers are used as electrodes in the corresponding solutions. Different plating potentials however, give different alloy compositions. We tried to measure the cathodic partial currents at the plating potential with the alloy as electrode and only gold or copper ions in solution. Because of changes in the electrode due to metal deposition, only the results for an alloy with approximately equivalent amounts of gold and copper are meaningful. The measured current densities at the plating potential ($E_{pl} = -0.577\text{V vs. SCE}$) in solutions containing 0.04M $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, 0.072M $\text{Na}_4\text{EDTA} \cdot 4\text{H}_2\text{O}$, 0.12M NaOH, 10^{-3}M KCN, and $7 \cdot 10^{-3}\text{M}$ $\text{K Au}(\text{CN})_2$, 0.032M EDTA $4\text{Na} \cdot 4\text{H}_2\text{O}$, 0.12M NaOH, 10^{-3}M KCN, are as follows: $i_{\text{Cu}} = 0.36 \text{ mA cm}^{-2}$, and $i_{\text{Au}} = 0.22 \text{ mA cm}^{-2}$. These values lead us to expect an alloy composition of 53 a/o Au and 47 a/o Cu which is in good agreement with what we find (51 a/o Cu and 49 a/o Au). The composition of the autocatalytically deposited alloys can therefore be deduced from the cathodic partial reactions.

Hydrogen gas analyses were performed on a gold-copper alloy with about 1.5 a/o copper in a plating solution with the composition given in Fig. 5 (a + b) and a potential of -0.470V vs. SCE . In two experiments, 0.70 and 0.73 mol hydrogen gas were measured when two equivalents of gold and copper were deposited. On autocatalytic layers with a composition of 26 a/o copper and 74 a/o gold

Fig. 3. The anodic and cathodic current-potential curves on a Au-Cu deposit with 2.5 a/o Au and 97.5 a/o Cu in solutions containing: top curve (anodic): 0.10M formaldehyde, 0.12M NaOH, 0.032M $\text{Na}_4\text{EDTA} \cdot 4\text{H}_2\text{O}$, 10^{-3}M KCN; bottom curve (cathodic): 0.04M $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$; $3.5 \cdot 10^{-4}\text{M}$ $\text{KAu}(\text{CN})_2$, 10^{-3}M KCN, 0.12M NaOH, 0.072M $\text{Na}_4\text{EDTA} \cdot 4\text{H}_2\text{O}$.

at a potential of -0.525V , we found about 0.90 mol hydrogen gas.

Discussion

In order to learn if the oxidation of formaldehyde takes place exclusively on copper or on the gold-copper alloy, we studied the reaction mechanism on the alloy. Van den Meerakker (5) found that the reaction on copper is different from that on gold.

Formaldehyde is completely hydrated in water

The hydrated formaldehyde is dissociated as a weak acid

It has been shown that the dissociated component, the methylene glycol ion, is the active reducing agent.

Fig. 4. The anodic and cathodic current-potential curves on a Au-Cu deposit with 49 a/o Au and 51 a/o Cu in solutions containing: top curve (anodic): 0.10M formaldehyde, 0.12M NaOH, 0.032M $\text{Na}_4\text{EDTA} \cdot 4\text{H}_2\text{O}$, 10^{-3}M KCN; bottom curve (cathodic): 0.04 $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$; $7 \cdot 10^{-3}\text{M}$ $\text{KAu}(\text{CN})_2$, 10^{-3}M KCN, 0.12M NaOH, 0.072M $\text{Na}_4\text{EDTA} \cdot 4\text{H}_2\text{O}$.

Fig. 5. The anodic and cathodic current-potential curves on a Au-Cu deposit with 98.5 a/o Au and 1.5 a/o Cu in solutions containing: top curve (anodic): 0.10M formaldehyde, 0.12M NaOH, 0.032M Na₄EDTA · 4H₂O, 10⁻³M KCN; bottom curve (cathodic): 0.04M CuSO₄ · 5H₂O, 1.4 × 10⁻²M KAUCN₂, 10⁻³M KCN, 0.12M NaOH, 0.072M Na₄EDTA · 4H₂O.

Atomic hydrogen is split from the adsorbed ions (5)

In a following reaction, an electron is released to the metal surface

and formate is formed in the solution. The atomic hydrogen at the metal surface can react in two ways

or

which gives an extra electron.

At a copper surface, only reaction [5] occurs, whereas on gold both reactions can take place; the ratio of the rates is dependent on the potential. Van den Meerakker (5) found on copper 100% reaction [5] and on gold at a potential of -0.500V vs. SCE 68% reaction [5] (0.68 mol hydrogen gas). During deposition of a gold alloy with 1.5 a/o copper at a plating potential of -0.470V vs. SCE , we determined 0.70 and 0.73 mol hydrogen gas. For an alloy with the composition of 26 a/o copper and 74 a/o gold (at a potential of -0.525V), we found 0.90 mol hydrogen. These results show that hydrogen gas is formed on the whole alloy and not only on the copper surface, as was suggested in Ref. 1.

A possible explanation could be that reaction [3] takes place on copper and the hydrogen atoms diffuse to the gold surface, on which reactions [5] and [6] then occur. This diffusion effect of hydrogen atoms over a large distance is called "spillover" and is mentioned frequently in recent discussions on catalysis (6). However, it is also possible that the overall oxidation reaction of formaldehyde takes place on the whole surface.

In Fig. 2, we have seen that the alloy layers have distinctive properties. Gold-copper layers do not passivate at potentials at which pure copper is oxidized. We compared the current at the plating potentials (i_M in Fig. 2) for each alloy with the current deduced from the deposition rate (i_{pl}) and found a reasonable agreement (Table I). From the current potential curve for the oxidation of formaldehyde at a pure electroless copper as electrode, we also calculated the current at the alloy plating potentials, assuming that only the copper in the alloy is responsible for the oxidation of formaldehyde and the copper atoms are homogeneously distributed throughout the layer. The resulting values (i_{Cu}) are given in the last column of Table I. The values in brackets are unreliable because pure copper is passivated at these potentials. A comparison of the calculated values with the plating rates indicates that the fraction of copper in the alloy cannot explain the low plating rates found in a range of gold-copper layers with more than 5 a/o gold (Table I).

It is possible that the concentration of copper at the surface is lower than in the bulk. The surface layer of an alloy is enriched in the component which has the lower surface free energy (7). The values for copper ($\gamma_{Cu} = 1800 \text{ mJ/m}^2$) and gold ($\gamma_{Au} = 1500 \text{ mJ/m}^2$) indicate that an enrichment of gold at the surface will take place; the effect is, however, not large (7). It is not likely that such an enrichment can explain our results. It is also possible that the copper in the alloy is less active than pure copper because of changes in the electronic structure of the metals. Since the work function of gold (5.1 eV) is larger than that of copper (4.65 eV), gold will accept negative charge from copper and the copper will be more positive in a gold-copper alloy. The electronic structure of the alloy may affect the competitive adsorption of cyanide and formaldehyde on the alloy surface. Cyanide ions inhibit the oxidation of formaldehyde on pure gold (1). Okinaka (8) has also shown that cyanide inhibits the oxidation of borohydride on gold. Horkans (9), using cyclic voltammetry, studied the effect of cyanide on the oxidation of formaldehyde on copper and gold at different potentials and found results similar to those reported in our earlier work (1). Cyanide ions poison the oxidation of formaldehyde on gold. On copper, however, higher formaldehyde currents can be sustained in the presence of cyanide. It is likely that the competition between the adsorption of formaldehyde and cyanide on the alloy determines the plating rate of the metallization.

Conclusions

In cyanide solutions, the oxidation current of formaldehyde on gold-copper alloys is lower when the alloys contain more gold. This decrease is accompanied by a shift of the passivation potential to more positive values. When the gold cyanide concentration in the plating solution is increased, the plating potentials are determined by the oxidation of formaldehyde (anodic current) and not by the deposition of gold and copper (cathodic current). The different plating potentials give a different cathodic current ratio for gold and copper. The currents at the plating potentials are generally in agreement with the plating rates, but not with the values calculated assuming that only the copper in the alloy is the active catalyst. Analyses of hydrogen evolution during electroless alloy plating lead us to conclude that hydrogen atoms are either formed on the whole alloy surface or that hydrogen atoms diffuse from the copper surface to the gold surface (spillover). It is suggested that the autocatalytic alloy deposition is determined by the competition between the adsorption of formaldehyde and cyanide on the alloy surface.

Operational Study of a Phosphoric Acid Fuel Cell with Hydrogen and Methanol/Steam

M. Ratcliff, F. L. Posey, D. K. Johnson, and Helena L. Chum*

Solar Energy Research Institute, Thermochemical and Electrochemical Research Branch, Golden, Colorado 80401

ABSTRACT

Studies were performed comparing the operation of phosphoric acid fuel cells on hydrogen and air at constant load as a function of time and after operation under other conditions, namely: (i) periodic direct injection of methanol-water vapor, simulating failure of the steam re-forming unit, and (ii) open-circuit excursion. Tests were carried out on two 3W fuel cells (Energy Research Corporation, Danbury, Connecticut). Detailed organic product analyses of condensed effluent gases of both anode and cathode reveals that trimethylphosphate, a suspect carcinogenic compound, is released. After 5-6h, direct addition of methanol/water vapor at a rate sufficient to support constant 200-100 mA/cm² performance on hydrogen (steam re-former unit assumed 90% conversion) 0.5 mg of trimethylphosphate were detected from both anode and cathode effluents. These results translate into about 10-30 ppm/h of trimethylphosphate in the anode effluent and about one-third or less of that amount in the cathode effluent stream. These results may impact *in situ* methanol re-forming in phosphoric acid fuel cells and also external reforming at low methanol steam reforming conversion.

Methanol is a likely alternative to petroleum-derived fuels (1). It can be derived from a variety of resources both renewable and nonrenewable. In particular, when fuel cell power generation is considered, methanol is an attractive fuel since its steam reforming into hydrogen and carbon dioxide is favorable thermodynamically at moderate temperatures (< 300°C). The use of steam-reformed methanol in various types of fuel cells for vehicular applications has been reviewed recently (2-5). Methanol steam re-forming coupled to a palladium membrane for hydrogen separation from carbon dioxide has been described for use with an alkaline fuel cell (6). Methanol is also the fuel selected for the development of tactical fuel cell power plants in special military applications at brigade and forward areas (7). Investigation of some aspects of methanol steam re-forming coupled to phosphoric acid fuel cells has been carried out by Landsman and Luczak (8). The economics of biomass-derived alcohol applications in fuel cells has been reviewed recently (9). This paper presents further investigations of the combination: methanol steam re-forming to a state-of-the-art phosphoric acid fuel cell (from Energy Research Corporation, Danbury, Connecticut). We have simulated periodic failures of the steam re-forming unit by adding directly steam and methanol vapor to a phosphoric acid fuel cell which was otherwise continuously operated on hydrogen and air (or oxygen). These were more drastic conditions than one would expect in the operation of a fuel cell. A practical reformed methanol fuel cell is maintained at temperature by the enthalpy difference between ΔH and $-nFV$, where V is the terminal voltage per reacting mole of fuel. If a failure occurs, the cell would be expected to rapidly cool down. The data are pertinent to the operation of a cell with lower than 100% conversion efficiency, in which case both hydrogen and vapor methanol would be added to the operating fuel cell at the operating temperature. These results are also pertinent to *in situ* re-forming of methanol in phosphoric acid fuel cells. Data concerning cell performance degradation and the nature of the organic products that can be condensed from the anode and cathode effluent gases, as well as those remaining in the phosphoric acid matrix after methanol vapor addition, are reported.

Experimental

Materials.—UHP H₂, UHP O₂, and zero air were from Scientific Gas Products. High purity methanol is used as supplied from Burdick and Jackson. H₂O was deionized and distilled. 100% H₃PO₄ was prepared from Baker reagent-grade P₂O₅ and the stoichiometric amount of H₂O. Aqueous formaldehyde, trimethylphosphate, and formic acid were reagent grade from Aldrich. Methyl formate

was Baker reagent grade. A methanolic solution of formaldehyde was obtained from Celanese.

Equipment.—The fuel cell test bench is equipped with Matheson 600 Series Rotameters to control gas flows. Temperature control of the fuel cell is accomplished with an Omega 4000 Series temperature control with a K-type thermocouple. Polarization data are read from GE 800 Series digital panel meters. Polarization is changed with variable resistors in the test circuit and a toggle switch is used to consistently go to open-circuit condition. IR-free data were obtained with a Tektronics 7613 oscilloscope. An ESC 640 coulometer was employed.

The methanol/water vapor delivery system consists of a Sage Model 355 syringe pump with one or two gastight syringes (5-25 ml) adapted through Teflon plumbing (for two syringes) into a single 11 in. long 20 gauge SS needle. This needle passes through a septum into 1/8 in. stainless steel tubing. The tubing is about 8 ft long and coiled for about 6 ft so that the vapor is always rising. A pressure gauge and relief valve are incorporated into the boiler. The entire length is wrapped with heater tape and insulation. A thermocouple is installed at the boiler outlet and controls the temperature with a Watlow controller. A temperature difference of 90°-200°C exists in the line from liquid injection point to outlet. Flow rate settings from 0.25-12 ml/h were calibrated, and gas chromatographic analyses of the condensed vapor verified the ratios of methanol/water injected (1:1.2 or 1:0.6 mole ratio). At 200 mA/cm² (5A), the cells require 1.17×10^{-1} mol/h of hydrogen (assuming a current efficiency of 80%). Injection of 1.0:1.2 mole ratio of methanol in water at 2.6 ml/h meets this fuel requirement (assuming a steam re-forming conversion efficiency of 90%). Typically, the cells are fed methanol/water vapor at 2.6 ml/h or less; most experiments used 1.0:0.6 methanol:water mole ratio to increase the collection yields.

The phosphoric acid fuel cells used were supplied by Energy Research Corporation (Danbury, Connecticut). They were constructed in late 1982 and are optimized to run on H₂ and air. Electrode area is 25 cm² with a Pt loading of ~0.5 mg/cm² on the cathode and ~0.25 mg/cm² on the anode.

Operation on H₂/O₂ or air.—Cells that had never been run were pretreated by heating to 150°C for ~16h with no gas flow on load. After that time, the cell temperature was readjusted to 190°C and the fuel and oxidant gases turned on. The cell was connected to the gas lines with 1/4 in. × 28 threads/in. connectors, and gas pressure was 20 psi. The gas flow rates were ~55 ml/min H₂, 500 ml/min air (or ~30 ml/min O₂). There were four electrical leads to the current collectors: one set for the voltmeter and the other for the load through the variable resistors and ammeter. We operated the cell at 200 mA/cm² current

*Electrochemical Society Active Member.

density most of the time. For the freshly assembled cell the open-circuit voltage was 920-980 mV with H_2/O_2 or 900-950 mV with H_2/air . When the performance was lower than these values, it generally indicated that more electrolyte (100% H_3PO_4) was needed. The cell was recharged with 0.7-1.0 ml electrolyte with a gastight syringe into the fill tube.

Operation on methanol/water/air.—The operation of the fuel cell on methanol/water was similar to that on H_2/air , with the following exceptions. Methanol/water mixtures (1:1.2 or 1:0.6 mole ratio) were prepared gravimetrically and filtered before being drawn into the syringes. The syringes were placed in the pump and connected to the Teflon tubing/20 gauge needle and the boiler was warmed to 200°C (outlet temp.). The syringe pump was then turned on and usually adjusted to 2 ml/h. The system was allowed to equilibrate for ~30 min before connection to the fuel cell. The H_2 was shut off and disconnected. The boiler was then plumbed into the PTFE anode inlet tube and insulated with glass wool. The cell exhaust tubes were routed into round-bottom flasks equipped with reflux condensers to collect the vapors yielding the condensates for analyses. Alternatively, the exhaust tubes were immersed in round-bottom flasks filled with saturated barium hydroxide to precipitate the CO_2 evolved.

Data analysis.—The current voltage polarization curves were analyzed through a multiple linear regression analysis on a Hewlett-Packard Model 85 computer.

Identification and quantitation of effluent compounds.—Carbon dioxide from anode and cathode effluents was determined by passing the gases through solutions of saturated barium hydroxide. The $BaCO_3$ formed was filtered, washed with deionized water, and dried in a vacuum desiccator to constant weight.

Condensed organic volatile components were identified by mass spectroscopy. Mass spectral data were obtained on a Hewlett Packard 5985 GC/MS using both direct insertion and a packed column coupled to the mass spectrometer (electron-impact mode). In the direct insertion mode, the initial probe temperature was 25°C. This temperature was held for 5 min, after which the probe was heated to 250°C at 5°C/min. The following organic products have been detected (numbers in parentheses are the major mass peaks in the mass spectrum, electron-impact mode): formaldehyde ($m/z = 30, 29, 28$); methanol ($m/z = 32, 31, 29$); methylformate ($m/z = 60, 31, 29$); dimethoxymethane ($m/z = 75, 45, 29$); formic acid ($m/z = 46, 45, 29$); another possible compound detected was hydroxymethoxy methane ($m/z = 62$). In addition, trimethylphosphate was detected [$m/z = 140, 110$ (major) 96, 80, 79]. The best separation and resolution of peaks of the organic products was achieved with a 6 ft \times 1/4 in. glass column packed with a 50/50 mixture of Porapak QS and Porapak T, 80/100 mesh. The column was held at 120°C for 2 min then heated to 240°C at 20°C/min. Quantitation for all organic materials except trimethylphosphate was performed on the Varian 3700 gas chromatograph equipped with a VISTA 401 data acquisition system. The internal standard was dioxane. Helium flow rate was 25 ml/min. Thermal conductivity detector was MA:206. Quantitation of trimethylphosphate was performed on the mass spectral data from the Porapak QS/T column described above under the same conditions. Amounts were determined by the internal standard method using areas of selected ion peaks monitored by the system computer (see examples in Fig. 1). Errors in the quantitation are $\pm 10\%$ (GC) and $\pm 30\%$ (single-ion monitoring technique) due to the small amounts of the compounds.

GC and mass spectral assignments were verified by injecting the authentic pure compounds and comparing their retention times and fragmentation patterns with those of the condensed products. The library editor program for probability-based search of the HP5985 GC/MS system was also used in the identification of the condensed products. The probabilities of correct identifica-

Fig. 1. Examples of single-ion monitoring of condensed anode (A, B) and cathode (C, D) effluent streams. Trimethyl phosphate ions: $m/z = 110$ and 140. Dioxane (internal standard): $m/z = 88$. TI = total ion. Injection of methanol/water vapor at 1:0.6 mole ratio at 2 ml/h for A and C: 7h and B and D: 5h.

tion of the various compounds ranged between 0.997 and 0.9999 (both in the standards and condensed effluent streams).

After cell shutdown, the phosphoric acid and possible esters were washed out of the silicon carbide matrix with D_2O and the proton NMR spectrum obtained. The spectrum obtained consists of one major doublet (3.63 ppm, $J = 11.2$ Hz) and another doublet of smaller intensity at 3.58 ppm ($J = 10.8$ Hz). The second doublet is probably due to the partially esterified products. Trimethylphosphate in D_2O presents a doublet (3.70 ppm, $J = 11.2$ Hz). (These chemical shifts are accurate to ± 0.05 ppm.) Under these conditions polyphosphates would most likely have hydrolyzed. Phosphorus NMR measurements confirmed the proton assignments.

Results and Discussions

Single cell performance.—A typical polarization curve of cell no. 1 is shown in Fig. 2 for hydrogen and air (or oxygen). The open-circuit voltage and the voltage on constant load to generate 200 mA/cm² as a function of time are displayed in Fig. 3. Also indicated in Fig. 3 is one period of 48h during which the cell was submitted to open circuit, a common condition in vehicular applications. After 120 days of operation on constant load, injec-

Fig. 3. Open-circuit voltage and voltage under load to produce 200 mA/cm² of fuel cell no. 1 as a function of time. Addition of phosphoric acid is represented by ∇. At *, the cell was left for 48h in open-circuit conditions. Cell temperature: 190°C.

tion of methanol/water vapor at 190°C was interspersed with operation on hydrogen (12 periods of ~6h [from 4 to 7h] over 35 days), as shown in Fig. 4. The amount of methanol added approximated that required to maintain 200 mA/cm² after steam re-forming (assumed 90% conversion). The upper curves display the open-circuit voltage and voltage on load on hydrogen and air. The lower curves indicate open-circuit voltage and voltage on load on methanol/water vapor and air. The second cell was also oper-

ated on constant load at 200 mA/cm² on hydrogen and air (or oxygen) except for ten (total 54h) periodic injections of methanol/water vapor in variable amounts (from equivalent amounts to produce 200-50 mA/cm²) over a period of 60 days (Fig. 5). Figure 6 shows an example of a polarization curve on CH₃OH/H₂O. In addition, one ethanol/water vapor injection was attempted. The cell performance on ethanol was much poorer than that shown for CH₃OH/water vapor in Fig. 6. After the ethanol addition, the anode was steamed to remove residual ethanol and methanol (air was continuously fed to the cathode). A substantial performance recovery of the anode was observed after steaming. After this experiment, four additional runs on methanol/water vapor were performed for collection of condensable products.

The cell voltage (V) can be expressed as a function of current density (i) by the equation

$$V = V_r - \frac{RT}{\alpha_a F} \ln \frac{i}{i_{0,a}} - \frac{RT}{\alpha_c F} \ln \frac{i}{i_{0,c}} - iR_i \quad [1]$$

assuming that the concentration overvoltage is negligible (10). V_r is the thermodynamic reversible voltage, α_a and α_c are the transfer coefficients, $i_{0,a}$ and $i_{0,c}$ the exchange current densities of the anodic and cathodic reactions, and R_i is the internal resistance of the cell. Equation [1] can be reduced to

$$V = A - B \ln i - iR_i \quad [2]$$

where

$$A = V_r + \frac{RT}{\alpha_a F} \ln i_{0,a} + \frac{RT}{\alpha_c F} \ln i_{0,c} \quad [3]$$

and

$$B = \frac{RT}{\alpha_a F} + \frac{RT}{\alpha_c F} \quad [4]$$

Fig. 6. Current-voltage polarization curve of cell no. 1 operated on direct methanol/water vapor added at 190°C in 1.0:1.2 mole ratio at 6 ml/h. ○: IR_1 -corrected measurements.

The values of A , B , and R_i were calculated by multiple linear regression analysis, and they are assembled in Table I. The value of A leads to an approximate value of the cathodic exchange current since the overpotential for hydrogen ionization is very small compared to that for oxygen reduction. For the same reason, the value of B effectively represents the Tafel slope for oxygen reduction. Larger experimental errors were associated with measurements of H_2/O_2 cells and those exposed to prolonged exposure to MeOH/ H_2O injection.

From Fig. 3, one can observe the performance degradation of cell no. 1 as a function of time compared to that

obtained after one period of 48h in open circuit. After 65 days on constant load, one observes degradation equivalent to that in the single open-circuit excursion. Similar faster degradation was observed after the periodic additions of methanol/water vapor, as shown in Fig. 4. When switching from the alcohol/water vapor fuel to hydrogen at the beginning of the test, voltage values at load recovered quickly (within a few minutes), and the voltages were stable. Towards the end of the test, the voltages were much less stable.

From the data in Table I, one can observe that, whereas the values of B are constant within the experimental errors, the values of A (± 10 mV), related mainly to the exchange currents, decrease faster both as a result of the open-circuit excursion and of methanol addition. At the same time the cell resistance increased 30%-40%. The decrease in A value is probably a result of the anode catalyst degradation possibly due to site reorganization and poisoning by the methanol oxidation intermediates. In addition, catalyst sites at the cathode are used in the chemical oxidation of methanol with air. Such utilization can lead to cathode catalyst degradation as well. The increased cell resistance is a result, among other factors, of trimethylphosphate (or methylpolyphosphate formation), which would contribute to the decreased conductance of the phosphoric acid electrolyte.

These trends were confirmed with the experiments using the second cell. This cell exhibited higher open-circuit voltages and A values; however, the initial cell resistance was 45% higher than that in cell no. 1 and increased significantly with addition of methanol/water vapor during one month (see Table I and Fig. 5). It is interesting to notice the remarkable performance recovery of the cell after steaming the anode. A values increased ~ 50 mV (cf. 10/11/83 with 9/26/83 data).

Collection of condensed products.—In most of the experiments described above, with addition of methanol/water vapor at constant load, the effluent gases from anode and cathode were condensed and analyzed. Initially, this test was performed on hydrogen/air to estimate the fraction of water vapor that can be effectively collected under our experimental conditions; 70% of the theoretically expected amount of water was condensed.

Direct injection of methanol/water vapor into a phosphoric acid fuel cell causes the following reactions to occur

Table I. Analyses of voltage-current density measurements of H_2 /air or oxygen fuel cells no. 1 and no. 2 according to $V = A - B \ln i - iR$

Other chemical reactions at the cathode:

through partial oxidations

In situ re-forming, $\text{CH}_3\text{OH} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 3\text{H}_2$, would not be favored under the experimental conditions.

Through GC and combined GC and MS (see experimental section) analytical techniques and NMR, we have evidence for reactions [5]-[11], [16], and [17].

Quantitation of reactions [5] and [16] is shown in Table II based on the precipitation of evolved carbon dioxide as barium carbonate. A comparison of the charge (current \times time) and that estimated from carbon dioxide evolution in the anode indicates that the mass and charge balance agree within 10%. The cathode released CO_2 indicates the amount of methanol which reaches the cathode and is chemically oxidized by oxygen in the presence of the catalyst. As seen from Table II, the higher the amount of methanol injected, the higher proportion of chemical oxidation. For instance, the ratio of methanol injected is 1:2:8 from C:B:A; it is closely followed in the amount of millimoles of carbon dioxide collected in the cathode. These two reactions account for 30% (A) to ~58%-65% (B and C) of the methanol injected. In parallel experiments, we have determined that 20%-30% of the excess methanol

can be condensed according to our experimental procedure. Therefore, we can account for 50%-70% of the methanol added, which compares well with the 70% recovered water from similar experiments on hydrogen and air.

The other organic intermediate products are present in small concentrations, in agreement with Landsman and Luczak (8) except for trimethylphosphate, which was not detected by these authors using infrared absorption spectroscopy. We positively identify trimethylphosphate both in the anode and cathode effluent streams and in the electrolyte matrix. Examples of the concentrations of the various organic compounds detected are shown in Table III.

Conclusions

The above results indicate that the 3W cell releases on the average a total of 4×10^{-3} mmol of trimethylphosphate, 88% of which is present in the anode effluent stream. This number represents ~0.56 mg of trimethylphosphate condensed after ~5h of addition of 195-295 mmol of methanol in an average of 6 milliliter of anode and cathode condensate. Since the collection efficiency of these experiments is ~70% for chemicals with lower boiling points (~100°C), it is expected that most of the trimethylphosphate was condensed, since its normal boiling point is 198°C. For experiments 6 and 9 described in Table III, our analytical results translate into approximately 10 and 30 ppm/h of trimethylphosphate in the anode effluent stream. The cathode stream effluent is estimated releasing one-third or less of that compound per hour.

Trimethylphosphate is a suspected carcinogenic compound. Some literature is available to date.¹ Our results show that this chemical could be released when cells are operated at 190°C when methanol vapor is added to the cells.

A large concentration of trimethylphosphate (see NMR data) and possible methylpolyphosphates is present in the electrolyte matrix. Ester formation could lead to power loss due to increased cell resistance. Benefits of steaming the anodes were derived, possibly by driving some of the excess alcohol from the cell.

Additional data for carcinogenicity of trimethylphosphate are necessary. Studies of the equilibria of ester formation in 100% phosphoric acid are underway, as well as the ester formation at lower level additions of methanol vapor simulating operating conditions (*e.g.*, 80% conversion efficiency in the presence of hydrogen).

A Close View of Gas Evolution from the Back Side of a Transparent Electrode

Paul J. Sides*,¹ and Charles W. Tobias**

Materials and Molecular Research Division and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Oxygen evolving on a transparent tin-oxide anode in aqueous potassium hydroxide was photographed by a high-speed motion-picture camera capable of 10,000 frames per second. With illumination by fiber optics and use of a microscope, sharp images of the emergence, growth, and coalescence of bubbles were obtained with a resolution as small as 1 μm . Bubbles grew by diffusion of oxygen and by coalescence with other bubbles still attached to the electrode. Detached bubbles in some cases reattached. Coalescing and detaching bubbles caused significant fluid motion close to the electrode surface. Bubbles in general were evolved in a cycle of growth by diffusion and various modes of coalescence.

Electrolytic gas evolution represents a significant and complicated problem in many electrochemical processes and devices. In spite of its scientific interest and economic importance, the physics of gas-bubble behavior is not well understood. The sequence of events in gas evolution can be divided into three stages: nucleation, growth, and detachment. Bubbles nucleate at electrode surfaces from solutions highly supersaturated with product gas, grow by mass transport of dissolved gas to the bubble surface or by coalescence with other bubbles, and detach from the electrode when forces pulling the bubbles away overcome the surface forces of adhesion. Many phenomena of gas evolution within each of these stages have been theoretically and experimentally investigated, but much remains to be understood.

Nucleation theory has been advanced for vaporization of pure substances (1) and for nucleation of bubbles from solutions containing dissolved gas (2, 3). Boiling nucleation on solid surfaces has been investigated (4) and reviewed (5), but there have been few studies of nucleation of electrolytically evolved bubbles. Westerheide and Westwater (6) reported that nucleation occurred at preferred sites such as pits and scratches on the electrode, and Janssen and Hoogland (7) observed that bubbles nucleated on a rotating platinum wire at specific sites which depended on pretreatment as well as current density. Other than the notable role of surface imperfections for nucleating bubbles, little is known about nucleation at an electrified interface.

The growth stage of gas-bubble evolution includes the mass transport of dissolved gas to the gas/liquid interface and the coalescence of bubbles to form larger bubbles. Scriven (8) gave a general analysis of the transport of dissolved gas to the bubble surface, which incorporated the approximate solutions of others, such as Plesset and Zwick (9) and Forest and Zuber (10). Using a microelectrode and a high-speed camera, Westerheide and Westwater (6) photographed single electrolytic hydrogen bubbles and quantitatively compared their growth data to the diffusive square-root-of-time growth dependence that is the result of the theoretical studies. They found agreement for a single bubble, but multiple bubbles interfered with each other's growth. Nevertheless, this work established diffusion of gas to the bubble surface as at least the initial mechanism by which bubbles grow. Of course, bubbles in practical gas-evolving processes stir the electrolyte close to the electrode and enhance mass transport to each other; nevertheless, diffusion is probably the controlling mechanism up to a bubble size of 1 to perhaps 10 μm , depending on the current density. Glas and Westwater (11) extended this work to include oxygen, chlorine, and carbon dioxide and various electrode materials.

The importance of mass transfer in the initial stage of growth being established, other investigators reported the equal significance of coalescence in gas evolution. Janssen and van Stralen (12) observed bubbles of oxygen evolved in aqueous potassium hydroxide on a transparent nickel electrode; photographing at 70 frames per second (fps), they observed frequent coalescence, lateral mobility of bubbles still attached to the surface, consumption of small bubbles by large ones at high current density, and a radial movement of small bubbles toward large ones. Putt (13) reported that hydrogen bubbles produced in acid grew large by a scavenging mechanism in which the bubbles slid along the electrode and consumed other smaller bubbles. One concludes from these studies that coalescence may largely determine the bubble size and that several modes of coalescence may be involved.

The third stage in the physics of gas evolution, detachment, also has been theoretically and experimentally investigated. Frumkin and Kabanov (14) found that bubbles detach when surface adhesive forces, related to bubble-contact angles, can no longer restrain them. In contrast to these equilibrium measurements, Westerheide and Westwater (6) observed the dynamics of gas evolution and noted that the bubble resulting from the coalescence of two large bubbles jumped off the electrode and sometimes even returned. They concluded that the expanding boundaries of the new bubble mechanically forced it off the electrode, and they speculated that bubbles' movement toward the electrode could be influenced by electrostatic forces operating on a moving bubble or by surface forces varying with concentration. Other investigators (13, 12) have also noted that coalescence often precedes departure. In an unusual and as yet unexplained mode of detachment, bubbles sometimes were ejected from the electrode in what Glas and Westwater (11) termed "rapid-fire emission." Janssen and Barendrecht (15) observed that hydrogen bubbles formed trains of noncoalesced small bubbles which left the electrode. Although the forces holding a bubble on the electrode at equilibrium and the role of coalescence in breaking bubbles away are established, the criteria or kinetics by which one may judge whether a given coalescence will lead to detachment or not are unclear; furthermore, the return of a detached bubble to the electrode surface and the rapid emission of bubbles await explanation.

The aim of our work was to photographically document bubble phenomena and to use these observations, in conjunction with the bewildering number of observations found in the literature, to establish an overall mechanism of oxygen-bubble growth and detachment in basic solutions. We used special techniques and materials to accomplish this because the events on gas evolving electrodes are microscopic, rapid, and obscured from the camera by the outer bubbles of the gas layer on the surface. Magnification and a high-speed camera can overcome the first two difficulties; we used a transparent electrode to over-

¹ Present address: Department of Chemical Engineering, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213.

come the third obstacle by viewing the phenomena close to the surface from the back side. Such an electrode also permits the microscope objective to approach the electrode without shielding it from current or affecting the dynamics at the surface. Furthermore, the electrode transmits light directly into the camera through the electrode, an important advantage when filming at high framing rates. The tin-oxide electrode used in this work transmitted essentially all of the incident light so that much faster framing rates could be used than were previously possible.

Experiments

We employed a $0.2\ \mu\text{m}$ antimony-doped film of tin oxide chemically vapor deposited on a 2 mm-thick glass substrate as a transparent electrode.² The electrode was incorporated into a cell which allowed electrical contact to parts of the surface but sealed off the contacts from the electrolyte. A cross section through the cell, shown in Fig. 1, shows two basins filled with silver epoxy for electrical contact to the "window electrode," the channel containing electrolyte, and the electrode itself which faces both silver epoxy and the electrolyte. The basins were sealed from the channel opening with insulating epoxy. The cell is shown in Fig. 2, which shows how the 2 cm square piece of the tin-oxide electrode fits into the opening in the Lucite body. The clear area in the center is where the electrode faces the electrolyte channel which was 0.3 cm wide, 0.5 cm deep, and 1.9 cm long. The wires leading out are copper electrical contacts. Because there was significant resistance in the tin-oxide film, the distance between the two contacts (of same polarity) on either side of the electrolyte channel was made as small as was practical for lowest resistance, easy departure of the bubbles, and avoidance of wall effects. There were holes leading out through the top and bottom of the cell for adding electrolyte and directing gas out of the cell. The counterelectrode was a platinum wire placed above the vertically positioned electrode so that gas evolving on it did not interfere with observation of the working electrode gas.

The arrangement of the apparatus is shown in Fig. 3 and 4. Intense light from an Ealing Corporation Model 22-0004 fiber optic light source passed through a clear Lucite plate which faced the window electrode across the channel of electrolyte. Images were magnified by a Bausch and Lomb microscope ($10\times$ objective and $15\times$ eyepiece) and received by a Red Lakes HYCAM high-speed camera. The 16 mm movie frame bounded an area 0.6 mm on a side as determined by photographing a calibrated microscope slide. Capable of framing rates from 10 to 10^4 fps, the camera accepted 100-400 ft rolls of KODAK TXR 430 high-speed camera film. Illuminated by a 250W slide-projector lamp, the fiber optic tip was placed 1 cm from the cell back and the power was turned on full. This transmitted enough light to produce clear images at film rates of around 10^4 fps after traveling through 1 cm of Lucite, electrolyte, and glass.

The cell was filled with aqueous potassium hydroxide from a reservoir above it and drained to a flask below. The electrode, polarized positively to produce oxygen, did not withstand electrolysis in acid or sodium chloride, but it performed well in alkaline solution; hence, oxygen was the only product investigated. When the microscope was focused, the distance from the camera to the eyepiece was set every time to the same length for optimum exposure of the film. An AMEL Model 551 potentiostat operated in galvanostatic mode provided the power for the reaction. After power was applied, the camera was manually activated and 400 ft of film was exposed in 5s; at the standard projection rate of 24 fps, 16 min is required to view the events. Many reels of film were taken

²Dr. Werner Kern at RCA Laboratories donated samples which had a film conductivity of $100\ \Omega/\square$. This unusual unit, used by thin film specialists, derives from the fact that the surface resistance of a square (measured from one side of the square to the other) is independent of the square's dimensions.

at various speeds and concentrations of aqueous potassium hydroxide (21).

Results and Discussion

The tin oxide proved to be an effective window electrode that was stable to oxygen evolution in basic solution. It was not stable to chlorine evolution in neutral solution or, for obvious reasons, hydrogen evolution.

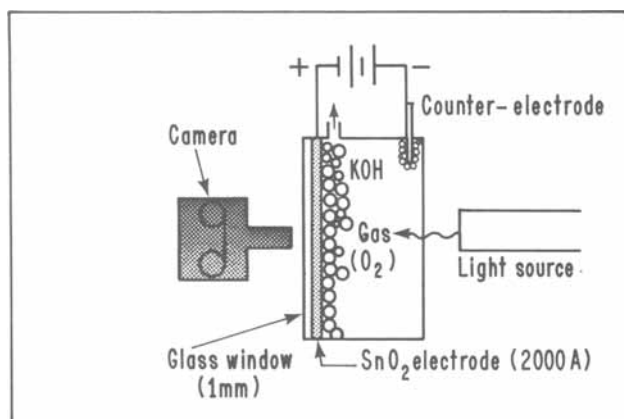

Fig. 3. Schematic of observation apparatus

Fig. 4. Apparatus: (1) fiber optic light guide; (2) transparent electrode cell; (3) microscope; (4) Red Lakes HYCAM camera.

Despite the electrode's unusual properties of electronic conductivity and transparency, gas evolution on it had much in common with observations reported in the literature, thus it seems valid to draw general conclusions from its behavior. To study gas evolution quantitatively, one should know the local current density and, hence, the local gas-volume production rate; but the current distribution on the tin-oxide transparent electrode was nonuniform because of the surface resistance to current flow in the oxide film. Of course, electrode kinetics, especially serious in the case of oxygen evolution, mitigate the nonuniformity of the current distribution. In addition, the initially higher current density at the electrode/wall boundary produced bubbles that stuck there and further deflected the current to the center, where the pictures were taken. For these reasons and because direct observation did not indicate that the gas evolution rate at the point of observation was significantly different from other positions on the surface, the step of solving Laplace's equation in the electrolyte and on the semiconductor strip bounding it, which itself would be an approximation because the presence of bubbles, which introduces a formidable mathematical complexity, disturb the current distribution even further, was not taken. The current density was calculated as an average of the total current over the area of the electrode. The results are reported qualitatively.

The intense fiber optic light penetrated the bubbles' spherical caps but was deflected by the curved sides; thus, the image was a two-dimensional dark annulus as shown in Fig. 5. An additional light pointed at the cell from the side gave the bubble a highlight and made it appear three-dimensional. Difficult to describe in words and still pictures, the growth process of bubbles is best viewed continuously; a 30 min motion picture summarizing the transparent-electrode studies may be obtained for viewing by contacting either of the authors.

Movies taken at the standard speed, 24 fps, showed only blurred motion, but slowing the action by a factor of 10 revealed many of the phenomena reported in previous work, such as the preference for nucleation at surface imperfections and rapid initial growth by mass transfer where the bubble expanded with no apparent coalescences. Most interesting was the frequent bubble coalescence and the detachment of bubbles from the electrode. Identification, documentation, and organization of bubble growth and detachment phenomena are the core of this work.

Fig. 5. Documentation of specific radial coalescence. The indicated bubble at time zero receives the four bubbles around it sequentially and visibly grows. One may observe this same effect around other bubbles in the sequence. Conditions: 10,000 frames per second; oxygen evolution; 298 K; no forced convection; 3% (wt) KOH; 500 mA/cm².

Coalescence of very small bubbles ensued after rapid initial growth by diffusion and marked the start of the coalescence phase of bubble growth. Bubbles nucleated, grew to a small size (<10 μm) by mass transfer and, upon touching, rapidly coalesced. There was no period of delay before the small bubbles in contact coalesced. Since coalescence between small bubbles and establishment of the final spherical boundary was always completed within 0.0001s, we never obtained images of intermediate stages. Although small bubbles coalesced almost immediately upon touching, large bubbles touched for many frames before coalescing. Perhaps the small newly formed bubbles did not have film stabilizing compounds adsorbed at their surfaces as did the large older ones. The bubble size in general depended on the number of coalescences, which means that one can limit bubble growth by controlling coalescence, that is, by removing the bubbles before they coalesce or somehow stabilizing the liquid film between the two touching bubbles so it cannot rupture.

Bubbles of a medium size, about 40 μm , established themselves as central collectors which received the smaller bubbles nucleating and growing around them. We call this "radial specific coalescence," a schematic of which appears in Fig. 6. The smaller bubbles translate radially across the electrode surface toward stationary central bubbles, two of which are represented in the schematic. A film sequence recording this mode of coalescence appears in Fig. 5. Small bubbles, while still attached, moved specifically in the direction of and coalesced with the medium bubble (at the arrow in Fig. 6) in whose sphere of influence, extending about three bubble diameters from the collector bubble, they were located. The central bubble swelled with the addition of the smaller bubbles but was not otherwise disturbed as it acquired them. Although there was an overall flow impressed on the system by movement of the buoyant bubbles, the radial movement of bubbles was symmetric 360° around the collector bubble, which remained anchored to the electrode; hence we concluded that the radial motion is a local phenomenon. The movement may have been a result of local flows established by continual coalescence, which entrains other bubbles toward the collector. Requiring a transparent electrode to be revealed, this phenomenon was also observed only by Janssen and van Stralen (12) on their transparent nickel electrode.

After the medium-size bubbles attained a size between 50 and 100 μm , large bubbles still attached to the surface and sliding from below the field of view scavenged them

Fig. 6. Schematic of specific radial coalescence

or coalesced between themselves and moved out of view. (The bubbles' flattened areas of attachment were visible from behind the transparent electrode.) Scavenging of medium bubbles by large ones was the third mode of coalescence observable on the transparent electrode and was the mechanism by which bubbles attained their final size. A film clip, Fig. 7, demonstrates that after a group of large bubbles passes, new bubbles nucleated and grew to a size of 10-15 μm in diameter. These small bubbles coalesced to form medium-size bubbles which then grew further by specific radial coalescence. Large bubbles (200 μm) attached to and moving along the surface scavenged the small- and medium-size bubbles in their path.

We term this sequence of events (nucleation, growth by mass transfer, coalescence of small bubbles, coalescence by radial motion, and scavenging coalescence) the cyclic process of bubble growth because it is repeated continu-

Fig. 7. Gas evolution slowed by a factor of 10. (1) Dispersion of small bubbles which grew on the electrode after a group of large bubbles swept through. (2) Several large bubbles travel along the surface and scavenge the small- and medium-size bubbles before them. (3) Empty area behind a large bubble showing its path. (*) Trail left by earlier scavenging bubble. Conditions: 240 frame per second; oxygen evolution; 298 K; no forced convection; 28% (wt) KOH; 100 mA/cm².

ally on the electrode and is the general way bubbles are "built." The period of the cycle, at a current density of 100 mA/cm², was approximately 0.1s. We hypothesize that this gas evolving electrode, and perhaps practical electrodes, are essentially a mosaic of regions in which this local mechanism governs the production of bubbles. Of course, this cannot be true for electrodes on which coalescence does not occur and can only be partly true for electrodes on which the bubbles are not mobile. If this cyclic mechanism of bubble evolution is valid, then modeling the mass-transfer enhancement due to bubble evolution is indeed a formidable task. In fact, the complexity of fluid motion induced by bubbles perhaps explains the divergent views on the model for mass-transfer enhancement.

Detachment of a bubble from the transparent electrode was also observed. Characterizing the detachment of a bubble from a vertical electrode is difficult because the buoyancy force does not act perpendicularly to the electrode; the only force continuously pushing the bubble away from the surface (at equilibrium) is exerted by the internal pressure of the bubble against the flattened bubble base. The sequence shown in Fig. 8 indicates that coalescence of two bubbles to form a new bubble, which being compressed against the electrode pushes away from it, is an important mechanism by which bubbles depart from vertical electrodes. This confirms the observation of Janssen and van Stralen (12). As mentioned by other investigators, especially by Glas and Westwater (11), the bubble, once detached, may return. This occurred on the tin-oxide electrode also. One can see the contact area under the bubbles in Fig. 8 as a slightly darkened spot on the left side of the light central area. When the bubbles coalesced and the new bubble had ceased its violent vibrations and had established its spherical boundary, the contact spot vanished but subsequently reappeared. Unfortunately, the still pictures cannot convey the impression one obtains from the motion pictures that there was indeed some kind of force which brought these oxygen bubbles back to the electrode because the bubble seemed to push its way back to the surface. Coehn and Neumann (23, 24) would argue that the return to the electrode was caused by the attraction of the charged bubble to the electrode surface. Glas and Westwater (11) speculated that a surface tension gradient caused the bubbles' return. A third possibility is that the bubble was still oscillating after the coalescence and then reattached when one part

Fig. 8. Detachment and return of a bubble after coalescing with another bubble. 1) A bubble on the electrode touches another off the frame to the left. 2) The two bubbles coalesce. 3) The new bubble is off the surface. There are small bubbles on the surface between the large bubble and the surface. 4) The bubble has reattached. Conditions: 10,000 frames per second; oxygen evolution; 298 K; no forced convection; 3% (wt) KOH; 500 mA/cm².

Fig. 9. Coalescence of two bubbles and subsequent vibration of the new bubble ($100 \mu\text{s}$ per frame). 1) Two bubbles touch for a number of frames while the film drains from between them. 2) The resulting bubble is compressed against the electrode. 3) The new bubble vibrates as it establishes its equilibrium boundaries. 4) The oscillations end after a half-millisecond. Conditions: 10,000 frames per second; oxygen evolution; 298 K; no forced convection; 28% (wt) KOH; 100 mA/cm^2 .

of it touched the electrode. The detachment and return of bubbles should be explored specifically.

The coalescence of large bubbles caused fluid motions close to the electrode surface, which may be important in mass-transport enhancement due to gas evolution reported by Ibl (22), Venczel (16), and Janssen and Hoogland (18). This mode joins the flow due to gas lift and fluid replacement due to bubble departure as an accelerator of mass transfer. A coalescence sequence between two large bubbles near the electrode and moving along it is shown in Fig. 9. The two bubbles appeared to touch for many frames as the film between them thinned and finally ruptured. The bubbles coalesced so quickly that the film rupture and the change from two bubbles to one occurred between two frames, that is, in less than $100 \mu\text{m}$. The new bubble was compressed along the axis of coalescence by the fluid rushing into the space behind the coalescing bubbles. The bubble vibrated like this for several frames before becoming spherical again. This is an example of coalescence of two relatively large bubbles, both traveling along the electrode surface.

Summary

The tin-oxide transparent electrode allowed observation of oxygen evolution in potassium hydroxide from the back side, a vantage from which to view the rapid and microscopic phenomena of gas evolution. Our study confirmed certain of the phenomena reported in the literature. Coalescence was most important in the overall process of gas evolution. The cycle of growth by mass transport and local coalescence followed by scavenging

coalescence determined bubble size on vertical electrodes. Small bubbles moved radially in toward a medium-size central bubble and coalesced with it; the new bubble in turn was scavenged by large bubbles moving along the surface. Coalescence also was important in bubble detachment. Some bubbles returned to the surface after leaving. In general, gas evolution on this electrode resembled a mosaic of local cycles of growth and detachment, the dimension of the localities being an order of magnitude greater than the largest bubbles.

The Reversibility of Sodium Insertion in Transition Metal Trisulfides

Margherita Zanini

Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The effects produced by the insertion of sodium in the trisulfides of titanium, niobium, and tantalum were investigated by electrochemical techniques. Cyclic voltammetry measurements were carried out in these materials using high-temperature sodium cells which utilize the solid electrolyte β' -alumina. The data demonstrate that TiS_3 disproportionates into TiS_2 and sulfur during the first cycle. NbS_3 appears to gradually undergo irreversible transformations which decrease the amount of sodium that can be reversibly inserted. TaS_3 was found to be more stable. The transformations induced in the trisulfides by electrochemical titration with sodium are discussed in terms of the structural and chemical bonding properties of these materials.

Compounds that can react with alkali metals with a large free energy of reaction are potentially useful for battery applications (1, 2). The requirement that the process be readily reversible has put a premium on these reactions (called topochemical), which occur without appreciably modifying either the structure or the chemical bonding of the host material.¹ Typical examples are the layered transition-metal disulfides in which alkali metals are inserted between the weakly bonded layers of the compound (1). Because these intercalation compounds usually form nonstoichiometric phases with a wide compositional range, their energy density is large.

Many efforts have been devoted to finding other materials which meet the reversibility requirements, but for which the reaction product contains a ratio of alkali metal to transition metal of 2 or 3 in order to achieve larger energy densities (3). It was recognized early that materials such as TiS_3 and NbSe_3 could incorporate up to three lithium atoms per formula unit (4, 5). However, it was found that only about one-third of the lithium incorporated in TiS_3 could be removed (6). The reaction was found to be reversible in NbSe_3 , but although its volumetric energy density was large, its gravimetric energy density was comparable so that of TiS_2 (7). Past studies have not fully explained why different trichalcogenides show different degrees of reversibility for the reaction with lithium. Tests of the charge/discharge behavior of these compounds under galvanostatic conditions have indicated that the reaction with lithium is more complex than a topochemical reaction and induced structural transformations in the host materials. Unfortunately, x-ray diffraction measurements of the reacted trichalcogenides have typically shown patterns of weak and broad lines which hamper the complete identification of the reaction products.

In this paper we report electrochemical studies on the effects produced by the insertion of sodium in the trisulfides of titanium, niobium, and tantalum. The reaction was carried out by electrochemical titration in high-temperature sodium cells which utilize the solid electrolyte β' -alumina (8). Because β' -alumina is stable in the potential range of the experiment, we have been able to study the process without interference from side reactions with the electrolyte, and in addition we have avoided the problem of electrolyte cointercalation. We discuss how cyclic voltammetry measurements allow us to detect the occurrence of phase transformations in the electrode material with higher sensitivity than possible with conventional galvanostatic measurements. We also show that the reaction products for TiS_3 can be identified with this technique.

The electrochemical behavior of the trisulfides in sodium cells is shown to be profoundly different from that of the corresponding disulfides because sodium strongly interacts with the polysulfide group $(\text{S}_2)^{-2}$, which is characteristic in these materials. Our cyclic voltammetry data indicate that structural and chemical transformations oc-

cur in these materials, but the effects are dissimilar in each compound. XPS measurements of the sulfur 2p core level for the trisulfides are reported which indicate that the sulfur bonding characteristics in TaS_3 may be different from those of TiS_3 and NbS_3 . The observed chemical bonding differences can be correlated with the different behavior of the trisulfides upon electrochemical titration with sodium.

Sample Preparation

Titanium trisulfide was prepared by direct reaction between sulfur granules (Asarco) and titanium powders (Cerac mesh -325) in sealed quartz ampuls. A small sulfur excess above the stoichiometric composition was used. The ampul was then inserted in a two-zone furnace. The temperatures in the two zones were adjusted so that one end of the ampul was kept at 440°C to avoid high sulfur vapor pressure, and the other end with the metal powders was kept at 560°C. Formation of the undesired disulfide phase was observed if the reaction was carried above 570°C. When the powders had reacted, the temperature of the colder zone was raised to 500°C and the material was annealed for three days. The ampul was then cooled slowly, maintaining the temperature gradient to deposit the small excess sulfur at one end. In this way, blue-gray ribbons of TiS_3 were obtained, and the largest were roughly 1 cm long and 0.5 mm wide.

NbS_3 and TaS_3 were prepared in a similar way, starting with Cerac metal powders of -325 mesh. The temperature in the reaction zone was kept at 600°C for NbS_3 and at 650°C for TaS_3 , while the cold zone was maintained at 440°C in both cases. TaS_3 grew as a light felt of fine and short fibers which filled the inside of the ampul. NbS_3 also grew as fine needles, but with excess sulfur we were also able to obtain long, flat ribbons, similar to TiS_3 . The lattice constants of the synthesized trisulfides were derived by x-ray diffraction analysis of powder samples and were found to be in agreement with the data in the literature.

Experimental

The cells used for the electrochemical experiments were made of alumina tubing at the end of which a disk of β' -alumina was sealed with a soft glass. The other end of the ceramic tubing had a ceramic-to-glass transition so that sodium could be vacuum distilled in the container and sealed off. The temperature of the cell was measured with a shielded thermocouple sealed in the sodium compartment, with its tip close to, but not touching, the β' -alumina disk.

The positive electrode was made by pressing transition-metal sulfide fibers on a disk of thin aluminum foil with a die. Upon pressing, the fibers became a compacted felt with a geometrical surface area of 0.1-0.2 cm². The felt stuck slightly to the aluminum foil, which made the handling of the electrode easier. Typically, a few tenths of a milligram of active material were used for the electrode.

The precise amount was determined with an electronic balance by weight difference between the aluminum substrate alone and the pressed electrode. The electrode was then put in the center of a flexible aluminum cup which fitted the ceramic half-cell so that it could be easily positioned against the electrolyte. Contact between the solid electrode and the electrolyte was achieved by slightly pressing the aluminum cup with a flat, rigid cup holder. To apply the pressure, the ceramic half-cell was rigidly mounted by means of a metallic collar into one end of a threaded cylinder made of steel. A spring-loaded plunger was then screwed into the other end of the cylinder so that it pushed the cup holder. A pin was machined in the back of the cup holder to act as a point of contact with the plunger to compensate for the lack of parallelism between the β -alumina disk, cup holder, and plunger. In addition, to improve the contact between the sulfide electrode and the solid electrolyte, a pellet of graphite powders, slightly pressed into a 1 mm-thick disk, was added between the aluminum cup and the flat cup holder. When the pressure was applied, the graphite pellet flowed and pressed the electrode uniformly against the solid electrolyte. With this procedure of mounting the electrode, we were able to obtain an electrode-electrolyte interface with reproducible characteristics, as was demonstrated by the very good reproducibility of the data from sample to sample. At the temperature of operation (less than 320°C), we did not observe any reaction between the sulfide and the aluminum substrate. The cells were assembled and tested in a dry box. The cell assembly was heated in a cylindrical heater whose temperature was regulated within $\pm 1^\circ\text{C}$.

The measurements were carried out using PAR electrochemical instrumentation (Model 173 potentiostat, Model 371 coulometer, Model 175 programmer) controlled by a Tektronix 4051 computer. Sodium was inserted in the sulfide electrode and removed from it by discharging and charging the cell at low rates. The charge measured during the electrochemical titration is proportional to the amount of sodium inserted in the electrode material because no side reactions, such as reduction of the electrolyte, occur, and nonfaradaic effects, such as double-layer charging, are very small. These assumptions were verified in our case by changing the thickness of the electrode.

The reaction was carried out under the condition that the voltage of the cell should change at a constant rate with time. Thus, the titration current was observed to increase and decrease as a function of the voltage. The rate of the reaction, monitored by the current, was kept low enough to insure quasi-equilibrium conditions throughout the test. Specifically, the concentration gradients in the particles which compose the electrode were kept small so that the lineshapes of the voltammograms would not become broad and distorted. The use of micro-electrodes has the advantage of keeping the time of the experiments relatively short. Because the geometry of the cell did not allow the addition of a reference electrode, the sodium electrode was used as both a counter and a reference electrode. This configuration did not introduce a large error, because the polarization of the sodium electrode was low. This was verified by current step measurements using a sodium/ β -alumina/sodium cell. The IR drop of the sulfide cells was also checked with the same technique and found to be less than 20 mV at currents up to 1 mA.

The XPS spectra were obtained with a Vacuum Generator ESCA 3 system using a magnesium anode x-ray source (1253.6 eV). The instrument was operated in the constant pass energy mode with a typical resolution of 1.1 eV full width at half maximum peak height on the Au 4f_{7/2} line.

Results

We report in Fig. 1 the results of the first and second scan for TiS₃ obtained at 280°C. In this experiment the electrode was 0.3 mg and the scan rate was 0.1 mV/s. On

Fig. 1. Cyclic voltammetry curves for a TiS₃ electrode at a sweep rate of 0.1 mV/s. The negative curves correspond to the insertion of sodium in the electrode, the positive curves to its removal. The solid and dashed lines correspond to the first and second cycles, respectively.

discharge (cathodic wave), a broad current peak appears at 1.7V. The integrated current indicates that the process involves two electrodes per molecule. Below approximately 1.2V, the background current increases slowly. On charge (anodic wave), a complex lineshape, made of four peaks, is observed between 2.0 and 2.4V. The measured titration charge indicates that at least 95% of the sodium inserted in the electrode is removed on charge. Lower coulomb efficiency is observed if the cathodic scan is extended beyond 1V. The second scan is, however, different. Three cathodic peaks are observed at 2.2, 2.1, and 1.4V, respectively. Corresponding peaks, with very similar lineshapes, are observed in the anodic scan shifted by 80 mV toward higher energies. These peaks are the characteristic features observed for TiS₂. Similarly, the total charge measured during the second intercalation cycle is equivalent to only a one-electron process, and intercalation is reversible. Subsequent scans give identical results. After the cyclic voltammetry tests, the cell was opened to inspect the electrode. In the case in which the electrode was taken out after a full charge cycle, the color of the electrode was gold. Inspection under an optical microscope revealed that the electrode was now a compacted powder and had lost its originally fibrous appearance. X-ray diffraction data revealed some of the characteristic lines for TiS₂, although they were very broad. In another test, a TiS₃ electrode was removed from a cell after the first discharge to 1.2V. Its color was dark gray black. Part of the electrode was enclosed in a glass capillary for x-ray diffraction analysis while still in the dry box. Only a few broad lines were observed from which it was not possible to identify the reaction products.

The cyclic voltammetry curves for niobium and tantalum trisulfides show different features. In Fig. 2 we report the first and sixteenth complete scans for a NbS₃ electrode of 0.3 mg, and part of the second. The voltammograms were obtained at 280°C and at a scan rate of 0.1 mV/s. The first discharge curve shows a large current peak at 1.7V, similar to that observed for TiS₃, but narrower. The charge corresponding to the peak indicates a two-electron reduction process. At 0.9V, another peak corresponding to a one-electron process is observed. In the subsequent charge scan, a peak is observed at 1.5V, a doublet appears at 2.1-2.2V, and a small peak can be seen at 2.4V. The coulomb efficiency during the first cycle is

Fig. 2. Cyclic voltammery curves for a NbS_3 electrode at a sweep rate of 0.1 mV/s. The solid and dashed lines correspond to the first and sixteenth cycles, respectively.

about 90%. Although the lineshape of the first cathodic voltammogram is quite different from that of the first anodic voltammogram, on subsequent cycles the cathodic and anodic curves become more symmetrical. To illustrate this point, the first part of the second voltammogram is included in Fig. 2. Three peaks appear at 1.95, 2.10, and 2.34V, respectively, which are similar to the peaks observed in the first anodic scan. Quite different behavior is observed for the peak at lower voltages. In fact, the cathodic peak splits into two components, which grow at 0.8 and 1.1V, respectively, and have a 2:1 intensity ratio. The anodic peak at 1.5V instead starts decreasing in intensity, and another peak starts growing at 1.3V. The total charge associated with these peaks decreases monotonically and after a few cycles is roughly $0.5 e^-/\text{NbS}_3$. At higher voltages, the weak peaks at 2.4V in the cathodic scan and at 2.5V in the anodic scan gradually increase in intensity, while the other two peaks become weaker. By the tenth cycle, the total charge measured during a discharge cycle was $1.5 e^-/\text{mol}$ and kept decreasing. Separate scans over either the 0.6-1.6V or 2.0-2.7V region gave similar results, indicating that the processes are independent.

In Fig. 3 we show the first and eighth complete scans for a TaS_3 electrode taken at 280°C. Part of the second scan is also shown. The scan rate was 0.1 mV/s and the weight of the electrode was 0.4 mg. A peak at 1.7V and a small peak at 1.9V are observed on the first discharge. The total integrated current indicates a two-electron process. Another peak, corresponding to a one-electron process, is observed at 0.6V. On charge, two peaks appear at 1.0 and 1.3V respectively, and a very broad feature, which appears to be made of at least three components, is observed to be centered at 2.3V. The coulomb efficiency of the first cycle is about 95%. On the second discharge an asymmetric peak appears at 2.1V. This peak shifts on subsequent scans by 100 mV to higher voltages, splitting into two components of 3:1 intensity ratio. After a few cycles, the peak lineshape remains constant. During the transformation, the charge associated with the higher voltage processes decreases by 20%. The lower peak instead shifts by 50 mV to lower voltages, increasing its intensity, so that the total charge measured during the entire scan remains constant within 1-2%. The peaks in the anodic waves change to become more symmetrical with the cathodic peaks. The peak at 1.3V disappears and the one at 0.9V becomes stronger. The peak lineshape near 2.2V becomes sharper as if the central component grew at the expense of the others. Although the cyclic voltammery curves measured for TaS_3 showed lineshape transformations similar to those observed for NbS_3 , the two compounds

Fig. 3. Cyclic voltammery curves for a TaS_3 electrode at a sweep rate of 0.1 mV/s. The solid and dashed lines correspond to the first and eighth cycles, respectively.

behave differently in the following respects. First, in TaS_3 , the lineshape modifications occur without substantial loss in electrode utilization and coulomb efficiency. Second, the TaS_3 peaks change their intensity, but they do not shift substantially in voltage. And last, the changes in TaS_3 occur within the first three or four cycles, after which subsequent voltammograms do not change appreciably.

The NbS_3 and TaS_3 electrodes did not seem to have lost their fibrous appearance after the electrochemical tests, at least under low optical magnification. They did seem, however, to react with air, probably due to the remaining sodium that cannot be removed from the material during the electrochemical titration. X-ray diffraction measurements were performed on pieces of fully charged electrodes after they had been cycled several times. The samples were sealed in glass capillary while still in the dry box to prevent reaction with air. Their diffraction patterns showed only a few broad lines, suggesting that both materials had become highly disordered during the reaction. The presence of disulfide or trisulfide species could not be conclusively demonstrated.

Discussion

Our cyclic voltammery results demonstrate that the effects produced by the insertion of sodium in TiS_3 , NbS_3 , and TaS_3 are more complex than those observed in the disulfides (10). Titration of layered dichalcogenides with alkali metals has been shown to produce ternary phases according to the equation

where M is the transition metal and X is either sulfur or selenium. Stoichiometric and nonstoichiometric reaction products have been reported for the disulfides (12). The redox process described by Eq. [1] does not have a simple Nernstian behavior because it involves solid-state species. Typically, the equilibrium voltage of the titration cell is not a linear function of the alkali-metal concentration in the electrode material, and it changes discontinuously when a new phase is formed during the process. These discontinuities are resolved with the cyclic voltammery technique, with much higher sensitivity than possible with galvanostatic measurements, because this method, at very low rates, is equivalent to a differential measurement of the curve representing the sodium concentration in the electrode as a function of its equilibrium voltage. Thus, current peaks are observed when the free energy of reaction changes and can be correlated with changes in the electroaffinity of the host material, with changes in the site occupied by sodium and/or with structural transformations of the ternary compound formed during the process. In particular, very sharp current peaks are seen when two phases coexist. Conversely, the current is approximately constant when the reaction produces a homogeneous phase such as a solid solution (10).

We previously reported voltammograms for TiS_2 , NbS_2 , and TaS_2 obtained with the same cell configuration and

using microelectrodes (10). For each of the disulfides, we observed characteristic current peaks which did not appreciably change upon cycling. In addition, the cathodic and anodic waves were fairly symmetrical. We discussed how these features are characteristic for an intercalation process which affects the stacking of the disulfide layers but not their chemical bonding. The voltammograms for the trisulfides instead show modifications in lineshape and shifts in peak position as a function of cycling, which indicates that profound structural modifications occur during the reaction with sodium.

Before discussing the electrochemical data, it is useful to summarize the structural and chemical bonding properties of the materials under study. The structure of these trisulfides can be regarded as being built with chains of sulfur trigonal prisms, stacked to share their triangular faces, with the metal at the center of each prism. To satisfy the valence rules, sulfur-sulfur bonds are formed in such a way that two anions in each unit become paired (11). The chains are alternatively displaced along their axis by half a prism length. Their relative distance is such that the separation between the metal in one chain and one sulfur from each of the two adjacent chains is similar to the intrachain metal-sulfur distance. As a consequence, the metal becomes eightfold coordinated, and the resulting cross linking produces slabs of coupled chains. The slabs are weakly bonded by van der Waals forces because sulfur pairs form their outer layers and thus, the materials are pseudo two-dimensional. Details of intrachain or interchain interactions differ from one compound to another, giving rise to different layering patterns and different unit cells. While in TiS_3 (13) and NbS_3 (14), the chains are all equal and the unit cell contains two columns; the orthorhombic polytype of TaS_3 (15) has a more complicated unit cell, containing 24 chains. Although the structure of orthorhombic TaS_3 has not yet been exactly determined, it has been proposed that it contains several types of chains that differ from one another by the degree to which sulfur atoms are paired. The presence of such inequivalent chains has been determined in similar compounds, such as TaSe_3 and NbSe_3 (11), and in the less common monoclinic polytype of TaS_3 (16), which can be obtained at high pressure. In addition, when the anion-anion pairing is relaxed, interchain anion bonding occurs. As a result, the slabs formed by cross-linked chains become somewhat puckered, making the van der Waals gap less defined (11).

One important structural characteristic of these trisulfides is the presence of sulfur-sulfur bonds. This pair is usually referred to as the polysulfide group, because x-ray diffraction studies in TiS_3 and NbS_3 have shown that this bond length is equivalent to that found in other known polysulfides. Therefore, the trisulfides have been formally described by the ionic formula $\{\text{M}^{+4}(\text{S}_2)^{-2} \text{S}^{-2}\}$, although they are mostly covalently bonded. We also have verified with XPS measurements the presence of sulfur in different bonding configurations (17). In Fig. 4 we show the XPS spectra of the sulfur 2p core level that we measured for TiS_3 , NbS_3 , and orthorhombic TaS_3 . The spectra for TiS_3 and NbS_3 can be decomposed into two doublets. Each doublet corresponds to the 3/2 and 1/2 spin-orbit split components of the 2p core level. The intensity ratio between the two doublets is 2:1, the more intense one being at higher binding energies. This indicates that less charge is localized on the more abundant species, as suggested by the ionic formula of the compound. In contrast, the lineshape observed for TaS_3 cannot be decomposed into only two components, suggesting a more complex bonding configuration as indicated by x-ray diffraction studies.

We have observed pronounced differences in the lineshapes of the voltammograms of the trisulfides and in the behavior of their voltammograms upon cycling. However, it is possible to identify one common feature: on first discharge, the three materials all undergo a two-electron reduction process at approximately the same potential. We associate this process with the reduction of the

Fig. 4. XPS spectra of the S_{2p} core level for TiS_3 , NbS_3 , and TaS_3 .

polysulfide group with concomitant insertion of 2 Na/unit. It seems likely that sodium diffuses into the van der Waals gap of the material, although we were unable to confirm from our x-ray diffraction data that the unit cell expands along only one direction during this process. The initial reduction process breaks the polysulfide bond and produces different effects in each compound. For example, TiS_3 becomes unstable because the trigonal prismatic coordination of the cation is stabilized by the sulfur pair. Once the pair is broken, the structure tends to assume the more stable octahedral coordination which is found in TiS_2 (18). The disproportionation of TiS_3 to TiS_2 is clearly demonstrated by the cyclic voltammetry results because the curves obtained for scans subsequent to the first one are the same as the ones obtained for TiS_2 . It could be argued that the formation of TiS_2 occurs when the polysulfide is oxidized and the sodium is removed from the compound, because during the first anodic cycle, the characteristic disulfide peak at 1.5V is missing, while the peak at 2.1V is present. Moreover, because all of the sodium is removed during the first charge and the first oxidation peak is found above 2.0V, it seems unlikely that sodium sulfide and titanium disulfide are formed during the first discharge. The few broad lines observed in the x-ray diffraction pattern of an electrode discharged to 1.2V did not seem to correlate with those expected for Na_2S . It should be noticed that in the voltammograms of TiS_3 , the two peaks at 2.1V are resolved, indicating that the particle size of the product is small and that the disulfide is stoichiometric. Either excess of titanium or large particle size have the effect of broadening the peak linewidths. The spectra do not show any feature that can be associated with the presence of free sulfur liberated after the first cycle. However, a faint yellow deposit could be seen at the edge of the alumina disk after opening the cell. The absence of electrochemical activity from the free sulfur may be due to a loss of electrical contact. Because the quantity of sulfur is small, it is possible that it evaporates away during the experiment due to the relatively high temperature. We checked the transformation into the disulfide's not just being caused by the high temperature. A fresh electrode was kept at 300°C in a cell in open-circuit conditions for several days before being cycled, and it showed the same behavior.

Contrasting with the behavior of TiS_3 , no abrupt loss of capacity is observed in NbS_3 and TaS_3 after the first cycle. In both materials, the peaks in the first anodic scan and second cathodic scan above 2V are fairly symmetric, and the corresponding charge is greater than $1.5 e^-/\text{mol}$, indicating that the redox process is still associated with a polysulfide species. It also seems unlikely that the cation should change coordination, because the trigonal prismatic coordination is more stable than the octahedral one, at least in both niobium and tantalum disulfides (18). In addition, in all the scans these materials show another well-defined reduction process at voltages lower than 1V, not observed in TiS_3 . It is tempting to associate the low-voltage redox process with the oxidation and reduction of the cation. However, the trisulfides are largely covalent, and their atomic orbitals are well hybridized, so assignment of a specific valence state to the cation is purely formal. It could also be argued that TiS_3 can be further reduced below 1V because the titration current increases below this voltage. This process is, however, irreversible, because the anodic current is very small below $\sim 1.7\text{V}$, suggesting that sodium sulfide may be formed below 1V.

For the case of NbS_3 , our results suggest that this material undergoes irreversible transformations upon reaction with sodium. NbS_3 appears to transform slowly under repeated cycling, because new peaks in the voltammograms become more prominent and the electrode utilization decreases within ten cycles to almost half of its first-cycle value. However, the possibility that NbS_3 disproportionates to the disulfide seems contradicted by the fact that, even after fifteen cycles, the material can be inserted with more than 1 Na/Nb. The large sodium capacity would indicate that the polysulfide bond is still involved in the redox process, because the disulfides are typically found to reversibly incorporate 1 Na/unit at most (10). The lineshape of the voltammograms, even after several cycles, is different from that measured for rhombohedral NbS_2 (10). It should be noticed, however, that several nonstoichiometric phases have been identified in the sulfur-niobium phase diagram (19) and that their behavior in sodium cells has not been determined. Peculiar to NbS_3 is the very sharp peak at 1.95V, which is a characteristic potential for polysulfide reduction. The intensity of this peak decreases rapidly with cycling, while the peak at 2.4V increases to a comparable intensity. This feature might indicate that a disulfide phase is being formed at the expense of the trisulfide, because the typical potentials observed for sodium intercalation in the disulfides range between 2.2 and 2.4V, and the lineshape of the peak at 2.4V is similar to that observed for intercalation in those compounds (10). X-ray diffraction measurements on a fully charged electrode after sixteen charge/discharge cycles showed only a few diffuse lines from which the reaction products could not be identified.

TaS_3 is the most stable of the three sulfides. After the first few cycles, sodium seems to be inserted and removed from this compound with little loss in the electrode capacity, as is typically observed in an intercalation reaction. We suggest that the greater stability of TaS_3 when compared to the other two trisulfides may be related to the presence of relaxed sulfur pairs. The occurrence of relaxed polysulfide groups could be attributed to an increased charge transfer from the cation to the anion as if tantalum prefers the pentavalent configuration (16). Relaxation of intrachain sulfur-sulfur bonds may also promote interchain chalcogen interactions as it is observed, for instance, in TaSe_3 (11). Thus, the reduction process at high voltage may be quite complex, involving either different sulfide species or the compound as a whole. It should be noted, in fact, that the line shape of the peak above 2V is asymmetrical and is quite different from that observed for TiS_3 and NbS_3 . In addition, after several cycles, the charge associated with the lower redox process is found to be larger than $1 e^-/\text{Ta}$, suggesting the presence of pentavalent cations. Some degree of electrochemical irreversibility is present in the behavior of the

material because the anodic and cathodic peaks are widely separated. In particular, the peaks at low voltages are shifted by 400 mV. A large peak separation could result if the cation ligand field is distorted during the reduction process so that the oxidation potential is shifted to higher values.

The energy density of the TaS_3 electrode alone extrapolated from the tenth cycle is about 350 Wh/kg, which is similar to the one found for TiS_2 in a similar sodium cell (360 Wh/kg) (9). Because the density of TaS_3 is almost twice as large as that of TiS_2 , the utilization of TaS_3 could be more advantageous in applications in which the volumetric energy density needs to be high. In addition, the fibrous morphology of TaS_3 makes it easier than for the platelet-like disulfide materials to construct high surface-area electrodes which have good mechanical integrity.

Some of the trisulfides have been tested in the past as electrode materials in room-temperature lithium cells, but no tests have been performed in sodium cells. TiS_3 and NbS_3 showed poor reversibility with lithium (1, 20). It was found that three equivalents of lithium could be inserted electrochemically in 1 mol of TiS_3 , but that less than 1 eq/mol could be removed at very low current rates. The lack of reversibility observed in the galvanostatic charge/discharge data was ascribed to the formation of lithium sulfide and titanium disulfide (1). However, neither x-ray data nor the electrochemical data could conclusively show the presence of either compound. Similarly, it was found that 2.6 eq/mol of lithium could be inserted in NbS_3 on first discharge, only 80% of which could be removed (20). Our electrochemical data seem to indicate that no sodium sulfide is formed in the trisulfides during the first electrochemical discharge. We also found in our experiments that sodium can be removed from both TiS_3 and NbS_3 after the first discharge in much larger percentage than that measured in the case of titration with lithium. The greater degree of rechargeability observed in our experiments is probably due to the higher temperature of operation, instead of being related to intrinsically different effects occurring from the two alkali metals. In fact, it was shown in our earlier results that TiS_2 in a similar high-temperature sodium cell was much more reversible and had a deeper discharge range than in room-temperature sodium cells with a liquid electrolyte (9, 21). There are no data in the literature about the behavior of TaS_3 electrodes in lithium cells. Because in our experiments this compound is found to be rechargeable, it is possible that it may also have good rechargeability characteristics in room-temperature lithium cells, as was found for NbSe_3 (7). This material can be reversibly titrated with three equivalents of lithium per mole, and under galvanostatic discharge, it exhibits two plateaus. We found in our sodium cells that NbSe_3 behaves similarly to TaS_3 (22). In particular, three equivalents of sodium can be inserted in one mole of NbSe_3 and removed from it; the material can be cycled several times with little loss in electrode capacity, and only small changes in the voltammograms occur after repeated cycling. However, three separate redox processes seem to occur in NbSe_3 after the first cathodic scan. NbSe_3 was found to contain three kinds of chains which differ by the degree of anion pairing (11). These similarities between TaS_3 and NbSe_3 seem to point out that the characteristics of the anion bonding in the trichalcogenides may be the important factors in determining their stability toward the insertion of alkali metals.

Conclusion

We have shown that the electrochemical behavior of the trisulfides of titanium, niobium, and tantalum is dominated by the redox process on the polysulfide group. As a consequence, irreversible transformations are induced in the trisulfides, unlike what is observed in the corresponding disulfides. Although the trisulfides have similar structural characteristics, some differences in their bonding properties can be identified. We suggest that the different degrees of stability toward insertion of sodium

observed in these compounds are a consequence of different sulfur-sulfur bonding configurations. Our voltammograms clearly show the disproportionation of TiS_3 into the corresponding disulfide. It is not possible, on the basis of our data, to identify the precise mechanisms by which NbS_3 loses electrode capacity, although decomposition to the disulfide cannot be ruled out. The electrochemical behavior of TaS_3 instead resembles more what is expected for an intercalation process: only small changes are observed in its voltammograms upon cycling. TaS_3 may be potentially useful as an electrode material for applications in which a high volumetric energy density is required.

ABSTRACT

The photoelectrochemical behavior of n- $CuIn_5S_8$, a chalcogenide having a spinel-type structure, has been studied in various electrolytes by measuring the spectral response, the current-potential characteristics, and the differential capacitance. The best results have been obtained in an aqueous sulfide-polysulfide solution, where the $CuIn_5S_8$ semiconductor electrode shows an excellent stability. The flatband potential of this semiconductor electrode has been found to depend on the solution composition. The most negative values have been observed in the sulfide-polysulfide solution, owing to specific adsorption of S^{2-} ions on the electrode surface. Preliminary results on the output power characteristic of the $CuIn_5S_8$ photoelectrochemical cell are also discussed.

Progress in the development of photoelectrochemical cells has required the investigation of new semiconductor electrodes exhibiting a good stability against photodecomposition and a high absorption in the visible portion of the solar spectrum. Some ternary semiconducting compounds have been shown to satisfy the above conditions, and, in particular, analogues of II-VI compounds, obtained by cross-substitution of the electropositive constituent, have lately been the subject of growing scientific interest.

In this work, we report the photoelectrochemical performance of $CuIn_5S_8$, whose optical and electrical properties are known (1). This n-type semiconductor has a cubic spinel-type structure similar to that of $CdIn_2S_4$ (2).

The ideal spinel structure can be viewed as a cubic close-packed partial structure of anions in which one-

eighth of the tetrahedral and one-half of the octahedral sites are occupied by cations.

Considering the general formula $M_{1/2}^+M_{1/2}^{3+}[M_2^{3+}]X_4^{2-}$ of a normal 1-3 spinel where the cations in the brackets occupy octahedral sites and the remaining cations occupy tetrahedral sites, $CuIn_5S_8$ may be written as $Cu_{1/2}In_{1/2}[In_2]S_4$. This formula can also be deduced by substituting monovalent copper cations and trivalent indium cations for divalent cadmium cations in $CdIn_2S_4$, which is, however, a partial inverse thio-spinel: $Cd_{1/2}In_{1/2}(Cd_{1/2}In_{3/2})S_4$ (3).

$CuIn_5S_8$ crystallizes in the space group $F\bar{4}3m$ (T^3d_h), has a cubic structure with lattice dimension $a = 10.6858\text{\AA}$ and has eight molecules per unit cell (4). Moreover, according to complete x-ray structural determinations, the tetrahedral sites are split into two nonequivalent groups with an unequal distribution of copper and indium ions. In fact, one site is occupied to the extent of 52.4% by cop-

* Electrochemical Society Active Member.

per ions and 47.6% by indium ions, whereas the opposite situation is found for the other site (4). However, Robbins and Miksovky (5) consider copper and indium ions to be crystallographically disordered on the sites having tetrahedral coordination, as usually occurs in 1-3 spinels.

The width of the forbidden bandgap of CuIn_5S_8 (1.26 eV, see below) is much closer to the optimal value for solar energy utilization than that of its structural analogue CdIn_5S_4 [2.28 eV (1)]. Following Usujima *et al.* (1), these values may be correlated with cationic atoms occupying the tetrahedral sites. For example, the large energy gap of CdIn_5S_4 seems to be connected with the strong ionicity of the cations at the tetrahedral sites, which is due to the large difference of the electronegativity between cadmium and sulfur. Up to now, ternary chalcogenides showing the spinel structure have scarcely been considered in photoelectrochemical studies, in comparison with ternary semiconductors showing a structure related to the zincblende type (e.g., a chalcopyrite structure), which either have a completely tetrahedral coordination [e.g., CuInS_2 (6-8), CuInSe_2 (9), CdGeP_2 (10), or a cation-deficient lattice], so that a smaller part (3/8 instead of 1/2) of the tetrahedral sites is occupied [e.g., CdIn_2Se_4 (11-12)].

Experimental

Single-crystal samples of n- CuIn_5S_8 , synthesized from the constituent elements, were kindly provided by Dr. J. L. Shay of AT&T Bell Laboratories. Some of the specimens gave a very low photoelectrochemical response, probably as a consequence of faults in their composition. In fact, sulfur vacancies have been shown to create donor levels in CuIn_5S_8 and thus to influence its resistivity and photosensitivity (1).

The material was also very sensitive to defects introduced during mechanical deformation; hence, the preparation conditions of the samples to be mounted on the sample holder were rather critical. As an example, often the mere action of cutting the crystals had a detrimental effect on the sample photoactivity, which practically decayed to zero. Therefore, the electrode surface was never polished.

Before mounting in the measurement cell, the electrodes were submitted to chemical etching. Various conventional etchants were tested, but the best results were obtained with a 1:1 $\text{H}_2\text{SO}_4\text{:H}_2\text{O}_2$ solution. Hence, all electrodes were treated with this solution for several minutes and then rinsed in bidistilled water.

The ohmic contact was established by soldering pure indium on the back surface of the crystal, taking care that no cracks formed during this operation. A copper wire was attached to the crystal by means of a silver paste, and insulating epoxy cement was used to seal the electrode except for its front surface.

A conventional three-electrode glass cell having a platinum foil (50 cm^2) as a counterelectrode and a saturated calomel electrode (SCE) as reference electrode were employed for studying the photoelectrochemical behavior of CuIn_5S_8 . This behavior was mainly examined in three different solutions, 1M Na_2SO_4 (pH = 4.8), 1M Na_2S + 1M S + 1M NaOH (in the following indicated as polysulfide solution), and 0.1M KI + 10^{-2} or 10^{-3} M I_2 . The various solutions were prepared from AR-grade reagents (Merck and Carlo Erba) and doubly distilled water.

The instrumentation included a standard photoelectrochemical setup with an Oriol 150 Xe-arc lamp, a UDT 61 radiometer, an Amel 553 potentiostat-galvanostat, an Applied Photophysics monochromator Model 7300 having 1200 grooves mm^{-1} , and a Wayne Kerr B 331 Mk 11 autobalance precision bridge (at a frequency of 1.6 kHz). A set of neutral density filters was used for changing the light intensity (13).

Results and Discussion

Spectral response.—Figure 1 shows the wavelength dependence of the short-circuit photocurrent of the n- CuIn_5S_8 electrode in the sulfide-polysulfide solution. Normalization was made for the spectrum of the lamp. The

Fig. 1. Normalized spectral response of CuIn_5S_8 in 1M Na_2S , 1M S, 1M NaOH. In the insert is shown the determination of the bandgap of the indirect (1.26 eV) and of the direct (1.54 eV) transition.

threshold photoresponse at a wavelength of approximately 970 nm corresponds to a bandgap of about 1.28 eV, whereas practically no sub-bandgap photoresponse was observed.

For the evaluation of the photoelectrochemical behavior of a semiconductor electrode, not only the bandgap energy but also the type of electronic transition must be considered. In general, semiconductors with direct transitions are preferred due to the large absorption coefficient for photons having energies higher than the bandgap.

In the case of CuIn_5S_8 , both direct and indirect transitions have been reported (1). According to the simplified Gärtner equation (14), which is assumed to apply also in this case, the plot of $(I_{ph}h\nu)^{1/n}$ (where $n = 2$ or 0.5 for an indirect or a direct transition, respectively) is a linear function of $h\nu$ for wavelengths close enough to the transition energy. The bandgap energy can be determined from the Gärtner plot. In the case here under study, the plot is shown in the insert of Fig. 1. The linear behavior indicates the validity of the equation and allows one to determine the two energy gaps of CuIn_5S_8 , the lowest at 1.26 eV, due to an indirect-allowed transition, and the other at 1.54 eV, due to a direct mode. The results are in agreement with those obtained by Usujima *et al.* (1) from optical absorption measurements (1.30 and 1.51 eV, respectively).

The width of the forbidden gap is close to the optimal value for terrestrial photovoltaics. Its value is clearly influenced by the presence of indium atoms [compare the 1.5 eV value of CuInS_2 (7)]. Knowing the energy gap values, the correctness of the results regarding the transition modes could be further verified by plotting $\log(I_{ph}h\nu)$ vs. $\log(h\nu - E_g)$ (14). In the case here under study, two straight lines having slopes of 2.1 and 0.5, respectively, were obtained. This confirms that the transition occurring at the lowest wavelength is indirect (theoretical slope equal to 2) whereas the other is direct (theoretical slope equal to 0.5).

The occurrence of both indirect and direct transitions is common for the CdIn_2X_4 (with X = S, Se, Te) materials. The difference between the energy of the two bands decreases from 0.34 eV for CdIn_2S_4 (1) to 0.22 eV for CdIn_2Se_4 (11) and to 0.1 eV for CdIn_2Te_4 (11). However, for the structural analogues CdIn_2S_4 and CuIn_5S_8 , such difference goes from 0.34 (1) to 0.28 eV.

Photocurrent-voltage characteristics and photocorrosion.—The current-voltage curve of CuIn_5S_8 in the sulfide-polysulfide aqueous solutions shows the typical trend of an n-type semiconductor (Fig. 2). In the dark (curve d) no current flows up to an applied voltage of approximately 0.2V vs. SCE. Large photocurrents are obtained under illumination, with an onset depending upon the nature of the redox couple in solution. The photo-

Fig. 2. Current-potential curves of CuIn_3S_8 in 1M Na_2S , 1M S , 1M NaOH (curve a); in 1M Na_2SO_4 , pH = 4.8 (curve b); in 0.1M KI , 0.001M I_2 (curve c). The dark curve in the polysulfide electrolyte is shown in curve d. Illumination: 100 mW/cm^2 white light. Scan rate: 4 mV/s.

current onset progressively shifts towards more negative voltages passing from the Na_2SO_4 solution (curve c) to the KI , I_2 solution (curve b) and to the polysulfide solution (curve a). The passage of current in the presence of the Na_2SO_4 , a "nonprotecting electrolyte" (2), indicates a photocorrosion process of the CuIn_3S_8 electrode. This process leads to the formation of sulfur on the electrode surface, as will be discussed below. This photocorrosion is consistently prevented not by the iodine-iodide couple, but rather by the polysulfide electrolyte, which shifts the onset potential to a very negative value.

The sulfide-polysulfide redox couple, which is known to give the best photoelectrochemical results in conjunction with cadmium calcogenide photoanodes, appeared then to be well-suited also for the CuIn_3S_8 electrodes. The large shift towards negative voltages is accompanied by a steep increase of photocurrent. The square of the photocurrent density vs. the applied potential for the CuIn_3S_8 electrode illuminated with 700 nm light chopped at 96 Hz in a polysulfide solution and in a Na_2SO_4 solution was measured. In both cases, a linear dependence is found, in agreement with the Gärtner equation (14), thus showing the absence of charge-carrier recombination in the near-surface region, when the charge-transfer reaction is not the limiting step. By extrapolating the I - V curve to the potential axis, a value of -1.2 V vs. SCE is obtained for the flatband potential of CuIn_3S_8 in polysulfide solutions, a value which is coincident with that determined from capacitance experiments (see below). Instead, the I - V characteristic in the Na_2SO_4 solution (see Fig. 2) had the typical delayed onset of the photocurrent indicative of surface recombination (due to the presence of surface states) or of a slow electron-transfer reaction, both preventing the semiconductor bands from flattening at potentials close to the flatband potential (15). Indeed, the latter is 0.25 V vs. SCE , a value less negative than the -0.55 V vs. SCE resulting from capacitance measurements (see below).

In order to determine the previously mentioned photocorrosion process, the CuIn_3S_8 electrode was polarized at 1 V vs. SCE in the Na_2SO_4 solution, and the photocurrent was measured as a function of time. A continuous decrease (the photocurrent decreased to one-half of its initial value in 1h) clearly indicated a progressive worsening of the photoelectrode due to the deterioration of its surface. After 3h of polarization, the electrode surface was examined by scanning electron microscopy (SEM). This observation showed that the entire sample surface was

(A)

(B)

Fig. 3. SEM micrographs of the CuIn_3S_8 electrode surface after 3h polarization at 1 V vs. SCE in Na_2SO_4 at pH = 4.8 under 100 mW/cm^2 illumination (A) and after a subsequent treatment with carbon disulfide (B).

covered with a yellow film with partly peeling flakes (Fig. 3a). Microprobe analysis indicated that both film and flakes were sulfur-based compounds, very likely elemental sulfur. This initial sulfur film seems unable to protect the electrode surface from further corrosion, as is the case for the selenium corrosion layer on CdSe (16). In fact, after having reached a certain thickness, the sulfur layer peels off from the substrate, thus reexposing fresh surface portions to the electrolytic solution. After partial dissolution of the film with carbon disulfide, the electrode surface was again examined in the SEM. Typical etch pits are clearly noticeable on the specimen surface (Fig. 3b).

At the end of the polarization test, a plasma emission analysis was run, showing that 6 ppm copper ions were present in the electrolyte. All these results agree with CuIn_3S_8 photocorrosion via the overall reaction

A similar polarization test (0 V vs. SCE) was also performed in the sulfide-polysulfide solution. As expected, no corrosion phenomena were detected: the photocurrent remained constant, the appearance of the electrode surface remained unchanged, with no sign of elemental sulfur, and no copper ions were detected in the electrolyte. The CuIn_3S_8 electrode is thus expected to be highly stable in this electrolyte (see below).

This is not the case for other redox electrolytes. For instance the I/I_2 redox couple appears to act as a protecting electrolyte in a limited range, the onset potential being more negative than the photodecomposition potential (about 0.2 V vs. SCE , see Fig 2c). Effectively, in a range of values starting from the onset potential up to approximately the redox potential of the I/I_2 couple, the photocurrent remains stable at high values (i.e., at about 2.5

mA/cm²). However, going to progressively higher potentials, photocorrosion takes place, producing the typical sulfur coverage of the electrode surface accompanied by a remarkable decay of photocurrent.

Since it has been reported (2) that, for CdIn₂S₄, the aqueous ferri-ferrocyanide redox couple gave better results than the sulfide-polysulfide solution, the former electrolyte was also tested for the CuIn₃S₈ electrode. However, also, in this case, photodecomposition of the electrode with the formation of elemental sulfur on its surface was clearly observed. Consequently, the sulfide-polysulfide electrolyte has been selected for all the CuIn₃S₈ photoelectrochemical tests which necessitated a prolonged operation.

Light intensity influence.—In Fig. 4 is shown the plot of short-circuit photocurrent *vs.* input light power, on a double logarithmic scale, for the CuIn₃S₈ electrode in the sulfide-polysulfide solution. The striking feature of this plot is the linear dependence of photocurrent on light intensity over more than two decades. In agreement with Gärtner theory (14), a linearity over at least two orders of magnitude shows that the rate of charge transfer across the interface between the CuIn₃S₈ semiconductor and the electrolytic solution is very fast, the rate-determining step being the photogeneration of the charge carriers.

Flatband potential.—Differential capacitance measurements were performed on the CuIn₃S₈ electrode in various electrolytic solutions. A typical Mott-Schottky plot of CuIn₃S₈ in the 1M Na₂SO₄ solution is shown in Fig. 5. The 1/C²-V dependence is strictly linear over a wide range; hence, the flatband potential U_{FB} could be determined from the intercept of the curve on the X-axis. A value of -0.55V *vs.* SCE was obtained, which, as already stated, is more negative than that deduced from the onset of the current-potential curve (about -0.25V *vs.* SCE). The value of the flatband potential determined from capacitance measurements is in fairly good agreement with that (-0.6V *vs.* SCE) calculated from Mulliken electronegativities of the constituent atoms of CuIn₃S₈, following the method proposed by Butler and Ginley (17) (see Appendix). As often done in these calculations, the potential drop across the Helmholtz double layer due to specific adsorption of positively and negatively charged potential-determining ions at the interface has been ignored. Therefore, it was implicitly assumed that the adsorbed surface charge was zero. This hypothesis seems to be justified in the case of the Na₂SO₄ solution where OH⁻, H⁺, and other ions are expected not to be specifically adsorbed on the electrode surface. As a matter of fact, no differences in flatband potential were observed as a function of the solution pH.

Fig. 4. Short-circuit photocurrent *vs.* light power for CuIn₃S₈ in 1M Na₂S, 1M S, 1M NaOH. White light.

Fig. 5. Typical Mott-Schottky plot of CuIn₃S₈ in Na₂SO₄, pH = 4.8 and at 1.6 kHz.

The other important parameter usually estimated from Mott-Schottky plots, *i.e.*, the density of the majority carriers, could not be calculated in the present case, since the dielectric constant of CuIn₃S₈ is unknown.

The Mott-Schottky plots of CuIn₃S₈ in the sulfide-polysulfide solution showed that the flatband potential is shifted towards a more negative value (-1.2V *vs.* SCE) than that obtained in the Na₂SO₄ solution.

This difference is explainable by considering the specific adsorption of solution sulfide species. These adsorbed ions produced an additional potential drop across the Helmholtz double layer, thus shifting the flatband potential to more negative values. Similar shifts in flatband potential have been observed for cadmium chalcogenide photoelectrodes, in particular for the spinel analogue CdIn₂S₄ (2) and for CdS (18).

Output power characteristic and stability tests.—The power characteristics of the following photoelectrochemical cell

obtained under an illumination intensity of 100 mW/cm² are reported in Fig. 6 both for pristine and etched CuIn₃S₈ specimens. The short-circuit photocurrent (~4 mA/cm²), the maximum power efficiency (~0.4%), and the fill factor (~0.3) are still unsatisfactory for practical applications.

Fig. 6. Output power characteristics of the CuIn₃S₈/1M Na₂S, 1M S, 1M NaOH cell under 100 mW/cm² white light and in the dark. The characteristics are reported for both untreated and etched (1:1 H₂SO₄:H₂O₂) CuIn₃S₈ crystals.

Fig. 7. Short-circuit photocurrent vs. time for a $\text{CuIn}_5\text{S}_8/1\text{M Na}_2\text{S}$, 1M S , 1M NaOH cell under continuous 100 mW/cm^2 white light illumination.

However, work is in progress to improve this performance with the study of the effects of various etching treatments.

The power characteristics were also measured in the presence of the $0.1\text{M KI} + 0.01\text{M I}_2$ solution, and comparable results were obtained. However, as already pointed out, this electrolyte solution cannot be used for prolonged operation. Therefore, stability tests of the CuIn_5S_8 electrodes were carried out using the sulfide-polysulfide solution, by monitoring the short-circuit photocurrent as a function of time during a 50h experiment (Fig. 7). Fairly constant values (around 1.8 mA/cm^2) were obtained, and no changes of the electrode surface morphology was observed after the test, thus confirming the stability of the semiconductor electrode in the polysulfide electrolyte.

Conclusions

The following conclusions can be drawn from the results discussed in this work.

1. The CuIn_5S_8 photoanode is stable in the sulfide-polysulfide electrolyte. Such extraordinary stability exceeds that of its structural analogue CdIn_2S_4 and may be attributed to a photodecomposition potential lying outside the bandgap of the semiconductor electrode.

2. The very negative value of the flatband potential of CuIn_5S_8 (-1.2V vs. SCE) in the sulfide-polysulfide electrolyte is not far from the value measured for cadmium-chalcogenide photoelectrodes in the same solution [i.e., 1.6V vs. SCE for CdS (2)]. This seems to indicate that, in the CuIn_5S_8 case also, adsorbed sulfide ions pin the semiconductor bandedges with respect to the redox potential of the solution, and it predicts a limiting open-circuit photovoltage.

3. Owing to the low photocurrents so far obtained, the solar conversion efficiency remains around 0.4%, a value lower than that obtained for other operating photoelectrochemical regenerative cells. Nevertheless, the initial results here reported appear sufficiently encouraging for promoting further work, particularly that directed to the enhancement of photocurrent values. In this respect, a systematic research of improved, *ad hoc* etching solutions, should be carried out.

Acknowledgments

The authors are highly indebted to Dr. J. L. Shay of AT&T Bell Laboratories for kindly providing the single-crystal samples and to Ms. E. Bet for assistance in performing the experiments. APPENDIX

Following Butler and Ginley (17), the flatband potential (U_{FB}) of a semiconductor can be predicted from its bulk electronegativity (χ) when the bandgap (E_g) of the material is known. In fact, assuming that the potential drop across the Helmholtz double layer is zero

$$eU_{\text{FB}} (\text{SCE}) = \chi - E_g/2 - 4.75 + \Delta E \quad [3]$$

where the flatband potential is referred to the saturated calomel electrode, e is the electronic charge, 4.75 eV is the constant relating the reference electrode to the vacuum level, and ΔE is the difference between the Fermi level of the semiconductor and the bottom of the conduction band. Clearly, ΔE depends on the doping level. However, for heavily doped semiconductors, commonly employed in photoelectrochemical cells such as metal oxides (19) and cadmium chalcogenides (20), this term is only about 0.1 eV .

The bulk electronegativity of the compounds is assumed to be the geometric mean of Mulliken electronegativities of the constituent atoms. Hence, for CuIn_5S_8 , it is given by

$$\chi(\text{CuIn}_5\text{S}_8) = [\chi(\text{Cu}) \chi^5(\text{In}) \chi^8(\text{S})]^{1/14} \quad [4]$$

introducing this relationship in Eq. [3] and assuming $\Delta E = 0.1 \text{ eV}$, $U_{\text{FB}} = -0.6\text{V vs. SCE}$, as already reported in the text.

Recently, Halouani and Deschamvres (20) suggested a modified calculation method, in which both Eq. [3] and [4] were empirically adjusted to better match experimental results on flatband potentials. Moreover, they also considered other atomic electronegativity scales, such as those of Pauling, of Simons (21) and of Phillips (22). First of all, expression [3] was simplified in

$$\chi(\text{CuIn}_5\text{S}_8) = [\chi(\text{Cu}) \chi(\text{In}) \chi(\text{S})]^{1/3} \quad [5]$$

and Eq. [4] was modified introducing a constant C that was experimentally determined

$$eU_{\text{FB}} (\text{SCE}) = C\chi - E_g/2 - 4.75 + \Delta E \quad [6]$$

where C is equal to 1.03 or to 2.5, respectively, when Mulliken or Pauling electronegativities are utilized. Following this approach, $U_{\text{FB}} = -0.7\text{V vs. SCE}$ in the first case, and $U_{\text{FB}} = -0.3\text{V vs. SCE}$ in the second one.

Although Halouani and Deschamvres (20) consider that the best results are achieved with Pauling electronegativities, the latter suffer from uncertainties too great, particularly when heavy metal atoms are involved, to obtain reliable data.

An Ambient Temperature Secondary Aluminum Electrode: Its Cycling Rates and Its Cycling Efficiencies

J. J. Auborn* and Y. L. Barberio

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Electrochemically active aluminum can be cathodically deposited and anodically stripped from acidic mixtures of 1-methyl-3-ethylimidazolium chloride and aluminum chloride at room temperature. The rates of deposition can be high (25 mA/cm²), and the deposited aluminum can be quantitatively cycled in large amounts (>25 C/cm²) at high efficiency (>99%).

Ambient temperature chloraluminatate ionic liquids are formed from mixtures of organic chlorides such as n-butyl-pyridinium chloride (BuPyCl) (1) or 1-methyl-3-ethylimidazolium chloride (ImCl) (2) and aluminum chloride (AlCl₃). When the Lewis acid, AlCl₃, is added to the organic chloride in less than a stoichiometric amount, a basic melt results in which the principal anionic species are AlCl₄⁻ and Cl⁻. An acidic melt containing principal anionic species Al₂Cl₇⁻ and AlCl₄⁻ is obtained when AlCl₃ is in excess.

We have previously shown that aluminum can be cathodically deposited from acidic 1-methyl-3-ethylimidazolium chloraluminatate melts containing reducible Al₂Cl₇⁻. Here we show that electroplated aluminum can be cycled efficiently without irreversibly decomposing the chloraluminatate melt. Electrodeposited aluminum is crystalline, nondendritic, and adherent to a variety of substrates (3). Figure 1 shows SEM photographs of aluminum deposits on a copper substrate plated at 20 mA/cm² from 0.67 mole fraction AlCl₃ melt. The maximum current density for both deposition and stripping of aluminum depends on the melt composition. Cycling rates were also found to be dependent on cell orientation and solution mixing because of the formation of dense, lower conductivity AlCl₃ rich melt near an aluminum electrode on stripping when it is located on the bottom of the cell. Both deposition and stripping may be performed at higher rates in stirred melts or at rotating electrodes.

Apparatus

The electrochemical experiments were performed in thin film and flooded cells. The thin film cell, shown in Fig. 2, consisted of an insulated micrometer head containing a 0.635 cm diam high purity aluminum rod as the counterelectrode, axially aligned with a 0.635 cm diam copper- or tungsten-rod working electrode in a Teflon holder. For experiments with the electrodes inverted, the micrometer head can be fitted with a tungsten or copper rod as a working electrode with the aluminum rod fixed in the holder. The faces of both counter and working electrodes were polished and aligned carefully to achieve a uniform current distribution when a 15.8 μl drop of melt was placed on the lower electrode and the micrometer was closed to leave a 0.05 cm gap between the electrodes.

*Electrochemical Society Active Member.

This configuration achieves a uniform current distribution across the surfaces.

The flooded cell used for cycling studies, shown in Fig. 3, consisted of a 5-50 ml Princeton Applied Research (PAR) polarographic cell modified with a no. 15 O-ring joint on the bottom to hold a high purity aluminum sheet (Alfa) counterelectrode. The reference electrode consisted of a high purity aluminum wire immersed in stoichiometric ImAl₂Cl₇ melt in a glass capillary tube with an asbestos fiber junction separating it from the 10-15 ml melt contained in the cell. The working electrode was a 0.635 cm diam tungsten rotating-disk electrode at 1000 rpm in a Pine MSR rotator.

The electrochemical experiments were controlled with a PAR 173 potentiostat/galvanostat containing a PAR 179 coulometer plug-in. This instrument was controlled with a Keithley 230 voltage programmer for the cycling studies. The electrometer output of the potentiostat was monitored with a Hewlett-Packard 7100B strip chart recorder.

Experimental

1-methyl-3-ethylimidazolium chloride was prepared by reacting stoichiometric amounts of distilled 1-methylimidazole (Alfa) and dry, condensed ethyl chloride (Matheson Gas Products) at 70°C according to Wilkes (2). This process produces pressure of about 50 psig within the reaction vessel. The salt was then recrystallized several times in acetonitrile and ethyl acetate (Fischer Scientific, HPLC) to remove impurities.

Fig. 1. SEM of aluminum deposit on a copper substrate at 20 mA/cm² in 0.67 mol fraction AlCl₃ melt.

Fig. 2. Diagram of thin film cell used for aluminum deposition and stripping studies in 1-methyl-3-ethylimidazolium chloraluminum melt.

We found that the salt can also be prepared by continuously stirring the reactants at room temperature with a slight excess of ethyl chloride (10-20% by volume). The pressure produced at this temperature is only about 10 psig, greatly reducing the risk of explosion. At room temperature, the reaction should be carried out for a week to ten days for a good yield. With this method of preparation, the salt needed only one recrystallization before use.

Binary melts are formed by mixing the purified ImCl with sublimed AlCl_3 (Fluka, puriss.) in a helium-filled glove box controlled to <1 ppm O_2 and H_2O . Because the mixing process is highly exothermic, the melt must be prepared in small batches and cooled to prevent decomposition of the organic cation.

Acidic melts can be cleaned up by electrolyzing at low rates between two high purity aluminum electrodes. An ECO electroprep cell (ECO Incorporated, Cambridge, Massachusetts) was used at rates of 0.1-1 mA/cm^2 for extended periods of time to prepare the melts for cycling

Fig. 3. Diagram of flooded cell used for aluminum cycling studies at a rotating tungsten electrode in 0.60 AlCl_3 melt.

studies. The cell consists of two high purity (99.983%) aluminum-plate electrodes (supplied by Reynolds Aluminum) separated by a Teflon gasket. Electrolyte is circulated through the cell by an external pump and reservoir. With this method of purifying melts, acidic mixtures can be made with unsublimed AlCl_3 , and then electrolyzed before use. Freshly prepared melt has a distinct yellow color which fades as the electrolyte is purified. When the melt is ready for use, it should be colorless. NMR spectroscopy can also be used to check the composition and purity of the melts (4).

The thin film cell was used to study the relationship between melt composition and maximum current density for plating and stripping aluminum. Varying the melt composition between 0.57 and 0.67 mole fraction AlCl_3 , the highest current density for plating and stripping aluminum without polarization was determined for each composition. Experiments were typically run for 30 min at each current density. The thin film cell was also used for electrolysis studies of the melt contained between the electrodes. Aluminum was continuously plated onto a copper substrate until the cell shorted out by the growth of a crystallite.

We checked the reversibility of a practical aluminum battery electrode by cycling aluminum from 0.60 melt onto a tungsten electrode. Plating and stripping current densities were controlled at rates varying from 2 to 25 mA/cm^2 . 2-25 C/cm^2 aluminum was cycled with 20-100% excess aluminum plated on the first cycle. The cells were cycled at equal plating and stripping rates until the working electrode polarized on stripping. Longer experiments were usually terminated after 100-200 cycles, and the remaining amount of aluminum was determined by stripping the electrode to polarization.

Initial cycling studies in the thin film cell proved to be troublesome. The experiments were limited to low currents (<10 mA/cm^2) and were frequently shorted out prematurely by crystallite formation. The electrolyte also began to evaporate during longer experiments (>24 h), changing the electrode contact area and current distribution across the surface.

Cycling experiments in the flooded cell were much more successful. The rotating electrode eliminated the problem of cell polarization by minimizing concentration gradients. In unstirred cells, dense, lower conductivity acidic melt (5) tended to collect at the bottom of the cell, impeding aluminum stripping from the lower electrode. In well-mixed electrolytes or at a rotating electrode, the orientation of the electrodes does not affect the plating or stripping process, because the concentration is homogeneous. The configuration of the flooded cell also made the addition of an $\text{Al}/\text{Al}_2\text{Cl}_7^-$ reference electrode possible and eliminated the problems of cell shorting.

Results

The maximum current density for plating and stripping aluminum from chloraluminum melts depends on the concentration of the melts. In an unstirred flooded cell, the maximum rate for aluminum deposition ranges from <1 mA/cm^2 for ImAlCl_4 to 20 mA/cm^2 for ImAl_2Cl_7 . Aluminum may be stripped at rates varying from 50 mA/cm^2 for ImAlCl_4 to <1 mA/cm^2 for ImAl_2Cl_7 (6).

Chronopotentiometric studies of acidic melts were used to determine the optimum composition for plating and stripping aluminum in the thin film cell. We found that we could sustain 10 mA/cm^2 without mixing in the thin film cell at a melt composition of 0.63 mole fraction AlCl_3 , with the aluminum anode on the top. We noted that polarized cells would recover if the cell were turned over and, therefore, repeated the above experiments with the cell inverted. The optimum composition for highest sustained current density (still 10 mA/cm^2) with the anode on the bottom was 0.60 mole fraction AlCl_3 . Figure 4 shows maximum current density vs. composition for stripping and plating in an unstirred flooded cell (6) and stripping-plating in the thin film cell with the aluminum anode on the bottom.

Fig. 4. Maximum current density vs. melt composition for aluminum plating (○) and stripping (●) in an unstirred flooded cell; aluminum cycling (▲) in a thin film cell with the aluminum anode on the bottom.

Exhaustive electrolysis of the 15.8 μl of 0.60-0.67 mole fraction AlCl_3 melt containing about 30 C ($\sim 100 \text{ C/cm}^2$) total aluminum could be sustained in the thin film cell at 5 mA/cm^2 for 17-30h with the aluminum anode on top. This corresponded to a 3-5 times complete turnover of the aluminum contained in the melt before the cell shorted out by the growth of an aluminum crystallite.

Cycling studies in the flooded cell demonstrated the efficiency of a secondary aluminum electrode. The cycling efficiency (E) of the aluminum electrode could be determined from the number of cycles to failure (N), the number of coulombs of aluminum plated or stripped on each half-cycle (A), and the excess number of coulombs plated on the first cycle (X), according to

$$E = (A - X/N)/A \quad [1]$$

We consistently obtained cycling efficiencies >0.99 at current densities up to 25 mA/cm^2 for cycling up to 25 C/cm^2 of aluminum if a 5-10 C/cm^2 excess amount of aluminum were plated on the first half-cycle. The results for a series of cycling experiments are shown in Table I. The best reported efficiency for a secondary lithium electrode is much lower (0.975) and requires a large excess capacity of lithium and a low current density (1 mA/cm^2) (7).

Discussion

Relatively large quantities (25 C/cm^2) of aluminum, suitable for battery-electrode applications, can be electrode-

posited and cycled efficiently (>0.99) at moderate rates (10 mA/cm^2) in acidic 1-methyl-3-ethylimidazolium chloraluminum melts at ambient temperature. The cycling efficiency does not significantly decrease as the current density is increased to 25 mA/cm^2 . The melt is not irreversibly decomposed by plating and stripping aluminum. A minimal quantity ($\sim 10 \text{ C/cm}^2$) of excess aluminum is required on a tungsten substrate to prevent the cell from polarizing after >100 cycles.

Although the cycling efficiency of aluminum is excellent compared to lithium as a secondary battery electrode, aluminum in acid melt is nearly 3V positive of lithium (8) and not useful with many of the positive-electrode materials used in lithium batteries. A strongly oxidizing, reversible positive-electrode material, compatible with acid chloraluminum melts, is required for a secondary aluminum battery. Several strongly oxidizing metal oxides, chalcogenides, and halides considered as possible positive-electrode materials (9) are limited by solubility in acidic melt. CuCl and AgCl are both reversible in acidic imidazolium chloraluminum melts at potentials positive of aluminum. However, they are both slightly soluble in acidic melt, limiting their usefulness as positive-electrode materials.

If the positive electrode is chosen to allow charging and discharging to change the acidity of the chloraluminum melt (10), large amounts of electrolyte would be necessary to keep the melt within the reversible (acidic) limit. As an example, consider an aluminum/chlorine formation cell. At the negative electrode, aluminum is reversibly oxidized and reduced in acidic melt, and at the positive electrode, chlorine is reduced and oxidized in basic melt. The reactions are as follows

with the free chloride ion allowed to pass through an ion-exchange membrane. The volume of melt needed is determined by the composition change of the catholyte and the solubility of chlorine in the anolyte. Here we have assumed that each Cl_2 complexes with a free chloride ion, forming a Cl_3^- ion. The actual solubility of chlorine in basic melt is higher and may approach twice this concentration. Using only the weight of active material (disregarding structural weight), the energy density of this cell as written would be 107 Wh/kg. Assuming an upper limit of two times this chlorine solubility, the energy density would be 153 Wh/kg. Alternatively, a cell which passes the Im^+ ion through an ion exchange membrane (Nafion) (11) would have a lower energy density (31.5 Wh/kg), assuming 1 dissolved Cl_2 per chloride ion. With Im^+ ion transport, the stoichiometry requires more melt than is needed for Cl^- ion transport. For comparison, a similar calculation for the conventional lead-acid battery yields an energy density of 169 Wh/kg. With the large amount of melt required, a cell of this type has a relatively low energy density. If a battery system is chosen where the melt is not affected by charge and discharge and serves only as a carrier for ionic charge, a more energetic cell would result.

Most of the polarization in an aluminum/imidazolium chloraluminum/aluminum cell results from the IR drop across the melt. Electrode polarization is low on both plating and stripping. This is favorable for a storage-battery electrode, but can be interpreted as low "throwing power" for electrodeposition. Therefore, uniform current density and very smooth electrode surfaces are essential for a smooth, even electroplated aluminum layer. Even slight irregularities on the plating surface will be exaggerated in the electroplated layer.

Summary

Large amounts of aluminum can be electroplated and stripped from acidic mixtures of 1-methyl-3-ethylimida-

zoliun chloride and aluminum chloride at ambient temperature. The plating and stripping rates are high for an ambient-temperature, nonaqueous system, and the quantity of aluminum is energetically useful for battery applications. The aluminum electrode shows high cycling efficiency which does not deteriorate as the rate is increased. The chloraluminum melt is stable and does not decompose on cycling. The relatively high positive potential of aluminum and the requirement of large quantities of melt to accommodate composition changes limit its application as a practical, high energy secondary battery.

Two-Phase Mass Transfer in Channel Electrolyzers with Gas-Liquid Flow

Demetre J. Economou** and Richard C. Alkire*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The electrochemical limiting current method was employed to study the mass transfer to a solid electrode in cocurrent gas-liquid flow through a vertical parallel-plate electrolyzer. Three systems were investigated: aqueous ferricyanide, aqueous ferricyanide containing a dispersion of nitrogen bubbles, and aqueous electrolyte containing a dispersion of oxygen bubbles in equilibrium with the liquid phase. The total mass-transfer rate was found to be the sum of three contributions: (i) the one-phase convective rate associated with the liquid as if it were flowing alone through the cell; (ii) the enhancement of mass transfer owing to disruption of the mass-transfer boundary layer, even by bubbles containing inert gas; and (iii) the further enhancement owing to penetration of the mass-transfer boundary layer by bubbles containing reactive gas. A series of controlled experiments was conducted to determine the dependence of these enhancement mechanisms upon operating variables such as gas and liquid flow rates, bubble size, and electrode material. It was found that, although the conversion per pass through the cell was negligible, a sevenfold increase in the mass transfer, as compared to one-phase flow with the same liquid velocity, was obtained with a reactive gas void fraction as low as 10%.

Because electrochemical reactions are heterogeneous, industrial processes require high mass-transfer rates to minimize capital investment and, simultaneously, large electrode surface areas to achieve high production rates. Strategies for obtaining high mass-transfer rates include increasing the concentration driving force, as by improving reactant solubility, and augmenting the mass-transfer coefficient, as by vigorous stirring. In the case of parallel-plate electrolyzers, such strategies include operation in turbulent flow, evolution of gas which causes vigorous agitation at the electrode surface, use of turbulence promoters, and judicious employment of two-phase flow phenomena. In particular, two-phase processes can meet competing requirements for high mass-transfer rates while maintaining low pressure drop through the cell and also high loading of reactive species, which may be sparingly soluble in the continuous conductive phase.

In the present work, a study was undertaken of the mass transfer to a solid electrode in upward, cocurrent flow of a gas-liquid mixture introduced into a channel electrolyzer (1). In such flows, the presence of gas bubbles results in an enhancement of the mass-transfer rates over those which would be obtained with one-phase liquid flow alone. This enhancement may be attributed to two effects. First, there is the physical disruption of the mass-transfer boundary layer, caused by the stirring action of dispersed gas bubbles, even by electrochemically inert gases. This type of enhancement will be referred to

as the "disturbance mechanism." Second, when the gas is electrochemically reactive, there is a further enhancement by extraction of reactive material from those bubbles which penetrate to regions very close to the electrode surface. This type of enhancement arises from the replenishment of reactants in depleted regions of the mass-transfer boundary layer and will be referred to as the "extraction mechanism." The purpose of this work was to conduct a series of controlled experiments to determine the dependence of these enhancement mechanisms upon operating variables.

Analysis of electrochemical mass-transfer limiting current data can provide information on the individual elements of the overall mass-transfer mechanism. For example, Lu and Alkire (2) studied mass transfer to solid electrodes in the presence of a second dispersed liquid phase and found that addition of individual coefficients could be used to predict the overall rate. With nomenclature applicable to gas-liquid systems, the concept would be

$$i_t = i_o + i_d + i_e = nF(k_o c_{bl} + k_d c_{bl} + k_e c_{bl}) \quad [1]$$

The first term within the parentheses represents the mass-transfer rate owing to the one-phase convective flow. The second gives the enhancement by the disturbance mechanism, and the third gives the further enhancement by the extraction mechanism. While k_o may be calculated from first principles for simple flow configurations, there is no such theory for prediction of k_d and k_e .

*Electrochemical Society Active Member.

**Electrochemical Society Student Member.

The different concepts for enhancing mass transfer in industrial or large-scale cells have been reviewed by Houghton and Kuhn (3). A detailed description of mass transfer in parallel-plate electrochemical reactors is available (4, 33). Transport processes to the walls of narrow gap channels have been studied by Acosta *et al.* (34). Mass (or heat) transfer from a two-phase mixture to a heterogeneous boundary such as pipe wall or electrode surface has been actively investigated. Postlethwaite and Holdner (5) obtained an enhancement of the mass transfer of dissolved oxygen to a pipeline wall of up to 100% when sand particles were suspended in the flowing liquid. Dworak *et al.* (6, 7) observed weakly enhanced mass transfer by dispersing CCl_4 in aqueous ferricyanide flowing past a horizontal Ni electrode. Furthermore, by using a micro-electrode and the reactant in the dispersed second phase only, they found that under the experimental conditions used the dispersed droplets did not wet the electrode surface.

However, Lu and Alkire (2) found a mass-transfer enhancement of up to 170% by dispersing inert toluene droplets in aqueous ferricyanide in laminar flow past vertical planar electrodes. In the presence of a reactive second phase, it was found that a nonpolar electrode (graphite) gave significantly higher mass-transfer rates when compared to a polar electrode (DSA[®]), which suggests that wetting occurred. It was further found that for reactants which are sparingly soluble in the aqueous phase, mass transfer could be augmented by orders of magnitude by using a reactive second phase.

Gas-liquid systems have been widely studied owing to their relevance to many chemical engineering operations. The literature on interfacial mass transport, bubble columns (8), and gas-liquid flows in general (9) is voluminous. Heat-transfer studies from the two-phase mixture to the walls of a bubble column have been reported by Mersmann (10), Steiff and Weinspach (11), and Deckwer (12), among others.

From the electrochemical engineering point of view, one may distinguish between two situations involving gas-liquid mixtures: (a) gas evolving electrodes and (b) gas sparging. Gas evolution is commonly found in the electrochemical industry (H_2O electrolysis, chlor-alkali cell, chlorate cell, etc.) and has been reviewed by Vogt (13). As the bubbles form and break away, they stir the solution adjacent to the electrode enhancing mass transport. The case of superimposed external hydrodynamic flow has been considered by Beck (14) and Vogt (15). In particular, Beck proposed an additive mass-transfer model to account for simultaneous gas evolution and fluid flow. The additivity of the mass-transfer coefficients was subsequently verified (16), and the same concept was used to describe mass transfer in two-phase flows (Ref. (2, 17) and Eq. [1]). Gas sparging is an attractive mode of artificial stirring in electrochemical processes (18, 24). For example, open-topped tanks with widely spaced electrodes used in the metal finishing industry are agitated by introducing air at the bottom of the tank. Significant contributions to the field have been made by Ibl and co-workers. Ibl *et al.* (18) introduced N_2 through porous frits at the bottom of a vertical parallel-plate cell having a sectioned cathode. The mass-transfer coefficient was uniform throughout the electrode surface and the mass-transfer rate increased with increasing gas flow rate, although the rate leveled off at high gas flow rates. Frit pore size and, therefore, bubble size had no effect on mass transfer. The authors noted that mass-transfer coefficients one order of magnitude higher than those in natural convection can be achieved.

In another study, Ibl (19) injected gas through porous frits in the annular space between two concentric cylinders and obtained mass-transfer coefficients of up to $5.2 \cdot 10^{-3}$ cm/s. The influence on the working electrode of gas bubbles generated by the counterelectrode in a parallel-plate cell was investigated by Sigrist *et al.* (20). The study was conducted with and without superimposed electrolyte flow. It was found that, irrespective of the mode of

operation, the mass-transfer coefficient was dependent on the gas void fraction alone. The experimental data were correlated with an equation resembling that of turbulent free convection. Ibl (21) presented a model to explain these results.

Several laboratory and micropilot scale experiments in two-phase flow with reactive gas have been reported. Examples include the production of H_2O_2 by O_2 reduction on graphite particles in fixed bed reactors (22) and the production of oxalic acid from CO_2 in a parallel-plate reactor (23). However, these studies concentrated on problems related to current efficiency and cell voltage and did not address fundamental mass-transport processes.

In summary, transport literature exists for a wide variety of multiphase processes involving gas-liquid-solid systems, but there are no known works on transport to a solid reactive surface exposed to two-phase flow in which the gas phase contains the reactant. This type of system, however, is encountered in the electrolysis of gaseous feedstocks. The present study was therefore carried out to improve fundamental understanding of the sequence of events which occurs and to establish correlations for multiphase transport processes in channel electrolyzers.

Apparatus

The parallel-plate electrolyzer was similar to that used previously by Lu (2) and consisted of a divided cell having two flow circuits as illustrated schematically in Fig. 1. The cell was machined from two polypropylene blocks. Working electrodes of DSA[®] (2.7×27 cm exposed, Diamond Shamrock Corporation) or of Pt (2.7×26 cm, pressed against a 316 SS sheet) were used. Adjacent to and coplanar with the working electrode were two additional electrodes made of DSA[®] (2.7×10 cm) which served to eliminate entrance and exit effects; of these electrodes, the downstream electrode was used as the reference electrode for the ferricyanide reduction experiments. The counterelectrode was made of porous DSA[®] (3.1×27 cm, Diamond Shamrock Corporation) and was positioned so that electrolyte flowed through the pores toward the working electrode compartment (Fig. 1). Electrical contact to electrodes was made by titanium screws pressed onto the back side of the electrodes and was found to have a contact resistance of less than 0.1Ω .

A microporous polypropylene separator (Daramic, W.R. Grace & Company) was used to prevent bulk flow between the anolyte and catholyte compartments. The separator had support ribs in the direction of flow to avoid buckling and was held at a distance of 0.2 cm from each electrode surface. On the working electrode side, there

Fig. 1. Schematic of the flow circuits inside the cell (not drawn to scale). Reference electrode shown was used for the ferricyanide reduction experiments.

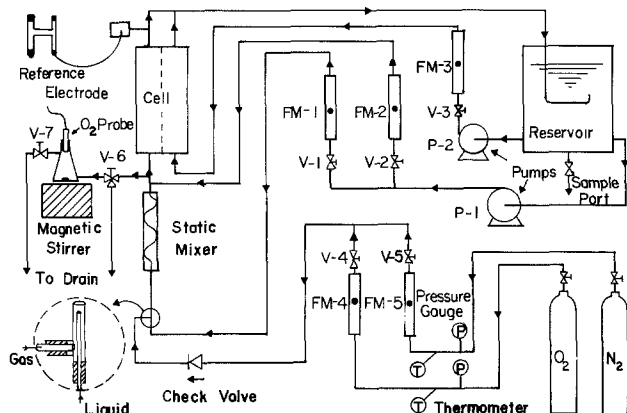

Fig. 2. Schematic of the flow system. Oxygen measuring system and reference electrode used for the oxygen-reduction experiments are included.

were three ribs dividing the catholyte chamber into two identical channels, each with cross-sectional dimensions of 1.35×0.2 cm. While in operation, the cell was positioned vertically.

Flow-visualization experiments were performed by replacing the separator and polypropylene counterelectrode block by a transparent Plexiglas sheet, of which the surface facing the working electrode was machined to exactly simulate the separator geometry.

The flow circuit illustrated in Fig. 2 consisted of delivery lines for gas and liquid streams which were combined in a Static Mixer[®] and passed to the working electrode compartment of the cell. Pump P-1 (March, no. TE-MDX-MT-3) fed the Static Mixer[®] with liquid electrolyte taken from the reservoir (4 liter capacity) at a rate controlled by valve V-1 and measured by meter FM-1 (Gilmont no. 4, Ti float). A second liquid metering system, V-2 and FM-2, was used to augment the flow from the Static Mixer[®] in order to achieve a wider range of variables. There were two gas-delivery systems containing calibrated flowmeters FM-4 (Gilmont no. 1, glass float) and FM-5 (Gilmont no. 2, glass float). Either or both systems could be used to control delivery rate of a single gas or of a gas mixture of known composition. The pressure of the gas was kept at 7 psig, determined by pressure gauges \textcircled{P} , while the gas temperature was measured with thermometers \textcircled{T} . The pressure in the cell was essentially 1 atm absolute.

The Static Mixer[®] (Kenics) used to generate a homogeneous dispersion of bubbles had a 3/16 in. id with 20 elements of 316 SS in a housing of the same material. The mean bubble size was measured from pictures of the two-phase mixture flowing through the working electrode compartment.

Pump P-2 (March, no. TE-MDX-MT-3) fed the counterelectrode compartment through flowmeter FM-3 (Gilmont no. 4, Ti float). After passing through the cell, the anolyte and catholyte streams merged and returned to the reservoir, where the gas was vented to the atmosphere and the liquid was recirculated. Anode and cathode reactions of ferri and ferrocyanide exhibited 100% c.e., so

there was no net concentration change in the recirculating system.

In experiments which involved oxygen reduction, the concentration of oxygen was measured just before the cell entrance with use of a calibrated dissolved- O_2 probe (Lazar, no. DO-166) in connection with the mV scale of a pH meter (Metrohm/Brinkmann pH-104). The O_2 concentration thus obtained was accurate to within ± 0.2 ppm.

Power to the cell was provided by a potentiostatic supply (Wenking, no. 70TS1) controlled by a function generator (PAR, no. 175). A cathodic-potential ramp was used to measure the limiting current plateau, which was displayed on an X-Y recorder (Houston, no. 2000).

Procedures

Table I lists the experimental systems that were used in this study. All solutions were prepared by mixing analytical-grade reagents with deionized, distilled water (conductivity $< 3 \times 10^{-6}$ ($\Omega\text{-cm}$)⁻¹). For the ferricyanide-reduction experiments, equimolar solutions of the redox couple were used in concentrations which ranged between 1 and 10 mM, as determined by iodometric titration (25).

The physical properties of the electrolyte solutions and the transport properties of the electrochemical reactants were measured and compiled in Table II. The density was measured by weighing a known solution volume, while the viscosity was found with an Ostwald viscometer. Diffusivities were determined with a Pt RDE (Pine, no. ASR, 366).

In order to obtain reproducible results, the Pt electrode was washed in acetone and distilled water, immersed in a chromic-sulfuric acid cleaning solution for 20 min, rinsed thoroughly, placed in the cell and activated in supporting electrolyte by sweeping five times between -1.2 and 0.8V vs. Hg/HgO (0.5M KOH), and then set at -1.2V vs. Hg/HgO for 2 min to reduce surface oxides. The DSA[®] electrode was degreased in trichloroethylene and rinsed with acetone and then water before being placed in the cell. No activation was necessary. The DSA[®] electrode was used for ferricyanide-reduction experiments only.

All electrolyses were carried out at about 25°C . For one-phase experiments with ferricyanide, the flow system was rinsed with distilled water and refilled with supporting electrolyte. An aliquot of stock solution containing reactant was then added, and the resulting solution was deaerated for 1h prior to use. The voltage scan was carried out at 5 mV/s . After completion of experiments at a given reactant concentration, an additional ali-

quot of stock solution containing reactant was added to increase the concentration to a new level, and the procedure was repeated.

For two-phase ferricyanide-inert gas experiments, the procedure was identical, except than N_2 gas was metered into the Static Mixer[®], and the scan rate was 10 mV/s. Limiting currents were measured in sequence of experiments, each at constant liquid flow rate with successively increasing gas flow rates.

For one-phase experiments with dissolved oxygen as the reactant, the electrolyte was circulated through the flow system for 30 min while air was sparged into the reservoir. The Pt electrode was then activated, the O_2 concentration was measured with the dissolved oxygen probe, and current-potential curves were recorded at a scan rate of 5 mV/s. A Hg/HgO (0.5M KOH) reference electrode (built in-house) was used for all the experiments involving the O_2 reduction reaction.

For two-phase experiments with reactive gas bubbles, air, or other N_2 - O_2 mixtures (depending on the desired O_2 concentration) were dispersed in the electrolyte phase. The procedure was similar to that followed for the two-phase inert-gas experiments, except that special care was taken to ensure that the Pt electrode remained active. The electrode was periodically reactivated, and the gas was periodically shut off and a one-phase experiment was carried out to confirm reproducibility of the Pt surface. Repeated experiments were reproducible to within 3% for one-phase flow and to within 12% for two-phase flow with reactive gas. Two-phase inert-gas experiments were reproducible to within 5%.

Results

Flow visualization.—Flow-visualization experiments indicated several types of flow patterns, depending upon the flow rates of the two phases, as shown in Fig. 3. In the bubbly-flow regime, the gas was uniformly distributed as a swarm of tiny bubbles. In the slug-flow regime, some gas was in large bullet-shaped bubbles which almost spanned the interelectrode gap; these large bubbles were separated by slugs of liquid containing tiny gas bubbles. In the region of low liquid flow rates, the flow patterns were not reproducible; this nonreproducible region was avoided in the measurement of mass-transfer coefficients.

It was found that the electrolyte composition had a strong influence on bubble coalescence. For example, the bubbles formed in 0.2M Na_2SO_4 were extremely fine in comparison with those formed, under otherwise iden-

Fig. 3. Flow-pattern map for N_2 -0.2M Na_2SO_4 two-phase flow through the working electrode compartment.

tical conditions, in distilled water or in 0.2M H_2SO_4 . It was further found that the mixed electrolyte solution (0.2M KOH + 0.1M Na_2SO_4) used for two-phase oxygen-reduction experiments displayed the same behavior, with respect to bubble sizes, as the 0.2M Na_2SO_4 solution used for the two-phase ferricyanide-reduction experiments.

Analysis of limiting current data.—The one-phase mass-transfer coefficient, k_o , was obtained from cathodic limiting current measurements on solutions having known concentrations of reactant, ferricyanide, or oxygen, as shown in Table I

$$k_o = \frac{i_o}{nF c_{bl}} \quad [2]$$

Under the conditions investigated, the O_2 reduction reaction proceeded by a 4-electron pathway. The two-phase disturbance-mechanism coefficient, k_d , was found from limiting current data obtained with ferricyanide solutions containing dispersed N_2 ; by subtracting the limiting current owing to the one-phase convective flow as found previously for the same liquid flow rate, the current attributable to the disturbance mechanism was obtained

$$k_d = \frac{(i_o + i_d)}{nF c_{bl}} - k_o \quad [3]$$

As indicated in Table I, the two-phase extraction-mechanism coefficient, k_e , was found by dispersing air (or other O_2 - N_2 mixtures) in a solution of mixed KOH- Na_2SO_4 electrolyte. The limiting current thus measured was due to all three mechanisms. After subtracting the limiting current measured under the same hydrodynamic conditions, with N_2 dispersed in ferricyanide solution (corrected for differences in diffusivity, concentration, and n value), the extraction-mechanism mass-transfer coefficient could be obtained

$$k_e H = \frac{(i_o + i_d + i_e)}{nF c_{bl}} - (k_o + k_d) \quad [4]$$

Equation [4] is obtained after manipulating Eq. [1], assuming that the equilibrium between gas- and liquid-phase compositions can be described for the O_2 system by Henry's law, $c_{bG} = H c_{bl}$.

One-phase convective flow mechanism.—The theoretical average limiting current density for mass transfer in laminar flow between infinite parallel plates is (4)

$$i_o = 1.85 \frac{nFD c_{bl}}{s} \left[\frac{V_L}{dDL} \right]^{1/3} \quad [5]$$

where $d = 2h$. However, as verified by Pickett and Stanmore (26), the same equation can also be used for channels with finite dimensions, provided that the hydraulic diameter of the duct replaces the equivalent diameter, i.e., $d = 2Wh/(W + h)$. Figure 4 indicates that data for both the ferricyanide and the dissolved oxygen electrode were in good agreement with Eq. [5] for Reynolds numbers up to 2100 (55 cm/s), where transition to turbulent flow sets in (4). A further consequence of Eq. [5] is that a graph of $i_o/V_L^{1/3}$ vs. c_{bl} should give a straight line through the origin. This relation was verified for ferricyanide reduction on both DSA[®] and Pt electrodes over the range of 1-10 mM.

The mass-transfer coefficient for one-phase flow is therefore

$$k_o = \frac{1.85D}{s} \left[\frac{V_L}{dDL} \right]^{1/3} \quad [6]$$

and can be used to estimate the diffusion-layer thickness, $\delta = D/k_o$. At the highest flow rate, the diffusion-layer thickness (50 μm) was ten times larger than the DSA[®] electrode-surface roughness (5 μm), so the electrode may be characterized as "smooth" for the one-phase ex-

Fig. 4. Normalized mass-transfer rate vs. liquid velocity in one-phase flow. Re refers to the ferricyanide-0.2M Na_2SO_4 solution Reynolds number.

periments. The shiny Pt electrode was essentially "smooth" for the one- and two-phase experiments.

The effect of a turbulence promoter (VEXAR 549V300, du Pont) was to increase the mass-transfer coefficient. In the range $6 < V_L < 60$ (cm/s), the mass-transfer limiting current density followed the correlation

$$i_0 = 0.0177 V_L^{0.70} c_{bl} \quad [7]$$

The exponent on velocity (0.70) is larger than in Eq. [5] and is indicative of the increased stirring effect. Over the range investigated, the limiting current was increased as much as threefold by the presence of the turbulence promoter.

Two-phase disturbance mechanism.—Because the gas bubbles rise with respect to the liquid during transit through the electrolyzer, they impart a transverse momentum to the surrounding fluid which is absent in single-phase laminar flow and which influences the mass-transfer processes near the electrode surface. Additional sources of mixing action would include sudden motions imparted during bubble coalescence and/or breakup in the shear region near the electrode surface, as well as agitation in the wake region behind rising bubbles. For these reasons, the mass-transfer enhancement by the disturbance mechanism cannot be solely attributed to decreased channel cross-sectional area available for liquid flow and to consequentially increased liquid velocity. This situation is especially true for the narrow channel used in this work (0.2 cm channel gap).

For the case of two-phase flow with inert gas, Eq. [1] is simplified ($c_{ng} = 0$) to

$$i_0 + i_d = nF(k_o + k_d) c_{bl} \quad [8]$$

where the left-hand side represents the experimentally measured current density, k_o is given by Eq. [6], and c_{bl} was measured experimentally. Figure 5 illustrates that the form of Eq. [8] correctly correlates the mass-transfer behavior of the disturbance mechanism, in that data fall upon straight lines which pass through the origin and exhibit slopes that depend upon liquid- and gas-flow velocities.

Figure 6 illustrates how the mass-transfer rate due to both the one-phase convective flow mechanism and the disturbance mechanism varies with gas superficial velocity for several values of liquid superficial velocity. The superficial velocities of both phases were calculated by dividing the corresponding flow rate (that for the gas at 25°C and 1 atm) by the channel cross-sectional area. The

Fig. 5. Mass-transfer rate in two-phase flow with inert (N_2) gas vs. ferricyanide concentration in bulk solution.

Fig. 6. Normalized mass-transfer rate in two-phase flow vs. nitrogen superficial velocity with the liquid superficial velocity as a parameter.

points on the $V_G = 0$ axis correspond to one-phase flow data. A substantial increase in the mass-transfer rate is obtained even when the gas flow rate is very small. For example, the limiting current is essentially doubled by gas velocities which are only 5% of the liquid velocity. This suggests that increased mass-transfer rates can be achieved for low gas-void fractions for which solution resistivity and pressure drop do not differ appreciably from the one-phase flow values.

Figure 6 also illustrates that the mass-transfer coefficient increases to a limiting value. For high gas velocities, a flow transition occurs from bubbly to slug flow, as indicated previously in Fig. 3. It is known (27) that slug flow is not as effective as bubbly flow in enhancing mass transport. A similar leveling of the transport rate in bubble columns has been reported by Ibl *et al.* (18), Novosad (27), Mersmann (10), and Steiff and Weinspach (11).

Figure 6 further shows that, for a given gas velocity, the mass-transfer coefficient increases with increasing liquid

velocity, a result which is in contrast to that reported by Sigrist *et al.* (20). However, in their experimental system, the interelectrode gap was at least five times wider than that used here, and, additionally, the liquid velocity employed was too low to be used in the present system while remaining in the bubbly flow regime. The explanation of these data by Ibl (21) was based on turbulent natural-convection concepts. Sigrist *et al.* realized that a decrease in the mass transfer with increasing liquid velocity (at constant gas velocity) would be observed provided that the liquid velocity is not too large. In studies of heat transfer in two-phase flow, others have reported conditions where the heat-transfer coefficient increases with liquid velocity (28) at high gas flow rates and where the coefficient is insensitive to liquid velocity (11) at low liquid flow rates. Thus it may be concluded that the disturbance effect is complex and that it depends upon the particular flow regime of operation. In the present work, the liquid velocity is appreciably higher than considered previously (20, 21), so explanations of behavior cannot be based on natural-convection phenomena.

Figure 6 also demonstrates that the disturbance mechanism can enhance the one-phase mass-transfer rate by up to 400%. Similarly, large enhancement factors have been reported elsewhere (11). In contrast, in studies on two-phase liquid-liquid systems, Lu and Alkire (2) reported an increase of up to 170%. The substantially greater enhancement in gas-liquid systems results from the significantly greater bubble-rise velocities in comparison with liquid droplets, owing to a greater density difference.

When the data in Fig. 6 are replotted on log-log coordinates, a slope of approximately 0.25 is found, which compares favorably to experimental and theoretical results reported for bubble columns (12).

After subtracting the contribution of the one-phase convective flow, the enhancement of mass transfer by the disturbance mechanism was found to be expressed by the empirical correlation

$$i_d = 0.007 V_L^{0.74} V_G^{0.36} C_{bL} \quad [9]$$

which describes the data, for the bubbly-flow regime, to within 8%.

For the two-phase inert-gas experiments, the DSA® electrode gave currents which were about 10% higher than on the Pt electrode. Because the two-phase mass-transfer boundary layer can be as thin as 10 μm , this effect was attributed to the roughness of the DSA® material (about 5 μm), while the shiny Pt was essentially smooth.

By using two different Static Mixers®, it was possible to vary the mean bubble diameter by a factor of two. For the 3/16 in. unit, the diameter ranged between 200 and 600 μm , and for a 1/4 in. unit, the diameter ranged between 400 and 1200 μm . The effect of bubble size upon the mass-transfer rate was smaller than 5%. Others have reported similar observations in both gas-liquid (18, 29) and liquid-liquid systems (2).

When a turbulence promoter was placed in the flow channel, the influence upon two-phase inert-gas mass transfer was negligible. These results suggest that the two-phase mixture was by its nature "well mixed" and that the turbulence promoter provided little additional mixing. While the promoter might be expected to alter the mean bubble size, the results of the previous paragraph indicate that the mass-transfer enhancement is insensitive to bubble size.

Two-phase extraction mechanism.—When an electrochemically reactive gas is introduced as the second phase, a further mass-transfer enhancement occurs, as is depicted in the upper portion of Fig. 7. The gas-side mass-transfer resistance is negligible (30), so the oxygen concentration at the gas-liquid bubble interface is at the saturation concentration. Furthermore, the solution far from the electrode is saturated in oxygen as well. However, a bubble may penetrate the mass-transfer boundary layer near the electrode surface and may provide, by extraction of oxygen from the bubble, an increase in local oxygen

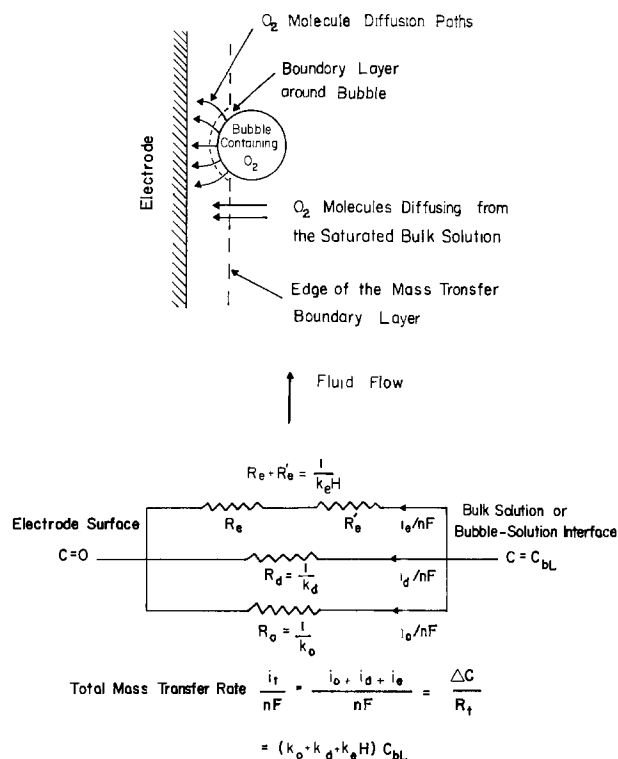

Fig. 7. (top) Mass-transfer mechanism in two-phase flow with reactive gas. (bottom) Equivalent resistive network.

concentration which would enhance the overall mass-transfer rate above that experienced by the disturbance mechanism of unreactive bubbles. It is to be expected that attachment of gas bubbles to the electrode is unlikely to occur at the polar electrode materials used in this study, so there will always be a liquid film separating the bubbles from the electrode. The lower portion of Fig. 7 indicates an equivalent resistive network describing the mass-transfer processes which are operative in the case of two-phase reactive-gas experiments. The extraction mechanism has been represented by two resistors in series, one of which (R'_e) accounts for the gas-to-liquid interfacial resistance, the other (R_e) for the further transport of the reactant to the electrode surface.

With use of Henry's law, Eq. [1] becomes

$$i_t = i_o + i_d + i_e = nF(k_o + k_d + k_e H) C_{bL} \quad [10]$$

For the conditions investigated in this study, the Henry's law constant for oxygen, $H = C_{bL}/C_{bL}$, had a value of 39. Data in Fig. 8 verify that the proposed additive correlation is appropriate. The variation in intercept may be attributed to drift in the "zero" of the oxygen probe and to uncertainty (at a level of 6.25×10^{-3} mM) in measurement of dissolved oxygen concentration by the probe. The data which follow were obtained at oxygen-saturation concentrations of 0.220 mM, for which probe errors were less than 8%.

The dependence of the measured total limiting current density on air superficial velocity is shown in Fig. 9 for three liquid superficial velocities. It is remarkable that for a given liquid velocity, the overall mass-transfer coefficient can be increased over the one-phase value by almost one order of magnitude by introduction of reactive gas. Indeed, the limiting current can be increased over the one-phase value by a factor of 7 with only 10% gas-volume ratio. The data shown in Fig. 9 exhibit similar behavior to the two-phase inert-gas data (Fig. 6) and, for the bubbly-flow regime, can be correlated by the empirical expression

$$i_t = 0.40 V_L^{0.60} V_G^{0.23} C_{bL} \quad [11]$$

which is good for $V_G > 1.8$ cm/s and describes the data to within 10%.

Fig. 8. Total mass-transfer rate in two-phase flow with reactive (O_2) gas vs. dissolved-oxygen concentration in bulk solution.

Fig. 9. Normalized mass-transfer rate in two-phase flow vs. air superficial velocity with the liquid superficial velocity as a parameter.

The relative importance of the extraction mechanism was found to be as follows

$$k_a H = (1.19 \pm 0.10) (k_o + k_d) \quad [12]$$

One intuitively expects that larger values of $(k_o + k_d)$ correspond to smaller bubble-electrode distances and, therefore, larger k_e . However, the linear relationship between i_e and $(i_o + i_d)$ implied by Eq. [12] may not be true in cases where, owing to high conversion of the reactant, replenishment of the bulk solution by the reactive bubbles occurs in addition to replenishment of the mass-transfer boundary layer.

Variation of bubble size, created with use of two different Static Mixers[®], had no influence on mass-transfer rates in two-phase reactive-gas systems. This is in contrast to data obtained in two-phase liquid-liquid systems

with reactive droplets (2). The difference may be attributed to the wettability of the electrode used by the dispersed organic phase. Similarly, the presence of a turbulence promoter in the working electrode compartment did not contribute additional mass-transfer enhancement beyond that afforded by the two-phase reactive gas in the absence of the promoter.

Conclusions

The limiting current method was used to study the mass transfer to a solid electrode in cocurrent gas-liquid flow through a vertical parallel-plate cell. Both an inert gas and a reactive gas were investigated. Flow visualization experiments showed that for the flow rates of gas and liquid used, the cell was in either the bubbly-flow or slug-flow regime. The total mass-transfer rate was expressed as the sum of the contributions of three different mechanisms: (i) the one-phase convective flow mechanism associated with the liquid as if it were flowing alone through the cell; (ii) the disturbance mechanism associated with the presence of bubbles "disturbing" the boundary layer; and (iii) the extraction mechanism associated with the presence of reactive bubbles replenishing the mass-transfer boundary layer. An experimental format was developed which enabled the contribution of each of the mechanisms to the total mass-transfer rate to be measured separately and enabled the additive model to be verified. Operating variables investigated included gas and liquid flow rates, bubble size, and electrode material. In addition, the effect of placing a turbulence promoter in the channel was determined.

The experimental results support the following conclusions.

1. The one-phase flow results compared well with theoretical expectations.

2. The mass-transfer rate due to the disturbance mechanism, as well as the mass-transfer rate due to the extraction mechanism, was proportional to the reactant concentration in the bulk solution.

3. At a constant liquid superficial velocity, the mass-transfer rate due to both the one-phase convective flow mechanism and the disturbance mechanism (i) reached values up to five times larger than those corresponding to the same liquid velocity in one-phase flow, (ii) increased sharply with increasing gas superficial velocity at low gas velocities, (iii) approached a constant value at high gas velocities, (iv) was dependent on the gas superficial velocity to the 0.25 power, (v) was independent of the bubble size for bubbles with diameters in the range 200-1200 μm , (vi) did not change significantly when a turbulence promoter was placed in the channel, and (vii) was always higher on an electrode with rough surface (DSA[®]) when compared to the rate on a "smooth" electrode (Pt).

4. The mass-transfer rate due to the disturbance mechanism was dependent on the liquid superficial velocity to the 0.74 power and on the gas superficial velocity to the 0.36 power (for the bubbly-flow regime).

5. At a constant liquid superficial velocity, the total mass-transfer rate in two-phase flow with reactive gas (i) reached values one order of magnitude higher than those corresponding to the same liquid velocity in one-phase flow, (ii) increased dramatically with increasing gas superficial velocity at low gas velocities, (iii) approached a constant value at high gas velocities, (iv) was dependent on the gas superficial velocity to the 0.23 power (for the bubbly-flow regime), (v) was independent of the bubble size for bubbles with diameters in the range 200-1200 μm , and (vi) changed insignificantly when a turbulence promoter was placed in the channel.

6. For a given gas superficial velocity, the total mass-transfer rate in two-phase flow with reactive gas was dependent on the liquid superficial velocity to the 0.60 power (for the bubbly-flow regime).

7. The mass-transfer rate due to the extraction mechanism was proportional to the mass-transfer rate due to both the one-phase convective flow mechanism and the

disturbance mechanism, the proportionality factor being 1.19 ± 0.10 .

The results of this study showed that the use of two-phase flow in electrochemical reactors incorporating a gas which is sparingly soluble in the liquid phase may be highly advantageous. In particular, high mass-transfer rates can be achieved at low gas-volume fractions. Thus, the solution resistivity and the pressure drop through the system do not differ significantly from the corresponding values in one-phase flow. Consider for example the case of a gas-void fraction $\epsilon = 10\%$. The conductivity of the solution (31) will be $\kappa = \kappa_0(1 - \epsilon)^{1.5} = 0.85\kappa_0$, and the energy consumption due to IR drop will increase by about 15%. Moreover, the pressure drop (32) will be

$$\frac{dP}{dx} = \left(\frac{1 + \epsilon}{1 - \epsilon} \right) \left(\frac{dP}{dx} \right)_l = 1.22 \left(\frac{dP}{dx} \right)_l$$

and the energy consumption for pumping will be 22% higher than that when operating in one-phase flow with the same liquid velocity. However, even at $\epsilon = 10\%$, the mass-transfer rate can be up to seven times that in one-phase flow (Fig. 9), which amounts to a 600% increase in productivity if the process is mass-transfer limited.

This work dealt with the case of negligible conversion per pass of the reactant through the cell. The enhancement due to the extraction mechanism was solely attributed to bubbles resaturating depleted regions within the mass-transfer boundary layer. In situations where the reactant conversion is high, however, the presence of the reactive bubbles resaturating the bulk solution as well will make the contribution of the extraction mechanism even more significant.

LIST OF SYMBOLS

c	reactant concentration, mM
d	equivalent diameter, cm
D	reactant diffusivity, cm ² /s
F	Faraday constant, 96,500 C/g-eq
h	gap of flow channel, cm
H	constant in Henry's law (= c_{ht}/c_{hl})
i	current density, mA/cm ²
k	mass-transfer coefficient, cm/s
L	electrode length, cm
n	number of electrons exchanged in electrode reaction
P	pressure, dyn/cm ²
R	equivalent mass-transfer resistance, s/cm
Re	Reynolds number in one-phase flow (dV_1/ν)
s	stoichiometric coefficient of reacting species
V	superficial velocity, cm/s
W	electrode width, cm

Greek Symbols

δ	diffusion-layer thickness, cm
ϵ	gas-void fraction

κ	solution conductivity, ($\Omega\text{-cm}$) ⁻¹
ν	solution kinematic viscosity, cm ² /s

Subscripts

b	bulk of gas or liquid phase
d	due to the disturbance mechanism
e	due to the extraction mechanism
G	gas phase
L	liquid phase
o	one-phase flow
t	total (all three mechanisms)

A Comparison of Photochemical Properties of Amorphous and Polycrystalline Fe₂O₃

Department of Physics, Brock University, St. Catharines, Ontario, Canada L2S 3A1

ABSTRACT

A comparison is made of the photoelectrochemical properties of Fe_{1.996}Sn_{0.004}O₃ in two forms: as polycrystalline sintered compacts and as amorphous thin films prepared by RF sputtering. There is no essential difference in optical bandgaps, Mott-Schottky intercepts, band-edge positions, and optical absorption spectra. For the photo-oxidation of water, the difference between instantaneous and steady-state photocurrents is much larger for the amorphous than for crystalline form, which indicates a difference in the density and/or effectiveness of surface states. This difference between instantaneous and steady-state currents disappears, for both amorphous and crystalline Fe₂O₃, on adding the S²⁻/S_n²⁻ redox couple to the solution. The dark current of the amorphous form is larger, and its quantum efficiency in the ultraviolet is smaller.

Ferric oxide has been studied extensively as a photoanode; its relatively small bandgap, good chemical stability, and easy preparation makes it an interesting material for application in liquid-junction solar cells. However, its properties as a photoanode for water oxidation are apparently far from simple: on exposure to light, the photocurrents show strong transient excursions, and they do not set in at the flatband potential. Moreover, the Mott-Schottky plots are often found to be curved, and dependent on the measuring frequency as well. These deviations from simple behavior have been reported for Fe₂O₃ in the form of single crystals (1, 2), polycrystalline ceramics (3-5), and flame-oxidized iron (6, 7). The extent to which these complexities occur seems to depend sensitively on the sample preparation conditions; this points towards an important role for defect states, either in the bulk or at the surface.

In this paper, we report a comparison of the photoelectrochemical behavior of polycrystalline and amorphous Fe₂O₃. Our basic result is that the absence of long-range order in amorphous Fe₂O₃ has no influence on those properties which are normally associated with the crystalline electronic band structure. Only those parameters which control the kinetics of the forward and back-reactions of the photo-oxidation of water (without added redox couples) differ significantly between the amorphous and crystalline forms.

Experimental

Polycrystalline samples of Fe_{1.996}Sn_{0.004}O₃ (labeled c-Fe₂O₃ from here on) were prepared from Fe₂O₃ and SnO₂ (both better than 99.999%, Johnson & Matthey, Puratronic grade). The oxide mixture was pressed into disks and fired in air for 16h at 1300°C, followed by a fast air quench. Sample area was 1.2 cm², and its thickness was 0.2 cm. X-ray diffraction showed only lines of α-Fe₂O₃ (hematite structure). Amorphous samples (a-Fe₂O₃) of the same composition were prepared in thin film form by using some of these disks as sputtering targets. Sputtering took place in a small RF triode sputtering system (Plasmax 121) in an argon atmosphere, onto stainless-steel disks for the samples used in the electrochemical experiments and onto fused silica substrates for control samples. Very low plasma power was used, resulting in a growth rate of only ≈ 1.0 μm/day, onto the water-cooled substrates. X-ray diffraction of a 3 μm thick control sample showed neither discernible lines nor broad bands. The excellent stability of the a-Fe₂O₃ films was tested by heating this control sample for a few hours in air at successively higher temperatures without crystallizing; only during heating at 950°C did the sample transform to the crystalline state, as was seen by the appearance of sharp α-Fe₂O₃ x-ray diffraction lines and by the roughening of the previously mirror-smooth surface. Previous experience with preparing amorphous compound oxides in our

equipment has shown that the chemical composition of the sputtered film is equal (within ±5%) to the target composition. The a-Fe₂O₃ films were insoluble in strong acid and base; only 35% HJ etched the film at a rate of ≈ 3 μm/h.

The resistivity (ρ), Hall coefficient (R_H), and thermoelectric power (S) were measured by standard techniques. Ohmic contacts were made with indium applied with an ultrasonic soldering iron. The electrochemical measurements were made in a one-compartment cell; the samples were properly masked and the counterelectrode was 7 cm² of freshly platinized Pt. Potentials were measured with respect to the SCE. Solutions were continuously flushed with hydrogen. Current-voltage curves were measured potentiostatically; illumination was with a pulse of xenon-arc light (0.90 W/cm² at the sample surface) and time-dependent currents were recorded with a storage oscilloscope. The quantum efficiency was measured, on an arbitrary scale, with chopped monochromatic light and a lock-in amplifier over the entire wavelength range 300-900 nm; in the sub-bandgap region, great care was taken to avoid spurious effect due to second-order radiation and stray light from the monochromator. The results were then put on an absolute scale (with a possible ±10% error) by measuring directly with the oscilloscope the instantaneous and steady-state currents, at the same sample potential, under monochromatic illumination at $\lambda = 400$ nm. Light intensities were measured with a calibrated radiometer, and were corrected for reflectivity losses at the sample surface. The electrode impedance was measured in 1M NaOH and 0.1M Na₂HPO₄ in the range $7 \times 10^{-1} < f < 7 \times 10^4$ Hz using a system similar to that described in Ref. (8).

Results

Both a- and c-Fe₂O₃ samples were n-type semiconductors with properties reproducible to ±5%. The room temperature electrical parameters for c-Fe₂O₃ were: $\rho = 40$ Ω-cm, $R_H = 15$ cm³/C, and $S = 580$ μV/K. For the 3 μm a-Fe₂O₃ film, $\rho = 4.5 \times 10^2$ Ω-cm; R_H and S could not be measured.

The real and imaginary parts of the complex impedance were both frequency dependent according to $Z_{i,R} \sim f^{-\alpha}$, with $\alpha \approx 0.8$ for both a- and c-Fe₂O₃; similar results have been reported previously (5). Interpreting the imaginary part as a pure capacitance, $Z_i = (\omega C)^{-1}$, then a slightly curved Mott-Schottky plot of C^{-2} vs. V at a given frequency can be obtained; for $f = 14.7$ Hz, such a plot is shown in Fig. 1. At this low frequency, the value of $C = (\omega Z_i)^{-1}$ at $V - V_{FB} = 0.5V$ is 0.44 F/m² for the polycrystalline sample. This compares with a theoretical depletion layer capacitance of 0.06 F/m² and a Helmholtz capacitance of $C_H = 0.2$ F/m². However, the significance of the measured capacitance is doubtful, since the Mott-Schottky slopes were found to be frequency dependent. The intercept voltages V_0 were found to be independent

Fig. 1. The Mott-Schottky plots of C^{-2} vs V (SCE) for amorphous (\blacktriangle) and crystalline (\bullet) $\text{Fe}_{1.996}\text{Sn}_{0.004}\text{O}_3$. Electrolyte: 1M NaOH. Measuring frequency: 14.7 Hz. Sample area: 3.6 mm².

of frequency. In the frequency range $2 < f < 3 \times 10^4$ Hz, V_0 is identical for a- and c- Fe_2O_3 , and equal to -0.85 ± 0.05 V (SCE) in 1M NaOH and -0.55 ± 0.05 V (SCE) in 0.1M Na_2HPO_4 (pH = 9.2) solution.

The time dependence of the photocurrent is shown in Fig. 2a, which also gives the definitions of the instantaneous (i_t), steady-state (i_s), and dark (i_d) currents. i_t and i_s were proportional to the incident light intensity in the range of 0.2-0.9 W/cm² for all solutions. i - V characteristics were reproducible to $\pm 10\%$ between different samples.

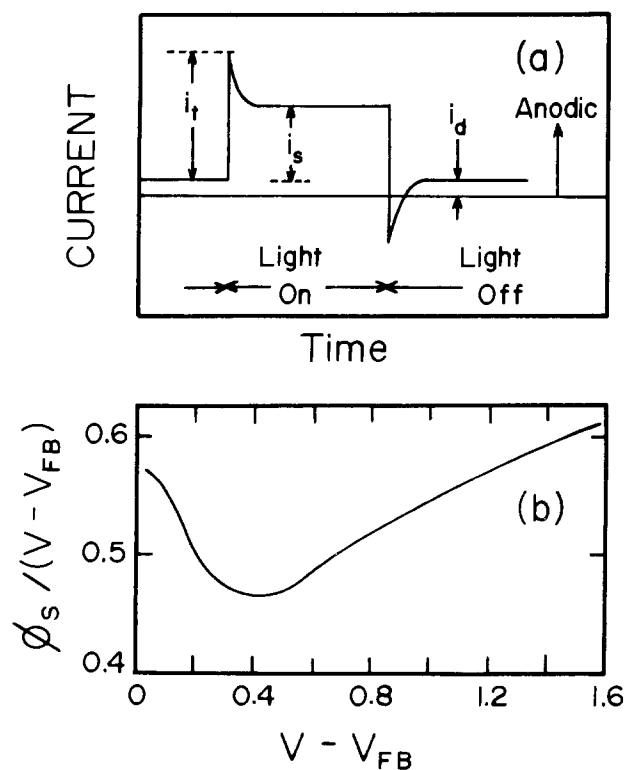

Fig. 2. (a): The time dependence of the currents. (b): The potential drop over the depletion layer (ϕ_s) as a function of the total potential drop ($V - V_{FB}$).

Fig. 3. The current-voltage curves of (a) crystalline and (b) amorphous $\text{Fe}_{1.996}\text{Sn}_{0.004}\text{O}_3$ in 1M NaOH. (—): i_t , (---): i_s , (· · ·): i_d . The top scale is ϕ_s , the potential drop over the depletion layer.

The risetime of i_t was ≤ 1 ms, the risetime of the light pulse; the decay time is of the order of 5-10 ms. Figure 3 shows the potential dependence of the currents in 1M NaOH.¹ For c- Fe_2O_3 , i_t sets in at $V_{ON,t} = -0.65$, but i_s becomes measurable only when $V \cong V_{ON,s} = -0.2$ V. Only at much higher anodic potential, $V \cong +0.5$ V, do the sharp transient current spikes disappear; there i_t and i_s are identical. The dark current is less than 10 μA over the entire potential range.

For a- Fe_2O_3 , i_t sets in also at $V_{ON,t} = -0.65$ V, but the steady-state currents cannot be observed until a potential of $V_{ON,s} = +0.4$ V (SCE) is reached. At higher potentials, i_s and i_d increase sharply, but i_t decreases. For $V \cong (V_{ON,s} + 0.2)$, the currents for a- Fe_2O_3 become very noisy and are not reproducible. The i - V curves of Fig. 3 do not change when changing the electrolyte to HClO_4 , H_2SO_4 , Na-acetate, Na-phosphate, or NaNO_3 solutions, except for a horizontal shift of approximately 60 mV/pH unit change. Saturating the solutions with O_2 instead of H_2 does not change the curves appreciably. Adding 0.01M KBr to the 1M HClO_4 solution reduced the difference between i_t and i_s by $\cong 80\%$. In 1M HClO_4 + 0.01M KI solution, the i_s curve was identical to the i_t curve for the c- Fe_2O_3 samples; data could not be obtained for the a- Fe_2O_3 samples since in this solution they dissolved very quickly as soon as the potential was increased from $V_{ON,t}$. The nearly complete disappearance of the transient current peaks was also observed in 1M NaOH + 0.1M Na_2S + 0.01M S_8 solutions; Fig. 4 shows the i - V curves. The a- and c- Fe_2O_3 samples

¹An anonymous referee has pointed out that the photocurrents of 2% Si-doped Fe_2O_3 samples are dependent on the quenching conditions. No such effect was found for our samples, as long as during preparation no Fe_3O_4 was formed by too high a temperature or too reducing an atmosphere during sintering.

Fig. 4. The current-voltage curve of (a) crystalline and (b) amorphous $\text{Fe}_{1.996}\text{Sn}_{0.004}\text{O}_3$ in 1M NaOH + 0.1M Na_2S + 0.01M S_8 . (—): i_t , (---): i_s , (· · ·): i_d . The top scale is ϕ_s , the potential drop over the depletion layer.

have now nearly identical i_t and i_s curves; they only give different i_d curves. In contrast, the photocurrents in 1M NaOH are always larger for c- than for a- Fe_2O_3 .

The quantum efficiency η for the instantaneous current [$\eta = i_t/(\text{photon flux at surface})$] is shown in Fig. 5. These measurements were performed in 0.1M Na_2HPO_4 (pH = 9.2) solution at a potential $V = +0.75\text{V}$ (SCE). At this potential i_d and i_s for a- Fe_2O_3 are still zero, and the other currents are very stable and noise free, allowing a reliable determination of η over 6 orders of magnitude. Figure 5 also shows the optical absorption coefficient α for c- Fe_2O_3 from Ref. (9) and the preliminary results of our measurements of α for a- Fe_2O_3 . Over the limited common wavelength range, α for a- and c- Fe_2O_3 are essentially identical. The energy of the interband transitions was determined from plots of $(\eta h\nu)^m$ vs. $h\nu$. In the range $2.1 < h\nu < 2.7$ eV, a linear plot was obtained for $m = 1/2$, giving an indirect allowed bandgap transition at $E_{g,1} = 1.96 \pm 0.03$ eV. For $2.9 < h\nu < 4.2$ eV, we found $m = 2$ and $E_{g,2} = 2.73 \pm 0.05$ eV. These energies were identical for a- and c- Fe_2O_3 and are in good agreement with values reported for single-crystal Fe_2O_3 (10). The $(\alpha h\nu)^m$ plots gave $E_{g,1} = 1.95 \pm 0.08$ eV for both a- and c- Fe_2O_3 . All samples showed a small subsidiary maximum in the η -spectrum at $h\nu = 1.50 \pm 0.1$ eV; very careful checking showed that this was not an artifact of the measuring procedures.

Discussion

In the simplest model (11) of photoelectrolysis, the photocurrent is basically determined by the solid-state properties of the semiconductor: the position of the conduction and valence bandedges, the bandgap(s), and optical absorption coefficients, and the depletion layer width and hole diffusion coefficient. The photocurrent is then equal to the flux of photogenerated holes arriving at the semiconductor-solution interface; the charge-transfer and chemical-reaction kinetics are not supposed to be rate limiting. From numerous experiments (3, 4, 7), it is clear that this is not valid for mono- and polycrystalline Fe_2O_3 ; specifically, the existence of transient photocurrents shows that transfer kinetics can be rate limiting

Fig. 5. Left scale: the quantum efficiency η of the instantaneous current for amorphous (\blacktriangle) and polycrystalline (\bullet) $\text{Fe}_{1.996}\text{Sn}_{0.004}\text{O}_3$, measured in 0.1M Na_2HPO_4 at $V = +0.75$ (SCE). Right scale: The absorption coefficient α for polycrystalline (—) Fe_2O_3 , [Ref. (9)] and for amorphous (-----) $\text{Fe}_{1.996}\text{Sn}_{0.004}\text{O}_3$.

with surface states playing an essential role. Only for the photo-oxidation of redox species such as I^- ions does Fe_2O_3 behave ideally (12). We will now discuss how the various parameters which influence the photoelectrochemical behavior differ between a- and c- Fe_2O_3 .

An exhaustive review (13) of the experimental data relating to electronic transport in c- Fe_2O_3 has shown that, most likely, the electrons, ionized from the Sn donors, move as large polarons with low mobility in a rather narrow 3d-conduction band. The electron effective mass is $(m^*/m_0) \cong 6$, and at the Sn doping level used in our samples the donor ionization energy is $E_D \cong 0.20$ eV. These parameters give a density of states $N_D \cong 3.65 \times 10^{20}$ cm^{-3} ; for a donor concentration $N_D = 8.0 \times 10^{19}$ cm^{-3} , the calculated carrier concentration is $n = 2.5 \times 10^{18}$ cm^{-3} and the Fermi level is $\Delta E_F = 0.13$ eV below the conduction bandedge. The calculated mobility is $\mu = 0.6$ cm^2/Vs , an acceptable value for a large polaron. The Hall effect is anomalous in Fe_2O_3 , and n cannot be calculated directly from R_H . An independent value of ΔE_F can be obtained from the thermoelectric power $S = (k/q)(A + \Delta E_F/kT)$, although the reliability of the result is somewhat doubtful due to impurity conduction effects. With $A = 2$ (13), the measured S value gives $\Delta E_F = 0.12$ eV, consistent with the previous estimate. For a- Fe_2O_3 , the conductivity mechanism is unknown, but oxides such as WO_3 which show large polaron conduction in the crystalline form are low mobility small polaron conductors in the amorphous form (14). The larger resistivity of a- Fe_2O_3 , as compared to c- Fe_2O_3 , indicates that such may be the case for Fe_2O_3 as well. For both a- and c- Fe_2O_3 , however, the resistivity is sufficiently small that photocurrents are not limited by slow carrier transport in the solid.

The experimental data show that for Fe_2O_3 the absence of long-range order has no discernible influence on the bandgap energies $E_{g,1}$ and $E_{g,2}$, whether they are determined from straight absorption or from quantum efficiency measurements. The absolute position of the bandedges can be determined from the flatband potential, which is, as we will show later, equal to -0.65V (SCE) in 1N NaOH for both a- and c- Fe_2O_3 . At the pH of zero charge [7.1 for Fe_2O_3 (15)], the Fermi level therefore lies $-0.65 + (14-7.1) \times 0.06 + 4.74 = 4.50$ eV below the vacuum level. This puts the conduction bandedge at 4.37 eV and the valence bandedge at 6.33 eV, in fair agreement with the value of 5.9 eV found from photoemission measurements (16). Presumably, the valence band wave functions are derived primarily from Fe^{3+} ($3d^5$) atomic terms; the band lies about 1V deeper than the 3d-valence bands in CuO (17) and NiO (18). Speculatively, we assign the $E_{g,2} = 2.73$ eV energy to a transition from a deeper lying O-2p valence band to the conduction band. This puts the O-2p band at 7.1 eV below the vacuum level, close to the position (7-7.5 eV) found for most metal oxides.

The quantum efficiency η for the instantaneous current (which is not limited by surface reaction kinetics) (7) will be proportional to the optical absorption coefficient α if both the depletion layer width W and the hole diffusion length L_p are smaller than the optical penetration depth α^{-1} (11). Close to the $E_{g,1}$ bandgap, η_a and η_c are nearly identical, but at higher photon energies they differ increasingly, even though α_a and α_c are essentially identical. It is unlikely that this difference is due to a difference in either W or L_p , since the samples are doped equally and since one expects L_p to be smaller, if anything, in the amorphous state. We have no explanation for this difference. Near and below $E_{g,1}$, the proportionality of α and η breaks down, since absorption processes which do not create hole-electron pairs contribute to α . The slope of $\log \eta$ vs. $h\nu$ near $E_{g,1}$ is larger for a- Fe_2O_3 than for c- Fe_2O_3 ; this may indicate that in a- Fe_2O_3 the bandedges are less sharp. We ascribe the small maximum at $h\nu = 1.5$ eV to a transition involving a state inside the bandgap, either from an occupied state 0.4-0.5 eV above the valence band or to an empty state below the conduction band [at the measuring potential of $V = +0.75\text{V}$ (SCE) in a pH = 9.2 solution the Fermi level lies between these two possi-

ble states]. c-Fe₂O₃ has two weak and broad absorption bands in this region (9), at $h\nu = 1.60$ and 1.43 eV, which are due to forbidden d-d crystal field transitions of the Fe³⁺ ion. Although it is, in principle, possible that the small η maximum at $h\nu = 1.5$ eV is due to a heating effect (19) from these crystal field absorptions, the sharpness of the maximum and the absence of any effect of increased stirring or chopper speed on the magnitude of η makes this very unlikely.

The strong frequency dependence of the complex impedance for both a- and c-Fe₂O₃ has been observed also in single crystals (2), polycrystalline (5), and thermally oxidized (6) iron samples; a satisfactory model for it is lacking. The slopes of the often curved Mott-Schottky plots cannot be used to determine donor densities N_D in any reliable manner. However, the intercept voltages V_o , at a given pH, are nearly equal for all different forms of Fe₂O₃; our value, $V_o = -0.85 \pm 0.05$ V (SCE) at pH ≈ 14 is valid for both a- and c-Fe₂O₃ and independent of frequency. V_o is related to the flatband potential according to (20, 21)

$$V_o - V_{FB} = \left(\frac{-kT}{q} r + \frac{kT}{q} \ln r \right) - (q\epsilon\epsilon_0 N_D / 2C_H^2) \quad [1]$$

with $r = N_D^+ / N_D$ the fraction of ionized donors in the bulk and C_H the Helmholtz layer capacitance. The first rhs term, due to incomplete donor ionization at flatband potential, can be calculated from the electronic properties determined previously and equals -0.09 V. The value of the second term, which comes from the contribution of the Helmholtz layer capacitance to the overall measured capacitance, depends strongly on the values adopted for ϵ and C_H . For Fe₂O₃, reported values of ϵ range from 20 (22) via 80 (4, 6) to 120 (1), depending on measuring frequency and sample preparation; we will use $\epsilon = 80$, measured (4) by a direct substitution method on undoped polycrystalline samples. A reliable value of C_H for oxide semiconductors is not available; we will use the generally accepted value $C_H = 0.2$ F/m² (23). We note that a recent report (2) shows a very large shift of V_o with N_D (determined from a MS slope) for single-crystal Zr-doped Fe₂O₃, leading to a value $C_H = 0.055$ F/m² with $\epsilon = 120$. This pair of values would give a second rhs term in Eq. [1] of 2.2 V, and lead to the conclusion that 90%-95% of the applied potential appears as a voltage drop over the Helmholtz layer; both consequences are difficult to accept. With $\epsilon = 80$ and $C_H = 0.2$ F/m² the correction term equals 0.11 V; therefore, the flatband potential in 1M NaOH is -0.65 ± 0.05 V (SCE).

If C_H is not very large compared to the depletion-layer capacitance C_s , then the applied potential $V - V_{FB}$ will partition itself between the Helmholtz layer (ϕ_H) and the depletion layer (ϕ_s). Values of $\phi_s / (V - V_{FB})$ can be calculated from the expressions (20, 21)

$$V - V_{FB} = \phi_s + \phi_H \quad [2]$$

$$\phi_H = Q_s C_H^{-1} \quad [3]$$

$$Q_s = (2N_D \epsilon \epsilon_0 kT)^{1/2} [(q\phi_s / kT) + r \{ \exp(-q\phi_s / kT) - 1 \} + \ln \{ r + (1 - r) \exp(-q\phi_s / kT) \}]^{1/2} \quad [4]$$

where the expression used for Q_s , the surface charge density, is valid for $(V - V_{FB}) \geq kT/q$. For the parameters $\epsilon = 80$, $C_H = 0.2$ F/m², and $N_D = 8 \times 10^{25}$ m⁻³, approximately half the applied total potential drop is over the depletion layer (Fig. 2b). We note that therefore the bandedges are not fixed on the energy scale when a potential is applied, but that they will shift by an amount $q\phi_H$ which can be obtained from Fig. 2b.

The onset voltages $V_{ON,i}$ for the instantaneous photocurrent i_i are equal for a- and c-Fe₂O₃, and are equal within experimental error to the flatband voltage V_{FB} ; Fig. 3 shows i_t , i_s , and i_d as a function of $(V - V_{FB})$ and ϕ_s . The smaller i_t values for a-Fe₂O₃ are a result of the smaller

η in the UV. A significant difference between a- and c-Fe₂O₃ shows up at larger bandbending. For a-Fe₂O₃, the potential $V_{ON,s}$ is 0.6V larger and coincides with the onset of a large dark current and a decrease in instantaneous current. The difference between i_t and i_s is generally attributed (3, 7) to the back-reaction (reduction) of an intermediate formed by the anodic photocurrent i_t . The cathodic reduction process under anodic bias has been shown (24, 25) to be a two-step process: transfer of electrons (surface concentration n_s) at a rate k_1 to surface states (density N_{ss}), followed by an isoenergetic transfer (rate k_2) to the solution species (concentration C_{ox}). The reduction current is given by

$$j_r = -qN_{ss}k_1n_s k_2 C_{ox} / (k_1 n_s + k_2 C_{ox}) \quad [5]$$

At small band bending, $k_1 n_s > k_2 C_{ox}$ and $j_r = -qN_{ss}k_2 C_{ox}$ independent of potential. At larger band bending, the current is limited by the transfer to the surface states and is given by $j_r = -qN_{ss}k_1 n_s$ with $n_s = n \exp(-\phi_s / kT)$. With this model $|j_r| = |j_t - j_s|$ and the onset voltage $V_{ON,s}$ is determined by a kinetic condition: $k_1 n_s \approx k_2 C_{ox}$. Now, C_{ox} is proportional to i_t and N_{ss} , and at the steady-state current onsets we have $(i_t)_a \approx (i_t)_c$. Therefore, the model parameters N_{ss} , k_1 , and k_2 for a- and c-Fe₂O₃ are related by

$$[(N_{ss}k_1/k_2)_a] / [(N_{ss}k_1/k_2)_c] \approx \exp[(\phi_{s,a}^* - \phi_{s,c}^*) / kT] \approx 5 \times 10^6$$

where $\phi_{s,a}^*$ and $\phi_{s,c}^*$ are the potential drops over the depletion layer at steady-state current onset. It is clear that the surface states are much more numerous and/or effective in a-Fe₂O₃ than in c-Fe₂O₃. We note, however, that this model has a serious difficulty in accounting for the magnitude of the current from the conduction band to the surface states; this is even more so for a-Fe₂O₃, where just before $V_{ON,s}$ the surface density of electrons is only 1.5×10^9 cm⁻². Tunneling through the depletion layer is unlikely to be important, since its width is at least 8×10^{-9} m.

Specifically, for a-Fe₂O₃, the simultaneous onset of i_s and i_d suggests that the position of the Fermi level determines $V_{ON,s}$. At small ϕ_s , the Fermi level will lie above the surface states which are then efficient electron transfer centers from the solid to the solution. At larger ϕ_s , the level is below the surface states, and the now unoccupied states become, in the dark, efficient centers for the reverse transfer, giving rise to a large dark current. The unoccupied states could also act as recombination centers for photogenerated holes, so that i_t starts to decrease for $V > V_{ON,s}$. These states must then lie $\phi_{s,a}^* + \Delta E_f \approx 0.5$ eV below the conduction bandedge, and they may be responsible for the small maximum in η at $h\nu = 1.5$ eV. Although this model may be valid for a-Fe₂O₃, it obviously cannot provide a common explanation for the different i - V curve of c-Fe₂O₃.

The addition of the S²⁻/S_n²⁻ redox couple to the solution results in the nearly complete absence of transient currents (7). Except for the early onset of a large dark current, the difference between a- and c-Fe₂O₃ also disappears. All photocurrents are small due to the absorption of UV by the yellow solution. The absence of a back-reaction is puzzling; the standard redox potential S²⁻/S_n²⁻ lies, at pH = 14, only ≈ 0.05 V below the conduction bandedge. There is, therefore, an appreciable overlap of the conduction band states with the sulfur states, so that a back-reaction could take place without the necessity of surface states. Whatever the reason for the absence of the back-reaction, the results show that for this photochemical reaction amorphous and crystalline Fe₂O₃ are not noticeably different.

Summary

The differences between amorphous and polycrystalline Fe₂O₃ are most pronounced in those photoelectrochemical properties which relate directly to defects; this shows clearly in differences in dark currents and in back-reaction current in the photo-oxidation of water. Proper-

ties which are not controlled by defects, such as S²⁻-photo-oxidation currents, absorption spectra, bandgaps, and bandedge positions are nearly identical for a- and c-Fe₂O₃. The only exception to this is the smaller quantum efficiency for the instantaneous currents in the UV for a-Fe₂O₃.

ABSTRACT

Electron-transfer processes at highly doped p-InP electrodes were investigated by monitoring the cyclic voltammetric dark currents of a series of metallocenes in acetonitrile solutions. The formal reduction potentials of the metallocenes span the bandgap of InP, allowing a comparison of the cyclic voltammetric response as a function of the formal reduction potential and the energetic condition of the electrode surface. Since the electron transfer of all of the metallocenes was electrochemically reversible on the timescale of cyclic voltammetry at a platinum electrode, differences in the voltammetric responses at p-InP were attributed to processes within the semiconductor or to surface phenomena. The energetic condition of the electrode surface during the cyclic voltammetric experiments was monitored by measurements of the capacitance of the space-charge region. Although a simple chemical etching and electrochemical cycling procedure yielded reproducible surface energetics, the p-InP/oxide/CH₃CN interface responded ideally to changes in electrode potential over a range of only about 0.8V. Metallocene redox couples with E⁰ located within that range exhibited reversible cyclic voltammetry when the experiment was performed within that range. The couples with E⁰ located outside of the ideal range displayed irreversible cyclic voltammetry. Voltammetric responses for p-InP electrodes with different crystal orientations and doping densities were compared.

Kinetics of electron-transfer processes occurring at metal electrode/solution interfaces have been studied for many years (1-5); however, kinetic processes at semiconductor electrode/solution interfaces have not received the same level of experimental scrutiny (6-12). This situation is a result of the relatively new use of semiconductor electrodes in electrochemical systems (13-16), the kinetic complexity of photoelectrochemical current flow, and the diversity of properties found for different semiconducting materials (8) and for different crystals of the same semiconducting material. In addition to the factors

that control the rates of electrochemical reactions at metals (e.g., diffusion of solution species, reorganization energies, and double-layer effects) (1-5), the rates of photoelectrochemical reactions are affected by processes that occur within the electrode (e.g., carrier diffusion and recombination) and by the dependence of these processes on light intensity and photon energy (6-12).

To investigate the ways that heterogeneous kinetics at semiconductor electrodes are affected by various combinations of the formal reduction potentials of solution species and the energetic condition of the electrode surface, we have measured cyclic voltammetric dark currents in acetonitrile solutions for cobaltocene and a number of ferrocene derivatives at highly doped p-InP electrodes.

Proper interpretation of the cyclic voltammetric data requires specific knowledge of the energetics at the semiconductor electrode/solution interface. This information has been derived from capacitance data that was obtained in the same solutions and within the same potential regions as the cyclic voltammetry experiments.

Indium phosphide was chosen as the electrode material in these studies because single-crystal samples are available from commercial sources with a variety of crystallographic orientations and doping densities. Furthermore, earlier reports indicate that if nonaqueous solvents are used in the electrochemical cell, InP electrodes with reproducible, stable, and nearly ideal surface characteristics can be prepared (17-19). There has been much interest in InP recently because it is a small bandgap material (1.35 eV) which allows for nearly optimal overlap with the solar spectrum. This makes InP a likely candidate for use in efficient photoelectrochemical devices (20).

Cobaltocene and a series of substituted ferrocenes were chosen to probe the heterogeneous kinetics at InP electrodes, because the reduction potentials for the couples involving the cation and neutral forms of these complexes span the bandgap of InP (Fig. 1). Although series of redox couples that include ferrocenes have been used in many photoelectrochemical studies, the sole use of metallocenes has several advantages. In addition to having identical charge types, the redox couples undergo outer-sphere electron-transfer reactions (21) because the metals are inert to substitution in both oxidation states.¹ Furthermore, the complexes are structurally similar, resulting in similar reorganization energies as evidenced by similar homogeneous self-exchange rate constants (22) and similar heterogeneous standard rate constants (23-24). The rates of heterogeneous charge transfer are rapid enough to ensure that the redox reactions at platinum will be diffusion controlled on the timescale of the cyclic voltammetry experiments. It can be assumed, therefore, that any differences in the heterogeneous kinetics as discerned by the voltammetric responses at p-InP can be attributed to processes within the semiconductor or to surface phenomena.

¹Cobaltocene and the ferricenium ions eventually undergo solvolysis reactions, but not within the timescale of these experiments.

Fig. 1. Formal reduction potentials of the metallocenes in relation to the energy of the bandgap of InP.

Experimental

Reagents and materials.—Gold-label acetonitrile (Aldrich) was thoroughly dried by refluxing over calcium hydride for 14h in a nitrogen atmosphere.² The supporting electrolyte, tetrabutylammonium fluoroborate, TBABF₄, (Southwestern Analytical Chemicals, Incorporated) was dried under vacuum for 2 days at 25°C. Ferrocene, acetylferrocene, 1,1'-diacetylferrocene (Aldrich), and decamethylferrocene (Strem) were purified by sublimation. Cobalticinium hexafluorophosphate (Strem) was used without further purification.

Electrochemical measurements.—All electrochemical measurements were performed in a Vacuum Atmospheres Controlled-Atmosphere Glove Box containing helium. An opaque, one-compartment cell was used for all electrochemical measurements. The acetonitrile solutions contained 0.5M TBABF₄ as the supporting electrolyte. The reference electrode was a silver wire immersed in a solution of 0.01M AgNO₃ and 0.5M TBABF₄ in acetonitrile, which was contained in a glass tube that was sealed at one end with a Vycor glass disk (Princeton Applied Research). This reference electrode has a potential of 0.29V vs. SCE (25). Its potential was monitored daily by comparison with the formal reduction potential, E^o, of the ferricenium/ferrocene couple, which occurred at approximately 0.07V vs. the Ag/Ag⁺ reference electrode. All potentials herein are reported against the E^o for ferrocene^{••} (26). The counterelectrode was a platinum foil.

Cyclic voltammetry, CV, was performed with a Princeton Applied Research Model 175 universal programmer and Model 173 potentiostat/galvanostat. The data were recorded on a Houston Instruments Model 2000 X-Y recorder. In experiments involving p-InP electrodes, the total capacitance of the electrochemical cell was measured by using a Princeton Applied Research Model 5204 lock-in analyzer and a Hewlett Packard Model 3325A synthesizer/function generator interfaced to a computer acquisition system.

The formal reduction potentials of the metallocenes were determined from CV data measured at the platinum electrode as the average of the anodic and cathodic peak potentials. The values of E^o so determined were within ± 70 mV of previously reported measurements (27-29). The approximate concentrations of the ferrocene derivatives were determined by comparing the magnitudes of the CV peak currents obtained at a platinum electrode with peak currents obtained in a solution containing a known concentration of ferrocene. In each CV experiment, the peak current densities obtained at the p-InP electrode were compared with the peak current densities obtained at a platinum electrode in the same solution.

Electrode construction, pretreatment, and characterization.—The platinum disk electrode was constructed by attaching a copper wire to one end of a 1 cm piece of platinum wire with conducting silver epoxy. The copper wire and the sides and back of the platinum wire were sealed in a glass tube with insulating epoxy to isolate them from the solution. The exposed platinum disk was polished with 5.0, 1.0, 0.3, and 0.05 μ m alumina until examination under a microscope revealed a smooth surface. The area of the disk was determined from the diameter of the platinum wire and was found to be 0.00817 cm².

A copper wire was attached to the back of a p-InP crystal (Varian) with conducting silver epoxy, after an ohmic contact was made, as described elsewhere (19). The copper wire and the sides and back of the InP crystal were sealed in a glass tube with insulating epoxy to isolate them from the solution. Prior to each experiment, the electrodes were etched for 1 min in a 50/50 solution of

²In some of the initial experiments, the acetonitrile was passed through a column of activated alumina prior to solution preparation. This procedure was discontinued because it was found to have no effect on the electrochemical behavior.

Table I. Electrode characteristics

Electrode	Orientation	Area (cm ²)	E_{FB} (V)	Doping density (cm ⁻³)

^b Averaged value from the slopes of 11 MS plots, $\pm 0.1 \times 10^{19}$ cm⁻³.

^c Determined from Hall conductivity measurements, $\pm 10\%$.

^d Determined from the X-intercept of a MS plot, ± 0.1 V.

^e Determined from the slope of a MS plot, $\pm 20\%$.

CH₃OH/concentrated HCl, rinsed with CH₃OH, and dried in a stream of argon. The areas of the InP electrodes were measured by using a photographic procedure.

The doping densities, N_A , and flatband potentials, E_{FB} , of the InP electrodes were determined from capacitance/potential data by using the Mott-Schottky equation (30)

$$1/C_{sc}^2 = (2/e\epsilon\epsilon_0 N_A) (E - E_{FB} - k_B T/e)$$

where C_{sc} is the capacitance of the space charge region, ϵ_0 is the permittivity of free space, ϵ is the static dielectric of the semiconductor, E is the electrode potential, and k_B is the Boltzmann constant. The data were modeled to a series RC circuit, and the total cell capacitance was assumed to be equal to C_{sc} (19). Values of C_{sc} were recorded at 100 mV intervals using a cyclic staircase potential program with the step time equal to 10s, which was superimposed upon an ac signal with a frequency of 5 kHz and an amplitude of 20 mV peak to peak. Since the response was found to be independent of frequency, the same frequency was used for all experiments.

The samples of p-InP employed in these studies were highly doped and had either a (100) or a (111) crystal orientation. The reproducibility of the voltammetric responses for different electrodes constructed from the same material was quite good. The characteristics of the various electrodes used in these studies are summarized in Table I. Despite the high doping densities, electrodes constructed from pieces of the same p-InP crystals as the electrodes in this study have been used to study photoelectrochemical phenomena (19, 31).

Results

Surface energetics in the absence of electroactive species.—A cyclic voltammogram of the P19 (100) 1 p-InP electrode (Table I) in electrolyte solution featured essentially no faradaic current between approximately -0.9 and -0.1 V vs. ferrocene (Fig. 2). Positive of -0.1 V, an anodic wave was observed which dramatically increased in magnitude when the electrode potential was swept positive of about 0.4 V. When the electrode potential was then swept negative of about -0.9 V, a small cathodic wave appeared. Similar scans utilizing a platinum electrode indicate that these waves are not due to electroactive impurities. Instead, the waves at p-InP appear to be a result of the oxidation of the electrode surface during the positive scans and the subsequent reduction of the surface during the negative scans. Typical Mott-Schottky (MS) plots for this electrode in electrolyte solution at three different frequencies are also shown (Fig. 2). The data were collected in the range of -0.9 to -0.1 V, which is within the bandgap of p-InP where the electrode exhibited essen-

Fig. 2. Cyclic voltammograms for five consecutive cycles and Mott-Schottky plots for the P19(100)1 electrode in a solution of 0.5 M TBABF₄ in acetonitrile. The Mott-Schottky plots represent three sets of forward (positive) and reverse (negative) scans at three frequencies: 1, 5, and 10 kHz.

tially no faradaic background current. Capacitance data collected in this voltage range resulted in linear MS plots with no hysteresis between the forward (positive) scans and the reverse (negative) scans. The slopes and intercepts of the MS plots were independent of frequency.

Capacitance data collected in electrolyte solution within potential ranges in which the electrode featured anodic and cathodic faradaic background currents resulted in MS plots that exhibited hysteresis (Fig. 3). As the electrode potential was swept positive of about -0.1 V during the forward scan, C_{sc} became constant and independent of potential. This behavior suggests that positive charge resided at the electrode surface at potentials corresponding to the appearance of anodic current in the CV

Fig. 3. Mott-Schottky plots for the P19(100)1 electrode in a solution of 0.5 M TBABF₄ in acetonitrile. The curves represent three sets of data collected with an initial potential of -0.3 V and switching potentials of -0.9 V (—), -1.1 V (---), and -1.4 V (-·-·-), and two sets of data with an initial potential of -0.9 V and switching potentials of 0.1 V (—) and 0.4 V (·····).

scans (Fig. 2). When the direction of the potential scan was reversed, the MS plot did not retrace itself. Although $1/C_{sc}^2$ vs. potential for the reverse (negative) scan was linear, it had a different X-intercept than it did for the forward scan, which indicates that the flatband potential had shifted in a positive direction during the forward scan. It was possible to remove the positive surface charge at the electrode surface and return the surface to its initial state by momentarily holding the electrode potential at $-0.9V$. A second capacitance vs. potential scan would then retrace the initial scan. This experiment indicates that the surface energetics could change during the cyclic voltammetry experiments if the switching potential, E_{λ} , was positive of about $-0.1V$. The result would be that the positions of the bandedges on the reverse scan might not be the same as they were on the forward scan.

Similar effects occurred when the electrode potential was swept more negative than about $-0.9V$. In this case as well, C_{sc} became constant and independent of potential, and the intercept of the MS plot on the reverse (positive) scan indicated a negative shift in E_{FB} . This behavior suggests that negative charge resided at the electrode surface at potentials corresponding to the appearance of cathodic current in the CV scans (Fig. 2). It was possible to remove the negative surface charge and restore E_{FB} to its original value by momentarily holding the electrode potential at $-0.3V$.

Permanent changes in E_{FB} resulted if the electrode potential was cycled repeatedly to potentials positive or negative of the initial positions of the bandedges (Fig. 4). If the electrode was cycled between -0.9 and $0.4V$, E_{FB} reached a constant value after a few CV scans and remained constant for more than 50 CV scans (triangles). If the electrode was cycled between -0.9 and $0.7V$, the flatband potential shifted in a positive direction during each CV scan and never reached a constant value (squares). Similarly, E_{FB} could be shifted to more negative values by repeated CV scans between -0.3 and $-1.6V$ (circles). After repeated cycling of an electrode between -0.9 and $0.7V$ or between -0.3 and $-1.6V$, the original E_{FB} could only be restored by re-etching the surface.

In the CV experiments reported below, each freshly etched electrode was cycled 5-10 times between -1.6 and $0.4V$ before data were collected in order to attain a stable E_{FB} . If the experiment required a switching potential posi-

Fig. 4. The flatband potential as a function of the number of cyclic voltammograms done between three different pairs of switching potentials at the P19(100)1 electrode in a solution of $0.5M$ TBABF₄ in acetonitrile. The squares are switching potentials of -0.9 and $0.7V$. The triangles are switching potentials of -0.9 and $0.4V$. The circles are switching potentials of -0.3 and $-1.6V$.

Fig. 5. Part A shows the switching potential dependence of 1 mM decamethylferrocene at the P19(100)2 electrode with $0.5M$ TBABF₄ supporting electrolyte in acetonitrile at a scan rate of 100 mV/s. Part B shows its scan rate dependence at 100 , 50 , and 20 mV/s with a switching potential of $-0.30V$.

tive of $0.4V$ or negative of $-1.6V$, fewer than ten scans were performed before the electrode was re-etched. Rapid loss of electrode response occurred if the electrode potential was swept positive of $0.7V$.

The effect of switching potential and scan rate on the cyclic voltammetry of metallocenes at P19 (100) p-InP electrodes.—Several aspects of the data described in the previous section indicated that the voltammetric behavior of the metallocenes would be affected by changes in the surface energetics of the semiconductor electrode and by changes in the surface oxide that occurred during the CV experiments. Decamethylferrocene would be expected to be the most sensitive probe for these changes, because its E° occurred within the region where there was neither bandedge movement nor surface charging, -0.9 to $-0.1V$. The E° value of ferrocene occurred just positive of that region, and the E° values of acetylferrocene and $1,1'$ -diacetylferrocene were found in the region where oxidation of the p-InP surface occurred in electrolyte solution. The E° value of cobaltocene was found in the region where reduction of the p-InP surface occurred in the electrolyte solution. The importance of the effects of surface energetics and surface redox reactions can be seen in Fig. 5A and 6A, in which the CV behavior of decamethylferrocene and ferrocene at P19 (100) 2 was recorded for different switching potentials. For decamethylferrocene, nearly reversible CV behavior was observed (Fig. 5B) until E_{λ} was made positive of about $-0.30V$. For more positive switching potentials, the cathodic waves became broader and decreased in magnitude, and the cathodic peak potential, E_{pc} , shifted to more negative potentials; however, when E_{λ} was made positive of $0.10V$, the cathodic wave began to

Fig. 6. Part A shows the switching potential dependence of 2 mM ferrocene at the P19(100)2 electrode with 0.5M TBABF₄ supporting electrolyte in acetonitrile at a scan rate of 100 mV/s. Part B shows its scan rate dependence at 500, 200, 100, 50, and 20 mV/s with a switching potential of 0.20V.

sharpen and increase in magnitude once again, and E_{pc} attained an approximately constant value of $-1.1V$. Nearly reversible CV behavior was also obtained for ferrocene when E_{λ} was 0.2V (Fig. 6B). For switching potentials positive of 0.2V, the cathodic peak became increasingly broad and decreased in magnitude, and E_{pc} shifted to more negative potentials. The switching potential dependence for acetylferrocene and 1,1'-diacetylferrocene was similar to that for ferrocene, except that the cathodic peaks were broader.

Close inspection of the currents observed during the reverse scans in Fig. 5A and 6A revealed another unusual feature that accompanied the changes in the cathodic waves. When E_{λ} was relatively positive, the Cottrell current for the oxidation of the metallocenes, which should decay as $t^{-1/2}$, suddenly decayed to zero at potentials that were well positive of $E^{o'}$. In general, the potential at which this current decay occurred tracked the switching potential.

For comparison between the responses of the ferrocene derivatives, cyclic voltammetry was performed in an extended potential range that was similar for each redox couple (Fig. 7 and 8). The oxidation waves for the ferrocenes occurred with only 100-200 mV overvoltages, with the larger overpotentials for the couples which had the most negative $E^{o'}$ within the bandgap. Plots of the anodic peak current, i_{pa} , vs. (scan rate)^{1/2} were linear. A plot of i_{pa} vs. ferrocene concentration from 10^{-4} to $10^{-2}M$ was linear as well, with a current density of 3.6 mA/cm² at the highest concentration when the scan rate was 100 mV/s. The magnitudes of the anodic current densities at P19(100) were at least 90% of the anodic current densities obtained at a platinum electrode in the same solution. These data suggest that the oxidations of the ferrocenes are controlled by the diffusion of solution species to the electrode surface.

When E_{λ} was several tenths of a volt positive of E_{pa} (Fig. 7 and 8), the reduction waves for the ferricenium⁺ ions occurred with substantial overvoltages. The overvoltages tended to be greater for the ferrocene derivatives with

Fig. 7. Cyclic voltammograms of 4 mM 1,1'-diacetylferrocene and 5 mM acetylferrocene at the P19(100)1 electrode with 0.5M TBABF₄ supporting electrolyte in acetonitrile. The response at 200, 100, 50, and 20 mV/s is shown for each redox couple. The formal reduction potentials, the approximate potentials of the bandedges, and the flat-band potential as determined from capacitance data before and after the cyclic voltammetric scans are shown.

more negative reduction potentials. The cathodic peak current, i_{pc} , was less than 50% of the magnitude of i_{pa} for all of the ferrocenes. Nevertheless, plots of i_{pc} vs. (scan rate)^{1/2} and i_{pc} vs. ferrocene concentration from 10^{-4} to $10^{-2}M$ were linear. The current density at the highest concentration was 0.83 mA/cm² when the scan rate was 100 mV/s. For the CV scans with more positive switching potentials, the values of E_{pc} for ferricenium⁺ and acetylferrocenium⁺ were more dependent on scan rate than the values of E_{pc} for 1,1'-diacetylferricenium⁺ and decamethylferricenium⁺.

Figures 5A and 6A clearly indicate that the CV behavior of the cathodic waves in Fig. 7 and 8 was a result of the effect of the switching potential on the condition of the electrode surface. When E_{λ} was just positive of $E^{o'}$ for decamethylferrocene or ferrocene, the values of E_{pc} were not dependent on scan rate, and values of i_{pa}/i_{pc} obtained using the equation proposed by Nicholson were close to unity at all scan rates (Fig. 5B and 6B) (32).

In cyclic voltammograms for the reduction of ferricenium⁺ in solutions of ferricenium tetrafluoroborate (Fig. 9), the initial potential was 0.4V. (This resulted in surface charging similar to that which occurred during the cyclic voltammograms of ferrocene with an anodic switching potential of 0.4V.) The surface charging caused the cathodic wave on the forward (negative) scan to occur with a 1.0V overpotential and a current magnitude that was approximately 50% of that obtained for the one-electron reversible wave at a platinum electrode in the same solution, indicating kinetic control. On the reverse (positive) scan, the anodic wave occurred just positive of $E^{o'}$. The values of i_{pc}/i_{pa} were close to unity at all scan rates, and plots of i_{pc} and i_{pa} vs. (scan rate)^{1/2} were linear. Although the anodic peak current magnitude on the reverse scan

Fig. 8. Cyclic voltammograms of 13 mM ferrocene and 3 mM decamethylferrocene at the P19(100)1 electrode with 0.5M TBABF₄ supporting electrolyte in acetonitrile. was only 50% of that obtained at platinum, the peak current was limited by the concentration of ferrocene in the diffusion layer and not by electrode kinetics. These results indicate that although the reduction of ferricenium⁺ in a scan with an initial potential of 0.4V is kinetically controlled, the oxidation of ferrocene is diffusion controlled.

The $E^{o'}$ value of cobaltocene⁺⁰ occurs far negative of the conduction bandedge of p-InP. Reduction and oxidation of this complex occurred with overvoltages of 100-500 mV (Fig. 9). The value of E_{pc} had a very small dependence on scan rate. A plot of i_{pc} vs. (scan rate)^{1/2} was linear, and the magnitude of i_{pc} was within 10% of the value calculated for a one-electron reversible wave at a platinum electrode in the same solution. The value of E_{pa} had a larger dependence on scan rate. A plot of i_{pa} vs. (scan rate)^{1/2} was linear, but the magnitude of i_{pa} was less than 50% of the value calculated for a one-electron reversible wave at platinum in the same solution. No dependence on cathodic switching potential was observed for the cobaltocene⁻⁰ couple.

Effects due to lattice orientation and doping density.—Analogous experiments were performed to compare the responses at the P19 (100) electrodes with electrodes having a similar doping density but a different crystal orientation, P19 (111) 1 and P19 (111) 2, and with electrodes having the same orientation but a lower doping density, P18 (100) 1 and P18 (100) 2. In acetonitrile solutions containing only electrolyte, these electrodes yielded background currents and capacitance vs. potential data that were nearly identical to the P19 (100) electrodes. The flatband potentials for all of the p-InP electrodes, which had been freshly etched and then cycled between -1.6 and 0.4V in electrolyte solution, were within the range of 0.4 +/- 0.1V (Table I).

When P19 (111) electrodes were used to examine the cyclic voltammetry of the metallocenes, the results were

virtually identical to those obtained for the P19 (100) electrodes. This indicates that lattice orientation did not have an effect on the kinetics of charge transfer at the highly doped electrodes.

Major differences in the voltammetry of the metallocenes were observed when the P18 (100) p-InP electrodes were used. Both decamethylferrocene and ferrocene could be oxidized near their reversible potentials at the P18 (100) electrodes (Fig. 10 and 11), but the heterogeneous kinetics associated with the reduction of the two redox couples were quite different. At the P18 (100) electrodes, the CV of decamethylferrocene showed only a small amount of cathodic current on the reverse scan that was independent of scan rate when E_{λ} was -0.2V. No cathodic current appeared when E_{λ} was positive of -0.2V. In addition, a CV with a switching potential positive of -0.2V resulted in a change in the electrode surface that caused the anodic wave of the next CV to be shifted positive with respect to the one in the previous scan. The absence of a cathodic peak indicates that the reduction of decamethylferricenium⁺ was controlled by processes within the semiconductor. Ferrocene exhibited a nearly reversible looking cathodic wave on the reverse scan at the P18 (100) electrodes if E_{λ} was not positive of about 0.2V, similar to the response at the P19 (100) electrodes. Acetylferrocene exhibited a similar response to that of ferrocene at the P18 (100) electrodes, but the CV of 1,1'-diacetylferrocene showed only a broad anodic wave and a small, broad cathodic wave at all switching potentials. Cathodic current for the reduction of cobalticenium⁺ could barely be observed at the P18 (100) electrodes at potentials negative of -1.6V. Two extremely small oxidation peaks were observed on the reverse scan at -1.2 and -0.6V. The magnitudes of the current densities of the anodic peaks were less than 0.60% of the anodic current density at the platinum electrode in the same solution.

Fig. 10. Part A shows the switching potential dependence of 1 mM decamethylferrocene at the P18(100)1 electrode with 0.5M TBABF₄ supporting electrolyte in acetonitrile at a scan rate of 100 mV/s. Part B shows its scan rate dependence at 200, 100, 50, and 20 mV/s with a switching potential of $-0.30V$.

Discussion

The p-InP/oxide/CH₃CN interface as a function of electrode potential.—The kinetics and mechanisms of electron transfer across a semiconductor/solution interface are heavily influenced by the position of the Fermi level with respect to the valence band and conduction band edges at the electrode surface. The three surface energetic conditions of an ideal p-type semiconductor/solution interface in the dark, which can be achieved by changes in the Fermi level, are depicted in Fig. 12. These diagrams represent the electrochemical potential of an electron as a function of distance into the electrode with respect to redox levels in solution (33). Although dark current flow for each of these energetic conditions has been addressed experimentally and theoretically (9, 12) many questions remain unanswered.

One factor that influences the surface energetics and the rate of electron transfer at many semiconductor electrodes is the presence of an oxide layer at the interface. Oxide layers form spontaneously at room temperature when most metals and semiconductors are exposed to air (34). In the case of InP and other III-V semiconductors (35, 36), the native oxide layer can vary in depth from 1 to 5 nm. The composition of the oxide layer will vary with thickness and growth conditions. In air-saturated aqueous acid, Heller and others have shown that the surfaces of p-InP electrodes become covered with a thin layer of hydrated, conducting indium oxide (20, 37-39). Other studies have emphasized the importance of the oxide film in determining the utility of p-InP as a photocathode (20, 40-43). Formation of the film prevents other undesirable anodic corrosion processes in water and retards surface recombination of electron/hole pairs, yet the film is conducting to photogenerated conduction-band electrons (20). At this time, the effects of surface oxide on the rates and mechanisms of faradaic reactions at semiconductor or metal electrodes are not clearly understood. These ox-

Fig. 11. Part A shows the switching potential dependence of 2 mM ferrocene at the P18(100)1 electrode with 0.5M TBABF₄ supporting electrolyte in acetonitrile at a scan rate of 100 mV/s. Part B shows its scan rate dependence at 500, 200, 100, 50, and 20 mV/s with a switching potential of 0.20V.

ides are generally either wide bandgap semiconductors or insulators; therefore, they represent a possible barrier to charge transfer.

Since the electrodes used in this study were etched in aqueous acid, it can be assumed that the lattice was terminated with an oxide film prior to immersion in the acetonitrile solutions. In order to obtain reproducible capacitance or voltammetric behavior, it was necessary to cycle the electrode several times between -1.6 and $0.4V$ in electrolyte solution. During these cycles, the current-

Fig. 12. Accumulation, depletion, and inversion as pictured for an ideal p-type InP/solution interface in the dark with respect to solution redox levels.

potential curves showed the passage of small currents. Because the addition of a small amount of water to the solution resulted in a dramatic increase in the background current, we interpret the anodic current flow to be a result of the oxidation of trace amounts of water present in the CH_3CN , causing the subsequent growth of additional surface oxide. The cathodic background current is interpreted as the subsequent reduction of the surface oxide. The p-InP/oxide/ CH_3CN interface prepared in this manner was relatively stable, as judged by the reproducibility (Table I) and stability (Fig. 4) of E_{FB} and by the consistency of the voltammetric responses observed for the series of metallocenes.

In principle, it should be possible to study faradaic redox processes at semiconductor electrodes under accumulation, depletion, or inversion conditions by adjusting the externally applied potential. Our data indicate that the positions of the bandedges at the p-InP/oxide/ CH_3CN interface are only stable within a limited potential range. The Mott-Schottky plots in Fig. 2 indicate that the interface responded to changes in the potential in a nearly ideal manner as long as the electrode potential was kept within the range of about -0.9V (near the conduction bandedge) and about -0.1V . Within this range, the electrode was in the depletion condition. As the electrode potential was swept positive of about -0.1V , the capacitance of the space charge region did not continue to increase but became nearly constant (Fig. 3). While a relatively potential-independent capacitance could result at an electrode under accumulation, our measurement of E_{FB} indicates that accumulation should not occur at the p-InP/oxide/ CH_3CN interface until the electrode potential is positive of 0.4V . Our data suggest that the potential-independent capacitance is associated with the anodic background current which occurs positive of -0.1V and is presumably due to the growth of surface oxide. Since Fig. 3 indicates that movement of E_{FB} accompanies the anodic background current, we conclude that accumulation is not achieved at p-InP/oxide/ CH_3CN interfaces.

Voltammetric scans to potentials negative of the conduction bandedge did not appear to result in chemically irreversible reduction of the electrode surface, such as the formation of metallic indium. The cathodic background voltammogram during negative scans was featureless, and sharp peaks that could be attributed to the oxidation of metallic indium were not observed on the reverse scans. The capacitance data in Fig. 3 reveal that the space-charge capacitance reached a nearly constant value at potentials negative of about -0.9V . This minimization and potential independence of C_{sc} is expected for ideal metal/insulator/semiconductor (MIS) devices if the capacitance is measured at high frequencies (44). This behavior has been observed at p-Si/ SiO_2 / CH_3OH and p-Si/ SiO_2 / CH_3CN interfaces (45). At an inverted p-type semiconductor/solution interface, excess electrons are stored near the electrode surface in the depletion layer, in surface states (46), or in interface states arising from the oxide layers (47). In any case, the excess surface charge causes the bandedges to become unpinned, that is, they shift with respect to the solution redox levels as the electrode potential is changed.

Figure 3 shows that during experiments in which the electrode potential was swept positive of about -0.1V or negative of about -0.9V , hysteresis in the capacitance of the space-charge region as a function of potential invariably occurred. The chemical processes responsible for this hysteresis are unknown, but a reasonable hypothesis would be that the storage and removal of charge in the oxide layer are not facile processes, owing to the chemical reactions that must accompany this redistribution of charge. Since the voltammetric and capacitance measurements were performed with similar effective scan rates and within similar potential ranges, it can be assumed that the hysteresis in the surface energetics also occurred during the cyclic voltammetry experiments.

Interpretation of cyclic voltammograms.—The CV experiments were designed to elucidate the factors that

control the voltammetric dark currents at a highly doped p-InP electrode for a series of structurally similar redox couples. Cyclic voltammetry is quite useful for qualitative experiments such as these, and it has been used extensively for such purposes in photoelectrochemical studies; however other studies involving cyclic voltammetry have typically not been closely paired with measurements of the capacitance of the space-charge region.

Decamethylferrocene⁺⁰ and ferrocene⁺⁰.—Based on capacitance measurements, the p-InP/oxide/ CH_3CN interface behaves as an ideal semiconductor/solution interface in the depletion condition when the applied potential is between about -0.9 and -0.1V . Figure 1 indicates that only the decamethylferrocene⁺⁰ couple can be examined under these conditions; however, the electrochemistry of the ferrocene⁺⁰ couple can be examined when the potential is close to the ideal region. Since the concentration of majority carriers at the electrode surface is extremely small when the electrode potential is within or near the ideal region, and since the electrons must transfer through a surface oxide layer, the observation of reversible cyclic voltammetry (Fig. 5B) is somewhat surprising. The mechanism of this facile redox process cannot be distinguished without further experiments (9, 12), however, the CV data reveal qualitative factors relevant to this issue. As shown in Fig. 10B, the rate of reduction of decamethylferrocenium⁺ is much more sensitive to the doping density of the electrode than the rate of oxidation of decamethylferrocene. This sensitivity of the cathodic process to N_A is apparently dependent upon the relationship between $E^{0'}$ and the bandedges, because the CV waves for ferrocene⁺⁰ remain symmetric when the doping density of the electrode is lowered (Fig. 6B and 11B). The behavior described above indicates that the p-InP/oxide/ CH_3CN interface is not a rectifying junction for the P19 (100) or P19 (111) electrodes. As the doping density is lowered and the width of the space-charge region increases, the interface becomes rectifying for decamethylferrocene⁺⁰ but not for ferrocene⁺⁰.

This behavior can be explained by drawing an analogy between the current flow across the p-InP/oxide/ CH_3CN interface and the current flow across a semiconductor/metal interface. A barrier to electron transfer is present at the p-InP/oxide/ CH_3CN interface, which is similar to the barrier at a semiconductor/metal interface. This barrier is a result of the gradient in potential across the space-charge region. At a p-type semiconductor, electron transfer between the solution species and the valence band is accomplished either by thermionic emission-diffusion over the barrier, which depends on the barrier height, or by quantum mechanical tunneling through the barrier, which depends on the width of the barrier as well as the barrier height (48). The barrier height ($E^{0'} - E_{\text{vb}}$ on the solution side of the interface and $E_{\text{F}} - E_{\text{vb}}$ on the semiconductor side of the interface) determines the concentration of holes at the interface at the energy of the valence bandedge that are available to accept the transferring electrons. The width of the barrier is related to the doping density of the electrode. The higher the doping density, the thinner the barrier.

Figure 13 illustrates the reason for the difference in rectifying behavior for decamethylferrocene and ferrocene. When the electrode potential is swept positive of the $E^{0'}$ of decamethylferrocene⁺⁰ so that oxidation is thermodynamically favorable, the barrier height in question is $E_{\text{F}} - E_{\text{vb}}$ (Fig. 13A), where E_{F} is the Fermi level. The concentration of holes in the semiconductor at the interface near the energy of E_{vb} is sufficient to accept electrons from the decamethylferrocene in solution via thermionic emission-diffusion at a rate controlled by the diffusion of decamethylferrocene to the electrode surface. When the electrode potential is swept negative of the $E^{0'}$ of decamethylferrocene⁺⁰ so that reduction is thermodynamically favorable, the barrier height in question is $E^{0'} - E_{\text{vb}}$ (Fig. 13B). This barrier height is larger, and the concentration of "holes" (empty states of decamethylferrocen-

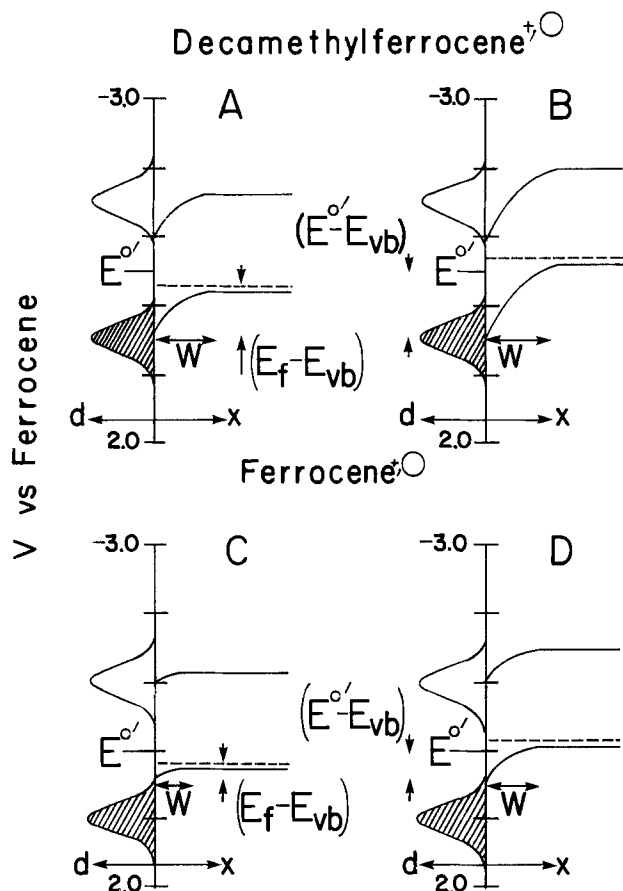

Fig. 13. Relationship between the height of the barrier to anodic current, $E_f - E_{vb}$ (parts A and C), or the height of the barrier to cathodic current, $E^{o'} - E_{vb}$ (parts B and D), and the distribution of the density of states, d , of decamethylferrocene $^{+0}$ (parts A and B) or ferrocene $^{+0}$ (parts C and D) in solution. The width of the space charge region, W , and the distance from the surface of the electrode, x , are also shown.

ium) near the energy of the valence bandedge is insufficient for thermionic emission-diffusion to be a facile process. At the P19 (100) and P19 (111) electrodes, the high doping density causes the barrier width, W , to be relatively small (about 200Å at the top of the valence band near E_f). Quantum mechanical tunneling of electrons from the semiconductor through the barrier into empty states of decamethylferrocene in solution becomes the dominant electron-transfer process for these electrodes. The rate is controlled by the diffusion of decamethylferricenium $^+$ to the electrode surface, resulting in a reversible cyclic voltammogram. At the P18 (100) electrodes, however the lower doping density causes the barrier to be too wide (about 400Å at the top of the valence band near E_f) for tunneling to be a facile process. Very little cathodic current appears at these electrodes for decamethylferrocene, resulting in an electrochemically irreversible wave.

In a similar way, when the electrode potential is swept positive of $E^{o'}$ for ferrocene $^{+0}$ so that oxidation becomes thermodynamically favorable, the barrier height in question is $E_f - E_{vb}$ (Fig. 13C). The concentration of holes in the semiconductor at the interface near the energy of E_{vb} is sufficient to accept electrons from the ferrocene in solution via thermionic emission-diffusion at a rate that is controlled by the diffusion of ferrocene to the electrode surface. In contrast to decamethylferrocene $^{+0}$, when the electrode potential is swept negative of $E^{o'}$ for ferrocene $^{+0}$ (Fig. 13D), the barrier height $E^{o'} - E_{vb}$ is low enough for a sufficient concentration of "holes" (empty states of ferricenium) to be present at the interface near the energy of E_{vb} to accept electrons from the semiconductor via thermionic emission-diffusion at a rate that is controlled by the diffusion of ferricenium $^+$ to the semiconductor. Because the doping density has little effect on the height of

the barrier, thermionic emission-diffusion is the dominant process for the electron transfer of ferrocene $^{+0}$, regardless of the doping density of the electrode.

The use of additional metallocenes which have $E^{o'}$ between the decamethylferrocene $^{+0}$ and ferrocene $^{+0}$ couples to explore this phenomenon further is desirable to further elucidate the relationship between the shape of the barrier and the voltammetric response.

Reasons for apparent electrochemical irreversibility.—When the electrode potential is swept outside of the region from about -0.9 to -0.1 V, electrochemically irreversible cyclic voltammograms are the result. The experiments depicted in Fig. 5A and 6A demonstrate that the irreversibility is not inherent to the heterogeneous kinetics. The apparent irreversibility is an artifact of the way that the CV experiment is performed. The most straightforward explanation for the onset of this pseudorectifying behavior is that it is directly caused by the oxidation and reduction of surface oxide during the CV experiment. The CV's for the ferrocene derivatives suggest two models by which the surface oxide may affect the electrochemical kinetics. The first model involves the formation of a thicker or less conducting oxide on the forward (positive) scan that would, by itself, subsequently inhibit the reduction of the ferricenium $^+$ ions on the reverse (negative) scan. In contrast, the second model involves only the movement of E_{FB} that occurs when the electrode potential is positive of about -0.1 V (Fig. 3). The timescales involved with the shifts in E_{FB} can result in different positions of the bandedges during the forward and reverse scans of a CV experiment. Figure 14 depicts the shift in E_{FB} that occurs during the cyclic voltammetry of decamethylferrocene at 19 (100) electrodes. The initial barrier to the reduction of decamethylferrocene, $(E^{o'} - E_{vb})_i$, is approximately 0.9V in magnitude (Fig. 14A). As the electrode potential is swept positive of -0.1 V, the surface oxide begins to charge and E_{FB} begins to shift in a positive direction, pushing E_{vb} to approximately 0.7V (Fig. 14B and 14C). As indicated by the hysteresis in the capacitance data (Fig. 3), E_{vb} remains at around 0.7V during the reverse (negative) scan (Fig. 14D). This results in a final barrier to the reduction of decamethylferrocene, $(E^{o'} - E_{vb})_f$, of approximately 1.2V. The final barrier is so high that neither thermionic emission-diffusion nor quantum mechanical tunneling is facile, resulting in no cathodic current. As the electrode is swept negative, charge is removed from the electrode surface and E_{vb} returns to its initial potential (Fig. 14E and 14F). The potential barrier is once again $(E^{o'} - E_{vb})_i$. As discussed previously, quantum mechanical tunneling of electrons through this barrier from the electrode to decamethylferrocene is a facile process, so cathodic current is observed at a large cathodic overpotential. A similar description can be used for the other ferrocenes.

The irreversibility associated with CV's of the cobaltocene $^{+0}$ couple (Fig. 9) is more difficult to interpret because mechanisms for electron transfer at inverted surfaces are not well understood (9). Here also, hysteresis in the space-charge capacitance occurs during the CV experiments when the electrode potential is negative of about -0.9 V (Fig. 3). The hysteresis could be responsible for the irreversible voltammograms in this case as well.

Mediation of electron transfer by surface states.—At the P19 (100), P19 (111), and P18 (100) electrodes, the oxidation waves for all of the ferrocene derivatives appeared to be diffusion controlled or nearly so. This behavior implies that the rate of oxidation was not limited by the rate of electron transfer between solution levels and vacant levels in the electrode (holes). An important question is whether the oxidation processes occurred by direct electron transfer between the ferrocenes and valence-band holes or via surface states that could mediate the electron-transfer process. Many theoretical and experimental studies have favored the latter explanation (47, 49-51). For reductions at n-InP/CH $_3$ CN interfaces, Kohl and Bard presented convincing evidence for the intermediacy of a

Fig. 14. Illustration of the shift in the valence band edge and the change in the height of the barrier to cathodic current, $E^{o'} - E_{vb}$, during a cyclic voltammogram of decamethylferrocene at a P19(100) electrode with an anodic switching potential of 0.6V and experimental conditions as reported herein. Part A: initial conditions. Part B: electrode potential swept positive of $E^{o'}$, oxidation of decamethylferrocene occurs. Part C: positive shift in the band edges and increase in the height of $E^{o'} - E_{vb}$ at positive potentials. Part D: the band edges remain at the more positive potential and the barrier height remains large during the reverse scan, so that no reduction of decamethylferrocene occurs when the electrode potential is swept negative of $E^{o'}$. Part E: sweeping the electrode to negative potentials returns the band edges and the barrier height to their initial conditions, allowing reduction of decamethylferrocene to occur. Part F: at the final potential, final conditions are identical to the initial conditions.

surface state (17). The reduction of many compounds occurred only after a certain negative potential was applied, and it was argued that this negative potential was

required to fill the surface state. This resulted in the "leveling effect" for the reduction of compounds with $E^{o'}$ positive of E_{CB} . A leveling effect was not observed in the present study, since the various ferrocenes were oxidized at p-InP at their individual values of $E^{o'}$ and not at a common potential that could be associated with the emptying of a surface state. Nevertheless, surface-state mediation cannot be ruled out, because surface states with a wide range of energies may be available.

The relationship of this work to previous studies.—The results of this study are summarized in Table II. Dark currents that are independent of experimental parameters can only be observed within a small range of electrode potentials. When the electrode potential is outside of the range of about -0.9 to -0.1V, the dark currents are controlled by experimental parameters such as the initial potential and the switching potential. Most of the qualitative differences in the cyclic voltammetry reported here and by Kohl and Bard (17) can be attributed to the fact that the potential regions identified in Table II were not identified in the earlier study.

Photovoltages and photocurrents at p-InP/oxide/ CH_3CN interfaces are affected by the surface energetics and dark currents. In this regard, it is interesting to examine the photovoltages reported by Dominey *et al.* for various redox couples in CH_3CN at p-InP photocathodes (18). Couples with $E^{o'}$ negative of -1.2V displayed a nearly constant photovoltage of -0.8V. Our data indicate that all of those couples have $E^{o'}$ negative of the E_{CB} of p-InP/oxide/ CH_3CN and that the band bending becomes constant at negative potentials. For couples with $E^{o'}$ between -0.6 and -0.1V, the photovoltages were smaller than 0.8V and were dependent on $E^{o'}$. Our data indicate that those couples have $E^{o'}$ in the range where p-InP/oxide/ CH_3CN behaves like an ideal semiconductor/solution interface.

Conclusions

Reproducible flatband potentials and cyclic voltammetric behavior at highly doped p-InP electrodes in CH_3CN solutions in the dark depend upon the formation of a stable oxide layer on the surface. The capacitance of the p-InP/oxide/ CH_3CN interface behaves ideally between -0.9 and -0.1V vs. the formal reduction potential of ferrocene⁺⁰. Surface redox reactions that occur outside of this potential range lead to potential independent and hysteretic space-charge capacitances and irreversible cyclic voltammetry for metallocene redox couples. Reversible CV behavior can be observed for decamethylferrocene⁺⁰ ($E^{o'} = -0.5V$) and ferrocene⁺⁰ ($E^{o'} = 0.0V$) at the electrodes with the highest doping densities. The heterogeneous kinetics observed are affected by the doping density of the electrode, but they are not affected by the crystal orientation.

Acknowledgments

We wish to thank Arthur J. Nozik (SERI) and Nathan S. Lewis (Stanford University) for useful discussions and Brad Thacker (SERI) for obtaining the Hall measurements of the doping densities of the p-InP crystals. This project was supported in part by a grant in aid from the Council on Research and Creative Work, University of Colorado in Boulder; in part by BRSG Grant number RR07013-18 awarded by the BRSG program, Division of Research Resources, NIH; and in part by the Department of Energy (Division of Chemical Sciences) Contract no. DE-FG02-84ER13247.

ABSTRACT

The spectral distribution of the quantum efficiency in the range 250-550 nm has been determined for a number of TiO₂ electrodes prepared by thermal oxidation in air (temperature range 500°-700°C). A red shift in the action spectra and an extensive decrease in the quantum efficiency in the short wavelength range (250-300 nm) were observed with increasing oxidation. The effect of different polishing procedures on the electrodes before and after the formation of the TiO₂ layers was also investigated. A marked increase in quantum efficiency, especially in the short wavelength range, was registered with increasing surface finish of the electrodes. The observed changes in the action spectra are discussed in terms of electron-hole recombination mediated via surface states and recombination in the rough surface. It was possible to describe the registered action spectra in the wavelength range 300-400 nm in terms of the known absorption coefficient and a modified Gärtner-Butler equation with three adjustable parameters. The experimental data also give evidence of a gradient in doping density normal to the surface of the TiO₂ layer electrodes.

Action spectra of single-crystal and polycrystalline TiO₂ as electrode material in photoelectrochemical (PEC) cells varies strongly with method of preparation (1-14) and history of the electrode (15-17). Some of these variations are well understood and can be described in terms of parameters of the electrode material and properties of the

* Electrochemical Society Active Member.

interface between electrode and electrolyte (18-24). The often-observed decrease in quantum efficiency of TiO₂ electrodes in the short wavelength range (250-300 nm), however, is still the cause of some controversy. Different and sometimes conflicting ideas of its origin can be found in the literature (3, 7, 15, 16). It is well known that variations in surface morphology can substantially affect

the efficiency of the photoactive electrode(s) in a PEC cell (1, 2, 15, 25-29).

In an attempt to clarify to what extent changes in the surface morphology contribute to the observed variations in the spectral response of polycrystalline TiO₂ layer electrodes, different oxidation conditions and polishing procedures were utilized to achieve electrodes with different surface finishes. The registered action spectra of the electrodes are compared with earlier published spectra. The observed changes in spectral distribution of the photoreponse are discussed with reference to models proposed in the literature. The concept of a "recombination layer" at the surface of the electrode is introduced and a semi-empirical equation, based on the Gärtner-Butler expression (18, 19), is utilized to describe the registered action spectra in the wavelength range 300-400 nm.

Materials

Titanium plate, which, according to the manufacturer, contains Fe < 0.10%, O < 0.35%, N < 0.07%, C < 0.10%, and H < 0.012%. An etching solution was made from 1 part 40% HF solution, and 1 part conc HNO₃ and 3 parts distilled water. Phosphate buffer solutions were prepared from p.a. Baker reagent chemicals and distilled water. These solutions were pasteurized and stored at 4°C.

Preparation of the TiO₂ Layers

1 mm thick circular (20 mm diam) titanium plates were mechanically polished to mirror brightness with aluminium oxide (Tornerde, Jean Wirtz, Dusseldorf, Germany) in a sequence down to a grain size of 0.25 μm. Some of the mirror bright plates were etched for 20s in the etching solution (see previous section). All plates were carefully cleaned and finally rinsed in distilled water before they were placed in the preheated oven. The oxidation was carried out in air at atmospheric pressure. The temperature was measured close to the samples with a Pt/Pt, Rh (10%) thermocouple. Zero time was taken when the samples were placed in the oven. [A more detailed description of the preparation procedure is given in Ref. (29, 39).]

Experimental

The TiO₂ film thickness was determined from the interference fringe pattern of reflection spectra recorded in the range 400-15,000 nm. (Zeiss DMR 10, Beckman DK-2a, and Perkin Elmer 157 IR spectrophotometers were used.)

A conventional three-electrode cell was used. The TiO₂ electrodes were mounted in a specially constructed O-ring (Viton) sealed plexiglass holder, exposing a circular area of 0.8 or 1.8 cm² to the electrolyte. Ohmic contact (metal to metal) was made by pressing a spring-supported stainless steel pin or a copper wire against an oxide-free spot at the back of the Ti plate. The surface of the TiO₂ electrode was placed in the cell behind an optically flat fused quartz (suprasil) window. A calibrated saturated calomel electrode (0.242 ± 0.001V vs. NHE) was used as reference electrode (RE). The counterelectrode (CE) was platinized Pt-foil (area approximately 3 cm²) separated from the TiO₂ working electrode (WE) and RE by a porous glass filter. The arrangement of the light source, the monochromator, and the arrangement for measuring the light intensity have been described elsewhere (13). Corrections for reflection losses at the window of the cell and absorption losses in the electrolyte were made. Those cases where correction for reflection losses at the TiO₂/electrolyte interface were made, will be specially noted in the following. A Schott filter UG5 was used to eliminate stray light in the wavelength region 250-350 nm. The second-order spectrum from the grating monochromator (Schoeffel GM 252) was filtered off with a Schott GG15 cutoff filter.

The potentiostatic measurements were performed with a PAR 173 instrument. Action spectra (at constant WE potential) were determined from alternating point by point measurements of the photocurrent and the light flux. Photocurrent registration was also made on a Hewlett-Packard Model 7044A X-Y recorder. All measurements

were performed at room temperature (approximately 20°C).

The surface profile measurements were made on a Sloan Detak surface profile measuring instrument (Sloan Technology Corporation, Santa Barbara, California).

Results and Discussion

Estimation of film thickness.—The TiO₂ film thickness was estimated using Eq. [1]

$$\frac{n}{\lambda} = \frac{1}{4d} \left(M - \frac{k}{\pi} \right) \quad [1]$$

Here n is the refractive index, λ is the wavelength at maxima and minima, d is the film thickness, M is an integer, and k is a constant equal to 0 or π , depending on the phase difference between the beams reflected at the two interfaces air/oxide and oxide/metal. Refractive indexes of polycrystalline TiO₂ (rutile) given by Hass (30) and Cardona and Harbecke (31) were used in the calculations.

Figure 1 shows some typical plots from which the film thickness d was determined. The Tolansky method recently used by Stillwell and Park (32) was also applied and gave (except for two very thin films) the same results within 5%.

Measured values are collected in Tables I and II. They agree well (29) with the results of the more extensive studies by Kofstad *et al.* (33, 34) and Dechamps and Lehr (35).

The effect of increased oxidation of the titanium plate.—Figure 2 shows the action spectra of 12 polycrystalline TiO₂ electrodes prepared by thermal oxidation in air in the temperature range 500°-700°C. All twelve electrodes were made from carefully polished titanium plates, which were slightly etched (ca. 20s) before oxidation. SEM pictures give evidence of an increasing surface roughness with increasing oxidation (29). The action spectra in Fig. 2 were registered point by point, going from longer towards shorter wavelengths at a working electrode potential of 1.25V vs. SCE (pH = 6.75). The quantum efficiencies

	4.0	1290	0.43	355	125	3.1
	15.0	2990	0.13	800	(63)	1.3

were calculated from the difference between the steady-state photocurrent and the dark current. A systematic change in the spectral distribution of the photoresponse with increasing oxidation can be seen. The trend of an overall increase in quantum efficiency with increasing oxidation (or TiO₂ film thickness) is succeeded by a rapid decrease in the range 250-300 nm (starting with the plate oxidized at 598°C for 4h). A shallow minimum at approximately 300 nm is seen. The maximum in the short wavelength region remains at approximately 270 nm, while the maximum in the long wavelength region (300-400 nm) undergoes a red shift with increasing oxidation.

A similar red shift has been observed by a number of workers (3, 5-9, 15, 16), e.g., by Matsumoto *et al.* (3) at thermally grown polycrystalline TiO₂ electrodes, and by Möllers *et al.* (7) at electrodes prepared by chemical vapor deposition. Liou *et al.* (16) and Wilson *et al.* (15), who investigated the aging of hydrogen-reduced single crystals of TiO₂, also report similar red shifts with increasing illumination time. Similarly, Mac Aleer and Peter (8) observed a red shift in the action spectra in their study of anodic oxide films on titanium. The shallow minimum near 300 nm is also present in the "anodic" action spectra of untreated polycrystalline TiO₂ electrodes (prepared much in the same way as in the present work) presented by Sprünken *et al.* (14), and in the action spectra of single-crystal TiO₂ electrodes registered by Wilson *et al.* (1). The minimum can be attributed to the higher reflection losses due to the large index of refraction (31) in this range (*vide infra*).

Different explanations of the observed changes in action spectra are proposed. Matsumoto *et al.* explain the observed red shift upon increased oxidation by referring to a model proposed by Goodenough. They suggest that the broadness and position of the photocurrent peak will mainly be determined by the degree of interaction be-

Fig. 2. Action spectra of 12-layer electrodes prepared by thermal oxidation of highly polished titanium plate. At each temperature (502°, 598°, and 704°C) the oxidation periods were: ○ 0.50h, ● 1.00h, □ 4.0h, and △ 15.0h. The solid lines show best fit of Eq. [2] to the experimental data. Electrode potential 1.25V vs. SCE; pH = 6.75.

tween the t_{2p} orbital of the Ti cation and the p orbital of the oxygen ion. If the interaction becomes weak, the peak becomes sharp and shifts towards longer wavelengths, and they propose that this is the case for samples prepared at temperatures above 700°C.

Table II. The obtained values of the parameters w and d_f are given for best fit of Eq. [2] to registered action spectra, as described in the text. In these calculations the parameter f was fixed at zero. Data collected from five different stages of polishing and six different electrode potentials, U vs. SCE.

The table also gives the thickness d at each stage of polishing. α_λ values from Ref. (13) were used in these calculations. $E_g = 3.05$ and $B = 8.7 \times 10^7$ eV⁻¹m⁻¹ were used to calculate α_λ in the wavelength range 340-400 nm. (See Eq. [3].) Allowed ranges of the parameters were: $0 < d_f < 2000$ nm, $0 < w < 2000$ nm

In the qualitative discussion of aging effects in H_2 -reduced single-crystal rutile anodes, Harris and Wilson explained some of the observed changes in the spectral distribution of the photocurrent by the formation of an "inert" layer which absorbs photons without contributing to the current. They also discussed the effects of surface roughness and "pores" at the surface of the crystal.

A narrowing bandgap and shifts in the refractive index are proposed by Liou *et al.* as an explanation of the red shift observed in their aging experiments. Sprünken *et al.* do not discuss the bandshift mentioned above, but do give interesting comments on the charge exchange and the reactions at the electrode/electrolyte interface. In terms of a slightly modified model proposed by Gerischer (36) and Bard (37), a qualitative explanation to the "anodic" and "cathodic" action spectra was given, which was registered at working electrode potentials close to the flatband potential. The model includes surface states in the bandgap as well as the existence of different energy states of reduced and oxidized species (*e.g.*, O^{2-}/O_2) in the liquid phase. Their experiments showed that when oxygen or other reducible species like Fe^{3+} are present in the solution, electrons generated close to the electrode surface by short wavelength light with small penetration depth, $1/\alpha_\lambda$, are transferred to the solution and contribute to a "cathodic photocurrent."

Electrons generated deeper in the TiO_2 electrode by long wavelength light with low absorption coefficient, however, are drained into the electrode. Sprünken *et al.* did not make any systematic investigation of the effect of surface roughness, but assumed that the less pronounced cathodic effects on single crystals compared with polycrystalline materials arise from the smaller surface area of the former. We will return to the ideas of Wilson *et al.* and Sprünken *et al.* in the following discussion.

The effect of different polishing procedures.—The effects of different polishing procedures on the photoresponse are illustrated in Fig. 3-6. The data presented in these figures were collected from electrodes made from the same titanium plate and oxidized under identical conditions (4h in air at 685°C).

The electrodes A, B, and C (Fig. 3 and 4) were prepolished with powders of grain sizes 150 μm (100 mesh), 50 μm (280 mesh), and 0.25 μm , respectively, before the oxidation procedure. Electrode D was subjected to the same prepolishing procedure as C, but after oxida-

Fig. 3. Action spectra of polycrystalline TiO_2 electrodes showing the effect of different preparation procedures. Corresponding electrode surface profiles and detailed preparation parameters are given in Fig. 4.

Fig. 4. Surface profiles of polycrystalline TiO_2 layer electrodes. The final polishing of the titanium plates before oxidation was made with the following grain sizes of the polishing media: A: 150 μm (100 mesh). B: 50 μm (280 mesh). C and D: 0.25 μm . After the oxidation procedure (4h at 685°C, air at 1 atm), D was polished to mirror brightness with 0.25 μm diamond paste.

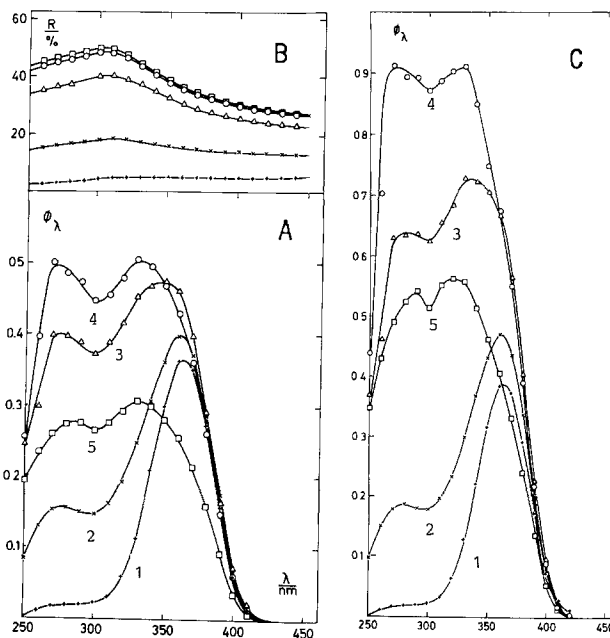

Fig. 5. The quantum efficiency (ϕ_λ) and the reflectance (R) as a function of wavelength (λ) of a polycrystalline TiO_2 electrode at different stages of surface finish. Corrections, except for reflection losses at the TiO_2 /electrolyte interface, had been made in A. In C, ϕ_λ has also been corrected for the specular reflection, as described in the text. Spectra of the unpolished electrode are in the different parts of the figure denoted with 1. Curves 2-5 represent different stages in the polishing procedure. The depth (d) of the layers, which decrease as the polishing proceeds, are given in Table II. The action spectra were all recorded at 1.0V vs. SCE at pH = 4.7. Note that the minima in the ϕ_λ curves coincide with the maxima in the reflectance spectra.

tion it was further polished with 0.25 μm diamond paste. The latter treatment will be discussed in detail below. The surface profiles of electrodes A-D are shown in Fig. 4. It is evident from these figures that there is a close connection between the surface structure and the registered changes in action spectra.

In addition to the overall decrease in quantum efficiency, a pronounced decrease in the efficiency of short wavelength light and a shift of the maximum towards longer wavelengths is registered with increasing surface roughness.

Figure 5 shows action spectra and reflectance spectra of a single polycrystalline TiO₂ electrode oxidized at 685°C for 4.0h in air at atmospheric pressure. This electrode was subject to successive surface polishing with 0.25 μm diamond paste after the oxidation. The polishing procedure was interrupted and the specular reflectance in air (Fig. 5B) and the action spectra were registered at five different stages of surface finish. From the interference pattern in the visible and infrared region of the reflectance spectra (not shown), the electrode thicknesses were determined as described above. The resulting film thicknesses, d , are collected in Table II.

In the action spectra shown in Fig. 5A, all corrections have been made except the correction for reflection losses at the TiO₂/electrolyte interface. The specular reflectance (Fig. 5B) was used to correct for these losses of light (see Fig. 5C). The latter correction is crude for two reasons: (i) the difference in refractive index between electrolyte and air has not been taken into account, and (ii) the diffuse part of reflection has been omitted.

As can be expected, the specular reflectance increases with polishing time. Curves 4 and 5 in Fig. 5B are almost identical, which indicates that the upper limit in specular reflection is reached. The reflectance at this stage is also very close to the value calculated from refractive index data given in the literature. The diffuse reflection is apparently very small and the electrode shows a mirror-like surface. The error introduced by omitting the diffuse reflectance at this stage is negligible. Note that the maxima in the reflectance spectra (at ca. 300 nm) correspond very well to the minima in quantum efficiency in curves 2-5 in Fig. 5A. For this reason, the minima in the corrected curves in Fig. 5C are less pronounced.

Examining the action spectra in the sequence from stage 1 to stage 5 (Fig. 5A and 5C), the following features are noticeable: (i) in spite of the increasing specular reflectance, the quantum efficiency in Fig. 5A increases with increasing polishing up to curve 4. The increase is most apparent in the range 250-300 nm. (ii) When the quantum efficiency decreases again (curve 5), the relatively larger quantum efficiency at short wavelengths persists and the spectrum more closely resembles curve 4 than curve 1. (iii) The edge of the action spectra just below the bandgap wavelength shifts towards longer wavelengths and then back again (curve 5) with increasing polishing.

As can be seen from Fig. 6, there is a marked increase in the sub-bandgap response after the first polishing procedure. The sub-bandgap response then remains fairly independent of further polishing.

Interpretation of action spectra.—Focusing our attention on the action spectra of the TiO₂ electrodes investigated in the present work, we will first consider the development of the TiO₂ layer as the oxidation proceeds. Starting with a highly polished Ti plate, a moderate oxidation (at low temperature for a short time) will result in a fairly smooth polycrystalline TiO₂ layer (Fig. 7A), in which the number of vacancies (or oxygen deficiencies expressed by y in TiO_{2-y}) rapidly increases inwards into the layer until the metal is reached. Thus an inhomogeneous doping density N_D will result. N_D will increase with the distance x from the surface. Increasing oxidation will give thicker TiO₂ layers (Fig. 7B and 7C), but also larger crystallites and a rougher surface. At high temperatures and long oxidation times, the rough surface region will be nearly completely oxidized. This means that the doping

Fig. 6. Same action spectra as in Fig. 5A extended into the sub-bandgap region. Note the overall increase in sub-bandgap response after the first polishing procedure.

density N_D will be low at the surface and then gradually increase with layer depth, but now with a smaller gradient than in the case of the more moderately oxidized electrodes. Thus, the increase in efficiency with increasing oxidation for long wavelength light (with large penetration depth) can be qualitatively understood in terms of decreasing doping density, which results in a wider space-charge region.

Furthermore, as proposed by Harris and Wilson (15), electron-hole recombination in the poorly doped surface region could make this region function as an "inert" layer, which like an optical filter absorbs light without

Fig. 7. Schematic representation of cross sections (normal to the macroscopic electrode surface) of TiO₂ layers formed by thermal oxidation of highly polished titanium plates. Shaded areas denote titanium, and unshaded TiO_{2-y}, where y is a small number representing oxygen deficiencies. y is a function of the distance (x) from the surface as described in the text. A-C illustrate the evolution of a layer electrode in a sequence of stronger oxidation conditions. The broken line gives the position of the border between the SCR and the bulk of the electrodes. Keeping the oxidation time constant, e.g., at 4h, A, B, and C may represent layers formed in air at ca. 500°, 600°, and 700°C, respectively. D shows the same electrode as C, but polished.

contributing to the photocurrent. The decreasing quantum efficiency (Fig. 2) of short wavelength light must, thus, according to this idea, be explained by electron-hole recombination in this surface "filter" region.

This is, however, not the only possible reason for low efficiency in the short wavelength range (250-300 nm) for the strongly oxidized titanium plate, e.g., electrodes prepared at temperatures above ca. 600°C (see Fig. 2). Recombination of charge carriers via states at the surface is another. Such states have been observed by a number of workers. For example, Sprünken *et al.* (14) and Wilson (38) have observed reduction peaks in their *i*-*V* curves just positive of the flatband potential. The reducible states observed by these workers were induced by light with energy exceeding the bandgap energy and at potentials positive of the flatband potential. The states were long lived and probably neutral (38). The observations of the referred author have been confirmed for polycrystalline TiO₂ electrodes at our laboratory. These experiments will be discussed further in a separate paper. Filling and unfilling such states may lead to recombination of electrons and holes.

At a rough, low doped surface (with irregular grains projecting into the electrolyte) a lateral transport of charge carriers to the interface is most probable [Compare the mechanism proposed by Lewerenz *et al.* for layered compounds (26).] Electrons and holes formed by short wavelength light will be generated predominantly in this low doped rough region and experience any field built up at the interface by surface states. Even if the bandbending is high deep in the electrode, at strong positive polarization (see Fig. 8), and a good charge separation is at hand in this particular region of the electrode, the photogenerated charge carriers in the low doped rough surface will experience not this field, but, rather, the field built up by the surface states. At positive polarization, the holes formed deep in the electrode, in the depletion layer, will be forced to the surface and the surface will become saturated with "oxidized" surface states. In the field created by these surface states, photoexcited electrons formed in the rough surface region will be

drained to the surface and consumed in a cathodic backreaction. The resulting "reduced" surface state will be rapidly reoxidized, since there is an excess of holes reaching the surface. The recombination thus mediated by the surface states will be experimentally registered as a decrease in quantum efficiency in the short wavelength range.

A mechanism such as the one proposed above may also explain the changes in action spectra with increasing TiO₂ layer thickness registered by Möllers *et al.* (7). Their TiO₂ layer electrodes made by chemical vapor deposition (CVD) show a similar decrease in quantum efficiency at short wavelengths with increasing layer thickness as observed for the electrodes in the present work (Fig. 2).

The aging experiment of reduced single-crystal TiO₂ electrodes performed by Harris and Wilson (15) shows that the surface roughness increases with time when the electrodes are illuminated under polarization. This increased surface roughness may be connected with the decrease in photocurrent below 300 nm. The red shift in spectral response registered by Harris and Wilson (15) and by Liou *et al.* (16) seems also to be associated with a decrease in doping density of the reduced electrodes in the course of the aging under illumination, as discussed by Butler (17).

The effects of different polishing and etching procedures of single-crystal TiO₂ electrodes reported by Wilson *et al.* (1) are somewhat puzzling. They propose in their report that mechanical polishing produces near the surface of the electrode a disturbed layer which (in contrast to the polycrystalline electrodes of the present work, Fig. 5) decreases the quantum efficiency in the entire spectral range observed. The sub-bandgap response observed at the polycrystalline TiO₂ electrodes in the present work (Fig. 6) and by Chang *et al.* (40) at polycrystalline SrTiO₃ might indicate a shearing of the crystallites during the polishing procedure. This shearing might, as proposed by Chang *et al.*, introduce new bulk levels in the bandgap.

The action spectra of single-crystal electrodes given by Wilson (1) also reveals that etching in molten NaOH gives a decrease in photoresponse in the short wavelength range, in much the same way as found for rough electrodes in the present work, while etching in sulfatesulfuric acid at 340°C does not. Only a more detailed analysis can clarify if these differences can be referred to differences in surface morphology.

A semiempirical equation to describe the action spectra.—An equation that fully describes the action spectra of the TiO₂ electrodes of the present work should include parameters that account for (i) a gradient in doping density normal to the electrode surface, (ii) recombination via surface states and via reactions at the surface, (iii) recombination in the bulk of the electrode as well as in the space-charge region (SCR) and in "the rough surface region," and (iv) effects of the variation of the morphology of the surface.

Models dealing with these phenomena have been proposed (20-24). Wilson (20) has considered surface recombination. Reichmann (21) has given a model for recombination in the SCR. In a recent paper, Allongue *et al.* (22) have incorporated both recombination in SCR and at the surface in a detailed analysis of redox stabilization of liquid-junction solar cells. Schoonman *et al.* (23) discussed the effect of surface roughness, and presented a modified Mott-Schottky equation to account for the lower donor density in a region near the surface of the electrode. None of the models fulfill all the demands stated above at the same time. A complete description of the action spectra in terms of existing models is thus not easily achieved. A combination of existing models would result in an equation with a large number of parameters. It is doubtful if adjusting experimental data to such an equation is meaningful.

We have therefore chosen to describe registered spectra in a simple "semi-empirical" equation. The quantum efficiency was thus expressed by

Fig. 8. A model of the TiO₂ layer electrode prepared by thermal oxidation of titanium. A shows the energy (*E*) diagram with the valence band (VB), the conduction band (CB), the Fermi level (*E_F*), and the band bending (eU_B). B visualizes a "real" electrode as illustrated in Fig. 7. C shows the corresponding idealized model on which Eq. [2] is based. The symbols (the layer thickness, *d*, the depletion layer width, *w*, the "recombination layer," *d_f*, the fraction of the surface not covered with the "recombination layer," *f*) as well as P and Q are all explained in the text.

$$\phi_\lambda = [f + (1 - f) \exp(-\alpha_\lambda d_r)] [1 - \exp(-\alpha_\lambda w)] \quad [2]$$

This equation is based on the well-known Gärtner-Butler expression (18, 19) and the proposed picture of the physical structure and energetic situation at the interface, as illustrated in Fig. 8. The figure shows a cross section (normal to the macroscopic surface) of an electrode prepared by thermal oxidation. Assuming an increase in doping density normal to the electrode surface, as discussed above, no simple expression for the depletion layer width, w , can be used. For our further discussion of the registered variation in the action spectra, however, such an equation need not necessarily be formulated. Assuming the existence of a smallest gradient in potential dU/dx needed to effectively separate photoinduced electron-hole pairs, we can at a given electrode potential choose to define w as a region, *e.g.*, between P and Q (see Fig. 8A), where this condition is fulfilled.

In Eq. [2], the concept of a "recombination layer,"¹ d_r , is introduced. The "recombination layer" is here defined as the region of the electrode, close to the surface, from which there is no net contribution to the photocurrent. As discussed above, recombination of charge carriers photo-generated in the rough surface region, via surface reactions, is a most probable process. If the recombination takes place via surface reactions, as proposed, or in the rough surface region itself, has, however, not been regarded in Eq. [2].

The parameter f has been introduced to account for the fraction of the surface not covered by the "recombination layer."

Figure 8B shows a "real" interfacial region, and Fig. 8C a model visualizing the parameters d_r and f in Eq. [2].

The absorption coefficient, α_λ , was in the indirect transition region 410-335 nm calculated from (13, 31)

$$\alpha_\lambda = B \frac{(h\nu - E_g)^2}{h\nu} \quad [3]$$

where h is Planck's constant, ν the frequency of the light, and E_g the bandgap. B is a constant which was adjusted to fit experimental data of α_λ , as described below.

The diffusion length of minority carriers, L_p , in polycrystalline materials is usually small. The Gärtner equation (18) has thus in Eq. [2] been approximated by assuming $\alpha_\lambda \times L_p \ll 1$. It can be argued that the approximation is not fully justified, especially in the short wavelength range, where the absorption coefficient is large. In the case of the investigated electrodes, short wavelength light will, however, be preferentially absorbed in the "recombination layer" and the depletion layer, and only to a minor extent contribute to diffusion currents. At wavelengths < 335 nm, the penetration depth $1/\alpha_\lambda$ is smaller than 100 nm (31, 13), a depth that can be judged to be in the range of, or smaller than, the sum of d_r and w for the investigated electrodes. Although not conclusive, the outcome of the calculations justifies the approximation for most of the electrodes, *vide infra* Tables I and II.

Application of Eq. [2] to experimental data.—Absorption coefficient data from both Cardona (31) and Lindquist *et al.* (13) were alternatively used. Different E_g values in the range 2.95-3.05 eV were used to calculate α_λ values from Eq. [3] in the range 340-400 nm.

The solid lines in Fig. 2 are the best fit of Eq. [2] to the experimental data in the range 300-400 nm.² The value of α_λ used in these calculations were in the range 340-400 nm determined from Eq. [3]. $E_g = 3.03$ eV and $B = 8.2 \times 10^7$ m⁻¹eV⁻¹ were used. Otherwise, the α_λ values were taken from Ref. (13). Resulting values of w , d_r , and f are col-

lected in Table I. Note that both d_r and w increase with increasing layer thickness d .

As can be seen from Table I, the parameter f reaches a maximum value of 0.063 (704°C, 0.50h). However, Eq. [2], with $f = 0$, fits the data almost equally well. The significance of f can therefore be discussed.

When interpreting the values in Table I, it should be remembered that the corrections for the reflection at the TiO₂/electrolyte interface have not been made.

In addition to the spectra shown in Fig. 5, which were recorded at 1V *vs.* SCE, action spectra were also registered at another five different electrode potentials at each stage of polishing. Two main sets of minimization calculations were made to adjust Eq. (2) to these data: (i) only d_r and w were adjusted, and f was fixed at zero, and (ii) all parameters (f , d_r , and w) were adjusted. Only the results of one of the sets of minimization calculations on the data from the polished electrode (compare Fig. 5), keeping f constant, will be discussed in some detail. Table II summarizes, as an example, a set of such runs on corrected ϕ_λ values (see Fig. 5C), in which f in Eq. [2] was fixed at zero. It can be deduced from Table II and Fig. 9 that the d_r values are almost independent of the electrode potential. The d_r values also decrease with decreasing layer thickness (that is, increased mechanical polishing). A minor increase in d_r is however found for the thinnest (837 nm) layer. The depletion layer width, w , at each stage of polishing increases with increasing electrode potential, as expected. The unpolished electrode gives the highest w values (see Fig. 9B). The w values then decrease with polishing. It is interesting to note (see Table II) that the change in layer thickness of the electrode and the decrease in d_r are of the same magnitude and that d_r is almost zero at stage 4—a fact which might indicate that the "recombination layer" has been polished away. On further polishing, the d_r values remain low and a noticeable decrease in w is registered (899 nm curve, Fig. 9). The latter, as mentioned, is consistent with a doping density gradient normal to the layer of the thermally grown TiO₂ electrodes.

In Fig. 9B, it is seen that the w values achieved in the calculations at each stage of polishing are gathered around lines which can be extrapolated close to or just above the flatband potential ($U_{FB} \sim -0.5$ V at pH = 4.7) (41-43). The main features of all runs with f fixed at zero were the same and independent of the set of α_λ values used.

Allowing all three parameters, f , d_r , and w , in Eq. [2], for the same set of data as used above, to be adjustable in the minimization gives a somewhat better fit of the calculated curve to the experimental data in Fig. 5C. The parameters f increases regularly, being only a few percent for the unpolished electrode and reaching approximately 90% at stage 4 in the polishing procedure. The values of w and d_r are at each polishing step both larger than in Table II (f fixed at zero). The w values increase in much the same way, as shown in Fig. 9. The values of d_r at each stage of polishing are surprisingly constant. A more complete description of the calculations is given in Ref. (39).

Summary

In an attempt to clarify the origin of the frequently observed variations in the distribution of the quantum efficiency of polycrystalline TiO₂ electrodes, action spectra and surface profiles from electrodes prepared under different conditions were registered. Three main sets of experiments were made: (i) highly polished titanium plates were oxidized at different temperatures and periods of time. Action spectra were registered. (ii) The surface of a few electrodes were deliberately made rough before oxidation by polishing with powders of larger grain sizes. The conditions of oxidation were kept constant. Action spectra (Fig. 3) and surface profiles (Fig. 4) were registered. (iii) A TiO₂ electrode with a rough surface was in a sequence of experiments carefully polished. Action spectra and reflectance spectra were recorded after each polishing procedure (Fig. 5 and 6).

¹ The name "recombination layer" (instead of "dead layer") has been used to emphasize the mechanism by which the photocurrent is believed to be suppressed, and to avoid the impression of a layer impenetrable for charge carriers.

² A computer program, UNIFIT, written by Peter Stilbs (Institute of Physical Chemistry, S-751 21 Uppsala, Sweden), was used. UNIFIT utilized the general minimization routine stepit version 7.4, written by J. P. Chadler, Department of Computer Science, Oklahoma State University, Stillwater, Oklahoma.

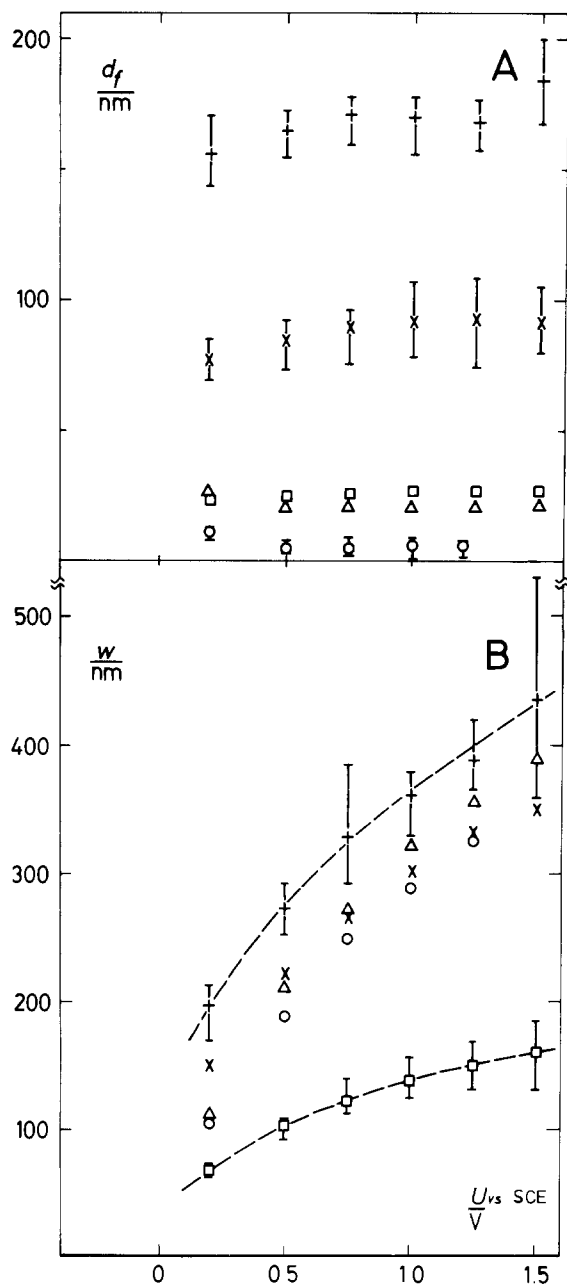

Fig. 9. The adjustable parameters d_f and w in Eq. [2] at five different stages of surface finish of the TiO_2 electrode, as a function of electrode potential U vs. SCE. The parameter f was fixed at zero. The layer thicknesses were: + 104, nm, \times 99, nm, \triangle 95, nm, \circ 89, nm, and \square 83, nm. The two lines drawn in that diagram are given to visualize the possible extrapolation to U_{FB} . For clarity, some error bars have been omitted.

It is evident from these experiments that the surface morphology of polycrystalline TiO_2 layer electrodes, prepared by thermal oxidation of titanium plate, is of the utmost importance for the performance of the electrode. As shown by other workers (3, 4) and in the present work, the spectral distribution of the quantum efficiency is for this reason strongly dependent on oxidation conditions. With increasing oxidation of highly polished titanium plates, the electrode surface gets rougher and a gradual decrease in quantum efficiency in the short wavelength range (250-300 nm) is registered. In this work, we have shown that the treatment of titanium plate prior to the oxidation procedure is also of importance. Starting with an already rough titanium surface before oxidation results in very poor photoresponse. Of more interest, however, is that careful surface polishing of the TiO_2 layer with a rough surface (e.g., formed at 700°C) gives a dramatic increase in photosensitivity of the electrode, especially in the short wavelength range.

To explain the observed changes in the action spectra and relate them to experimental data the effects of recombination of charge carriers, photogenerated in the rough surface region, was considered. It was proposed that the charge carriers, photogenerated in the low doped surface region of the electrode, are laterally transported to the interface. At a positive polarization of the electrode, the surface is saturated by "oxidized" surface states. In the field created by these states, the electrons photoexcited in the rough surface region are drained to the surface, where they are consumed in cathodic backreactions. As short wavelength light has small penetration depth in TiO_2 , it is mainly absorbed in the rough region. Thus, the quantum efficiency in the short wavelength range will decrease comparatively more than in the long wavelength range even at electrode potentials well positive of the flatband potential.

The action spectra were described by a modified Gärtner-Butler equation at different stages of oxidation and polishing of the electrodes. The best fit of the equation gave reasonable values of the adjustable parameters, although the significance of the parameter f can be discussed in some cases.

The increase in quantum efficiency in the range 250-300 nm due to the polishing of the polycrystalline TiO_2 electrodes prepared by thermal oxidation, is in contrast with what has been observed with SrTiO_3 (40) and TiO_2 single crystals (44). The changes in sub-bandgap response upon polishing are, however, the same.

The increase in quantum efficiency achieved by surface polishing is probably not unique for polycrystalline TiO_2 layer electrodes. Surface polishing can be expected to be equally important for the photoresponse of other commonly used polycrystalline electrode materials. Work in this direction is in progress.

Acknowledgments

We thank Dr. C-G. Ribbing and his colleagues at the Institute of Technology, Uppsala University, Uppsala Sweden, for their assistance in the optical measurements and research engineer Kjell Magnusson (at the same institute) who performed the surface profile measurements. This work was supported by the Swedish Natural Science Research Council. A grant from the Swedish Institute (SI) made Zhu Yan-Ning's visit in Uppsala possible.

Technical Notes

The Electrochemical Oxidation and Polymerization of Polycyclic Hydrocarbons

Robert J. Waltman and A. F. Diaz*

IBM Research Laboratory, San Jose, California 95193

Joachim Bargon

Institut für Physikalische Chemie, Universität Bonn, 5300 Bonn-1, Germany

The electrochemical oxidation reactions of polycyclic aromatic hydrocarbons are complex and usually irreversible (1,2). Although the more usual reaction pathway is the formation of soluble products whereby $n = 1$ (1), some compounds will undergo multielectron oxidations (2). In most cases, their oxidation is inevitably coupled with a rapid irreversible chemical reaction. This is often further complicated by the formation of an insulating film on the electrode surface. For example, the electro-oxidation of pyrene or triphenylene gives rise to such films (2). While formation of these films have often been ignored, it is only recently that interest has actually shifted to these films. For example, the recent finding that the polycyclic nonbenzenoid hydrocarbon azulene undergoes electrochemically induced polymerization (3-8) and, furthermore, that its polymer films are electrically conducting ($10^{-2} - 1$ S/cm) and display electrochromic behavior (8) has stimulated an investigation of the polymerization aptitude of other aromatic hydrocarbons. The electrical properties that these materials possess have been of interest both for the case of the polycyclic hydrocarbons which display modest intrinsic electrical conductivity (9) and their crystalline radical cation salts which exhibit high electrical conductivities (10). Accordingly, we report

*Electrochemical Society Active Member.

herein electropolymerization studies of the polycyclic hydrocarbons pyrene, triphenylene, fluorene, and fluoranthene. In considering the oxidation reactions of these compounds and the properties of their corresponding polymer films, pyrene is found to be considerably different from the other three aromatic compounds.

Experimental

All monomers were obtained from commercial sources and recrystallized prior to use. Electrochemical measurements were achieved in a three-electrode, single- or two-compartment cell using platinum, gold, and a saturated sodium chloride calomel (SSCE) as the working, counter, and reference electrodes, respectively. The solutions typically contained $10^{-3}M$ of monomer in 0.1M tetraethyl ammonium fluoroborate (TEAFB)/acetonitrile solution. The acetonitrile (Burdick and Jackson, spectrometric grade) was used as obtained without further purification. The electrical conductivities of pressed pellets were measured utilizing a Magne-Tron Instruments Model 700 four-probe apparatus.

Results and Discussion

Electro-oxidation reaction.—The electro-oxidation reactions of the four polycyclic hydrocarbon compounds

Table I. Cyclic voltammetric data for 2.5-4.0 $\mu\text{mol}/\text{cm}^3$ of compound in 0.1M TEAFB/acetonitrile. Sweep rate equals 40 mV/s.

Compound	E_{pa} (V)	$i/AC\nu^{1/2}$ ($\text{A} \cdot \text{cm} \cdot \text{mol}^{-1/2} \text{V}^{-1/2}$)	n^a	n^b
Pyrene	1.33	2003	1.7	^c
Pyrene ^d	1.30	2034	1.7	2.31
Fluorene	1.82	3676	2.5	2.23
Fluoranthene	1.68	2726	2.0	2.28
Triphenylene	1.83	4155	2.7	2.20

^a Value from cyclic voltammetry.

^b Value calculated using elemental analysis data.

^c No analysis due to poor quality of film.

^d Measured using perchlorate electrolyte.

shown below were measured using TEAFB electrolyte. These data are summarized in Table I. All of the compounds electro-oxidize irreversibly, and produce complicated cyclic voltammograms. The voltammograms

contain multiple peaks which are broad and overlapping. Even the first oxidation wave for all of the compounds listed in Table I is ill-defined and occurs as a shoulder on a much larger peak, which probably results from the oxidation of the polymeric product being formed on the electrode surface. The current response for the first oxidation reaction of pyrene, although a shoulder, is more distinguishable than with the other compounds. The voltammogram shown in Fig. 1 was measured using TEAFB and provides a value for E_{pa} of 1.33V. The oxidation of pyrene was also measured using tetrabutylammonium perchlorate electrolyte. The resulting voltammogram is very similar to that with the TEAFB electrolyte, but the E_{pa} value is slightly shifted to 1.30V. This result is not unexpected since our experiences with the electro-oxidation of azulene (5), pyrrole (11, 12), and thiophene (6) have revealed that the electropolymerization reaction is insensitive to the difference between the BF_4^- and the ClO_4^- electrolyte. The E_{pa} value for pyrene of 1.30V compares well with a previous literature value (2) of 1.24V (in a perchlorate/acetonitrile solution). Since it is known that the E_{pa} value for EC reactions are slightly dependent on both solution concentrations and sweep rate (13), reproducibility of the E_{pa} values for these polycyclic hydrocarbon compounds is not expected to be better

Fig. 1. Cyclic voltammogram of 3 $\mu\text{mol}/\text{cm}^3$ pyrene in 0.1M TEAFB/ CH_3CN at sweep rate of 100 mV/s, with 60% iR compensation.

Fig. 2. Cyclic voltammogram of 3 $\mu\text{mol}/\text{cm}^3$ pyrene in 0.1M TEAFB/ CH_3CN at sweep rate of 200 mV/s, with 60% iR compensation. Successive sweeps reveal growth of polymer film on electrode surface.

than ± 10 to 20 mV, unless all experimental parameters are identical (13). The n value of the first oxidation peak for pyrene was estimated utilizing the Nicholson and Shain treatment (14) for a totally irreversible oxidation reaction. The diffusion constant was assumed to be $D = 2 \times 10^{-5}$ and $\alpha = 0.5$. The same n value of 1.7 was obtained with both the BF_4^- and the ClO_4^- electrolyte. This value is low (less than 2.0) and suggests that only a fraction of the monomer electropolymerizes. As is shown below, only half of the reaction produces film on the electrode. Because the electro-oxidation reaction of these compounds produces polymeric films on the Pt anode, each successive sweep in the cyclic voltammogram is different due to a buildup of polymer film. This is seen in Fig. 2 for pyrene in 0.1M TEAFB/acetonitrile, where the peaks for the oxidation-reduction reaction of the film product increase and there is a corresponding distortion of the current response for the oxidation of pyrene.

The E_{pa} values for fluorene, fluoranthene, and triphenylene are more difficult to determine, even at very slow sweep rates. For these three compounds, the E_{pa} values were estimated by deconvolution and, therefore, should be considered to be approximate. However, they appear to be consistent with literature values (15). The n values for fluorene, fluoranthene, and triphenylene are 2.5, 2.0, and 2.7, respectively. These values are consistent with values obtained for other film forming reactions (6, 17) and suggest that, within experimental error, the reaction that produces polymer film is the only reaction and it has a value for n equal to 2. As with pyrene, the buildup of the polymer film on the electrode can be followed in their cyclic voltammograms by successive cycles.

Polymeric films.—At constant potential electro-oxidation of the monomers, thicker films deposit at the electrode surface. Upon drying, these thick polymeric films become brittle and crack easily. They can be scraped off from the electrode surface to yield black, amorphous powders. The elemental composition of these materials indicate that the polymeric films are polymer-anion composites which contain ca. 12% anion by weight (Table II). This corresponds to a stoichiometry of 0.2-0.3 anions per repeating aromatic unit. This stoichiometry is in the range observed for the conducting polypyrrole films (12)

Table II. Elemental composition and electrical conductivity (σ) for some polymers derived from polycyclic hydrocarbons

Monomer	Polymer composition	σ (S/cm)
Pyrene (C ₁₆ H ₁₀)	C _{16.0} H _{12.0} (ClO ₄) _{0.31}	10 ⁻¹⁻¹
Fluorene (C ₁₃ H ₁₀)	C _{13.0} H _{9.3} (BF ₄) _{0.23}	10 ⁻⁴
Fluoroanthrene (C ₁₆ H ₁₀)	C _{16.0} H _{9.6} (BF ₄) _{0.28}	10 ^{-6-10⁻³}
Triphenylene (C ₁₈ H ₁₂)	C _{18.0} H _{11.4} (BF ₄) _{0.20}	10 ⁻⁴

and polyazulene films (5), but is higher than the stoichiometry found for the conducting polythiophene films (8). From these results, n values of 2.23, 2.28, and 2.20, can be calculated for the reactions producing polyfluorene-BF₄, polyfluoroanthrene-BF₄, and polytriphenylene-BF₄, respectively. These values are somewhat smaller than those estimated from the electrochemical data and are still consistent with the range of values obtained for other electropolymerization reactions of aromatic heterocyclic compounds (3). For example, pyrrole (16), thiophene (8), azulene (6), indole (17), or carbazole (18) all electropolymerize with n values between 2.0 and 2.8.

The tetrafluoroborate film of polypyrene, *i.e.*, polypyrene-BF₄, was much too brittle to handle. Therefore, the perchlorate film was prepared for elemental analysis. From this analysis, the stoichiometry of 0.31 anions/aromatic unit and an n value of 2.31 for the film forming reaction is calculated. This value which is a closer estimate of the electrochemical stoichiometry of the film forming reaction is greater than the n value for the overall reaction, 1.7. This difference may result from the presence of competitive reaction pathways with different electrochemical stoichiometries and different products, *e.g.*, polymer *vs.* soluble products. Thus, in the electro-oxidation of pyrene, film formation on the electrode surface occurs, but the solution also becomes discolored, indicating the production of soluble products. Since n_{app} (1.7) for the total reaction, and n_p (2.31) for the film forming reaction are known for pyrene, the fraction of pyrene which leads to polymer can be estimated, assuming that reaction leading to the formation of the soluble product, *i.e.*, dimerization, has an $n_s = 1$ (19), and that it is the only competing reaction.

Thus, if f is the fraction of pyrene which electropolymerizes, then $(1 - f)$ is the fraction which forms soluble species, and the following relationship can be written

$$n_{app} = n_p f + n_s(1 - f) \quad [1]$$

Thus, considering the above values, the fraction of pyrene which gives rise to polypyrene is 0.54, *i.e.*, only half of the reaction yields polymer film during electro-oxidation. The separation of the first peak in the voltammogram for pyrene, which is not observed with the other compounds, may simply be due to smaller current levels for the film products due to their low yield.

The elemental compositions of the polymers also reveal that they are all somewhat hydrogen-rich. Polypyrene is again different from the other polycyclic hydrocarbon polymers in that it is highly hydrogenated. The C/H elemental ratio for this compound is 16/12 and is consistent for an oligomer of polymeric material whereby the pyrene structure is *bis*-coupled and has two double bonds hydrogenated. The amount of hydrogen in the film produced from fluorene, fluoroanthrene, and triphenylene is also high. It is 10%-20% higher than the amount anticipated for a polymer or for a blend of low molecular weight oligomers where the aromatic rings are simply *bis*-coupled. The structure of these polymeric materials remains to be determined.

Of particular concern with polypyrene is the large excess of hydrogen content as revealed by the elemental

analysis data. The ESCA results of neutral polypyrene-BF₄ revealed the presence of only C and O, and the absence of any N or F. The absence of F is certainly expected in the neutral polymer, whereby an ionic complex is not formed with the BF₄ electrolyte. The lack of nitrogen reveals no contribution from alkyl ammonium ions or acetonitrile, both of which could be a source of high H content. The ESCA results also reveal the presence of oxygen uptake at the surface of the neutral film. For pyrene, an oxygen content of 0.3-1.3 oxygens per sixteen carbons (*i.e.*, one pyrene unit) is revealed.

The films are also electrically conducting, and the conductivity of the pressed pellets is summarized in Table II. Again, polypyrene is unique in that its electrical conductivity is in the range of 0.1-1 S/cm, similar to polythiophene (20) and polyazulene (5). The same conductivity level was measured for both the perchlorate and tetrafluoroborate film. The polyfluorene, polyfluoroanthrene, and polytriphenylene films are not as conducting and have values in the range 10⁻⁵-10⁻³ S/cm.

Scanning electron micrographs (SEM) for polyfluorene-BF₄, polyfluoroanthrene-BF₄, polytriphenylene-BF₄, and polypyrene-BF₄ are shown in Fig. 3. The brittle character of the polymer films can be seen in the SEM of polyfluorene-BF₄, where the cracking can be clearly seen. Otherwise, all exposures show nonspecific amorphous surface features found previously in polypyrrole (14), polythiophene (20), and polyazulene (5). Before any practical application can be considered for these materials, their intrinsic brittleness must be overcome. Although the mechanical properties of these films is not the subject of this paper, such properties may be improved by combining these electrically conducting polymers with an otherwise insulating, compatible matrix polymer with appropriate mechanical properties. For example, we have found (21) that incorporation of an electrically conducting polymer such as polypyrrole (PPY) into polyvinyl chloride (PVC), which has excellent mechanical properties, yields a composite material with the following properties: its electrical conductivity is governed predominantly by the PPY content, whereas the

Fig. 3. Scanning electron micrographs of (a) polyfluorene-BF₄, (b) polyfluoroanthrene-BF₄, (c) polytriphenylene-BF₄, and (d) polypyrene-BF₄.

mechanical properties of the composite are effectively those of the PVC matrix polymer (21). Thus, electrochemically produced composites of this type allow one to overcome the shortcomings of the often very brittle yet highly conducting films, such as of PPY or even of polypyrrole. Further details about the preparation of these conducting composites and their electrical and mechanical properties will be described elsewhere (21).

Conclusion

The stoichiometric electrochemical polymerization reaction first described with polypyrrole appears to be quite general (6, 12). It is applicable not only to other heterocyclic systems such as thiophene (8), indole (17), and thianaphthene (17), and even a non-benzenoid aromatic hydrocarbon such as azulene (5), but also to polycyclic aromatic hydrocarbons. The electrochemical polymerization reaction proceeds with an electrochemical stoichiometry of 2.0 electrons/aromatic unit and the charge in excess of 2.0 is consumed in the partial oxidation of the polymeric film which forms on the electrode surface. As with any other preparative procedure, the yield of the desired product varies with the starting compound. While the heterocyclics produce 100% polymer film, the yields can be low as is observed with pyrene (50% film product). The principal difference between the aromatic hydrocarbon and the heterocyclic compounds lies in the quality of the resultant films. The former tend to be brittle and easily cracked. However, the incorporation of these films within a host matrix appears a viable and promising solution (21).

Acknowledgments

We thank J. Duran of this laboratory for taking the SEM pictures, and Professor M.-A. DePaoli, University of Campinas, SP, Brasil, for stimulating discussions.

Long-Term Stabilization of Polythiophene-Protected n-GaAs Photoanodes in Aqueous Solution

G. Horowitz and F. Garnier

Laboratoire de Photochimie Solaire, C.N.R.S., 94320 Thiais, France

Among the different approaches that have been used to stabilize small bandgap n-type semiconductors against photocorrosion in photoelectrochemical (PEC) cells, the grafting of electrogenerated conducting polymers have been reported for Si (1-3), GaAs (4-6), CdS (7), and CdSe (4) photoanodes. Although long-term stabilization, up to 450h, has been reported for polypyrrole (PP)-coated n-Si in I^-/I_3^- aqueous solution (3), the stabilization of n-GaAs is limited by a phenomenon of film peeling that occurs after 10-20 min for PP (4) and 2h for polystyrene pendant $Ru(bpy)_3^{2+}$ (5). We have recently reported a 17h stabilization, with no film peeling, on poly(3-methylthiophene) (PMeT)-coated GaAs (6), but a continuous decrease of the photocurrent was observed, together with the appearance of corrosion holes visible to the naked eye after removal of the film. The lack of long-term stabilization of PP (4) and PMeT (6) covered GaAs was attributed to porosity of the polymer, which allows molecules of the solvent to reach the electrode surface.

However, recent experiments carried out in our laboratory have shown that hydrogen evolution does not occur at a reduced (quasi-insulating) PMeT-coated platinum electrode in 1N HCl aqueous solution (pH = 0) even at potentials as negative as -0.6 V/SCE (7). This result tends to prove that the permeability of PMeT to solute/solvent species is questionable. The origin of the photodegradation of polymer-coated GaAs has then to be reconsidered. We show in this paper that this photodegradation can be attributed mainly to breakings of the film and to its lack of intimate contact with the electrode surface. An improvement of both the solidity and adherence of the polymer allowed us to obtain a long-term stabilization of PMeT-coated n-GaAs in $Fe(CN)_6^{4-}$ aqueous solution.

Experimental

Semiconductor electrodes were prepared from nonintentionally doped (100)-oriented n-GaAs wafers purchased from RTC-Caen (France). The doping level was 2

$\times 10^{16} \text{ cm}^{-3}$ and the thickness 0.35 mm. Ohmic contact was obtained by evaporating Au-Ge alloy and annealing at 400°C under N_2 . The wafers were then cut into 1 cm diam disks and attached to brass disks with Ag paint. The disks were mounted in a Teflon holder, in which an O-ring delimited a 0.26 cm^2 circular active surface. This holder has been designed in order to allow the electrodes to be dismounted for scanning electron microscope (SEM) observation.

As mentioned in a previous paper (6), platinization of GaAs enhances PMeT growth rate (50 nm are then grown in less than 1 min), thus preventing concomitant photo-corrosion of the semiconductor, and allowing homogeneous films to be obtained. Prior to platinization, the electrodes were dipped into concentrated (30%) HCl, in order to remove the oxide layer, and rinsed thoroughly in twice-distilled water. Electroplating of Pt was then carried out at -0.6 V/SCE in a $(\text{NH}_4)_2\text{Pt Cl}_6/\text{LiClO}_4$ aqueous solution. The amount of deposited Pt, which was followed with the help of a digital coulometer, would correspond to a 1-2 nm thick continuous layer. SEM observation showed that the platinum formed in fact disconnected islands. The PMeT electrodeposition was performed in 0.5M distilled 3-methylthiophene, 0.02M $\text{Bu}_4\text{N SO}_3 \text{ CF}_3$, acetonitrile solution, at $+1.5 \text{ V/SCE}$ under a 150W Xe arc lamp illumination ($15 \pm 5 \text{ mW/cm}^2$). Again, the film thickness was controlled by using a digital coulometer. Since we need relative, rather than exact, values of the thickness, we assumed that the linear variation of 1 nm per mC/cm^2 observed on Pt electrodes (8) is also true for platinized n-GaAs.

Stability tests were made in 0.1M $\text{K}_3\text{Fe}(\text{CN})_6/0.25\text{M K}_4\text{Fe}(\text{CN})_6$ aqueous solutions ($\text{pH} = 6$) under illumination by the xenon arc lamp equipped with a 515 nm long pass filter in order to avoid the photodecomposition of ferricyanide by short wavelength light (9), and a water filter to cut the undesirable IR radiations.

Fig. 1. Scanning electron micrographs of PMeT films grown on platinized n-GaAs electrodes. Thickness of the films: 70 (a) and 220 nm (b).

Results and Discussion

Scanning electron micrographs of 70 and 220 nm thick PMeT films grown on platinized n-GaAs, shown in Fig. 1, reveal a decrease of the homogeneity of the film as its thickness increases. A short-term stability test (ca. 15 min) was performed for both of these films. The charge passed during that test was about 2 C/cm^2 . No change of the polymer surface could be detected on the 70 nm film by SEM observation, and the electrode surface presented its original topography after removal of the PMeT film. This was not the case for the 220 nm film, for which corroded areas were visible to the naked eye. Figure 2 shows SEM photographs of a corroded area before and after film removal. The corrosion clearly occurs at micro-cracks of the film, through which the solution is able to reach the semiconductor surface. The fact that a corrosion of the electrode is observed is noteworthy, since at the value of the pH of the solution used for this experiment, passivation of GaAs should result, rather than corrosion. Although this phenomenon is not understood, it can be compared to a classical corrosion behavior of layer-protected metals. The swell of the polymer film at corrosion sites is probably due to a penetration of the solution under the film, which also explains the fact that the size of the corroded areas largely exceeds the width of the cracks. Importantly, the GaAs surface remained unchanged where no bursting of the polymer occurred.

These results indicate that the photodegradation of PMeT-coated GaAs is not due to an inherent porosity of the film, in which case one should observe a corrosion of the whole surface of the electrode, but rather that it initiates at places where cracking of the polymer occurs. Moreover, it appears that thin films present a better homogeneity and intimate contact with the semiconductor electrode. No interpretation can yet be given to this behavior. However we have observed similar topographies

Fig. 2. Corrosion pictures on a 220 nm PMeT film-covered n-GaAs photoanode operated 15 min in aqueous $\text{Fe}(\text{CN})_6^{4-\beta-}$ solution. Charge passed: 1.85 C/cm^2 . Micrographs taken before (a) and after (b) PMeT film removal. Some ferra/ferricyanide crystals that have not been washed away by water rinsing can be seen on the polymer film (photograph a).

Fig. 3. Short-circuit current vs. time for bare, platinized, and 40 nm PMeT-coated n-GaAs photoanode in 0.1M $K_3Fe(CN)_6/0.25M K_4Fe(CN)_6$ aqueous solution. Illumination by Xe arc lamp with 515 nm long-pass filter. Electrode area: 0.26 cm^2 .

on PMeT grown on Pt electrodes (10). Our results clearly showed that thin films (some tens of nanometers) are very smooth and adherent, whereas thicker films present morphological inhomogeneities and losses of adherence.

A long-term stability test was then carried out with a 40 nm PMeT-coated electrode in $Fe(CN)_6^{4-3-}$ aqueous solution. This test consisted in measuring the short-circuit current, at a load resistance of 1Ω , of a PEC cell constituted with the polymer-coated GaAs photoanode and a platinum counterelectrode. The incident light power was 14 mW/cm^2 . The results are shown in Fig. 3. The photocurrent remained very constant for 90h, whereas it decays to negligible values within 1 min for bare GaAs, and within less than 1h for platinized GaAs. The charge passed during the test is 280C, i.e., 1100 C/cm^2 . This last value is noteworthy since it corresponds to the corrosion of almost twice the part of the electrode in contact with the solution. Figure 4 shows that only very slight degradation of the power characteristic of the cell is observed. The corresponding power efficiencies under filtered Xe illumination are 10.9% before and 9.4% after the stability test, which can be compared to the 12% solar efficiency of redox-stabilized n-GaAs-based PEC cells (11-13). The decrease of the power efficiency can originate, at least in part, from an increase of the light absorption by the polymer, due to its redoping by ferricyanide ions. This assumption is argued for by the change of the color of the film from red-brown to green, and by the possibility of doping PMeT grown on Pt in aqueous solutions (14). This implies that water molecules are able to penetrate the bulk of the polymer, which is in contrast to a nonpermeability of the polymer. We then think that the nonporosity of PMeT is limited to the first layers close to the substrate. Importantly, the decay of the fill factor is very slight, indicating that no oxide film has grown on the electrode. Also shown in Fig. 4 is the power characteristic of a platinized GaAs electrode after only 45 min operation. The shape of this characteristic is typical of an oxide covered (passivated) electrode.

No weight loss of the protected electrode could be measured but SEM observation showed a few tiny corrosion sites, mainly near the edge of the polymer-coated area. This corrosion was probably due to the presence of some pinholes in the polymer film. It must be noted that this very localized corrosion did not induce any loss of the intimate contact between the polymer and the semiconductor substrate. The great adherence of PMeT thin films on both metal and semiconductor electrodes seems then to be at the origin of the possibility of stabilizing GaAs photoanodes. The mechanism of this high adhesion power, which could be due to the presence of a sulfur atom in the thiophene ring, is presently under study in our laboratory.

Fig. 4. a: Power characteristic for PMeT-coated n-GaAs in aqueous $Fe(CN)_6^{4-3-}$ solution, under 14 mW/cm^2 Xe arc lamp illumination. Open-circuit voltage: $V_{oc} = 0.655 \text{ V}$; short-circuit current density: $J_{sc} = 3.52 \text{ mA/cm}^2$; fill factor: $FF = 0.66$. b: Same as curve a after 90h of continuous operation. $V_{oc} = 0.625 \text{ V}$; $J_{sc} = 3.46 \text{ mA/cm}^2$; $FF = 0.61$. c: Power characteristic for a platinized n-GaAs photoanode in the same solution after 45 min of operation. $V_{oc} = 0.57 \text{ V}$; $J_{sc} = 0.52 \text{ mA/cm}^2$; $FF = 0.27$.

In conclusion, we have reported the first example of long-term stabilization of polymer-protected n-GaAs in aqueous solution. This result was obtained by using thin film of polymer, which appeared to be more homogeneous and adherent. Corrosion sites that form on thick-film-coated electrodes initiate at cracks of the film, which means that the photodegradation of the semiconductor is not due to a porosity of the polymer. Work is presently under way on GaAs-based photoelectrolytic cells.

The Minority Carrier Recombination Resistance: A Useful Concept in Semiconductor Electrochemistry

J. E. A. M. van den Meerakker, J. J. Kelly, and P. H. L. Notten

Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

ABSTRACT

The impedance characteristics for redox reactions involving minority carrier recombination at semiconductor electrodes differ markedly from those involving majority carriers. In this work, holes were generated in the valence band of n-GaAs by illumination or injection from solution. A recombination resistance is used to characterize the process by which these holes recombine with electrons from the conduction band. This resistance is shown to be independent of the method of hole generation, the pH of the solution, and the nature of the injecting species, but dependent on the generation rate.

In semiconductor electrochemistry, it is of considerable importance to know which of the bands in the solid is involved in the reaction with a redox system in solution. For example, an oxidizing agent may be reduced either by electron capture from the conduction band or by hole injection into the valence band. On the basis of the standard potential of the redox system and the flatband potential of the semiconductor, it is generally obvious which of the two bands is important. However, the situation becomes more complex when an unstable intermediate is involved in the charge-transfer reaction (1) or when charging of an inversion layer or of surface states causes a considerable change in the Helmholtz potential and thus in the position of the semiconductor bandedges (2). In such cases, more sophisticated methods are often necessary to elucidate the reaction mechanism.

In a previous paper (3), we described how, in the photoanodic dissolution of an n-GaAs electrode, hole transfer to the solution was inhibited by an oxide film on the electrode surface. We showed an analogy between the impedance characteristics of this electrolyte-oxide-semiconductor (EOS) system, with enhanced minority carrier recombination, and that of an illuminated MOS device. The concept of a "recombination resistance" was used in the description of the recombination of the minority carriers created by illumination. The dependence of this resistance on light intensity was very similar to that found for the Si MOS transistor (4).

In principle, it should be possible to use such a concept more generally in semiconductor electrochemistry for cases in which recombination of minority carriers is important, irrespective of how these carriers are created. In this work, we describe the generation of holes in the valence band of n-GaAs by two methods, injection from solution and illumination, and we consider the effect of this generation and subsequent recombination on the impedance characteristics of the electrode. A comparison with results involving hole injection into p-GaAs, for which recombination can be disregarded, emphasizes the significance of the recombination resistance. We suggest that this concept may be useful, in certain cases, for deciding which type of charge carrier in the solid is determining for the electrochemical reaction.

Impedance of GaAs Electrodes under Depletion Conditions

In order to clarify what we mean by the recombination resistance, we shall first briefly consider the creation, recombination, and Faraday reactions of minority carriers in n-GaAs under depletion conditions.

Hole reactions at GaAs electrodes.—Under depletion conditions, the extent of the band-bending at the electrode surface determines what happens to holes injected from an oxidizing agent in solution into the valence band of n-GaAs. At relatively large band-bending [Fig. 1(a)], the holes are held at the surface by the electric field, and rupture of surface bonds occurs; the injection is compensated by dissolution of the GaAs, and the resultant net current is very small (5). At lower band-bending, the injected holes can recombine with electrons either at the surface or within a diffusion length of the surface [Fig. 1(b)]. A net cathodic current, carried by electrons in the bulk, is observed in this case.

In an n-type semiconductor, minority charge carriers can also be created by light. In this case, dissolution gives an anodic (photo-) current whose magnitude is determined by the light intensity [Fig. 1(c)], while recombination results in a net zero current [Fig. 1(d)].

Holes, injected under depletion conditions into a p-type GaAs electrode move away from the surface under influence of the electric field [Fig. 1(e)]. This hole-flow through the valence band of the solid is registered as a cathodic current. Recombination is, of course, not important in this case.

Equivalent circuits for GaAs electrodes.—Myamlin and Pleskov (6), using the analogy with MOS devices (7), propose a complete equivalent circuit for the impedance of an n-type semiconductor electrode under depletion conditions. In Fig. 2, the situation is shown for the case in which the recombination rate in the space-charge layer equals zero. C_D , C_S , and C_I are the capacitances of the depletion layer, the surface states, and the inversion layer, respectively. The Helmholtz capacitance C_H replaces the oxide capacitance of the MOS transistor. $R_{n,D}$ and $R_{p,D}$ are the resistances which characterize the transfer of elec-

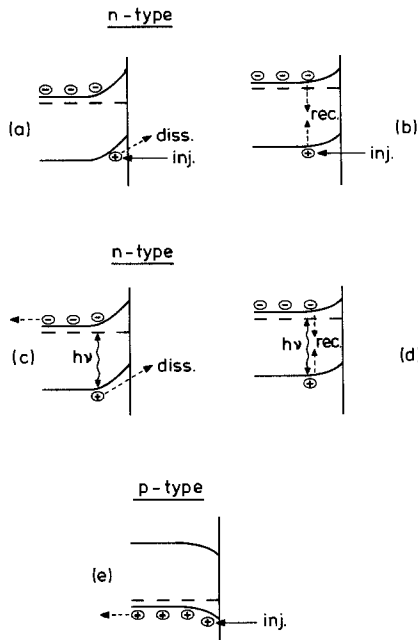

Fig. 1. Band diagrams for a semiconductor electrode under depletion conditions. (a) and (b) refer to hole injection (inj.) into an n-type electrode. At large band bending, (a) dissolution (diss.) dominates, while at moderate band bending, (b) recombination (rec.) dominates. (c) and (d) are the analogous cases when holes are generated by light. (e) shows hole injection into a p-type electrode.

trons and holes through the depletion layer, while $R_{n,s}$ and $R_{p,s}$ represent the transfer of electrons from the conduction band and of holes from the valence band to surface levels. R_B is the bulk semiconductor resistance. The impedance Z_r describes the generation and recombination of holes and their flow rates in the region of quasi neutrality in the bulk adjacent to the space-charge layer (7). Finally, if an electrochemical reaction occurs at the electrode, current flow through the surface must be taken into account. i_n and i_p represent the electron and hole currents.

In this work, we are mainly interested in the case in which recombination within the space-charge layer is dominant, i.e., the recombination rate is very high. Here the current in the space-charge layer changes from a predominantly electron current at the bulk side to a predominantly hole current near the surface. It becomes meaningless then to represent the current flow through the depletion layer by separate impedances for holes and electrons. The complex impedance Z_r together with $R_{n,D}$ and $R_{p,D}$ can therefore be replaced by a frequency-independent resistance R_D (7) [Fig. 3(a)]. Since, for the

Fig. 2. Equivalent circuit for an n-type semiconductor under depletion or inversion conditions with zero recombination rate in the space-charge layer.

hole injection experiments described here, the rate of reduction of the oxidizing agent may be diffusion controlled, a Warburg impedance W is introduced into the hole injection path.

The equivalent circuit given in Fig. 3(a) is too complex for practical use, but can be further simplified. Pierret and Sah have shown (8) that the resistance R_D is essentially determined by the recombination process in the space-charge region. We now assume that one of the interface capacitances, C_I or C_S , is dominant, and we represent it by C_{if} [Fig. 3(b)]. If inversion can be disregarded, which is very likely to be the case here, then the space charge and surface resistances can be combined into a single recombination resistance which we denote by R_r . Alternatively, when surface states are unimportant, then inversion may determine the interface capacitance C_{if} . If the impedance is measured using a rotating disk electrode at potentials at which reduction of the oxidizing agent is completely diffusion limited, then the Warburg impedance becomes purely resistive and has a very high resistance value (R_w). For measuring frequencies in the range 1-10 kHz, this part of the circuit may be omitted and current will flow through the Helmholtz capacitance. Finally, on combining the electrolyte and bulk semiconductor resistances R_e and R_B into a term $R_{e,B}$, we obtain the simplified circuit shown in Fig. 3(b). This circuit also covers the generation/recombination case in which minority carriers are created by light instead of injection. The circuit is, in fact, the circuit deduced from composite impedance theory by Pierret and Sah for the illuminated MOS transistor without external current flow (8) and used by us for the GaAs EOS system; in the present case, the oxide capacitance is replaced by C_{if} .

For a p-type electrode under depletion conditions, the recombination resistance R_r appears in the current path for electrons. Since holes are being injected from solution [Fig. 1(e)], the Warburg impedance is found in the current path for majority carriers. Mott-Schottky measurements with p-GaAs show no evidence of surface state or inversion effects under depletion conditions in the dark. Since minority carrier processes are not important, a circuit equivalent to that shown in Fig. 2 can be simplified to one containing C_D , C_{if} , R_w , and $R_{p,D}$. The Helmholtz capacitance should be much larger than that of the depletion layer, and $R_{p,D}$ is negligible with respect to R_w . So, a simple circuit results: the depletion layer capacitance C_D is short-circuited by a large resistance R_w and is connected in series to the solution/bulk semiconductor resistance $R_{e,B}$.

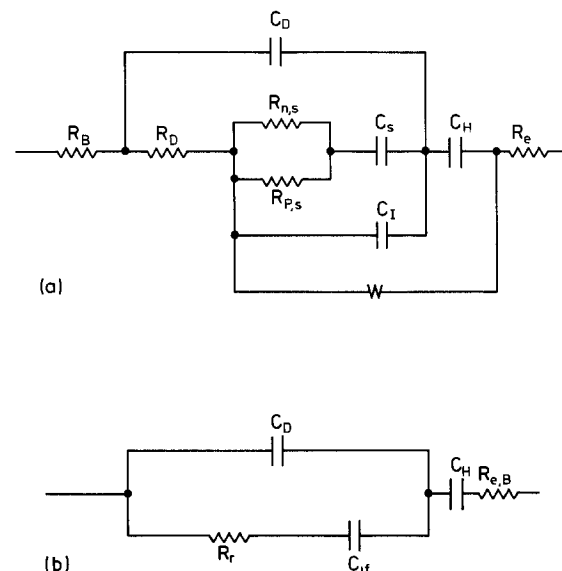

Fig. 3. (a) Equivalent circuit for an n-type semiconductor under depletion or inversion conditions with infinite recombination rate in the space-charge layer. (b) Simplified circuit of a, when the generation rate is diffusion controlled.

SSST

In order to characterize the recombination resistance R_r , we measured the frequency dependence of the impedance of an n-GaAs electrode in which holes were created by illumination or injected from Ce^{IV} or $Fe(CN)_6^{3-}$ ions in solution. Current-potential curves were used to distinguish the regions in which recombination and dissolution were dominant, and the results were compared with those of hole injection into p-GaAs.

Experimental

The GaAs single-crystal wafers were obtained from MCP Electronics, England, and had the 100 orientation. The n-type material was Si doped ($8.6 \times 10^{16} \text{ cm}^{-3}$) and had a resistivity of $0.019 \Omega\text{-cm}$. The p-type wafers were Zn doped ($8.4 \times 10^{17} \text{ cm}^{-3}$) and their resistivity was $0.042 \Omega\text{-cm}$. The diameter of the rotating disk electrodes made from these materials was 4 mm. Prior to use, all electrodes were etched at room temperature in a mixture of $H_2SO_4(98\%)-H_2O_2(30\%)-H_2O(3-1-1)$ and dipped in a 6N HCl solution.

The measurements were made in a conventional electrochemical cell using a platinum disk as a counter-electrode and a saturated calomel electrode (SCE) as a reference. All potentials are given with respect to this SCE. Impedance measurements were done under potentiostatic control with the aid of a Solartron 1172 Frequency Response Analyser and an rms signal of 10 mV. For illumination, a Spectra Physics 1 mW 133 He-Ne laser was used in combination with a glass fiber light cable. The penetration depth of this light is small compared to the diffusion length of holes in n-GaAs.

All solutions were prepared with reagent-grade chemicals and deoxygenated using a nitrogen flow. The measurements were performed at room temperature.

Results

Current-potential measurements.—The reduction of Ce^{IV} at pH 0 and $Fe(CN)_6^{3-}$ at pH 14 occurs at GaAs electrodes by means of hole injection into the valence band (9). The reduction reaction is diffusion controlled in a wide potential range, as is clear from the current-potential curves measured at p-GaAs [dashed lines in Fig. 4(a)]. An identical limiting current is found at n-GaAs [solid lines in Fig. 4(a)] at potentials more negative than -0.60V . In this range, which corresponds to moderate band bending [Fig. 1(b)], holes injected into the electrode recombine with electrons from the conduction band. At more anodic potentials, the band bending increases, the electron concentration at the surface is greatly reduced, and dissolu-

tion competes with recombination [Fig. 1(a)]. At potentials more positive than -0.35V , all holes injected into the electrode are used for the dissolution reaction, and the current tends to zero. The current-potential curves for $K_3Fe(CN)_6$ at pH 14 are similar to those given in Fig. 4(a) but are displaced by approximately 0.8V on the potential axis as a result of the higher pH.

Minority carriers can also be created in n-GaAs by illumination in an inert electrolyte [Fig. 1(c) and (d)]; in this case, the current-potential characteristics are "reversed" [Fig. 4(b)]. Efficient recombination at negative potentials results in very low current. At more positive potentials, the increased electric field at the surface ensures an efficient separation of charge carriers, and a photoanodic current resulting from dissolution is found. The ranges in which recombination or dissolution dominates are exactly the same as in the previous case. From these current-potential curves, the potential range can be deduced in which recombination of minority carriers is important. This is, of course, determined by the nature and the density of the recombination centers at and near the electrode surface and is therefore sensitive to the state of the electrode. The kinetics of the oxidation reaction involving the minority carriers (dissolution of GaAs in this case) are also important. In the present case, we have available a potential range of a few tenths of a volt, in which recombination dominates.

An important parameter in this work is the minority carrier generation rate I_g , which can be assessed from the limiting currents. In the case of illumination, this is given by the limiting photocurrent and is directly proportional to the light intensity. For hole injection from solution, the diffusion-controlled reduction current determines I_g ; its value can be varied by changing the concentration of the oxidizing agent in the solution and the rotation rate of the electrode [Fig. 4(a)].

Impedance measurements.—The equivalent circuit shown in Fig. 3(b) should be valid for n-GaAs when recombination is dominant. An analysis of this circuit gives two equations

$$\frac{1}{Z_{re} - R_{e,B}} = \frac{(C_D + C_{if})^2}{R_r C_{if}^2} + R_r C_D^2 \omega^2 \quad [1]$$

$$\frac{-\omega Z_{im}}{Z_{re} - R_{e,B}} = \frac{(C_D + C_{if})(C_D + C_{if} + C_H)}{R_r C_{if}^2 C_H} + \frac{R_r C_D(C_D + C_H)}{C_H} \omega^2 \quad [2]$$

in which Z_{re} and Z_{im} are the real and imaginary components of the complex impedance. $R_{e,B}$ could be obtained from the high frequency limit of Z_{re} . Plots of $1/(Z_{re} - R_{e,B})$ and $-\omega Z_{im}/(Z_{re} - R_{e,B})$ as a function of ω^2 should give straight lines. For all cases involving efficient recombination, we indeed found this to be the case. An example is shown in Fig. 5 for $Ce(SO_4)_2$. This implies that our assumptions with respect to the circuit of Fig. 3(a) are correct, and that the impedance behavior of n-GaAs can be represented by the simplified circuit of Fig. 3(b), when the recombination process dominates.

As C_D is negligible compared to C_{if} , R_r and C_D could be deduced from the slope of the lines in Fig. 5. The recombination resistance, R_r , depends strongly on the generation rate. Figure 6 summarizes the results both from the illumination and hole injection experiments. The slope of this log-log plot is approximately -1.1 . The most striking aspect of these results is that R_r is independent of the method of minority carrier generation (by illumination or injection from the solution). It is also independent of the species which injects the holes, the pH of the solution, and the potential in the recombination range.

The values of C_D measured during injection increased with decreasing potential, as might be expected. These values, however, were somewhat higher than those measured in an indifferent electrolyte in the dark, and showed an increase with increasing generation rate.

Since R_r and C_D are known, C_{if} could be calculated from the intercept of the plot of Eq. [1]. Its value varied from

Fig. 4. (a) Current-voltage curves of p-type (dashed lines) and n-type (solid lines) GaAs at different rotation speeds (300, 1500, 3000, and 5000 rpm) in $0.05M Ce(SO_4)_2/1N H_2SO_4$ solution. (b) Photocurrent of n-GaAs in $1N H_2SO_4$ solution.

Fig. 5. Impedance results, plotted according to Eq. [1] and [2] for n-GaAs in $5.10^{-4}M$ $Ce(SO_4)_2/1N$ H_2SO_4 solution at $-0.70V$ (SCE) and 100 rpm. $\omega = 2\pi f$, where f is the measuring frequency in Hz.

approximately $0.1 \mu F \cdot cm^{-2}$ at very low injection rates to $15 \mu F \cdot cm^{-2}$ at the highest rates.

The impedance behavior of a p-GaAs electrode was, of course, totally different. It was consistent with a capacitance (C_D) shunted by a very large resistance (R_w), as expected. Recombination is not important in this case. For n-GaAs under conditions in which dissolution dominates (at potentials more positive than $-0.35V$), recombination also does not occur. In this situation, the impedance picture was similar to that for p-GaAs.

Discussion

These results show clearly the importance of recombination for the impedance characteristics of GaAs electrodes. In the absence of such recombination, as when holes are injected into p-GaAs or when dissolution ac-

Fig. 6. Recombination resistance as a function of the generation rate for n-GaAs. $Ce(SO_4)_2/1N$ H_2SO_4 solutions at different $Ce(SO_4)_2$ concentrations and rotation speeds at $-0.60V$ (\blacktriangledown), $-0.65V$ (\blacktriangle), or $-0.70V$ (\triangle) vs. SCE. $K_3Fe(CN)_6/1N$ NaOH solutions at different $K_3Fe(CN)_6$ concentrations and rotation speeds at $-1.50V$ vs. SCE (\circ). $0.5M$ K_2SO_4 solution at $pH = 5.0$ under illumination at $-1.00V$ vs. SCE (\square). $1N$ H_2SO_4 solution under illumination at $-0.70V$ vs. SCE (\blacksquare).

counts for all holes introduced into n-GaAs, the depletion layer capacitance is shunted by a large Warburg-type impedance. On the other hand, when recombination within the space-charge layer or at the surface is important, the impedance of the electrode resembles that of the MOS and EOS devices (3, 4). This impedance is characterized by a capacitance associated with charge storage at the electrode/electrolyte interface and by a resistance which describes the recombination of minority carriers in the valence band with electrons from the conduction band [Fig. 3(b)].

The relatively large values of C_{if} found at higher injection rates indicate a considerable charge localization at the interface. This is supported by the increased value of the space-charge capacitance C_D relative to the value found when injection does not occur. This points to a shift in potential from the space-charge layer of the semiconductor to the Helmholtz layer. This change can be calculated from Mott-Schottky theory and used to determine the interface charge density (3). On assuming a value of $20 \mu F \cdot cm^{-2}$ for C_H , we obtain charge densities ranging from $6.10^{12} cm^{-2}$ at low injection rates to $3.10^{13} cm^{-2}$ at the highest injection rates used.

The recombination resistance R_r , measured here at potentials at least $0.2V$ positive with respect to the flatband potential, depends on the minority carrier generation rate but not on the method of generation. Since R_r is also insensitive to the electrode pretreatment and the pH and composition of the electrolyte, we may conclude that it is mainly determined by recombination not at the surface but in the space-charge layer; R_r is thus an intrinsic property of the material. The recombination resistance is therefore not coupled directly to the interface capacitance. This is also supported by the fact that such a coupling would lead to a time constant τ ($= R_r C_{if}$) in the range $0.1-1$ ms, which is much too high to account for the very efficient recombination occurring in this case.

Pierret and Sah have developed a quantitative model for the band-to-band communication in illuminated MOS devices under depletion and inversion conditions (8). Their treatment is based on Shockley-Read theory assuming a single-level recombination center. The theory is valid at low injection levels (8), i.e.

$$\frac{\Delta p}{n_i} < \exp \frac{|E_i(\text{bulk}) - E_F|}{kT} \quad [3]$$

where Δp is the deviation from the equilibrium minority carrier concentration as induced by light, n_i is the intrinsic carrier concentration, and E_i and E_F are the intrinsic and equilibrium Fermi levels, respectively. If the injection level is low, the model is obviously applicable to the present case in which the electrode is illuminated in an indifferent electrolyte at potentials negative with respect to the photocurrent-onset potential; in this range, recombination is dominant so that no external current flows [Fig. 1 (d)]. From Eq. [3] it is clear that the condition of a low injection level is indeed satisfied in the present case ($\Delta p < 10^{17} cm^{-3}$, i.e., $\Delta p < n_0$); light intensities were such that the photocurrent was linearly dependent on photon density (10). Sah has shown (11) that, for an extrinsic semiconductor, the nonequilibrium equivalent circuit for the case involving external current flow is identical to the equilibrium case with regard to carrier trapping, recombination, and generation, provided the steady-state carrier concentrations are considered instead of the equilibrium values. This means that the recombination model for the illuminated MOS device (8), also involving steady-state carrier concentrations, must be applicable to hole injection from solution when recombination of minority carriers dominates [Fig. 1 (b)]. Pierret and Sah derive an expression for the recombination resistance on the basis of a transition, within a narrow spatial region in the space-charge layer, from a predominantly hole current at the surface to an electron current in the bulk. This resistance is shown to be potential independent in a wide range. The relationship between the recombination resistance and the generation rate is deter-

mined by the nature of the recombination center. For an efficient level located near midgap with approximately equal capture cross sections for electrons and holes, an inverse square root dependence is predicted ($R_r \propto 1/\sqrt{I_g}$). An inverse linear dependence ($R_r \propto 1/I_g$), as found in the present work, indicates a dominant recombination center somewhat displaced from midgap and with a ratio of capture cross sections considerably different from unity. A similar dependence was found for the Si MOS device and the GaAs EOS system (3, 4).

In this work, we have only considered the two extreme cases: negligible and complete recombination. For an n-GaAs electrode at potentials in the intermediate range at which the anodic photocurrent and cathodic reduction current increase to their limiting values, the recombination resistance increases and the impedance picture becomes more complicated (12). Nevertheless, the presence of a recombination resistance in the equivalent circuit is a clear indication that minority carriers are responsible for the electrochemical reaction. In a subsequent paper, we shall show how this approach can be used to obtain information concerning a more complex reduction reaction at GaAs (13).

Epitaxial Growth and Characterization of β -SiC Thin Films

P. Liaw^{*1} and R. F. Davis

Department of Materials Engineering, North Carolina State University, Raleigh, North Carolina 27695-7907

ABSTRACT

Crack-free monocrystalline β -SiC films having very smooth final surfaces may be reproducibly grown at 1600 K and 760 torr on (100) Si substrates using SiH₄ and C₂H₄ and H₂ if the Si is initially reacted with the C₂H₄ alone. This initial step produces a buffer layer which reduces the mismatches in expansion coefficients and lattice parameters and thus allows the subsequent growth of the β -SiC film to a thickness exceeding 5 μ m. It is necessary to heat the Si wafers from room temperature to the reaction temperature in a C₂H₄ and H₂ environment rather than preheating the substrates to the reaction temperature. An off-axis orientation of the Si in excess of approximately 3° results in a very rough final growth surface on the β -SiC film.

Silicon carbide (SiC) possesses a unique combination of properties which are not available from other more common semiconductor materials. In addition to its high thermal conductivity and melting point, extreme hardness and excellent resistance to chemical attack and mechanical damage, it is also characterized by a range of high energy bandgaps [2.2-3.3 eV, depending on the structure type; (see following discussion and Ref. (1) and (2))] and a high saturated drift velocity [$2.2.7 \times 10^7$ cm/s (3-5)], which are particularly important for electronic applications. As such, this material has, for several years, been considered the leading candidate material for future employment in thin film solid-state electronic devices which would be subjected to high temperatures or high frequencies or high power loads or a combination of these severe conditions.

Silicon carbide may exist in one particular crystallographic structure, if grown under carefully selected and controlled conditions. However, as a result of its low stacking fault energy, this material frequently occurs as a collection of several slightly different one-dimensional polymorphs or "polytypes" having different stacking sequences along the directions perpendicular to the closest packed planes. Alpha SiC forms in more than 140 identified hexagonal or rhombic polytypes, whereas, β -SiC possesses only the cubic zinc blende structure. An excel-

lent review of these polytypes and their formation has recently been published by Jepps and Page (6).

The common occurrence of the β polytype as a product of vapor and liquid growth processes, its transformation to one or more of the alpha forms at high temperatures and its recent commercial availability have caused it to be considered almost as a separate material. Because of its small bandgap (2.3 eV) and ease of growth at relatively low temperatures, the β form is currently considered the most desirable polytype for microelectronic applications.

The previous (1956-1973) major research periods concerned with the growth of SiC as an electronic material concentrated heavily on very high temperature sublimation-condensation (Lely) processes which formed an unreproducible variety of alpha polytypes within each crystal. Solution growth via the reaction of molten Si with its graphite container was a common method of growing β -SiC; however, these crystals were invariably small and highly twinned and therefore of little use for electronic applications. Chemical conversion of the Si surface and chemical vapor deposition (CVD) processes were also employed. However, the results in terms of thickness, single crystallinity, and/or device quality of the films were not sufficient to engender continued substantial funding of this research. For an essentially complete record of these earlier studies, the reader is referred to the published proceedings of the three previous SiC conferences (7-9) and their bibliographies.

Research in SiC for semiconductor applications has continued, albeit at a reduced level of effort, with positive

results in thin film growth, characterization, and the fabrication of simple devices. The most active group has been Matsunami and co-workers with the development of blue LED's by liquid-phase epitaxy (10) and chemical vapor deposition (11), photoluminescence studies of Al, Ga, and B acceptors in 4H, 6H, and 3C polytypes grown from a Si melt (12), the determination of site dependent impurity levels in 4H, 6H and 15R polytypes (13), the thermal oxidation (14) and C-V characterization of Al-SiO₂-SiC MOS structures (15), and the structure and properties of sputtered amorphous SiC films (16). Research in Germany directed by Münch has also led to the fabrication of blue LED's (17) as well as field effect and bipolar transistor (18) via vapor growth and liquid-phase epitaxy, additional understanding concerning thermal oxidation and electrolytic etching of SiC (19), and the determination of the high field saturated electron drift velocity (5) and the breakdown field in vapor-grown SiC p-n junctions (20). Finally, research has continued in the Soviet Union, primarily in the laboratory for Wide Band Gap Semiconductors in Leningrad, directed by Tairov. In addition to the solid-state physics studies on doped SiC [e.g., see Ref. (21)], considerable progress has been reported in the controlled growth of SiC single crystals having a preselected polytype [see Ref. (22) for a review of this work].

Essentially, all the studies noted above were concerned with the growth or characterization of selected α -SiC forms. However, very recently, Nishino and co-workers in Japan and the U.S. (23, 24) and Addamiano and Sprague (25) have employed a two-step CVD process whereby a "buffer" or "converted" layer is initially formed on a Si substrate surface via a reaction with propane followed by the growth of thin films of β -SiC.

The objectives of the research program reported herein have been: (i) the extension of the aforementioned two-step approach to determine the exact conditions for the formation of single-crystal β -SiC films of sufficient thickness and quality for microelectronic applications, and (ii) the characterization of these films by a variety of techniques. The following sections present the experimental aspects of this program, a discussion of the results obtained, and the major conclusions drawn from this research.

Experimental

An RF heated cold-wall barrel-type CVD reactor was designed and constructed in house especially for the growth of the β -SiC films. Highest purity silane (SiH₄), ethylene (C₂H₄), and H₂ (further purified to 0.1 ppm total impurities via Pd/Ag cell) were used as the Si and C source gases and carrier gas, respectively. HCl provided *in situ* gas phase etching of the (100) and (111) Si single-crystal substrates prior to deposition. Argon was employed for purging the input gas lines and the reaction chamber after each deposition. Nitrogen continually purged the mechanical pumps and the exhaust line to prevent the pyrophoric reaction of SiH₄. The use of the cold-wall vertical reactor noted above contrasts with the uncooled horizontal reactors used by other investigators (23-25). Our use of the former not only allowed films of excellent quality to be produced but also forced a change in the scenario for the two-step deposition process used by others which is described below. This type of reactor was also necessary because of the endothermic nature of SiH₄.

The total pressure in the reaction chamber and the flow rates of each of the gases were independently measured and set-point controlled using a capacitance manometer² and servo-mechanical valves³ for the former and mass flowmeters⁴ and magnetically proportioning valves⁵ for the latter. In this way, fluctuations in the nucleation rates of the reactant species were minimized.

⁴Model FM-260, Tylan Corporation, Carson, California.

⁵Model 5835A, Brooks Instruments, Hatfield, Pennsylvania.

Both n-type ($\rho = 37$ -420 Ω -cm) and p-type ($\rho = 10$ -50 Ω -cm) Si wafers, having a nominal 1.1 cm diam, were ultrasonically trepanned from larger wafers using 30-40 volume percent (v/o) SiC in distilled H₂O as the abrasive. One side of the as-cut wafers was simultaneously chemically and mechanically polished using the Silver-Rugh-Gardiner method (26). All wafers had a thickness of 0.064 cm and were 1° or 6° off axis from the (100) plane and 2° and 4° off axis from the (111) plane.

Up to 16 of the Si wafers were loaded onto a tapered (3°) 8.9 cm long SiC-coated graphite⁶ susceptor having less than 10 ppm total impurities. The impervious SiC coating eliminated both the possibility of auto-doping and the diffusion of excess C from the susceptor onto the Si substrate.

Prior to each CVD step, the reaction chamber was three times pumped to 10 torr and purged with high purity Ar. Furthermore, the reactant and carrier gases initially bypassed the 6.3 cm id H₂O-cooled, double-wall quartz deposition chamber and were mechanically pumped into a lower stainless-steel chamber. When the preset flow rates were established, the gas mixture was switched via pneumatic valving into the top of the reaction chamber, where it subsequently reacted with the Si substrates. The deposition temperatures were measured on the SiC-coated graphite with an optical pyrometer because of the changing emissivity of the Si with the progressive deposition of SiC.

Initially, a single-step CVD process involving the simultaneous deposition of Si and C directly on the Si surface at 1 atm as well as reduced (to 38 torr) total pressures was employed. The occurrence of more than one phase at low total pressures prompted subsequent computer-aided thermodynamic calculations for the deposition of β -SiC as a function of total pressure, Si/Si+C ratios, and temperature. These results (27) showed that the limits of formation of the β -SiC phase field gradually narrow to essentially a straight line as the total pressure is reduced. Thus, 1 atm was used for the remainder of the experiments. The poor surface quality and the high residual stresses in the films (28) produced by this process promoted the use of the much more successful two-step approach noted in the introduction. In this latter process, approximately 0.30 v/o of C₂H₄ in flowing (3000 sccm) H₂ was introduced into the cold reaction chamber. The substrates were immediately and rapidly heated at approximately 500 K/min from room temperature over a total period of 2.5 min. The maximum possible temperature of 1600 K was achieved during the last 30s of this step. The chamber was subsequently flushed with H₂ for 5-10 min. A standard CVD process was then employed using 0.20 v/o SiH₄ and 0.10 v/o C₂H₄ in flowing (3000 sccm) H₂ at 1600 K. The growth rate was ~ 0.04 μ m/min. When the desired growth had been achieved, the SiH₄ and C₂H₄ valves were closed, the chamber allowed to flush for 5 min with H₂ and the temperature reduced to ambient. No etching of the final growth surface by the final H₂ flush was chemically or visually detected.

Surface characterization and thickness measurements were conducted using SEM and optical microscopy (OM). Conductive coatings or staining was unnecessary as the films were sufficiently conductive for the SEM studies and easily distinguished from the Si in the OM. For structural characterization, both x-ray and selected area electron diffraction techniques were employed. A reflection-type pole-figure device (Schulz goniometer) was used to determine the single- or polycrystallinity and the existence of epitaxy of the grown films. The transmission Laue method was also extensively used for more complete characterization of the crystal structure of the β -SiC films. As both the diamond cubic structure of Si and the zinc blende structure of β -SiC give exactly the same Laue patterns, it was necessary to wax⁷ the entire specimen,

⁶Ultra "F" grade UT-22 graphite, Ultra Carbon, Corporation, Bay City, Michigan.

⁷Apiezon Type W, James G. Biddle Company, Plymouth Meeting, Pennsylvania. The wax was removed using trichloroethylene.

except for a 2 mm central spot in the back of the Si substrate, and immerse the sample in an $\text{HF}+\text{HNO}_3$ (2:3 ratio) mixture until a hole was etched in the Si. The remaining Si substrate served as a support for the film. A 16h exposure at 35 kV and 20 mA was usually required to obtain the pattern. The distance between the specimen and the film was 5 cm.

Fig. 2. X-ray diffraction spectrum of an epitaxial β -SiC thin film grown on a (100) Si substrate (this sample was first tilted 45° on the Schulz goniometer and then scanned from 45° - 62°).

Transmission electron diffraction (TED) samples were prepared by ion milling from the Si side at an angle of 15° to the surface. No sample preparation was necessary for the RED diffraction research.

Electrical properties of the films were measured by the van der Pauw technique. These intentionally undoped samples were n-type in character. Ohmic contacts were obtained by sintering an electron-beam evaporated 2000\AA Ni film at 1373 K for 5 min in vacuum. After the measurement, a very thin Ni film was burned into the β -SiC film as a result of Joule heating.

Results and Discussion

Reproducible epitaxial growth of single-crystal β -SiC thin films on (100) and (111) Si has been achieved via the initial reaction of C with the Si surface and the subsequent deposition of a SiC film. Using only the latter half

Fig. 4. Transmission electron diffraction patterns of β -SiC thin films grown on (100) Si substrates under the conditions of $P = 1$ atm and $T = 1343$ K (a), 1408 K (b), and 1633 K (c).

of this process did not allow reproducibility or equivalent quality to the two-step process on either of the Si planes.

Figure 1 shows a 2θ scan from 44° to 62° for an epitaxial β -SiC film grown on a (111) Si substrate. In this 2θ range, the (220) peaks resulting from both the β -SiC film and the Si substrate are included if the sample is tilted 35° on the Schulz goniometer so that the (220) is the diffracting plane. By rotating the sample one turn about its normal axis, one can detect three peaks of (220) β -SiC reflections which are separated 120° from each other. This indicates the normal three-fold symmetry of the (220) about the $\langle 111 \rangle$. One may surmise from this study that the crystal structure of the grown (111) β -SiC film is single crystalline in nature.

As for the β -SiC film grown on the (100) Si substrates, Fig. 2 shows the results of a 2θ scan from 45° to 62° . As in the example noted above, the (220) again becomes the principal diffracting plane when the sample is tilted 45° . However, with the (100) Si substrate orientation, the (220) β -SiC peaks are monitored at a 90° separation because of the four-fold symmetry of (220) about [100]. The presence of this symmetry as revealed by the diffraction pattern allows one to conclude that the crystal structure of the grown (100) β -SiC film is also a single crystal.

The above results were also supported by transmission Laue patterns (TLP) for the same film and substrate combinations (28). The (111) pattern also contained twelve spots in three groups of four spots each, which were very close to the (111) spots and which were more difficult to identify. Further investigations showed that these satellite-like spots were on three zone axes and on two rings, which correspond to the (111) β -SiC reflections from the K_α and K_β characteristic radiations of the Cu target. Normally, bending of crystallographic planes as a result of residual stresses causes streaks along the zone axis. However, because a Cu target was used to produce the "white" radiation, wherever the reflections from the characteristic radiation satisfied Bragg's law, a spot occurred instead. Thus these satellite spots note the existence of residual stresses in the grown (111) film.

The (100) pattern also contained extra spots very close to the (221) spots. In this case, it was determined that the extra spots were on two zone axes and on two rings, which correspond to the (220) β -SiC reflections from the K_α and K_β characteristic radiations of the Cu target. Again this indicated the existence of curved planes which formed as a result of stresses in the (100) β -SiC films. A complete discussion of this residual stress phenomena is given in Ref. (28).

Growth temperature was a very important factor in the attainment of single crystallinity in the films. As shown in the TED patterns of Fig. 3a and 4a, the β -SiC films

grown on the (111) and (100) Si substrates, respectively, were polycrystalline when the growth temperature was 1343 K. As the substrate temperature increased to 1408 K, the grain size increased and spot-containing rings were observed, as revealed by Fig. 3b and 4b. Increasing the temperature further to 1633 K allowed monocrystalline films to grow on both substrates (see Fig. 3c and 4c). Additional x-ray Laue research showed that monocrystallinity could be achieved on the (111) Si at temperatures as low as 1583 K. However, the critical temperature for similar results on (100) Si was approximately 1600 K. Thus, the epitaxial growth of (111) β -SiC films can be achieved at a relatively lower temperature than that required for the (100) films using the two-step deposition process.

Scanning electron microscopy was also used extensively to characterize both the chemical conversion process and the growth of the β -SiC thin films. The former

was initially conducted under isothermal conditions at 1600 K with all other conditions being the same, as in the rapid heating procedure noted above. This produced relatively large localized deposits of C, as shown in Fig. 5. These deposits were triangular in shape on the (111) Si and rectangular on the (100) Si substrates. These shapes are characteristic of the voids found in the Si in these orientations, as noted below. It is believed that these areas acted as nucleation sites for the subsequent CVD growth, as the β -SiC films tended to be polycrystalline with very rough surfaces. By contrast, heating the Si substrates from room temperature to 1600 K in flowing C_2H_4 in H_2 at 760 torr produced thin but much more uniform deposits, as shown in Fig. 6. The voids revealed in the micrographs are principally on the Si surface; however, some portion of these defects may also extend to the surfaces of the converted layers as well as the final films. An acute example of this phenomenon is shown in Fig. 7. It is be-

Fig. 8. Surface morphology of epitaxial β -SiC thin films grown on Si substrates with various off-axis orientations.

lieved that the existence of the voids is related to the growth mechanism involved in the chemical conversion of the Si substrate. In this process, the Si atoms diffuse out through the converted layer to react with the C atoms at the growth surface (29, 30). Thermal etching of the Si during heating was not responsible for the pitted Si surfaces; no such depressions were found in several (111) and (100) Si wafers heated to 1600 K in flowing H_2 for 10 min.

Abnormal needle-type growth also occurred but only in the polycrystalline β -SiC films having either (111) or (100) orientation. The initial growth conditions were found to be very critical to the presence of these needles. For example, no such needles were found in the subsequent β -SiC layers when the initial chemical conversion of the Si substrate was conducted from room temperature to 1600 K for 2.5 min. However, needles were observed when the chemical conversion was performed under isothermal conditions at 1600 K for 1 min. The nucleation in the latter case was much less controlled and resulted in the formation of occasional needles. Finally, it was also found that using a prolonged (e.g., 10 min) conversion time resulted in a very rough final surface on the β -SiC films.

During the latter stages of this research program, the growth techniques were sufficiently refined so as to produce very smooth final growth surfaces on both the (111) and (100) β -SiC films. However, the degree of smoothness decreased markedly with increase in off-axis orientation of the Si substrates. Using the same growth conditions and two-step growth procedure noted in the section on experimental procedure for all samples, it was found that the final surface of the films on (111) Si and (100) Si hav-

ing 2° and 1° off-axis orientations, respectively, were very smooth, as shown in Fig. 8a and 8c. However, films grown on similar wafers with 4° and 6° off-axis orientations had a moderate or very rough appearance.

The results of preliminary van der Pauw measurements are given in Table I for typical (100) β -SiC films having different thicknesses. All films were n-type, which may have been caused by the incorporation of nitrogen, which is a donor impurity, or by the existence of defects in the films. Additional study concerned with the correlation of defect substructure with electrical properties is now ongoing.

Summary

Reproducible growth of high purity monocrystalline thin films of β -SiC have been produced on Si using a unique cold-wall barrel-type reactor and a two-step process of surface conversion and subsequent film deposition. Direct growth of monocrystalline β -SiC films on (111) or (100) Si at temperatures up to 1600 K was difficult and nonreproducible. However, crack-free films having very smooth final surfaces can be grown on (100) Si if the Si surface is initially reacted with C_2H_4 carried in H_2 . This step is then followed by conventional CVD of the β -SiC using a mixture of SiH_4 and C_2H_4 , which are separately decomposed on the initial converted layer. It was found necessary to rapidly heat the Si substrates from room temperature to the conversion temperature in a C_2H_4 and H_2 environment rather than preheating the substrates to the reaction temperature. The off-axis orientation of the Si substrate was also found to be important in the smoothness of the final surface.

Transient Behavior during Film Removal in Diffusion-Controlled Plasma Etching

Richard C. Alkire* and Demetre J. Economou**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A mathematical model is formulated to analyze transient behavior during film removal from closely spaced wafers in a barrel plasma etching reactor. The model incorporates diffusion and simultaneous reactions which include the etching process as well as recombination reactions of both volume and surface types. The analysis relates the effect of geometric and operating variables to process characteristics such as etch uniformity, over-etch exposure, and throughput. Dimensionless system parameters are identified and are used to express computed results in general form. Regions of operating conditions that permit etch uniformity within specified tolerances are found, and optimum settings for inter-wafer spacing and reactor pressure to achieve maximum throughput are calculated.

Important goals for plasma processing include yield, throughput, and uniformity. Variables which are commonly controlled to achieve these goals include reactor geometry, design and operating conditions, choice of chemicals introduced into the plasma, and adjustment of wafer position within the reaction zone. It is the nature of such complex systems that engineering trade-offs exist in identifying "optimum" settings. Often, however, a seemingly minor adjustment in a sensitive variable can cause a major change in performance. Also, it is invariably difficult to translate successful experience with one system to a new system on the basis of intuition alone. For these reasons, purely empirical programs of development can be time consuming.

Mathematical methods have been used to model a wide variety of chemical reactor systems, and have been found useful in guiding development strategies for improvement. In the present study, a mathematical model was developed to predict transient behavior during film removal from closely spaced wafers in a barrel etcher.

The barrel plasma etching reactor, shown schematically in Fig. 1, consists of a cylindrical quartz chamber that has input gas manifolds and a vacuum pumping outlet. RF power, commonly at 13.56 MHz, is coupled to the reactor through external electrodes and an impedance matching network. The wafers are loaded on a boat in a stand-up configuration with the wafer axes along the barrel axis. In order to achieve high throughput, the interwafer spacing is made small so that the reactor may hold dozens of wafers in a single batch. During operation, gas is continuously introduced into the reactor. Active species, which are generated by electron-impact dissociation in the plasma region, diffuse in the interwafer space and react with the film on the wafer surface. At the same time, the active species may degrade by recombination reactions within the reactor volume or on the walls. Since etching is solely due to neutral species, the resulting edge-profile exhibits mask "undercut" characteristic of isotropic etching. Hence, the barrel etcher cannot be used for etching

fine line geometries. Sometimes an Al perforated cylinder is placed coaxially around the wafers. With the "etch tunnel" present, the plasma is confined in the annular region between the metal cylinder and the reactor wall; active species have then to diffuse through the perforations and, since the diffusion path is lengthened, the etch rate is smaller with the etch tunnel.

Stripping of photoresist in an oxygen plasma in a barrel-type reactor was the first application of plasma etching in semiconductor processing (1). Etching of Si, poly-Si, and Si₃N₄ in fluorine containing plasmas (especially in CF₄/O₂ mixtures) quickly found widespread applications (2). Similar reactors are also used for LPCVD processes (4, 18).

Etch uniformity and throughput are of particular importance in any plasma etching process. Across-wafer and wafer-to-wafer uniformity are both critical in etching patterned films since local loading can rapidly enhance mask undercut after the end point has been reached. Parameters that affect uniformity and throughput include RF power input, chamber pressure, gas flow rate and distribution, wafer spacing, wafer diameter, and tem-

Fig. 1. Schematic of a barrel plasma etching reactor

**Electrochemical Society Student Member.

perature. Several investigators have reported models for diffusion-controlled plasma etching in barrel reactors (5, 6). With assumption of steady-state conditions, the effect of process parameters on etch uniformity was studied.

In the present work, transient removal of a film from a wafer stacked in a barrel plasma etcher is investigated. Transport and reaction phenomena are used to predict behavior and to identify dimensionless scale-up parameters. This study differs from past work in that transient behavior is included so that the duration of etch cycle (throughput) and of over-etch exposure may be investigated. While actual plasma systems are more complex, the following model provides a basic framework which may be expanded as additional refinements are added.

Theoretical Formulation

Let us for the moment concentrate on events happening in the interwafer space, regarding the gas discharge outside the wafer stack as simply the source of etchant species. The plasma region is treated later. Figure 2, not drawn to scale, is a schematic representation of the radially symmetric cell formed by two wafers facing each other. Prior to the onset of etching, a film of uniform thickness exists on the wafer surfaces. The rate of film removal depends on the concentration distribution in the interwafer gap. To an extent that depends upon operating conditions, the etch rate is highest on the periphery of the wafer. Film in this region thus clears first, and subsequent film removal would then take place in more inaccessible regions. Figure 2 illustrates the situation part way through the process, where film has been cleared entirely from the outer portion of the wafer, while the inner region is yet to clear. As etching proceeds, the concentration distribution changes to conform to the reactivity distribution along the wafer surface. While the film may eventually be removed everywhere, the peripheral regions would meanwhile be exposed to overetching conditions which, in many systems, adversely affect product quality.

The following assumptions preserve the salient features of the system and also streamline the task of computation. 1. The spacing between adjacent wafers is sufficiently smaller than the wafer radius so that significant concentration variations occur only in the radial direction. 2. Convection is negligible with respect to diffusion

Fig. 2. Schematic of the radially symmetric region between two successive wafers.

in the interwafer region owing to the large value of the diffusion coefficient. An order of magnitude calculation showed that, even if all the gas were flowing parallel to the wafer surfaces, the Pe number ($=R_0 u_0 / D$) would be less than 0.05. In practical systems, with the gas outlet at the back of the quartz barrel, most of the gas flow is normal to the wafer surfaces. Thus, practical Pe numbers are even smaller. 3. The etching reaction is first order; this has been shown for photoresist stripping in oxygen (6) and Si etching in fluorine (7). 4. The etching reaction proceeds to completion at or near the film surface (6) over a distance much smaller than the diffusion length of the etching species, and the reaction products do not affect the etching process (8). 5. The substrate is not etched. Hence the model is applicable to processes such as photoresist stripping in an O_2 plasma or Si etching in a CF_4/O_2 plasma with SiO_2 as the substrate. 6. The pressure remains constant during an etch cycle; this can be achieved by using a pressure feed-back control system. 7. Operation is isothermal with no spatial variations of diffusivity or reaction rate constants. This assumption will not be valid in cases of highly exothermic etching reactions. For example, in etching Si at $0.5 \mu\text{m}/\text{min}$ in a F containing plasma, the adiabatic temperature rise of a 10 cm diam 0.5 mm thick slice will be $1.3^\circ\text{C}/\text{s}$. Furthermore, severe temperature variations will occur during start-up, unless a preheat-treatment with a N_2 or Ar plasma is applied. 8. The concentration of etchant at the wafer edge remains constant during the etch cycle. However, if the etching reaction is the main loss mechanism for the etchant species, and the reaction rate distribution along the wafer surface is nonuniform, the etchant concentration at the wafer edge (c_0) will change with time during a single etch cycle. This is because the amount of film remaining on the wafers will also change with time (loading effect). Such a change in c_0 could be predicted by Eq. [19] to be derived later. The calculations presented in this work did not account for any changes in c_0 during an etch cycle (see also "Conclusions" section). 9. The concentration profiles adjust rapidly to the gradual movement of the film front during depletion. Therefore, at any particular moment, the concentration distribution is at the steady-state distribution which corresponds to the reactivity conditions prevailing at that moment. This "pseudo-steady-state" approximation is valid provided that the time scale over which film depletion occurs (equal to $\chi h_0 / k_2 c_0$, see also expression for τ in Eq. [5]) is much greater than the "characteristic" diffusion time (R_0^2 / D). In other words, the following inequality should hold: $\chi h_0 D / k_2 c_0 R_0^2 \gg 1$. For typical values of the parameters (Table I), this ratio is found to be greater than 10^3 .

During etching, the thickness of etchable material left at a certain location and time will be given by

$$h(r,t) = h_0 - \int_0^t \frac{k_2}{\chi} c(r,t) dt \quad [1]$$

The concentration distribution $c(r,t)$ varies with time during the etching process and is calculated by application of transport laws to the movement of etchant species. The remaining text in this section consists of three segments: the general model, a limiting case valid in the absence of recombination reactions, and a method for determining the concentration of etching species at the edge of the wafer stack.

General model.—Under the foregoing assumptions stated above, the conservation equation for the etching species is

$$D \frac{1}{r} \frac{d}{dr} \left(r \frac{dc}{dr} \right) = \frac{2k_2}{L} c + 2k_1 c^2 [A_2] + \frac{v_0 \omega}{2L} c \quad [2]$$

with the boundary conditions

$$c = c_0 \text{ at } r = R_0$$

$$\frac{dc}{dr} = 0 \text{ at } r = 0$$

The left-hand side of Eq. [2] represents the radial diffusion of etchant into the region between the wafers, while the right-hand side (rhs) corresponds to the various reactions which occur. The first term on the rhs of Eq. [2] represents etching. Since only radial concentration gradients are assumed to exist, the heterogeneous reaction rate k_2c is transformed to a homogeneous rate term by multiplication by the surface to volume ratio $2/L$. Both surfaces have been assumed reactive, *i.e.*, the wafers stand back to back during etching. When etching patterned films, this term has to be multiplied by the fraction of the surface occupied by etchable material. Note that $k_2 = 0$ for $r > R$, where the film no longer exists (Fig. 2). The second term on the rhs of Eq. [2] represents volume recombination reactions of the active species of the form

A_2 is the parent molecule which gives A, the etching species, by electron-impact dissociation. A_2 acts as a third body for recombination to occur. The presence of a third body is required to conserve momentum and energy during recombination. The reverse of reaction [3] proceeds at negligibly small rates at the low temperatures used in plasma etching [*e.g.*, the equilibrium constant for the reaction $F_2 \rightleftharpoons 2F$ is $\approx 10^{-24}$ mol/cm³ at 300 K (19)]. When the concentration of the etching products is low, $[A_2] \approx P/R_g T - [A] = P/R_g T - c$. The third term on the rhs of Eq. [2] accounts for wall recombination of the active species in reactions of the form

This term results by multiplying the random flux of etchant striking the wafer surface ($1/4 v_0 c$) by the surface to volume ratio ($2/L$) and by the wall recombination coefficient w , which is assumed constant throughout the wafer surface. The wall recombination reaction is first order since an impinging atom recombines with an atom already adsorbed on the surface (9).

Before proceeding further, it is convenient to rewrite the governing equations in terms of dimensionless quantities based on the following definitions

$$\begin{aligned} \zeta &= \frac{r}{R_0} & H &= \frac{h}{h_0} \\ C &= \frac{c}{c_0} & \tau &= \frac{k_2 c_0}{\chi h_0} t \end{aligned} \quad [5]$$

When the variables defined in Eq. [5] are introduced into Eq. [1] and [2], the following dimensionless equations arise

$$H = 1 - \int_0^r C d\tau \quad [6]$$

$$\frac{d^2 C}{d\zeta^2} + \frac{1}{\zeta} \frac{dC}{d\zeta} = \phi_0^2 C + \alpha C^3 + \beta C^2 + \gamma C \quad [7]$$

with

$$\begin{aligned} \alpha &= -\frac{2k_1 R_0^2 c_0^2}{D} & \gamma &= \frac{v_0 w R_0^2}{2LD} \\ \beta &= \frac{2k_1 P R_0^2 c_0}{(R_g T) D} & \phi_0^2 &= R_0^2 \frac{2k_2}{LD} \end{aligned} \quad [8]$$

The dimensionless boundary conditions become

$$C = 1 \text{ at } \zeta = 1$$

$$\frac{dC}{d\zeta} = 0 \text{ at } \zeta = 0$$

Dimensionless number ϕ_0 is comparable to the Thiele Modulus found in catalytic reactor design (17); ϕ_0 represents the relative importance of the kinetics of etching as

compared to diffusion. If $\phi_0 \gg 1$, for example, diffusion is the controlling step, and one may expect concentration gradients to develop in the interwafer space and the etch rate distribution to be nonuniform. Under such conditions, the outer edge of the wafer would be exposed to overetching, while the center is yet to clear. If $\phi_0 \ll 1$, the etching reaction is sluggish and the reaction rate distribution is uniform all over the reacting surface.

Dimensionless groupings α and β describe volume recombination *vs.* diffusion effects. For example, if $\beta \gg 1$, the reactive species recombine before they have any chance to diffuse and etch the wafer surface. Volume recombination reactions are strongly dependent on pressure. For instance, α and β increase with the third power of pressure. Notice that since the partial pressure of the etching species is usually less than 10% of the reactor total pressure, $|\alpha| \leq 0.1\beta$. Finally, grouping γ describes surface recombination *vs.* diffusion effects and is affected by both the surface to volume ratio and the wall recombination coefficient. The latter depends critically on the nature and the condition of the surface.

By solving Eq. [6] and [7], the effect of process parameters (c_0 , P , D , k 's) and of geometric factors (L , R_0) on etch uniformity, overetch exposure, and total etch time can be determined. In particular, optimum conditions for high throughput can be identified. The above model extends previous studies by accounting for both volume and surface recombination reactions. In addition, the model includes transient effects owing to the pseudo-steady-state clearing of the film.

Note that Eq. [7] is general enough to handle more complex recombination reaction schemes. An example concerning an oxygen plasma is given in the Appendix.

The solution to Eq. [6] and [7] was obtained in a stepwise manner. The wafer was divided in a number of concentric rings of equal width. At each time step, the concentration profile was found by linearizing Eq. [7] about a trial solution and casting the linearized equation into finite difference form by using the central difference approximation. The resulting tridiagonal system was inverted in a CDC Cyber 175. Calculations started about the trial solution obtained analytically when all reaction terms are assumed to be first order in concentration. After the true concentration profile was found, the time required to completely strip the outer ring was determined, and a new film thickness distribution was computed by using Eq. [6]. A new concentration profile was then determined for which the wafer surface was reactive everywhere except for the ring already etched away. With the revised concentration distribution, the time necessary to completely strip the second ring was found. In a like manner, the time needed to strip each successive ring was calculated. The total etch time was the sum of the partial times. For each time step but the first, the solution found in the previous time step was used as the trial solution. No convergence problems were experienced for the values of the parameters used. Results did not differ appreciably by changing the number of rings from 150 to 200. Results were checked against the analytic solution for the limiting case of no recombination reactions discussed below.

Limiting case: no recombination reactions.—When recombination reactions can be neglected ($k_1 = w = 0$), *i.e.*, when the etchant has a long lifetime in the absence of etchable material, Eq. [2] can be simplified into the following two equations

$$D \frac{1}{r} \frac{d}{dr} \left(r \frac{dc}{dr} \right) = \frac{2k_2 c}{L} \quad [9]$$

for $0 \leq r \leq R$, *i.e.*, for the region still occupied by the film, and

$$r \frac{dc}{dr} = \text{const.} \quad [10]$$

for $R \leq r \leq R_0$, *i.e.*, for the film-free region near the periphery of the wafer.

It is convenient to introduce the following dimensionless variables

$$\psi = \frac{r}{R}, C = \frac{c}{c_0}, \text{ and } \phi^2 = R^2 \frac{2k_2}{LD}$$

The film radius R (and not the wafer radius R_0) was used in these definitions so that, although R is changing, the value of ψ is pinned at 1 for $r = R$. The dimensionless form of Eq. [9] is

$$\frac{d^2C}{d\psi^2} + \frac{1}{\psi} \frac{dC}{d\psi} = \phi^2 C \quad [11]$$

which is a Bessel equation. The boundary conditions are

$$C = C_R \text{ at } \psi = 1$$

$$\frac{dC}{d\psi} = 0 \text{ at } \psi = 0 \quad [12]$$

The dimensionless form of Eq. [10] is

$$\zeta \frac{dC}{d\zeta} = \text{const.}$$

with $\zeta = r/R_0$ as before in the general model. The pertinent boundary conditions are

$$C = 1 \text{ at } \zeta = 1$$

$$C = C_R \text{ at } \zeta = \frac{R}{R_0} = \sigma$$

C_R is eliminated by requiring the flux to be continuous at $r = R$. The final result for the concentration distribution is

$$C = \frac{I_0(\phi\psi)}{I_0(\phi) - \phi I_1(\phi) \ln \sigma} \quad 0 \leq r \leq R \quad [13]$$

$$C = 1 + \frac{\phi I_1(\phi) \ln \zeta}{I_0(\phi) - \phi I_1(\phi) \ln \sigma} \quad R \leq r \leq R_0 \quad [14]$$

where

$$I_0(x) = \sum_{n=0}^{\infty} \frac{(x/2)^{2n}}{(n!)^2}$$

is the modified Bessel function of the first kind of order zero and

$$I_1(x) = \sum_{n=0}^{\infty} \frac{(x/2)^{2n+1}}{n!(n+1)!}$$

is the modified Bessel function of the first kind of order one. Since $R = R(t)$, Eq. [13] and [14] have a time dependence built into the equations.

The overall etch rate at any given time is

$$2\pi R_0 LD \left. \frac{dc}{dr} \right|_{r=R_0} = 2\pi LD c_0 \frac{\phi I_1(\phi)}{I_0(\phi) - \phi I_1(\phi) \ln \sigma}$$

If the concentration of the etchant were c_0 throughout the wafer surface, the etch rate would be

$$2k_2 c_0 (\pi R^2)$$

Thus, the "effectiveness factor" η is

$$\eta = \frac{2\pi R_0 LD \left. \frac{dc}{dr} \right|_{r=R_0}}{2k_2 c_0 \pi R^2} = \frac{2I_1(\phi)}{\phi [I_0(\phi) - \phi I_1(\phi) \ln \sigma]} \quad [15]$$

The effectiveness factor is an expression of the actual overall reaction rate as compared to the reaction rate that would be obtained if the concentration were at the bulk value throughout the reacting surface (17). A more general expression for the effectiveness factor is

$$\eta = \frac{2 \int_0^R r e(c) dr}{R^2 e(c_0)} \quad [16]$$

When the reaction rate is first order in concentration, $e = k_2 c$, Eq. [16] becomes

$$\eta = \frac{2 \int_0^R r c dr}{R^2 c_0} = 2 \int_0^1 \psi C d\psi \quad [17]$$

The effectiveness factor concept is used below for the prediction of the etchant concentration in the plasma space surrounding the wafer rack.

The analysis up to this point has concentrated on events occurring in between the wafers. A similar analysis can be applied to LPCVD processes. The recent work by Meyerson and Olbricht (24) is quite relevant. Up to this point, the plasma existing outside the wafer stack has been regarded as simply the source of etchant species. The only parameter, related to the plasma region, that is required for the solution of Eq. [6] and [7] is the etchant concentration at the edge of the wafer stack, c_0 . This quantity depends on a complex way on reactor geometry and operating parameters such as power, pressure, flow rate, etc. Prediction of c_0 would be less difficult for "clean" systems involving a single gas. An example of such a system is photoresist stripping in an O_2 plasma. The procedures for evaluating c_0 are given below.

Etchant concentration in the plasma.—The bulk etchant concentration (c_0) can be predicted by writing a conservation equation for the etchant species (10, 20). These species are generated by electron-impact dissociation of the parent molecules and are eliminated by recombination reactions (Eq. [3] and [4]), etching, and gas flow. Rapid backmixing tends to eliminate concentration gradients in the annular region outside the wafer rack where the plasma exists, particularly when the gas is symmetrically fed through manifolds parallel to the barrel axis. A conservative order of magnitude calculation gave a value for the Pe number less than 0.1. Thus, complete mixing can be assumed in that region (continuous stirred tank reactor model, CSTR). The species balance equation will then read

$$2k_e \langle n_e \rangle [A_2] V_p = \eta k_2 c_0 (N \pi R^2) + \frac{v_0 w}{4} S_p c_0 + 2k_1 c_0^2 [A_2] V_p + F c_0 \quad [18]$$

The term on the left-hand side of Eq. [18] represents production of etchant species via the reaction

The electron density has been assumed constant at the average value within the annular plasma space. This may be a good approximation if the thickness of the annular space is small compared to its length. Thus, the assumption is better if an etch tunnel is present. In addition, if the principal loss of electrons is a volume process (e.g., attachment), the electron density will tend to be uniform irrespective of the geometry.

The first term on the right-hand side of Eq. [18] represents loss of etchant in the etching reaction. This term depends on the number of wafers (N) and on the area of etchable material left on each wafer (πR^2). The last term in Eq. [18] represents etchant loss by flow. Under the assumption that the gas is essentially composed of A_2 and A (i.e., low loading of wafers), $[A_2] \approx P/R_g T - c_0$. Then, Eq. [18] gives

$$-c_0^3 + \frac{P}{R_g T} c_0^2 + \frac{\eta k_2 \pi R^2 N}{V_p} + \frac{v_0 w}{4a} + \frac{F}{V_p} + 2k_e \langle n_e \rangle + \frac{k_e \langle n_e \rangle P}{k_1 (R_g T)} = 0 \quad [19]$$

The solution to the cubic Eq. [19] provides c_0 . Note that since both R and η are functions of time, c_0 will be time dependent except in the case $\eta k_2 \pi R^2 N / V_p < < v_0 w / 4a$ or F / V_p or $2k_e < n_e >$. Neglecting the volume recombination reaction ($k_1 \equiv 0$) results

$$c_0 \approx \frac{2k_e < n_e > \left(\frac{P}{R_e T} \right)}{\frac{\eta k_2 \pi R^2 N}{V_p} + \frac{v_0 w}{4a} + \frac{F}{V_p} + 2k_e < n_e >} \quad [20]$$

This equation correctly predicts the loading effect in that a plot of $1/c_0$ vs. N results in a straight line (10).

Both the average electron density $<n_e>$ and the dissociation reaction rate constant k_e depend on pressure. In particular, k_e depends on the E_d/P ratio which is a unique function of the electron temperature. In general, determination of $<n_e>$ or k_e is an extremely difficult task. The presence of "hot" electrons, the multiplicity of the reaction channels, and the large number of chemical species involved make the problem of analyzing a gas discharge a very complicated one. The papers by Kushner (21, 22) illustrate the complexity of the problem. A rigorous analysis of the discharge requires knowledge of cross-sectional data for the various collisional processes occurring. Such data are scarce for most of the plasmas used in practice. However, the situation is less complicated when dealing with discharges of a single gas. For the O_2 discharge, in particular, the required physical data are available and a reasonably accurate analysis of an O_2 plasma can be realized. For such a discharge, the effective electric field-to-pressure ratio E_d/P as well as the average electron density $<n_e>$ can be evaluated for given pressure, power density, and reactor geometry from Fig. 1.19 of Ref. (11). After finding the E_d/P ratio, k_e can be obtained from Fig. 1.26 of the same reference. Then c_0 can be computed by using Eq. [20] or the more complicated Eq. [19], if necessary. Hence, the effect of reactor pressure and power input on the bulk etchant concentration can be evaluated for this particular discharge. The plots in Fig. 1.19 and 1.26 of Ref. (11) can be used for analyzing etching in an O_2 plasma as long as the byproducts of etching (CO_2 , CO , H_2O , etc.) are in low enough concentrations not to alter the discharge properties. Measurement of $<n_e>$ is usually done with Langmuir probes and is associated with certain experimental difficulties (23). The etchant concentration can be measured by optical emission spectroscopy (12) or by gas-phase titration (13, 14).

Results and Discussion

The foregoing model was employed to predict across-wafer uniformity, etch cycle duration, optimum throughput, and overetch exposure.

Consider first the situation where recombination reactions are negligible, and where steady-state concentration profiles have become established but film clearing has not yet begun. Such a situation corresponds to the simple limiting case described by Eq. [13] with $\sigma = 1$. Figure 3 illustrates how the concentration distribution in the interwafer region depends upon the Thiele Modulus (ϕ_0). For values of ϕ_0 less than 0.3, the concentration distribution (and thus the etching rate distribution) is nearly uniform. That is, the wafer surface is uniformly accessible to the etchant species. For a given wafer diameter and reactor pressure, small ϕ_0 values can be achieved by increasing the wafer spacing, although such action serves also to decrease the throughput. For high ϕ_0 values, diffusion is sluggish compared to the etching reaction so that etching species become depleted from the interwafer region and large radial concentration gradients build up. This will be the case when the wafer spacing is small, or the diffusivity is low (i.e., pressure is high), or the etching reaction is rapid.

A plot of the effectiveness factor η vs. the Thiele Modulus ϕ_0 (Eq. [15]) for two values of the dimensionless film radius $\sigma (= R/R_0)$ is shown in Fig. 4. When $\phi = \phi_0$, $\sigma \ll 1$ (i.e., $\phi < 0.1$), Eq. [15] reduces to

Fig. 3. Effect of Thiele Modulus ϕ_0 on the concentration distribution in the interwafer region prior to film depletion ($\sigma = 1$, $\alpha = \beta = \gamma = 0$).

$$\eta = \frac{4}{4 + \phi_0^2 \sigma^2 (1 - 2 \ln \sigma)} \quad [21]$$

For any value of σ , the effectiveness factor tends to unity for small values of the Thiele Modulus ϕ_0 . This agrees with the fact that for small ϕ_0 the concentration is at its bulk value (c_0) throughout the wafer surface (e.g., Fig. 3 with $\phi_0 = 0.1$).

When $\phi \gg 1$ (i.e., $\phi > 10$), Eq. [15] reduces to

$$\eta = \frac{2}{\phi_0 \sigma (1 - \phi_0 \sigma \ln \sigma)} \quad [22]$$

Before film depletion sets in, $R = R_0$ or $\sigma = 1$. Then Eq. [22] becomes

$$\eta = \frac{2}{\phi_0} \quad [23]$$

and a log-log plot of η vs. ϕ_0 will result in a straight line with a slope of -1 . (Fig. 4 for $\sigma = 1$.)

For any film radius R less than the wafer radius R_0 , ($\sigma < 1$), and for high enough values of the Thiele Modulus ϕ_0 so that $-\phi_0 \sigma \ln \sigma \gg 1$, Eq. [22] becomes

$$\eta = -\frac{2}{\phi_0^2 \sigma^2 \ln \sigma} \quad [24]$$

and a log-log plot of η vs. ϕ_0 will result in a straight line with slope of -2 . (Fig. 4 for $\sigma = 0.2$.)

Figure 5 depicts the concentration distribution in the interwafer space for several values of, in essence, the vol-

Fig. 4. Effectiveness factor η as a function of the Thiele Modulus ϕ_0 with the dimensionless film radius σ as a parameter (Eq. [15]).

Fig. 5. Effect of volume recombination reactions on the concentration distribution in the interwafer space prior to film depletion ($\sigma = 1$).

ume recombination reaction rate constant k_1 . As k_1 increases so that $|\alpha| \gg 1$ and $\beta \gg 1$, strong concentration gradients develop which result in a highly nonuniform etch rate and a longer etch time. That is, reactants recombine to inactive species before they can diffuse into the wafer stack and etch the film. However, if k_1 is low enough so that $\beta < 1$, volume recombination reactions can be completely neglected (compare cases ① and ② in Fig. 5). This is true for the commonly employed O_2 or/and CF_4 discharges at pressures less than 1 torr. However, it may not be true for Cl_2 discharges, where the volume recombination rates are faster.

Figure 6 shows the film thickness distribution during transient film clearing with the dimensionless time as a parameter. Initially, the film has a uniform thickness h_0 ($H = 1$). After a dimensionless time of 1, the film begins to recede from the periphery. For this particular example, the film will be completely cleared after a dimensionless time of 10.1 has elapsed. The intersects with the ordinate provide the film radius R as a function of time.

Figure 7 shows the time dependence of the concentration profile during transient clearing of the film. After the outer rings have been cleared, the reactant penetrates more readily to the inner portion of the wafer and thus the concentration increases with time at a given radial position. This increase is less pronounced close to the center of the wafer since this region stays reactive almost throughout the cycle. Figure 6 gives the film thickness distribution as a function of time under the same conditions.

Fig. 6. Film thickness distribution at different cumulative etch times τ ($\alpha = -1$, $\beta = 10$, $\gamma = 0$, $\phi_0^2 = 25$ and total etch time $\tau_0 = 10.1$).

Fig. 7. Concentration distribution in the interwafer space at different cumulative etch times τ (parameter values are the same as in Fig. 6).

Exposure to overetch is to be avoided in etching most patterned films since local loading can result in rapid mask undercut after the end point has been reached. The percent overetch exposure as a function of the Thiele Modulus ϕ_0 is shown in Fig. 8 for four different radial positions on the wafer surface ζ ($=r/R_0$). In constructing Fig. 8, only surface (not volume) recombination reactions have been included ($\alpha = \beta = 0$, $\gamma = 1$). The percent overetch was computed by

$$\% \text{ overetch} = \frac{\tau_0 - \tau}{\tau} \times 100$$

where τ_0 is the total etch time (shown in the insert Table in Fig. 8), and τ is the time required to clear the film up to a given radial position ζ . Since the portion of the wafer closer to the periphery clears first, the overetch exposure is higher for larger ζ values. Furthermore, as the Thiele Modulus ϕ_0 increases, the radial distribution of the reaction rate becomes nonuniform, resulting in an increase of the overetch exposure.

A related plot is shown in Fig. 9, where the total etch time τ_0 has been plotted against the Thiele Modulus ϕ_0 .

Table I. Typical parameter values for barrel plasma etchers

Parameter value	Comments
$[A_2] = 6 \times 10^{-8} \text{ mol/cm}^3$	Parent gas partial pressure of 1 torr
$c_0 = 6 \times 10^{-9} \text{ mol/cm}^3$	Etchant partial pressure of 0.1 torr
$D \approx 350 \text{ cm}^2/\text{s}$	Estimated for O in O_2 at 400 K and 1 torr. Varies as P^{-1} and approximately at $T^{1.5}$
$h_0 = 10^{-4} \text{ cm}$ (1 μm)	—
$k_1 = 10^{15} \text{ cm}^3/(\text{mol})^2/\text{s}$	Corresponds to the reaction $O + O + O_2 \rightarrow 2 O_2$ (11)
$k_2 \approx 50 \text{ cm/s}$	Calculated from the value of $k_2/D = 0.158 \text{ cm}^{-1}$ given by Battey (6)
$L_r = 1 \text{ cm}$	Reference interwafer spacing
$P_r = 1 \text{ torr}$	Reference reactor pressure
$Q = 100 \text{ sccm}$	Corresponds to 1850 cm^3/s at 400 K and 1 torr
$R_0 = 5 \text{ cm}$	—
$T = 400 \text{ K}$	—
$v_0 \approx 7 \times 10^4 \text{ cm/s}$	Thermal velocity of O at 400 K
$w = 3 \times 10^{-4}$	For O recombining on silica at 400 K (9)
$\chi = 0.33$	very sensitive to surface conditions
	Corresponds to the reaction $Si + 4F \rightarrow SiF_4$

Fig. 8. Overetch exposure (%) vs. Thiele Modulus ϕ_0 for different radial positions on the wafer surface ζ ($\alpha = \beta = 0$, $\gamma = 1$).

with the surface recombination number γ as a parameter. No volume recombination reactions are considered. Since the edge of the wafer clears at a time $\tau = 1$, the percent maximum overetch will be $(\tau_0 - 1) \times 100$ and is also shown on the vertical axis. From Fig. 9, we observe that for $\gamma < 0.1$ and $\phi_0 < 0.3$ the film clears uniformly, i.e., there is no overetch exposure. As one expects, etch time and overetch increase as γ or/and ϕ_0 increase. In addition, for a particular value of γ , the corresponding curve approaches asymptotes for $\phi_0 \ll 1$ and $\phi_0 \gg 1$.

The effect of wafer spacing on throughput is illustrated in Fig. 10, where $1/L^*\tau_0$ (multiplied by 100) has been plotted against the dimensionless wafer spacing L^* . If the wafer thickness and the turnaround time are neglected, $1/L^*\tau_0$ is proportional to the throughput. The curve has been constructed by assigning a value of 5 to ϕ_0^2 and a value of 1 to γ for a dimensionless wafer spacing of $L^* =$

Fig. 9. Total etch time τ_0 and maximum overetch exposure (%) vs. Thiele Modulus ϕ_0 with the surface recombination number γ as a parameter ($\alpha = \beta = 0$).

Fig. 10. Effect of wafer spacing on throughput

1. The values chosen for ϕ_0^2 and γ have been calculated by using typical values for the system parameters shown in Table I. By changing the wafer spacing L , γ and ϕ_0^2 change inversely proportionally. No volume recombination reactions have been considered since the corresponding dimensionless groups have no L dependence. The maximum in the plot can be explained as follows. As L^* becomes large, the total etch time $\tau_0 \rightarrow 1$ and by further increasing L^* the ratio $1/L^*\tau_0$ decreases. However, as L^* becomes small, τ_0 increases more rapidly, resulting in decreasing throughput $1/L^*\tau_0$. Thus, there is a maximum in the throughput as a function of the wafer spacing. For the parameter values used, this maximum is found from Fig. 10 to occur at $L = 0.4$ cm. This is to be compared with a spacing of 3/16 in. usually employed in stripping photoresists in an O_2 plasma. Direct quantitative comparison with published experiments is difficult since not all of the required system parameters (for example, wall recombination coefficient) are known.

Another parameter affecting the throughput is reactor pressure. Figure 11 depicts the dependence of the total etch time τ_0 on the dimensionless pressure P^* . In constructing Fig. 11, base values of $\alpha = -0.005$, $\beta = 0.05$, $\gamma = 1$, and $\phi_0^2 = 5$ have been assigned for a value of pressure $P^* = 1$. Again, the parameter values have been calculated by using Table I. In order to correctly determine the effect of pressure on τ_0 , the dependence of the bulk etchant con-

Fig. 11. Effect of reactor pressure on total etch time

centration c_0 , on pressure must be known. A linear relationship is assumed here (Eq. [20] and Ref. (15) and (16)), so that the dimensionless groups depend on pressure P as follows: $\alpha \sim P^3$, $\beta \sim P^3$, $\gamma \sim P$, $\phi_0^2 \sim p$ (diffusivity $\sim P^{-1}$), and $\tau \sim P$ (since $\tau \sim c_0$). The minimum in the etch time can be explained as follows: at high pressures, the etchant concentration is high but recombination reactions and low diffusivity establish large concentration gradients in the interwafer space. As a result, the etch time increases. However, at low pressures, diffusion is facile and recombination reactions are sluggish but there is not enough etchant species to etch the film. Thus, the strip time is again high. For this particular choice of the parameter values, the minimum in etch time is found from Fig. 11 to occur at about $P^* = 2$ or $P = 2$ torr. Note that $\tau = t/t_0$, where $t_0 = (k_2 c_0 / \chi h_0)^{-1}$ (Eq. [5]) is the "characteristic" etch time equal to 1.85 min for the parameter values of Table I. Hence, the minimum etch time of Fig. 11 would correspond to an etch duration of about 4 min.

The optima shown in Fig. 10 and 11 have been obtained under otherwise no constraints. For example, maximum allowances in overetch exposure are not accounted for. Thus, a pressure of 2 torr (resulting in $\phi_0^2 \sim 10$ for the case considered) would be too high for etching a patterned film.

The present analysis has limitations with respect to the range over which wafer spacing L and pressure P can vary. For example, for wafer spacings comparable to the wafer radius, the one-dimensional model is no longer valid. Furthermore, at low pressure and small wafer spacing, the diffusion mode may be of "Knudsen diffusion" when the mean free path becomes comparable to wafer spacing. This will happen for $PL < 0.05$ torr-cm. Nonetheless, the optimum L and P values are within the range where the model assumptions are valid. For instance, for the optimum wafer spacing of 0.4 cm, the pressure value below which Knudsen diffusion prevails is 0.125 torr. This is far from the optimum pressure value.

Conclusions

A mathematical model for transient clearing of films from restricted geometries has been developed. Dimensionless groupings of system parameters were used to compile behavior and to reveal scale-up principles. The effect of these parameters on etch uniformity, overetch exposure, and throughput was determined, and optima were identified. The model can be extended without much difficulty to handle more complex situations such as: (i) arbitrary etching reaction kinetics, (ii) other types of volume or surface recombination reactions, (iii) non-uniform initial film thickness, (iv) etchable substrate (reaction rate nonuniformities are critical in this case, since the substrate layer may be seriously damaged), (v) time varying bulk concentration (this requires solution of Eq. [19] at each time step after the effectiveness factor has been found from Eq. [15]), and (vi) spatial dependence of the wall recombination coefficient.

The model represents a simplified view by virtue of several assumptions. For example, the wafer temperature may change during etching if the reaction is accompanied by heat effects. Furthermore, the wafer temperature may depend on the reactor pressure. Since chemical reactions are affected by temperature, the reaction rate constant (k_2) may not be a constant. Other assumptions include one-dimensional concentration distribution and pseudo-steady state. Both assumptions can be relaxed, but at the expense of much higher computation time. Finally, detailed analysis of the plasma region is, for the majority of situations, extremely difficult.

Despite its simplicity, the model can serve as a basis for studying more complex systems. An example is removal of polymer drill smear from the holes of multilayer printed-circuit boards (3). Experimental work aimed at testing the model predictions is currently in progress in our laboratory.

Plasma processing systems are complex in the sense that several different phenomena may control overall be-

havior depending upon the choice of operating conditions. As a consequence, the efficient design and scale-up of plasma systems is usually difficult to accomplish by intuition alone. The use of mathematical models can assist in organizing scientific concepts into strategies for engineering design.

APPENDIX

Recombination Reactions in an Oxygen Plasma

Oxygen plasmas are frequently employed for stripping photoresist masking layers. If the wafer load is small enough so that the stripping products are at negligible concentration, the pertinent recombination reactions will be (11)

For this system, Eq. [7] will be of exactly the same form but with the dimensionless groupings redefined as follows

$$\begin{aligned} \alpha &= \frac{2(K_2 + K_3 - K_1)R_0^2 c_0^2}{D} \\ \beta &= \frac{2(K_1 - 2K_3)PR_0^2 c_0}{(R_g T)D} \\ \gamma &= \left[\frac{v_0 w}{2L} + \frac{2K_3 P^2}{(R_g T)^2} \right] \frac{R_0^2}{D} \end{aligned}$$

with ϕ_0 remaining the same as before.

LIST OF SYMBOLS

a	specific volume of plasma space (V_p/S_p) (cm^3/cm^2)
A_2	etchant species
A_2	parent molecule
c_0	etchant concentration at the wafer edge (mol/cm^3)
c	etchant concentration (mol/cm^3)
C	dimensionless etchant concentration (c/c_0)
c_R	etchant concentration at $r = R$ (mol/cm^3)
D	etchant diffusivity (cm^2/s)
e	etch rate ($\text{mol}/\text{cm}^2/\text{s}$)
E_e	effective electric field in the plasma region (V/cm)
F	gas volumetric flow rate (cm^3/s)
h	film thickness (cm)
h_0	initial film thickness (cm)
H	dimensionless film thickness (h/h_0)
k_1	volume recombination reaction rate constant ($\text{cm}^6/(\text{mol})^2/\text{s}$)
k_2	etch rate constant (cm/s)
k_e	electron-impact dissociation rate constant ($\text{cm}^3/\text{mol}/\text{s}$)
L	wafer separation distance (cm)
L_r	reference interwafer spacing (1 cm)
L^*	dimensionless wafer separation distance (L/L_r)
$\langle n_e \rangle$	average electron density (mol/cm^3)
N	number of wafers
P	pressure (torr)
P_r	reference pressure (1 torr)
P^*	dimensionless pressure (P/P_r)
r	radial position (cm)
R	film radius (cm)
R_0	wafer radius (cm)
R_g	gas constant ($62,360 \text{ torr}\cdot\text{cm}^3/\text{mol}/\text{K}$)
S_p	surface area in contact with plasma (cm^2)
t	time (s)

T temperature (K)
 u_g gas velocity in interwafer space (cm/s)
 v_0 random thermal velocity of etchant species (cm/s)
 V_p volume occupied by the plasma (cm³)
 w wall recombination coefficient

Greek characters

α, β, γ dimensionless groups defined in Eq. [8]
 ζ dimensionless radial position, r/R_0
 η effectiveness factor (Eq. [15])
 σ dimensionless film radius, R/R_0
 τ dimensionless time, $k_2 c_0 t / \chi^2 h_0$
 τ_0 dimensionless total etch time
 ϕ Thiele Modulus based on the film radius, $R(2k_2/LD)^{1/2}$
 ϕ_0 Thiele Modulus based on the wafer radius, $R_0(2k_2/LD)^{1/2}$
 χ moles of A consumed per cm³ of film etched (mol/cm³)
 ψ dimensionless radial position, r/R

Reaction Kinetics of Hg_{1-x}Cd_xTe/Br₂-CH₃OH

R. T. Talasek* and A. J. Syllaios*

Texas Instruments, Incorporated, Equipment Group, Dallas, Texas 75266

ABSTRACT

Bromine methanol solutions are extensively used in HgCdTe device processing technology. The relative reaction rates of Hg, Cd, and Te and HgCdTe with bromine in methanol have been studied. The reaction rate constants, reaction order, and some conclusions about the mechanisms of the reactions of the elements with bromine are reported here. The anisotropic nature of the reaction of the semiconductor with bromine has been demonstrated. The effects of mechanical action on the relative rates of the semiconductor constituents have been studied and are also discussed.

Mercury cadmium telluride is a semiconductor widely used in the fabrication of infrared detectors. Since it is a compound, HgCdTe is especially sensitive to chemical processing, and some processing may leave the semiconductor surface depleted of one or more elements. This depletion may affect the performance of devices dependent on the surface behavior of the semiconductor. One of these processes is the chemical etching or polishing of HgCdTe, which uses solutions of bromine in methanol. Electrolyte electroreflectance (EER) measurements indicate that the surface of HgCdTe is left tellurium rich after such chemical treatments (1). To study the chemistry of this polishing further, the chemical kinetics of the HgCdTe/Br₂-CH₃OH system were investigated by studying the reactions of the elements Hg, Cd, and Te and of HgCdTe with Br₂ in CH₃OH. The semiconductor reaction was studied under noncontact (etch) conditions and by making contact to a Pelon polishing pad.

The extent of a reaction in a kinetic study is generally monitored by some physical constant of the system proportional to the concentration of a particular component (2). In this case, the amount of product (metal in solution) was monitored by measuring the UV-visible absorption of metal ion complexes formed with diphenylthiocarbazonate (dithizone) for Hg and Cd and with sodium diethyldithiocarbamate for Te (3-5). The reactions were quenched at various time intervals, rather than continuously moni-

toring absorption, so that nothing was added to the etch solution that might affect the reaction.

For any physical measurement, λ (in this case, metal complex absorption) that is proportional to reaction extent, the following relation holds (2)

$$\frac{\lambda_{\infty} - \lambda}{\lambda_{\infty} - \lambda_0} = \frac{C}{C_0} \quad [1]$$

where λ_{∞} is the measurement at full extent of reaction, λ_0 the measurement at reaction initiation, λ the measurement at time t , C_0 the initial concentration of limiting reactant, and C the concentration of limiting reactant at time t .

Reactions of Hg, Cd, and Te with Br₂/CH₃OH

The following elemental oxidation reduction reactions were studied

The reactions were studied by reacting the elemental metal with solutions of bromine in methanol in concentrations approximately equal to the effective metal concentration under convection-controlled conditions ($10^{-4}N > [\text{Br}_2] > 10^{-7}N$). For each reaction, a specific rate equa-

*Electrochemical Society Active Member.

tion can be written for each metal M

$$\frac{d[M^{n+}]}{dt} = k[M]^x[Br_2]^y \quad [2]$$

In the case of heterogeneous reactions such as these, the effective elemental metal concentration is

$$[M] = \frac{\text{Surface atoms}}{\text{Volume of solution}}$$

and was held constant throughout the reaction by maintaining a constant surface area of metal exposed to the solution. The rate equation can then be simplified to

$$\frac{d[M^{n+}]}{dt} = k'[Br_2]^y \quad [3]$$

where k' is an experimentally observed rate constant. Integrating this rate expression yields for $y = 1$

$$-\ln \frac{[Br_2]}{[Br_2]_0} = k't \quad [4]$$

and for $y = 2$

$$\frac{1}{[Br_2]} = k't + \frac{1}{[Br_2]_0} \quad [5]$$

or

$$\frac{[Br_2]_0}{[Br_2]} - 1 = k'[Br_2]_0 t$$

The reactions were quenched by removing the methanol solution from the reaction vessel. Determination of metal ion concentrations using the previously described complexing agents was done immediately.

By following the reaction extent at various time periods, reaction orders and rates were determined (Fig. 1a-1c). Resulting observed rate constants and orders were

Hg $k' = 2.9 \pm 0.5 \times 10^{-3} s^{-1}$; pseudo-first order

Cd $k' = 2.5 \pm 0.6 \times 10^{-3} s^{-1}$; pseudo-first order

Te $k' = 8.4 \pm 1.1 \times 10^{-4} M^{-1} s^{-1}$; pseudo-second order

From this data, it was concluded that, for the elemental reactions, the Hg and Cd reaction rates were equivalent within experimental error and that both rates were much faster than the Te reaction rate.

Although a mechanism could not be confirmed by such a limited study, some conclusions were drawn from this data. Obviously, the Te reaction proceeded by a different mechanism than the other reactions since it was second order. Also, given that (from transition-state theory)

$$k = CK_{eq}^\alpha \quad [6]$$

where k is a rate constant, C an integration constant, K_{eq} an equilibrium constant, and α a constant (for a particular reaction) related to the nature of the transition state $0 < \alpha < 1$, a comparison of the Hg and Cd mechanisms can be made (2). From reduction potentials, the following equilibrium constants were calculated (8)

$$K_{eq} (CdBr_2) \approx 10^{26}$$

$$K_{eq} (HgBr_2) \approx 10^3$$

Although C is not known, the wide variation in the values of K_{eq} for $CdBr_2$ and $HgBr_2$ indicate a large difference in α values for Cd and Hg. Therefore, it can be concluded that the mechanisms for the Hg and Cd reactions must be different, since the mechanism is related to the nature of the transition state.

Reaction of HgCdTe with Br₂/CH₃OH

Etch.—The material used for the semiconductor reactions was Hg_{1-x}Cd_xTe with $x = 0.225 \pm 0.003$ ($E_g \approx 0.12$ eV at 77 K), grown by solid-state recrystallization techniques (6). Nominal carrier concentrations and mobilities (by Hall effect measurements) were $7 \times 10^{14} cm^{-3}$ and $1.2 \times$

Fig. 1. a (top left): Reaction rate of mercury with bromine in CH₃OH. C is the concentration of bromine at time t . C_0 is the initial bromine concentration. $\lambda_{meas} = 486$ nm. b (top right): Reaction rate of cadmium with bromine in CH₃OH. $\lambda_{meas} = 516$ nm. c (left): Reaction rate of tellurium with bromine in CH₃OH. $\lambda_{meas} = 428$ nm.

Fig. 2. a (top left): Mercury standard curve. b (top right): Cadmium standard curve. c (left): Tellurium standard curve.

10^5 $\text{cm}^2/\text{V}\cdot\text{s}$, respectively. No effort was made to orient crystals; however, an averaging effect would be observed on any orientation dependent rate effects.

For normal processing conditions, *i.e.*, $[\text{Br}_2] \approx 0.1N$, $[\text{Br}_2] \gg [\text{metal surface atoms}]$. Therefore, $[\text{Br}_2]$ can be assumed to be constant for normal processing times and it follows directly from Eq. [3] that

$$\frac{d[\text{M}^{n+}]}{dt} = k' \quad [7]$$

which can be described as pseudo 0th order (constant rate conditions). Any deviation from this would yield a nonlinear plot of product formation *vs.* time. Since all three products (Hg^{2+} , Cd^{2+} , Te^{4+}) were in the same solution, it was necessary to separate the ions prior to determination. Separation techniques using dithizone in CHCl_3 for Hg and Cd, and sodium diethyldithiocarbamate in CCl_4 for Te are detailed elsewhere (7). Standard curves from these separations are shown in Fig. 2. By following

the reaction *vs.* time, the rate plot (Fig. 3) was determined for Hg, Cd, and Te. From this data, experimental rate constants were calculated for the constituents of the semiconductor

$$\begin{aligned} k'_{\text{Te}} &= 5.3 \times 10^{-8} \text{ M s}^{-1} \\ k'_{\text{Hg}} &= 1.8 \times 10^{-7} \text{ M s}^{-1} \\ k'_{\text{Cd}} &= 5.3 \times 10^{-7} \text{ M s}^{-1} \end{aligned}$$

The relative rates of reactions of the elements comprising the semiconductor serve to illustrate the anisotropic nature of the reaction at the surface.

Chemical mechanical polishing.—A common technique in processing HgCdTe is chemical-mechanical polishing, whereby $\text{Br}_2/\text{CH}_3\text{OH}$ is flowed across a Pelon polishing pad, and the sample is polished using normal (hand) polishing techniques. Although pseudo-0th order kinetics should be observed as in the etching process, two important differences exist which may cause differences in the kinetics of the two processes. First, disturbance of the

Fig. 3. Reaction of HgCdTe with bromine in CH_3OH under etch conditions.

Fig. 4. Reaction of HgCdTe with bromine in CH_3OH under chemical-mechanical polishing conditions.

boundary layer may cause a deviation from the relative rates observed for etching. Also, since larger amounts of material are removed during the polishing process than the etching process, anisotropy is magnified. The resulting rate plots from this reaction are shown in Fig. 4. The experimentally determined rate constants were

$$\begin{aligned}k''_{\text{Te}} &= 8.3 \times 10^{-7} \text{ M s}^{-1} \\k''_{\text{Hg}} &= 8.3 \times 10^{-6} \text{ M s}^{-1} \\k''_{\text{Cd}} &= 4.2 \times 10^{-5} \text{ M s}^{-1}\end{aligned}$$

Normalizing the rates to Te yields rates of 1, 10, and 50 for Te, Hg, and Cd. These results demonstrate an accentuation of the anisotropic nature of the semiconductor reaction by the addition of mechanical action. The results also indicate a faster reaction rate for Te in the chemical-mechanical reaction than for any of the components in the etch reaction, indicative of the larger amount of material removed in the former.

Conclusion

The rate constants and reaction orders of Hg, Cd, and Te with Br₂ in methanol solutions have been determined. From these results, it was also determined that the three reactions proceed by entirely different mechanisms. The reaction of HgCdTe with Br₂ was also studied. The results show that this reaction is anisotropic, depleting Cd and, to a lesser extent, Hg from the semiconductor surface, in agreement with EER data mentioned earlier. It was also shown that the addition of mechanical action to the surface during the reaction enhanced the anisotropic nature of the reaction.

Influence of Substrate Preparation on the Morphology of GaSb Films Grown by Molecular Beam Epitaxy

Mitsuru Kodama, Jun Hasegawa, and Morihiko Kimata

Department of Electrical Engineering, School of Science and Engineering, Waseda University, Shinjuku, Tokyo, Japan

ABSTRACT

The chemical etching of (100)-oriented GaSb substrate by several different treatments has been studied. The morphology of the MBE-grown GaSb films strongly depends on the substrate preparation prior to epitaxial growth. It is shown that some defects which originate at the substrate propagate to the surface of the films, in case of the improper chemical treatment, and degrade the morphology of the films. The excellent surface morphology of the film could be obtained reproducibly by treating the substrate with CH₃COOH-HNO₃-HF and subsequent HNO₃-HCl solutions.

In order to obtain high quality films grown by molecular beam epitaxy, the chemical treatment of the substrate prior to epitaxial growth is important. GaSb has been used as a substrate material for AlSb-GaSb superlattices (1) and GaSb-AlGaSb double heterostructure lasers (2). Moreover, it is a lattice-matched substrate for AlGaAsSb and InGaAsSb quaternary compounds, which are applicable for optoelectronic devices. However, the detailed chemical treatment of GaSb substrate prior to epitaxial growth has not been reported. In a state of equilibrium such as liquid- or vapor-phase epitaxy, the meltback (3) and vapor-etch technique (4) is usually used for the preparation of GaSb substrate prior to the epitaxial growth. Very little material, however, is removed from the substrate surface in the vacuum chamber prior to MBE growth. Therefore, improper substrate preparation can lead to poor epitaxial films. It has been previously reported that some morphological defects exist at the film surface and substrate-film interface in MBE-grown GaAs films (5).

The present work is conducted to determine the most proper chemical processing for the preparation of nondoped GaSb (100) substrates with reproducible smooth surfaces and to obtain MBE-grown GaSb films with reproducible excellent surface morphology.

Experimental Procedure

Nondoped (100)-oriented GaSb substrates (Sumitomo, a residual carrier concentration of $1 \times 10^{17} \text{ cm}^{-3}$) were used for experiments. At first, specimens were polished with 3.0 μm SiC and subsequent 0.3 μm alumina powder on a polishing pad. Then the polishing on a pad with fresh water was done to reduce the mechanically damaged surface effectively. As a result, we expect that the damaged layer on the surface is less than 1 μm . These were approximately 300 μm thick and $10 \times 10 \text{ mm}^2$ in area. The specimens were cleaned in trichlorethylene, acetone, and methanol, and etched by several treatments listed in Table I. The etched depth of each sample was evaluated by a conventional photolithography and a scanning electron micrography (SEM). The surface condition of chemically etched substrates was evaluated by an optical micrograph. Just after the samples were etched, they were inserted in an MBE apparatus such as reported previously (6). The GaSb substrate was mounted on a Mo substrate holder using Ga for adhesion. Ga is effective in keeping the substrate surface less oxidized during the process for adhesion (7). After the bakeout of a vacuum system, base pressure could be reached of less than 1×10^{-9} torr. The surface condition of the substrates was studied *in situ* by RHEED observation at a beam voltage

Table I. Chemical treatment procedures for nondoped GaSb(100) surface

Treatment	Composition and etching condition
I	2%Br ₂ -CH ₃ OH (R.T., 2 min)
II	CH ₃ COOH-HNO ₃ -HF (40:18:2, R.T., 40s)
III	CH ₃ COOH-HNO ₃ -HF (40:18:2, R.T., 40s) + Hot HCl (10 min)
IV	CH ₃ COOH-HNO ₃ -HF (40:18:2, R.T., 40s) + 2% Br ₂ -CH ₃ OH (1 min)
V	CH ₃ COOH-HNO ₃ -HF (40:18:2, R.T., 40s) + HNO ₃ -HCl (1:30, 5°C, 1 min)

R.T. indicates room temperature.
The post-treatment sequences are rinsing in methanol and drying with a spinner.

of 20 keV. After the heat-treatment of the substrates, a nondoped GaSb film was grown at a growth rate of 0.5-1.0 $\mu\text{m/h}$. The source materials for molecular beams were Ga (7N) and Sb (6N), which were evaporated from PBN and quartz Knudsen cells, respectively. The growth temperature has been used in the range of 420°-480°C. The morphology of MBE-GaSb films was evaluated by an optical micrograph. The cleaved and stained sections of the films using HF-HNO₃-H₂O solution were evaluated by SEM.

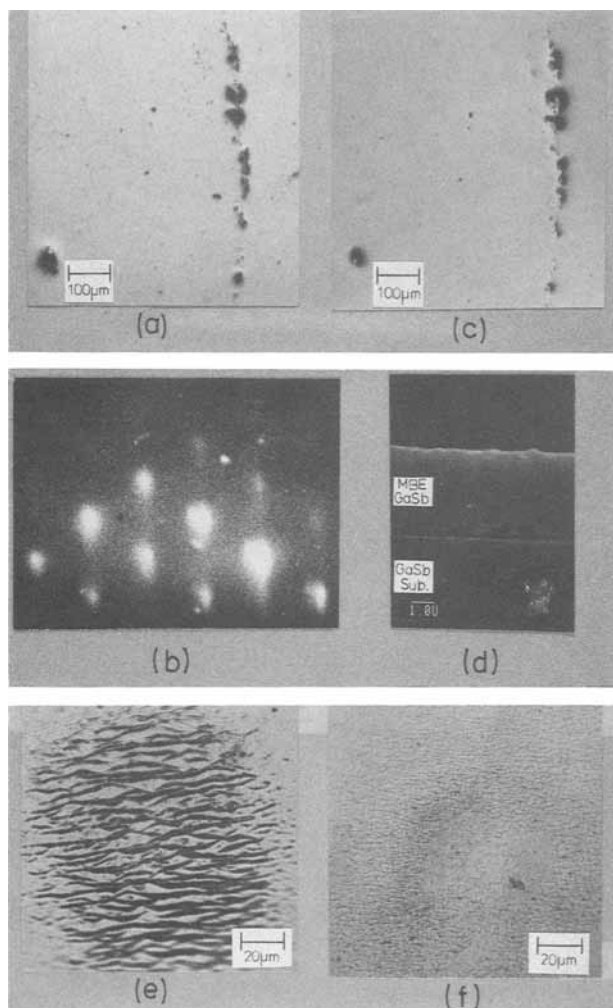

Fig. 1. (a): Surface of GaSb substrate etched by the treatment I. (b): RHEED pattern ($\langle 0\bar{1}1 \rangle$ azimuth) of substrate etched by the treatment I at heat-cleaning temperature T_{HC} about 535°C. (c): Surface morphology of deposited GaSb film. Thickness of film is about 3 μm . (d): SEM photograph of stained-cross sectional view of GaSb film. (e) and (f): Polycrystalline growth region which substrate contamination has produced.

Results and Discussion

Figure 1(a) shows an example of the etched surface by treatment I. The etching rate using 2% Br₂-CH₃OH solution, which was approximately 0.05 $\mu\text{m/s}$, was nearly constant. In this figure, small pits and scratches due to the selective etching at the damaged area on mechanically polished surface were observed on the surface. Such typical defective surfaces were sometimes observed independently of Br₂ content in the solution. Similar results were previously reported for the chemical etching of InP substrates using Br₂-CH₃OH solution (8). As the heat-cleaning temperature T_{HC} was raised to about 535°C, a spotty diffraction pattern started to appear as shown in Fig. 1(b). The appearance of such pattern can be regarded as a clear evidence of surface oxide being removed by a thermal decomposition process. However, it means that the initial, thermally cleaned surface is rough in an atomic scale, which produces a diffraction pattern of spots (9). It is shown in Fig. 1(c) that the surface of the MBE-GaSb film grown on the substrate shown in Fig. 1(a) is the same defect pattern as that of the substrate shown in Fig. 1(a). Therefore, it is clear that these surface defects propagate from the substrate. Figure 1(d) shows the stained cross-sectional view of the film. Some defects exist at the substrate-film interface. Moreover, Fig. 1(e) and 1(f) show the typical region where the substrate contamination has produced polycrystalline growth (5, 10), which is attributed to the involatile contaminants on the surface such as carbon. Oxide on the surface could be removed by the thermal treatment. However, it was found in our preliminary XPS observation that carbon could not be reduced effectively by the thermal treatment. The carbon remaining on the surface receiving treatment I was about 5% of a monolayer or more. Cho and Arthur (9) previously reported the polycrystalline GaAs over area with carbon contamination, and pointed out that carbon is the most troublesome contamination for MBE growth. Such

Fig. 2. HF content dependence for etching rate of nondoped GaSb(100) etched by CH₃COOH-HNO₃-HF solution.

Fig. 3. (a): Surface of GaSb substrate etched by the treatment III. (b): Surface of GaSb film grown on the same substrate as shown in (a). Thickness of film is about 2 μm .

defects at the substrate-film interface and polycrystalline growth region were sometimes observed in case of treatment I. Therefore, the chemical etching of GaSb substrates by $\text{Br}_2\text{-CH}_3\text{OH}$ solution is not a proper procedure for the MBE growth. However, no pits and scratches were observed on the substrate surface etched by treatment II. The etching rate using $\text{CH}_3\text{COOH-HNO}_3\text{-HF}$ solution which was approximately $0.12 \mu\text{m/s}$ was nearly constant. The etching mechanism of this solution is not clear at this time. However, it was found in our experiments that this solution was most proper to remove the damaged surface completely. Figure 2 shows the HF content dependence of etching rate. The etching rate increases linearly with increasing HF content. However, with HF content of more than 7.0 volume percent, the etched surface was not smooth. Moreover, the residual surface oxide which degrades the morphology of the films sometimes remained on the substrate surface, irrespective of any HF content in the solution. This residual surface oxide was identified as Sb_2O_3 and Ga_2O_3 , as determined by XPS (11). In order to effectively remove this residual oxide, treatment III, IV, and V in Table I were applied. Treatment III and IV give rise to small pits. Figure 3(a) shows an example of the etched surface by the treatment III. Figure 3(b) shows the morphology of the film grown on the substrate shown in Fig. 3(a). A number of small pits which were in nearly the same order of density with that of the substrate were observed similar to treatment I. However, in case of treatment V, such small pits were not observed, and reproducible smooth etched surfaces were obtained as shown in Fig. 4(a). A subsequent $\text{HNO}_3\text{-HCl}$ solution could reduce the residual surface oxide content to the amount of about 20%, which was convinced by XPS. The resulting oxide which could be removed by the subse-

quent thermal treatment was estimated to be less than 10Å thick. The RHEED pattern of the substrate surface at the heat-cleaning temperature T_{HC} about 525°C was streaky as shown in Fig. 4(b), suggesting that the initial, thermally cleaned surface is atomically flat. Under Sb_4 flux (Sb cell temperature about 600°C) supplied by an evaporation cell, the substrate surface exhibited surface reconstruction. Figure 4(c) shows a $\text{C}(2 \times 6)$ structure along $\langle 0\bar{1}1 \rangle$ azimuth, already observed in MBE studies (12). The same sharp streaking RHEED pattern was maintained throughout the MBE growth of GaSb film. Figure 4(d) shows a typical surface morphology of the film grown on the substrate etched by treatment V. The surface is smooth relative to the former cases, and does not show any microscopic defects. Figure 4(e) shows the SEM photograph of the stained cross-sectional view of the film. The interface between the substrate and film was flat, and no defects exist at the interface. This result using treatment V was very reproducible as far as the morphology, substrate-film interface, and RHEED pattern were concerned. The streaky RHEED pattern of the substrate etched by treatment V was maintained to the substrate temperature about 580°C , and changed to a fairly diffuse spotty pattern about 590°C , due to the thermal faceting of the substrate surface. This may be attributed to the desorption of volatile atoms from the substrate surface due to the difficulty of maintaining a congruent evaporation. Figure 5(a) shows the thermally damaged substrate surface after the prolonged heat-treatment at 600°C . Figure 5(b) shows the corresponding RHEED pattern. Such a thermal faceting is also a source of defects in grown films (5).

Summary

The chemical etching of (100)-oriented nondoped GaSb substrates by several different treatments has been studied. The morphology of the MBE-grown GaSb films strongly depends on the substrate preparation prior to the growth. The conventional $\text{Br}_2\text{-CH}_3\text{OH}$ etching is not proper treatment for the substrate preparation. It is shown that some defects which originate at the substrate propagate to the surface of the films and degrade the morphology of the films. The excellent surface morphology of the film can be obtained reproducibly by treating the substrate with $\text{CH}_3\text{COOH-HNO}_3\text{-HF}$ and subsequent $\text{HNO}_3\text{-HCl}$ solutions.

Large-Scale Growth of GaAs Epitaxial Layers by Metal Organic Chemical Vapor Deposition

J. L. Tandon and Y. C. M. Yeh

Applied Solar Energy Corporation, City Of Industry, California 91749

ABSTRACT

Physical and electronic properties of both p- and n-type GaAs layers grown by metal organic chemical vapor deposition (MOCVD) are discussed and correlated with reactor control parameters. Crucial questions about the uniformity and reproducibility of layer growth in a large-scale reactor are addressed. Data are presented which demonstrate large-scale viability of MOCVD technology. Under optimized operating conditions, good quality layers with thickness and carrier concentration variations of $\leq 10\%$ and $\leq 50\%$, respectively, have been grown on 60×4 cm wafers at a time. Such large-volume growth of GaAs layers has important implications in the production of GaAs devices and circuits.

In recent years, growth of epitaxial GaAs layers by MOCVD has received considerable attention (1). Since the first demonstration of the concept in 1968 (2), many laboratories have reported successful growth of doped layers using a variety of dopants (1, 3). The quality of layers grown by MOCVD has now attained a level which is as good, if not better, than that claimed by liquid-phase epitaxy, vapor-phase epitaxy, or molecular beam epitaxy (1, 4). This can be attributed primarily to a significant advancement in the availability of highly pure AsH_3 and organic sources for Ga (trimethyl-gallium and triethyl-gallium).

Although good success of the MOCVD technique has been achieved in small laboratory-type reactors, and large-scale reactors have been contemplated (5), the potential of the technology in production is yet to be realized. In this paper, large-scale growth of high quality GaAs epitaxial layers by MOCVD is reported. The properties of the layers as a function of flow rates of gases, temperature, and pressure are discussed. Specific questions about the uniformity and reproducibility of layer growth are addressed. Variations in the layer properties in a single growth run are correlated with temperature gradients and gas-flow dynamics within the reactor. Optimized control parameters for the reactor are determined, and data are presented which demonstrate good quality growth on 60×4 cm wafers at a time, with thickness and carrier concentration variations of $\leq 10\%$ and $\leq 50\%$, respectively.

Experimental Methods

Growth of epitaxial GaAs layers was carried out in a modified large-scale low pressure (< 760 torr) MOCVD reactor MR-200 built by Cambridge Instruments. The schematic diagram of the system is shown in Fig. 1. The reactor consists of a hollow SiC-coated graphite susceptor which sits on a quartz dome. The vertical lamp heating elements are arranged uniformly inside the quartz dome, and the heating of the susceptor is accomplished by radiation. Stabilization of the susceptor temperature is attained by controlling the power to the lamp heating elements, and the temperature is measured by a pyrometer. The pressure inside the reacting chamber is controlled by a throttle valve in front of the vacuum pump. The susceptor has an outer diameter of about 30.5 cm and has ten facets on its periphery, each comprising of four pockets [see Fig. 1(b)]. The dimensions of each pocket are 7.6×4.6 cm. Three wafers, each 2×4 cm, can be loaded in each one of the pockets. Thus, if desired, growth can be carried out on 120×4 cm wafers at one time. The vertical distance between the entry and the exit points of the gases in the reactor is about 25 cm. During growth the susceptor was rotated with a speed of ~ 5 rpm, and was covered with a stationary water-cooled barrel. The flow rate of carrier gas H_2 was ~ 120 liter/min for most growth runs.

GaAs wafers (semi-insulating or n-type ($n \sim 2 \times 10^{18} \text{ cm}^{-3}$) oriented $2^\circ\text{-}3^\circ$ off $\langle 100 \rangle$ axis) were used as substrates for growth experiments. The flow rates of the gases were controlled by mass flowmeters and microprocessor-

Fig. 1. Schematic diagrams of the MOCVD reactor system (a) and of the susceptor (b). The susceptor has ten facets (b) on its periphery, each containing four pockets for loading wafers. If desired, growth could be carried out on 120×4 cm wafers at one time.

activated valves. After growth, the surface morphology of the grown layers was examined by optical and secondary electron microscopy. Free carrier concentration and mobility values were determined by Hall-effect measurements performed on layers grown on semi-insulating GaAs wafers. The depth profiles of carrier concentrations and the thicknesses of the grown layers were measured by a Polaron British Post Office profiler. This instrument calculates and automatically plots carrier concentration as a function of depth. The carrier concentration is determined by measuring the capacitance *vs.* voltage of the reverse biased Mott-barrier formed between the GaAs wafer and an electrolyte. *In situ* depth measurements are obtained by controlled etching (in the same electrolyte), accomplished by passing a current generated either by a light source or by applying a bias. The carrier concentration values measured by the Polaron profiler cross checked very well (better than $\pm 20\%$) with the values obtained from Hall-effect measurements. As estimated by "alpha-step" stylus-type measurements performed on the etch pits created after Polaron profile measurements, the inaccuracy in the depth scale of the Polaron Profiler was less than $\pm 3\%$.

Results and Discussion

Surface morphology and crystalline quality of layers.—Epitaxial layers were grown in the temperature range 660 – 800°C . In some cases, island-type growth was observed in isolated regions. Figure 2 shows an example of such growth. This type of growth occurred around contaminant particles which clung to the surfaces of

GaAs wafers prior to growth. By energy dispersive x-rays these contaminant particles were found to be rich in Si and O concentration, indicating that they were SiO_x particles. Electrostatic charge is believed to be associated with these particles, which accounts for their strong clinging to the GaAs surface. Conventional cleaning procedures (rinsing with organic solvents) were found to be insufficient to remove them. An automated scrubbing procedure, whereby the wafers were scrubbed with nylon brushes in acetone, was developed and adopted, which considerably reduced their density. Such an automated procedure was especially required in the batch-process cleaning of a large number of wafers for growth.

In addition to the surface morphology features described above, growth defects comprising of pits and hill-locks (6) were also occasionally observed in localized areas. The origin of these defects and their relationship to growth parameters and/or substrate quality are not well understood yet. However, layers grown at high temperatures possessed less density of these defects.

The crystalline quality of the grown layers was measured by backscattering spectrometry with channeling, employing a 2 MeV He^+ beam. In all cases examined, the epitaxial layers were single crystalline with crystalline quality as good as the substrates.

Growth rate vs. trimethyl-gallium (TMG) mole fraction.—With the AsH_3 mole fraction maintained a factor 4-100 higher than the TMG mole fraction, the growth rate was found to be linearly dependent on the TMG mole fraction. Figure 3 confirms this result, where growth rate

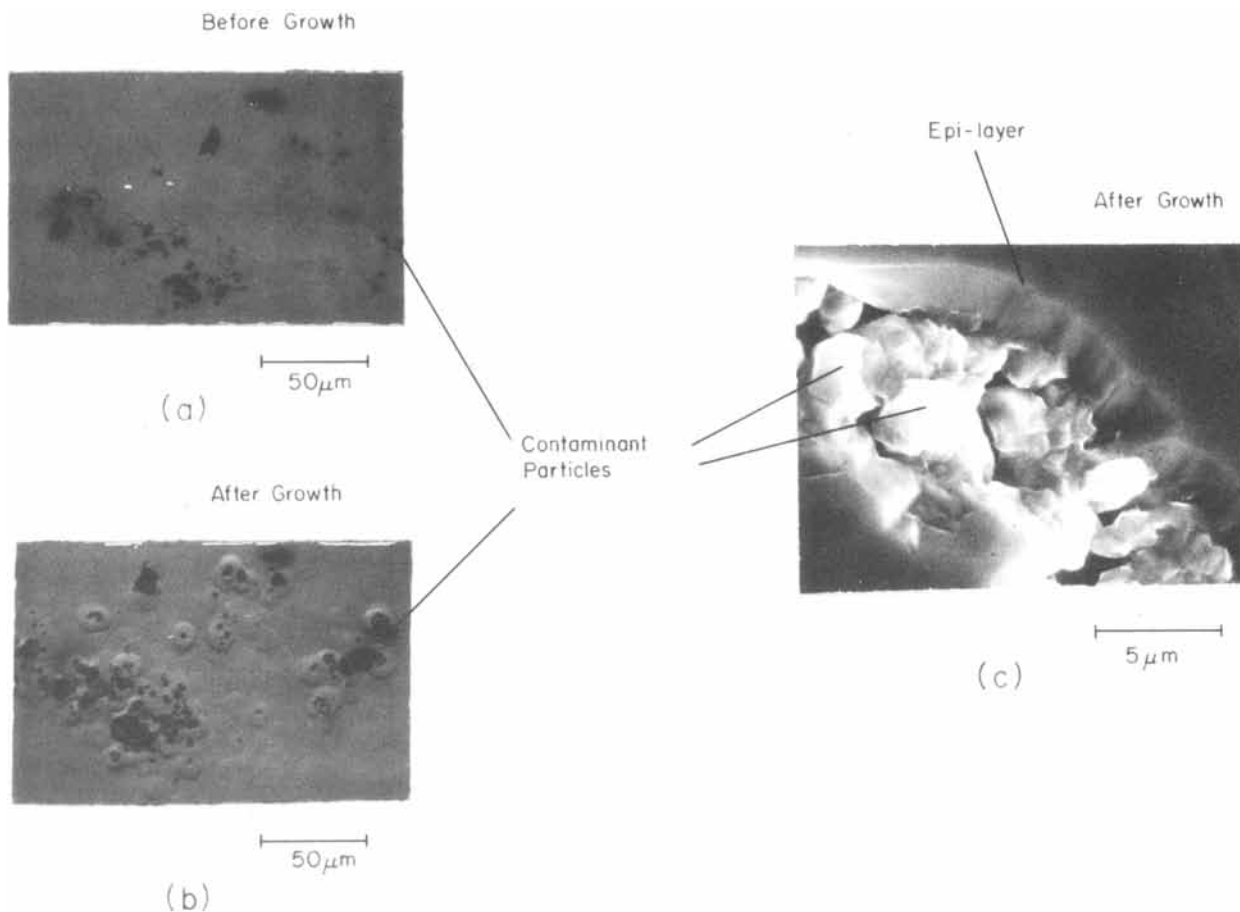

Fig. 2. Micrographs showing contaminant particles before growth (a), and morphology around these particles after growth (b) and (c). The micrographs (a) and (b) were obtained using an optical microscope (with Nomarski interference), and (c) using an SEM. The island-type growth around contaminant particles is evident from (c). By energy dispersive x-ray measurements, the contaminant particles were found to be rich in Si and O concentration, indicating that they were SiO_x particles.

is plotted as a function of TMG mole fraction for both n- and p-type layers. Similar observations have also been reported elsewhere (7-10).

n-type layers.—Several n-type layers were grown with various concentrations of H_2Se in the gas stream, while keeping all other parameters constant. Two identical growth runs were carried out for each concentration of H_2Se . In the runs, samples were placed all across the sus-

ceptor in the third and fourth pockets from the top [see Fig. 1(b)]. Figure 4 shows free-electron concentration (n)

Fig. 3. Growth rate as a function of TMG mol fraction (x_{TMG}). All other parameters were kept constant: $x_{\text{AsH}_3} = 3.25 \times 10^{-3}$, $T = 730^\circ\text{C}$, $P = 132$ torr.

Fig. 4. Free electron concentration (n) in the grown layers as a function of H_2Se mole fraction ($x_{\text{H}_2\text{Se}}$). Other parameters: $x_{\text{TMG}} = 2.87 \times 10^{-4}$, $x_{\text{AsH}_3} = 3.25 \times 10^{-3}$, $T = 730^\circ\text{C}$, $P = 132$ torr.

Fig. 5. Free electron concentration (n) of MOCVD grown n-type layers as a function of electron mobility (μ_n). The solid line ($\mu_{n, sze}$) is obtained from Ref. (11).

measured in these samples as a function of H_2Se mole fraction. Each point plotted in Fig. 4 is an average of four to five measurements made on randomly picked samples from the various pockets in the two identical runs. The error bars indicate scatter in the measurements. An analysis of the scatter revealed that variations across the susceptor and from run to run were small ($< \pm 20\%$), and within measurement errors. Most of the scatter in the data points could be attributed to a systematic variation in the doping of layers grown on samples placed at different vertical locations in the susceptor. This variation in a single growth run is discussed below. The straight line in Fig. 4 is a least-mean-square fitted line with a slope very close to 1. Thus, for the range of H_2Se mole fraction considered, n is found to vary linearly with H_2Se mole fraction.

The room temperature mobility of the grown n-type layers as a function of electron concentration is given in Fig. 5. The measurements reported here were made on samples loaded in the various pockets of the susceptor during several growth runs carried out with different concentrations of H_2Se . As expected, the mobility decreases with the increase in n , and the trend is similar to the estimated $\mu_{n, sze}$ given in Ref. (11) (solid line). However, the mobility values in the grown layers are lower than $\mu_{n, sze}$. This may be due to compensating impurities in gases which could get incorporated in the layers during growth.

p-type layers.—Figure 6 gives the hole concentration (p) measured in p-type layers as a function of dimethyl-zinc (DMZ) mole fraction. The data plotted here were collected on samples prepared in a similar fashion as described in the previous section. Again, a linear dependence is observed for the range considered, with the slope of the fitted line close to 1. The room temperature mobility decreases with increasing hole concentration (Fig. 7), following a trend similar to $\mu_{p, sze}$ (11). However, the measured mobility values in the grown layers are somewhat lower, which may again be due to compensating electronic impurities.

Doping vs. growth rate.—Free carrier concentrations were measured in both p- and n-type layers grown with varying growth rates. Different growth rates were obtained by changing the TMG mole fraction, while keeping the mole fractions of AsH_3 and the dopants constant. Figure 8 shows the dependence of hole concentration (p) on the growth rate of p-type layers. The error bars ascribed to the data again represent scatter in the measurements made on samples in different pockets of the susceptor and from run to run (see the "n-type layers" section). A significant increase in p is observed for higher growth rates. Similar results were also obtained on n-type layers grown with Se as dopant. Higher doping efficiency of

both p- and n-type dopants with higher growth rates is not intuitively clear. This behavior cannot be explained by variations in the buried compensating impurities alone during growth. The increase in both n and p with the increase in growth rate is most likely due to the increase in the incorporation of respective dopant atoms during growth. The dopant incorporation appears to be linked with the mass transport of Ga atoms which controls the growth rate. This effect, also reported elsewhere (7), has been attributed to surface kinetic effects. More diagnostic studies of the reacting species during growth are, however, required to understand this phenomenon better.

Spatial variation in carrier concentrations and thicknesses of grown layers at different growth temperatures.—n-type layers were grown on samples loaded all across the susceptor. Vertically, the samples spanned a distance of approximately 14 cm from the location of the injection of gases to the exit point where the gases were

Fig. 6. Free hole concentration (p) in the grown layers as a function of DMZ mole fraction (x_{DMZ}). Other parameters: $x_{TMG} = 2.87 \times 10^{-4}$, $x_{AsH_3} = 3.25 \times 10^{-3}$, $T = 730^\circ C$, $P = 132$ torr.

pumped out. The pressure inside the reacting chamber was kept constant by manipulating the throttle valve (see Fig. 1). Three growth runs were carried out at three different temperatures measured at about the center of the susceptor. Other parameters (mole fractions of reacting gases and flow rates) were kept constant. Figure 9 shows the distribution in the free electron concentrations (n) and in the thicknesses of the grown layers as a function of vertical distance in the reactor (zero distance corresponds to the point of injection of the gases). Variations across the susceptor, at a fixed vertical distance, were within measurement errors (see "n-type layers" section). The three curves are for three different temperatures of growth. The value of n , at a fixed vertical distance, for constant mole fractions of reacting gases, pressure, and flow rates, decreases with increasing temperature of growth. Similar behavior was also observed for p-type layers with Zn doping. Decreased dopant incorporation with increased temperature of growth has also been reported earlier (7), and is related to increased kinetic energy of reacting species. Again, for better understanding of this effect, detailed characterization of chemical species at the growth surface is needed.

Another important feature of Fig. 9 is the variation in n with spatial vertical distance in the reactor. An identical trend for the three cases of growth temperatures implies an establishment of a steady-state spatial temperature gradient during growth. [The not-so-conspicuous trend in the lowest temperature case may be due to n-type dopant saturation effects at $\sim 2 \times 10^{18} \text{ cm}^{-3}$ level (12)]. The injection point is cooler than the exit point. The hottest point is located close to, but not at, the exit point. The existence of this temperature gradient was also verified by

measurements performed with a pyrometer under simulated growth conditions. The cooling of the surfaces of the samples near the injection point can be explained by the heat taken away by the cold gases entering the reacting chamber. At the exit point, the slight increase in n appears to be due to a slight drop in the temperature resulting from increased velocity of gases caused by pumping.

It is interesting to point out that spatial carrier concentration distribution, as measured and plotted in Fig. 9, serves as a sensitive probe for detecting temperature gra-

Fig. 8. Free hole concentration (p) as a function of TMG mole fraction (x_{TMG}), or growth rate (see Fig. 3). Constant parameters: $x_{AsH_3} = 3.25 \times 10^{-3}$, $x_{DMZ} = 3.47 \times 10^{-6}$, $T = 730^\circ\text{C}$, $P = 132 \text{ torr}$.

Fig. 9. Free electron concentration (n) and thicknesses of grown layers as a function of spatial distance in the reactor (see Fig. 1 and text for details). The three curves are for three different temperatures of growth, measured about the center of the susceptor. Constant parameters: $x_{TMG} = 2.87 \times 10^{-4}$, $x_{AsH_3} = 3.25 \times 10^{-3}$, $x_{H_2Se} = 5.63 \times 10^{-8}$, $P = 132 \text{ torr}$.

dients within the reactor. From the dependence of the carrier concentration on the temperature of growth, and from pyrometer measurements, a temperature gradient of $\sim 70^\circ\text{C}$ was estimated at an operating total pressure of 132 torr.

The spatial variation in the thicknesses of the grown layers is not as dramatic as the carrier-concentration variation. This implies that the growth rate is not a function of the temperature of growth. The drop ($\sim 30\%$) in the thicknesses of the layers near the exit point of the gases can be explained by a reduction in the growth rate due to a decrease in the available concentration of TMG per unit time. This decrease in TMG concentration may be caused by depletion and/or by the mechanism of differential pumping used in the reactor which increases the velocity of reacting gases at the exit point.

Spatial variation in carrier concentrations and thicknesses of grown layers at different pressures of growth.—To investigate the effect of total pressure on the carrier concentrations and the thicknesses of the grown layers, four growth runs were made with four different values of pressure. Other parameters, such as temperature, mole fractions of the reacting gases, and flow rates, were kept constant. Loading of the samples for growth in the reactor was carried out in a similar fashion as described in the previous section. Figure 10 shows the vertical spatial distribution in the electron concentrations (n), and in the thicknesses of the grown n-type layers. Similar behavior was also observed for p-type layers. For low values of total pressure, a large variation in the distribution of n is observed, which is due to a steady-state temperature gradient established in the reactor during growth (see the previous section, Fig. 9). An increase in the pressure of growth results in a reduction of temperature gradient. With the growth pressure of 400 torr, the gradient collapses, resulting in fairly uniform distribution of n . This behavior can be explained by the effect of total pressure

inside the reacting chamber on the temperature at the reacting surfaces of loaded wafers. An increase in pressure reduces the velocity of reacting gases, so that the gases become less effective in taking the heat away from the loaded wafers. This results in an increase in temperature, more significantly near the injection point of the gases in the reactor. A total pressure of 400 torr, for the operating growth parameters chosen in this case, thus homogenizes the temperature distribution within the reactor.

It should be noted that with the "optimized" operating conditions, good uniformity ($\leq 50\%$) in doping concentration is achieved over a region of about 14 cm in the reactor. Considering the geometry and dimensions of the susceptor (see Fig. 1), this implies that growth with a uniform distribution in carrier concentration can be carried out on 90×4 cm wafers at a time. The "optimized" conditions should not be considered as universal conditions, and indeed would depend on flow rates of gases, spatial distribution of lamp heating elements in the reactor, pumping speed in the below-atmosphere system, geometrical construction of the reactor, angle of susceptor facets with respect to the direction of flow of gases, etc.

As with the variation with temperature (see Fig. 9), the spatial variation in the thicknesses of the grown layers does not depend strongly on the pressure of growth. Again, thin growth near the exit point of gases results from the decreased concentration of available TMG per unit time (see the previous section). As can be seen from Fig. 10, layers with thickness variations of $\sim 10\%$ can be grown over a distance of ~ 10 cm, which corresponds to 60×4 cm wafers at a time (see Fig. 1).

Conclusions

Large-scale viability of a low pressure MOCVD system in the growth of epitaxial GaAs layers has been demonstrated. The reactor has the capability of handling 120×4 cm wafers at a time. Physical and electronic properties of the grown layers as a function of reactor operating parameters have been measured. Under "optimized" conditions, layers with doping and thickness variations of $\leq 50\%$ and $\leq 10\%$, respectively, have been grown on 60×4 cm wafers at a time.

The spatial uniformity in the properties of grown layers depends strongly on the gas-flow dynamics and the physical construction of the reactor. In the real growth cycle, establishment of temperature gradients are found to be most influential in producing nonuniformities. When designing and constructing large-scale reactors, to assure uniformity, dynamical growth conditions should be considered to obtain a laminar flow with constant temperature distribution. It should be pointed that a simulation of exact growth conditions is rather difficult because of the complicated processes involved. Thus, in this respect, another approach whereby modifications are made on the basis of feedback provided from layer measurements should be more useful and appropriate. Modifications along these lines are continually being carried out in our operating of the reactor.

Large-scale growth of epitaxial GaAs layers, as reported in this paper, has important implications in the production of GaAs devices. Currently, Applied Solar Energy Corporation is engaged in the production of GaAs solar cells using the MOCVD technology.

Thermal Annealing of Si-N Absorption Bands in Nitrogen-Implanted Silicon

H. J. Stein*

Sandia National Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

The behavior of nitrogen in silicon after implantation and annealing has been investigated by infrared (IR) absorption. Concentrations of N were chosen to represent those implanted into the Si layers in the formation of buried silicon nitride layers. Local mode frequencies similar to those for Si doped with N in the melt are observed after implantation. Intensities for the IR bands associated with the local modes increase when displacement damage is removed by annealing at temperatures between 200° and 600°C. Precipitation of implanted N upon annealing at 750°C is suggested to explain the appearance of additional Si-N bands with frequencies near those for Si-N absorption in crystalline Si₃N₄. Annealing at 900°C is required to remove Si-N absorption bands, whereas 600°C annealing removes Si-O bands in O-implanted Si. This difference may be important for ion and temperature selection when forming buried dielectric layers by ion implantation since impurity-defect accumulation must be controlled to maintain crystallinity in the Si overlayer.

Ion implantation is pervasive in the semiconductor industry. Conventional uses for implantation of electrically active dopants include doping for drive-in diffusion, self-aligned gates, and threshold voltage adjustment. These uses typically require energies < 100 keV and fluences of $\approx 10^{15}$ cm⁻². There has also been limited use of electrically active dopant implants at higher energies to achieve retrograde doping (1) and buried grids (2). Another potential use of ion implantation is the formation of buried dielectric layers in Si by implanting nitrogen or oxygen at high fluences and high energies (3). Typical depth dimensions for implanted silicon-on-insulator (SOI) structures are illustrated in Fig. 1. Circuits may be formed directly in the crystalline overlayer, or an epitaxial layer may be grown on the overlayer before circuit fabrication.

In contrast to conventional uses, buried dielectric layer formation requires energies > 100 keV and ion fluences of $\approx 10^{18}$ cm⁻². Implanting with a fluence sufficient to form a buried dielectric layer subjects the overlayer to high levels of energy into displacement processes and to concentrations of O or N which are above solid solubility limits in crystalline Si (4, 5). The present paper reports (6) studies of the chemical bonding and thermal stability of implanted N in Si at concentrations representative of those in the Si overlayer when a buried Si₃N₄ layer is formed. Infrared absorption was used for the studies, and the annealing characteristics for Si-N absorption bands are compared to the characteristics for Si-O absorption bands in O-implanted Si.

Background

Implantation with 2×10^{18} 200 keV N ion/cm² introduces sufficient N to produce a silicon nitride buried layer $\approx 2000\text{\AA}$ thick, as illustrated by the solid line in Fig. 2 for the N profile calculated using the Brice transport code (7). Sputtering, which is expected (8) to remove about 300 \AA , was not included in the calculation. In addition

to changes in Si produced by specific implanted ions, properties of the overlayer are also affected by displacement damage that accompanies ion implantation. The calculated energy deposited into displacement processes (7) is illustrated by the dashed line in Fig. 2. It is known (9) from previous work that crystalline Si is converted to an amorphous phase by an energy deposition of 10^{24} eV/cm³ into displacement processes at 300 K. Fortunately, significant dynamic annealing occurs for implantations performed above room temperature (9), so that crystallinity can be maintained in the Si overlayer by performing buried layer implantations at temperatures $\geq 400^\circ\text{C}$ for beam currents on the order of 10 μA .

The linear scale for the N concentration in Fig. 2 illustrates the expected buried nitride layer and Si overlayer. However, the same calculated profile plotted on a log scale (Fig. 3) shows N concentrations which are orders of magnitude above the solid solubility limit for N in Si (4.5×10^{15} cm⁻³). Nitrogen affects mechanical (10), electrical (11, 12), and optical properties (5, 13) of crystalline Si. Luminescence (13) and DLTS (14) studies have shown that N produces deep levels, and a deep level associated with substitutional N was identified (SL5 center) in EPR studies (15) of N-implanted Si.

A previous study (16) showed that N implanted into Si forms Si-N bonds which have vibrational modes detectable by infrared absorption. Absorption bands for implanted N in Si appear at the same frequencies as those for Si doped in the melt with N, even though the implanted N concentrations after implantation are orders of

Fig. 2. Calculated depth distributions for nitrogen concentration and energy into displacement processes.

magnitude above equilibrium solid solubility. Absorption by Si-N local modes is used in the present investigation to characterize the effects of postimplantation annealing on Si-N local modes for high concentrations of implanted N in crystalline Si.

Experimental Details

A high resistivity p-type float zone <111> Si wafer 0.5 mm thick and polished on both sides was diced into 1/4 x 1/4 in. samples for implantations with N and Ne. An entire second wafer was implanted with O and subsequently diced into samples. Implantations were performed at ~50°C with scanned ion beams. Infrared absorption spectra were measured at room temperature at 2 cm⁻¹ resolution with a Nicolet 60SX FT-IR spectrometer. Annealing was performed in flowing N₂ for 1h periods and 100°C steps below 600°C, and 150°C steps above 600°C. Samples were given an HF dip after annealing to remove surface oxides.

Results and Discussion

An absorption spectrum for N implanted Si is shown in Fig. 4. Maximum intensities for Si-N bands are observed after a fluence of ~ 2 x 10¹⁵ N/cm² for ion energies between 100 and 200 keV. In order to increase the measured absorbance for Si-N bands, each of the two polished faces

Fig. 3. Illustration of the nitrogen concentration profile implanted into the silicon overlayer.

Fig. 4. Infrared absorption bands for Si-N centers in nitrogen-implanted crystalline silicon.

was implanted with 2 x 10¹⁵ of both 100 and 200 keV ¹⁴N/cm². Isotopic substitution was utilized in a previous study (16) to confirm that bands at 764 and 963 cm⁻¹ are associated with Si-N bonds. The broad features in Fig. 4 are interference effects which are not specific to N implantation. Mode frequencies, and therefore the force constants, for N in Si are higher than those for substitutional impurities such as carbon and boron, and they are more comparable (16) to those for oxygen-vacancy and interstitial carbon defects in Si. The 963 cm⁻¹ band is also close in frequency to major absorption bands for Si-N in crystalline Si₃N₄ (17, 18).

Absorption spectra taken after annealing the implanted samples at 600°, 750°, and 900°C are compared in Fig. 5. Spectra have been displaced along the absorbance axis for presentation. Intensities for the 963 and 764 cm⁻¹ bands increase upon annealing at 600°C and the peak for the lower frequency band shifts to 767 cm⁻¹. Henceforth, this band will be referred to as the 767 cm⁻¹ band. Annealing at 750°C decreases the intensities for the 767 and 963 cm⁻¹ bands but new bands appear at 790, 807, 895, and 1025 cm⁻¹. Frequencies for Si-N bands in crystalline Si₃N₄ are indicated in Fig. 5 for comparison to those in the implanted layer after annealing at 750°C. Similarities are evident between 856, 895, 963, and 1025 cm⁻¹ bands in annealed N-implanted Si and the strong bands in Si₃N₄. This similarity is taken as evidence for small precipitates of Si₃N₄ in the implanted layer. No bands appear in crystalline Si₃N₄ near the bands at 767, 790, and 807 cm⁻¹. Absorption in this frequency range has been reported for

Fig. 5. Annealing effects on Si-N absorption bands in nitrogen-implanted crystalline silicon.

N-doped α -Si (19), and may, therefore, be a consequence of embedding Si-N oscillators in a Si host. Intensities for the Si-N bands are decreased to below the detection limit by annealing at 900°C.

Thermal stability of the implanted impurity in the overlayer is a factor in the choice of ions for buried-layer SOI. Consequently, spectra for Si-O absorption after O implantation and annealing at 300°, 400°, and 600°C are shown in Fig. 6 for comparison to annealing of Si-N bands. Bands at 830 and 1103 cm^{-1} are associated with neutral charge state oxygen-vacancy, O-V, and interstitial oxygen, O_i , centers, respectively (20). The additional band at 889 cm^{-1} after annealing at 300°C is associated with the negative charge state of O-V centers. Similar intensity for the 830 and 889 cm^{-1} bands indicates that the Fermi level is near the $E_c - 0.17$ eV level for O-V centers (20). Absorption bands for O-V centers are nearly removed by annealing at 400°C, and both the O-V and O_i centers are removed by annealing at 600°C. These centers, therefore, would be essentially eliminated by dynamic annealing during implantations near 500°C, which is a typical substrate temperature for buried dielectric layer formation. However intensities for Si-N absorption bands are at a maximum after annealing at 600°C.

More detailed isochronal annealing characteristics for the 767 and 963 cm^{-1} Si-N bands are shown in Fig. 7 where peak absorbance is plotted vs. isochronal annealing temperature. Increase in band intensities occurs primarily between 200° and 600°C. Nitrogen concentrations determined from the intensity of the 963 cm^{-1} band using a previously published calibration (5) are plotted on the right ordinate in Fig. 7. Comparing deduced densities to the density of implanted N atoms indicates about 12% of the implanted N incorporated into the local mode centers after annealing at 600°C. It should be emphasized that the concentration of Si-N inferred from the IR data is only approximate because of potential matrix effects in the IR cross sections. Annealing characteristics for the IR bands are quite different from those for the substitutional N SL5 center (15), and the centers must therefore be structurally different. The general characteristics for the 767 and 963 cm^{-1} bands are similar even though the ratios of their intensities are somewhat dependent upon the annealing temperature. Two modes for a single defect would obviously explain similar annealing characteristics; annihilation of two different defects by a common process is also a possibility.

Implanted samples annealed at 600° and 900°C were subjected to bombardment by 10^{15} 180 keV Ne/cm² and subsequently annealed. No Si-N bands were regenerated in the sample annealed at 900°C by the bombardment/anneal sequence. Bombardment with Ne reduced intensities

for Si-N bands in the sample annealed at 600°C as illustrated by the data in Fig. 8. Intensities for the bands recover upon subsequent annealing, similar to the results shown in Fig. 7 for the as-implanted sample. The 200°-600°C temperature range for recovery of the Si-N modes corresponds to the temperatures required to remove major defects produced by displacement damage (21). It is concluded, therefore, that disorder caused by displacement damage quenches local mode band intensities.

Intensities for the 767 and 963 cm^{-1} bands decrease, and additional bands form with annealing above 600°C in both the as-implanted and Ne-bombarded samples. These changes are attributed to motion of N on a local scale, resulting in precipitation of implanted N in Si. Growth and loss of the additional IR bands parallel annealing characteristics reported for shallow donors (11, 12) in N-implanted Si so that a relationship is suggested between precipitates and shallow donors. Loss of Si-N absorption bands at temperatures $> 750^\circ\text{C}$ agrees with the temperature reported for diffusion of N from Si layers toward free and internal surfaces (22).

Summary

Absorption bands associated with Si-N vibrational modes are introduced by implantation of N into crystalline Si. The implanted N concentrations are representative of those in the Si overlayer when implanting to form a buried silicon nitride layer. The Si-N bands are quenched by displacement damage and increase upon annealing between approximately 200° and 600°C for both as-implanted and samples which are rebombarded after annealing at 600°C. Similarities are apparent between frequencies for bands in crystalline Si_3N_4 and for Si-N bands in N-implanted Si after 750°C annealing. It is suggested, therefore, that precipitation of implanted N in Si occurs at 750°C. Measurements of N profiles by secondary ion

mass spectroscopy and of defect structures by transmission electron spectroscopy are needed to confirm N motion and precipitation in implanted layers.

Heating at 900°C is required to remove Si-N absorption bands in N-implanted Si, compared to 600°C for removal of Si-O bands in O-implanted Si. This difference in the annealing behavior may be important when selecting the implantation temperature and the species to optimize for dynamic annealing during buried layer SOI formation. In particular, it may be necessary to perform N implants at higher temperatures than those for O implants to achieve comparable defect annealing and impurity gettering.

ABSTRACT

Etching rates of HCl/H₃PO₄ preferential etchant for the InP (100) surface are determined experimentally, particularly at low HCl concentration suitable for submicron fabrication processes. A very slow but reproducible etching rate of 1000 Å/min is obtained at 5% HCl concentration at room temperature with almost vertical (011) facets on a (100) plane. Concentration dependence of the etching rates and surface pretreatment effects are also investigated.

The chemical etching of InP crystals with HCl/H₃PO₄ etchant seems to be favorable for fabricating a submicron pattern which is essential for making optoelectronic or millimeter-wave electronic devices. It is expected that an InP crystal can be etched preferentially with use of HCl/H₃PO₄ etchant (1), but little is known about the etching characteristics relevant to submicron fabrication. Those characteristics on the (100) surface are essential because most of the device structures are fabricated on it. In order to find a slow but preferential etchant of the InP (100) surface, HCl/H₃PO₄ etchants, particularly with low HCl concentration, are investigated in the present paper together with some SEM (scanning electron microscope) observations of the etched facets at various crystal orientations.

Experimental

Multiple processes of photoresist coating/baking and etching with use of AZ1350 photoresist were applied to a Fe-doped semi-insulating InP wafer (supplied from SUMITOMO, resistivity larger than 10⁶ Ω-cm and etch-pit density below 1 × 10⁴ cm⁻² cut to the orientation (100) ± 0.5°) to form a steplike pattern on it for the purpose of determining the etching speed of the solution. The chemicals used were all of reagent grade, 12N with HCl (purity 35.0%), 15N with H₃PO₄ (purity ≥ 85.0%). The etching solution at various HCl concentrations ranging from 5% to 25% volume ratio was kept in a glass beaker and stirred at room temperature (23°C), while the wafer was face down at the bottom and frequently hand shaken in the solution. The etched depths on the (100) surface were measured by

Fig. 1. Etched depths as a function of etching time with HCl/H₃PO₄ solution at 23°C, HCl concentration as a parameter. ● with pre-etching, ○ without pre-etching; 5% HCl concentration. Experimental standard deviations are within circles.

Fig. 2. Etching rates of (100) surface as a function of HCl concentration. Insets give those of other typical etchants.

a surface profiler with a stylus sweep speed at 0.01 mm/s on the sample surface. The etched samples were cleaved on (011) or (01 $\bar{1}$) surfaces, and the etched surfaces appearing on the cleavage were observed by a SEM (Akashi type ISI-DS130).

Results

The etched depths measured by the surface profiler are shown in Fig. 1 as a function of the etching time at low HCl concentration. In order to remove the native-oxide layer formed on the as-bought wafers, the wafers were pre-etched by a 10% HCl concentration for 60s just before the application of photolithographical processes for the etching depth measurements. As the open circles indicate, the wafers without pre-etching treatment have about a 30s delay time to start etching, i.e., we need about 30s to remove the native-oxide layer. Once the native-oxide layer

Fig. 3. Schematic diagram of etched pattern with respect to crystal orientation.

ers are removed, the surfaces are etched with the same etching speed as that of pre-etched surfaces (marked as the closed circles). At various HCl concentrations up to 25% volume in H₃PO₄, the etching depth in the pre-etched surfaces was measured as a function of etching time and plotted in Fig. 1. No saturation of the etching speed was observed with any of these solutions, and the etching speeds were determined from the slopes of the curves and plotted as a function of the HCl concentration ratio in Fig. 2. The etching speeds are 0.09 $\mu\text{m}/\text{min}$ for 5% HCl, 0.24 $\mu\text{m}/\text{min}$ for 10% HCl, 0.40 $\mu\text{m}/\text{min}$ for 15% HCl, 0.70 $\mu\text{m}/\text{min}$ for 20% HCl, and 1.05 $\mu\text{m}/\text{min}$ for 25% HCl. The etching speed of the (01 $\bar{1}$) and (111) surfaces are 3.4 $\mu\text{m}/\text{min}$ and 2.6 $\mu\text{m}/\text{min}$ for 20% HCl concentration, respectively. These are 4.9 and 3.8 times faster than that of the (100) surface at the same HCl concentration. Comparison with some other etching solutions, also shown in Fig. 2, makes clear the characteristics of the present solution. The etching speed of Br solutions (2, 3) seems to have a rather large dependence on both the temperature and Br concentration and must be cooled to below 0°C in order to attain a slow etching speed. We may therefore make a

Fig. 4. SEM photographs of etched patterns. (A) (011) cleave; (B) [01 $\bar{1}$] cleave.

Fig. 5. SEM photographs of (011) and (01 $\bar{1}$) cleave of etched patterns at various HCl concentration. (A) 20% HCl/80% H₃PO₄; (B) 10% HCl/90% H₃PO₄; (C) 5% HCl/95% H₃PO₄.

fine submicron pattern with good reproducibility by using the present solution.

An optical ridge waveguide 2 μm in width was patterned parallel and perpendicular to the (100) surfaces and was cleaved to observe the facets by SEM. The crystallographic orientation and observation are schematically shown in Fig. 3. As shown in the following photographs, we have nearly vertical (01 $\bar{1}$) facets on the (100) plane, while (111) facets have an angle to the (100) plane. Figure 4 shows SEM photographs of the etched surfaces which are mechanically cleaved. The (01 $\bar{1}$) facets on the (100) surface give nearly vertical planes, as shown in Fig. 4(A), while (111) facets make an angle about 25.5° to the (100) plane, as shown in Fig. 4(B). The (01 $\bar{1}$) oriented ribs on the (100) InP surface therefore seem to be suitable for fabricating low-scattering optical waveguides with smooth (01 $\bar{1}$) facet vertical sidewalls. Forms of the (01 $\bar{1}$) and the (111) facets are further observed by SEM at various HCl concentrations, and the results are summarized in Fig. 5. Both (01 $\bar{1}$) and (111) facets change little in their forms with HCl concentration while maintaining smooth (100) etched surfaces. By changing either the HCl concentration or the etching time, therefore, we may fab-

ricate fine optical waveguides with smooth (01 $\bar{1}$) vertical sidewalls.

Summary

The etching rates of InP substrates with HCl-H₃PO₄ solution, especially with low HCl concentration, are studied experimentally, and the facets formed on the substrate surfaces are observed with use of SEM. Nearly vertical (01 $\bar{1}$) sidewalls with [011] ribs are fabricated by the present preferential etchant with good repeatability, indicating a promising technique for fabricating submicron structures like optical waveguides and other electronic devices.

The Chemical Mass of Holes in Semiconductors

Carl D. Thurmond*

807 San Juan de Rio, Rio Rancho, New Mexico 87124

ABSTRACT

The equation $0 \rightleftharpoons e^- + e^+$ is a legitimate chemical equilibrium equation. Because the conservation of mass equation holds, the hole, e^+ , has a chemical mass that is the negative of the mass of the electron. The fact that the equation is not balanced with respect to charged particles is consistent with chemical equilibrium equations of charged particles in general. The hole is an abstraction. It has two masses. One mass, arising from its physical dynamic properties, is positive. The other, arising from its chemical thermodynamic properties as expressed in equilibrium chemical equations, is negative.

Is the equation

representing the formation of holes and electrons in semiconductors a legitimate chemical equation? Kröger, Stieltjes, and Vink, in an important paper in 1959 (1), have demonstrated that it is. But the question can be asked, "Isn't something surely wrong?" The conservation of mass condition that applies to all chemical equations apparently does not apply here because the mass of the hole is known to be about the same as the mass of the electron. Furthermore, chemical equations always have reactants and products. What are the reactants of Eq. [1]? Certain rules are used to write the equilibrium constant of chemical equations in terms of the concentrations of products and reactants. These rules do not seem to apply to Eq. [1].

These questions have led to a reconsideration of the source of Eq. [1]. Based on the approach used by Kröger, Stieltjes, and Vink (1) [also see Kröger (2)], it can be shown that Eq. [1] follows all the rules applicable to the usual equilibrium equation for charged particles. The major clarifying conclusion is that the chemical mass of the hole is not the same as the physical mass, the so-called effective mass of the hole. Rather it is the negative of the mass of the electron.

The primary intent of this paper is to prove this conclusion. While this conclusion is of no great scientific import, it is an interesting curiosity. It also makes clear that Eq. [1] is a legitimate chemical equation. The secondary intent of this paper is pedagogical. The means by which it will be proven that the mass of the hole as used in chemical equations must be the negative of the mass of

the electron will serve to clarify the meaning and use of chemical equilibrium equations. For chemists and chemical engineers, this should serve as a review with certain clarifying features. For semiconductor physicists, electrical engineers, and others, it may serve as an illustration of the use of chemical thermodynamics, as well as an explanation of the meaning and use of the chemical equilibrium equation.

Shockley has stated that "the hole is really an abstraction which gives a convenient way of describing the behavior of electrons" (3). This description leads to the conclusion based on the physical dynamic properties of semiconductors that the hole has a mass, called the effective mass. The mass of the hole is introduced as a convenient mathematical description of the movement of electrons in a nearly filled valence band. Just as in the description of the movement of electrons in the conduction band, where the acceleration produced by a force defines an effective mass for the electron by Newton's law, the hole is a convenient way of describing the acceleration of the valence electrons produced by a force. The effective masses of the electron and hole are, in general, of the same order of magnitude as the mass of the free electron, although in some cases the discrepancy is larger. It is to be shown that, based upon the chemical thermodynamic properties of semiconductors, the chemical mass is the negative of the mass of the electron. There is no conflict. The abstraction leads to two masses for the hole, one based upon the physical properties of the semiconductor, the other on its chemical properties.

Experimental evidence will be cited in support of the conclusion that the chemical mass of the hole is the negative of the mass of the electron.

*Electrochemical Society Active Member.

The method of proof follows the method used by Kröger, Stieltjes, and Vink (1), but with significant points of clarification. The method is based upon the properties of the chemical potential of atoms, molecules, and charged particles. In the next section, only neutral atoms and molecules are considered. A following section considers charged particles.

Chemical Thermodynamic Properties of Atoms and Molecules

The well-known thermodynamic function, the Gibbs energy, has been defined for any group of atoms and molecules (4). The group must be large enough in size so that the properties assigned to each kind of atom or molecule are not a function of size. This function has a minimum value as a function of the numbers of atoms and molecules present, and this can be shown to correspond to an equilibrium condition for this group of atoms and molecules. Gibbs showed that a function called the chemical potential could be defined (5) for each type of atom or molecule that leads to a very useful way to describe the equilibrium condition. The chemical potential of a particular atom or molecule is the change in the Gibbs energy of the total number of atoms and molecules when one atom or molecule is added. The numbers of each of the other kinds of atoms or molecules must not be changed when this is done. The temperature and pressure must also be held constant.

Gibbs then showed that a condition that must be met when equilibrium occurs is that the sum of the chemical potentials of the products of a reaction must equal the sum of the chemical potentials of the reactants. Each chemical potential will have the appropriate coefficient that assures that the law of conservation of mass is obeyed.

The Gibbs condition for equilibrium can be written in a concise way. If μ_i is the chemical potential of a particular atom or molecule (in units of energy per atom or per molecule) and ν_i is the appropriate coefficient called the stoichiometric coefficient, for each atom or molecule that assures conservation of mass in the reaction, the following equation is the Gibbs condition (6)

$$0 = \sum_i \nu_i \mu_i \quad [2]$$

In this form, the statement is that the sum of the chemical potentials, each taken with the appropriate coefficient, is equal to zero, with the convention that the stoichiometric coefficients, ν_i , are positive numbers for the products and negative numbers for the reactants.

The chemical reaction that corresponds to the Gibbs condition describes the conversion of a particular group of atoms and molecules to another group of atoms and molecules, as if all of the original group, the reactants, were converted to all of the final group, the products. This chemical reaction implies the conservation of mass, which can be stated as

$$0 = \sum_i \nu_i M_i \quad [3]$$

M_i is the mass of each atom or molecule in the reaction. When the number of atoms or molecules is Avogadro's number, 6.023×10^{23} , the masses, M_i , are the atomic and molecular weights. The ν_i 's are the same stoichiometric coefficients as in Eq. [2].

The chemical equation can be written as

$$0 = \sum_i \nu_i A_i \quad [4]$$

A_i is the chemical symbol or group of chemical symbols representing the atoms and molecules of the reactants and the products. For example, consider the reaction describing the formation of water vapor from the gaseous elements

Equation [5] follows from Eq. [4], with $A_1 = \text{H}_2\text{O}$, $A_2 = \text{O}_2$, $A_3 = \text{H}_2$, $\nu_1 = +1$, $\nu_2 = -1/2$, and $\nu_3 = -1$.

A general property of Eq. [4], illustrated in Eq. [5], is that the number of each kind of atom in the reactants is the same as the number of each kind in the products. This conservation of atom condition may be represented by the following equation

$$0 = \sum n_\alpha \quad [6]$$

The subscript α stands for a particular atom. The number of those atoms is n_α ; it is positive if from the products, negative if from the reactants. For example, in Eq. [5], n_{O} (products) is +1, n_{O} (reactants) is -1; n_{H} (products) is +2, n_{H} (reactants) is -2. Equation [6] is implied by the conservation of mass condition, Eq. [3], and justifies the use of the equal sign in chemical equations, Eq. [4] and illustrated in Eq. [5].

Equilibrium Constant

The equilibrium constant follows from Eq. [2] when the dependence of the chemical potentials on composition is included. G. N. Lewis (7) has defined a function called the activity, α_i , that is related to the chemical potential by the equation

$$\mu_i = \mu_i^\circ + RT \ln \alpha_i \quad [7]$$

When the activity, α_i , is unity, the phase is pure and the chemical potential of the atoms or molecules, μ_i , is that of the pure phase, μ_i° , solid or liquid, which is a function of temperature and pressure, not composition. For the gas phase, the activity is replaced by the fugacity. Equation [7] implies Avogadro's number of atoms or molecules because R , the gas constant, is used, rather than k , the Boltzmann constant, which is per atom or molecule.

The usefulness of Eq. [7] lies in the fact that for some cases of interest, α_i is equal to the atom fraction or molecule fraction of a component present in a solution, the mole fraction. In other cases of interest, it is proportional to the concentration, and the chemical potential is related to the concentration by

$$\mu_i = \mu_i^* + RT \ln C_i \quad [8]$$

For many gas phases, the fugacity is simply the partial pressure.

Substituting Eq. [7] into Eq. [2], the Gibbs condition for equilibrium, the equation for the equilibrium constant is obtained

$$\prod_i \alpha_i^{\nu_i} = \exp \left(- \sum_i \nu_i \mu_i^\circ / RT \right) = K \quad [9]$$

When activities are proportional to concentrations, Eq. [9] becomes

$$\prod_i C_i^{\nu_i} = \exp \left(- \sum_i \nu_i \mu_i^* / RT \right) = K_c \quad [10]$$

In a somewhat more familiar form, Eq. [10] becomes

$$\frac{C_1^{\nu_1} C_2^{\nu_2} \dots}{C_3^{\nu_3} C_4^{\nu_4}} = K_c \quad [11]$$

This equation was first obtained by Guldberg and Waage. It follows from their law of mass action, which states that the rate of a reaction is proportional to the active masses of the reactants and that at equilibrium the rate of the forward reaction equals the rate of the reverse reaction.

The equilibrium constant for Eq. [5] is simply

$$\frac{P_{\text{H}_2\text{O}}}{P_{\text{H}_2} P_{\text{O}_2}^{1/2}} = K_p \quad [12]$$

Equation [2], the Gibbs condition, was written before Eq. [4], the chemical reaction. Given Eq. [2], Eq. [4] fol-

lows. Usually the reverse situation occurs. The chemical reaction is written first, from which the stoichiometric coefficients of the Gibbs condition for equilibrium are obtained. But for electrons and holes, the Gibbs condition can first be written, followed by the chemical equation.

The proof that the chemical mass of the hole is the negative of the electron mass first requires the proof that Eq. [1] is legitimate. This proof cannot be made, however, without recognizing that the electron and the hole are charged particles. One of the important properties of chemical reactions has been expressed in Eq. [6], namely, the number of atoms of one kind in the products must equal the number of atoms of the same kind in the reactants. This rule does not apply to a reaction of charged particles and explains why Eq. [1] does not obey Eq. [6]. The Gibbs condition, Eq. [2], and the conservation of mass, Eq. [3], both apply to chemical reactions of charged particles. But Eq. [6] does not apply; the reaction equation, Eq. [4], must be modified, and a new condition must be introduced, the conservation of charge.

Chemical Thermodynamic Properties of Charged Particles

First, some comments about the chemical potential of charged particles should be made. As long as the group of charged particles of interest, which may include neutral particles, *i.e.*, atoms and molecules, is electrically neutral, the total Gibbs energy of the group of particles possesses "all of the properties which we have established for non-ionic systems" (8). Again, the group of particles must be large enough so that the properties of each kind of particle are not dependent on the size of the group.

The chemical potential of charged particles is frequently called the electrochemical potential to call attention to the fact that if an electric field is imposed and the group of particles of interest is no longer electrically neutral, the chemical potential and the electrochemical potential are no longer equal.

The chemical potential of a charged particle is, as before, the change in the Gibbs energy of the total number of particles when one of the charged particles is added. But for charged particles, the numbers of each of the other particles cannot be held constant. They are not independent variables if the charge of the total group of particles is to be kept zero. The chemical potential of each charged particle can be defined, but it will always occur in combinations of particles that assure electroneutrality.

The Gibbs condition for equilibrium of charged particles can then be written as in Eq. [2], as can the chemical potential of the electron. The conservation of mass equation, Eq. [3], still applies. The chemical reaction with charged particles may now be written as

$$0 = \sum_i \nu_i A_i^{z_i} \quad [13]$$

where z_i is the charge on the i th particle and may be zero. In addition, the condition of electroneutrality must be met

$$0 = \sum_i \nu_i Z_i \quad [14]$$

But the conservation of atoms, Eq. [6], is not observed. An atom is not equivalent to an ion. They differ in mass by the mass of the electron. This difference is generally ignored by chemists in the use of charged-particle equations because the mass of the electron is so small compared to that of an atom. But concerning the argument that the chemical mass of the hole is the negative of the mass of the electron, this difference cannot be ignored. Consequently, charged-particle equations are generally unbalanced and the equal sign in Eq. [13] is inappropriate.

The double arrow symbol, \rightleftharpoons , rather than the equal sign, is frequently used by chemists to emphasize the dynamic properties of an equilibrium reaction, *i.e.*, that the rate of the reaction in the forward direction equals the

rate of the reaction in the reverse direction at equilibrium. Kröger (2) uses it for both atom and charged-particle equations. Prigogine (4) uses it sometimes for charged particle equations and sometimes not. Lewis, Randall, Pitzer, and Brewer (7) always use the equal sign. The double arrow sign will be used here to imply that Eq. [6] does not hold for charged particle reactions. It also implies a dynamic equilibrium. Consequently, the general equilibrium reaction equation for charged particles should be written as follows, rather than as in Eq. [13]

$$0 \rightleftharpoons \sum_i \nu_i A_i^{z_i} \quad [15]$$

To give some examples, first consider the ionization of the compound AB

Neither A^+ nor B^- appear on the left side of the equation. In some cases, it would be appropriate to consider AB as made up of A^+ and B^- , but that need not be necessarily so. The equation for ionization of water

is not balanced; the species H^+ and OH^- are not thought to exist in H_2O as useful conceptual entities. The ionization of a donor in a semiconductor

is not a balanced equation. Nor is a charge-transfer reaction

The Gibbs equilibrium condition, the conservation of mass, and the conservation of charge conditions all hold, but an atom or particle conservation condition does not hold for charged particle equations.

Equilibrium Between Electrons and Holes in Semiconductors

The chemical potential of the electron can always be written in the form of Eq. [8] over some concentration range

$$\mu(e^-) = \mu^*(e^-) + RT \ln C(e^-) \quad [20]$$

The concentration of electrons can be varied under the electroneutrality condition by the addition of positive charge. The source of the positive charge is the donor impurity. Its presence need not be explicitly stated, but it is implicitly recognized.

The band model of a semiconductor leads to the following equation for the Fermi level, E_F , as a function of the electron concentration at thermal equilibrium (9)

$$E_F = E_c - RT \ln N_c + RT \ln C(e^-) \quad [21]$$

Equation [21] holds as long as $C(e^-)$ is significantly less than N_c , the effective concentration of states in the conduction band. E_c is the energy of electrons at the bottom of the conduction band. By comparing Eq. [21] with Eq. [20], it is seen that the Fermi level is the chemical potential of electrons (10)

$$E_F = \mu(e^-) \quad [22]$$

Similarly, the chemical potential of holes can always be written in the form of Eq. [8] over some concentration range

$$\mu(e^+) = \mu^*(e^+) + RT \ln C(e^+) \quad [23]$$

In this case, it is to be remembered that the hole concentration is varied by the addition of an acceptor impurity which, when ionized, has a negative charge.

The band model of a semiconductor can also be used to obtain a relationship between the chemical potential of holes and the concentration of holes at thermal equilibrium (11)

$$-E_F = -E_v - RT \ln N_v + RT \ln C(e^+) \quad [24]$$

This relationship holds as long as $C(e^+)$ is significantly less than N_v , the effective concentration of states at the top of the valence band of energy E_v . By comparing Eq. [24] with Eq. [23], it is found that the Fermi energy is the negative of the chemical potential of the hole

$$E_F = -\mu(e^+) \quad [25]$$

Consequently, at thermal equilibrium, the negative of the chemical potential of the hole is equal to the chemical potential of the electron

$$-\mu(e^+) = \mu(e^-) \quad [26]$$

Equation [26] may be rewritten in the form

$$0 = \mu(e^-) + \mu(e^+) \quad [27]$$

It is this equation, expressing the Gibbs condition for thermal equilibrium between electrons and holes, that implies, from Eq. [15], the charged particle equilibrium equation

$$0 \rightleftharpoons e^- + e^+ \quad [28]$$

The conservation of charge condition is met. The conservation of mass is implied, and consequently

$$M(e^+) = -M(e^-) \quad [29]$$

Equation [28] can be demonstrated to have other properties of any equilibrium equation. According to Eq. [10], the equilibrium constant is the product of the electron and hole concentrations

$$C(e^-) C(e^+) = K_c \quad [30]$$

There are no reactants, only products. Equation [28] may be written in the reverse direction

$$e^- + e^+ \rightleftharpoons 0 \quad [31]$$

The equilibrium constant for this equation, according to the rules applying to all equations, is just the reciprocal of the equilibrium constant of the forward direction

$$\frac{1}{C(e^-) C(e^+)} = \frac{1}{K_c} = K_c' \quad [32]$$

There are no products, only reactants.

The equilibrium constant obtained from the band model is

$$C(e^-) C(e^+) = N_c N_v \exp(-\Delta E_{cv}/RT) \quad [33]$$

where ΔE_{cv} is the bandgap energy, $E_c - E_v$. One of the factors in the term N_v , appearing in the equilibrium constant, is the effective mass of the hole, a positive number. But the equilibrium constant is derived from the Gibbs condition and the equilibrium equation that imply the mass of the hole is a negative number. There is no contradiction. The mass occurring in the N_v term is obtained from a consideration of the dynamic properties of electrons in a nearly filled valence band. Newton's law is used. The hole has two masses, one obtained from its physical dynamic properties, the other from its chemical thermodynamic properties as expressed in an equilibrium chemical equation.

Experimental Confirmation

When photons of energy larger than the bandgap energy are absorbed by a semiconductor, excess electrons and holes are generated. There are a number of mechanisms by which the energy absorbed by the crystal is redistributed, but one process is the annihilation of electrons and holes, which may be represented by the equation

The energy of the photons emitted from a semiconductor by this process is the energy of the bandgap, ΔE_{cv} . If a hole had a positive mass, its annihilation, along with the annihilation of the electron, would generate a photon en-

ergy of approximately half a million electron volts rather than the bandgap energy of an order of magnitude of an electron volt. The annihilation of a hole proceeds by a chemical process analogous to the annihilation of a positron by an electron. But the hole must have a mass which is the negative of the electron mass.

Comments

The chemical thermodynamic significance of Eq. [1] can be underscored by noting that important thermodynamic functions can be obtained as functions of temperature for this reaction, such as the standard Gibbs energy (the bandgap energy), the standard enthalpy, the standard entropy, and the standard heat capacity (12). These thermodynamic functions, on the other hand, can be used to stimulate the conception of physical models for the fundamental processes occurring in a semiconductor crystal (13-15).

The conclusion has been reached that the mass of the hole is the negative of the mass of the electron. What is meant, the effective mass of the electron or the mass of the free electron? Pragmatically, it does not matter. Philosophically it does, and the question can be simply answered. The effective mass of the electron has potential-energy terms in it which make no contribution to the mass equivalence of the electron. The average velocity of the electron in the conduction band is so small compared to the velocity of light that this contributes no significant equivalent mass to that of a free electron. The mass of the hole is the negative of the mass of the free electron.

As a final point of clarification, the conservation of mass condition is only an approximation. It is the conservation of energy condition that is implied. But because the Gibbs energy released or absorbed in a chemical reaction under all circumstances of interest has a negligibly small mass equivalent, the conservation of energy condition becomes the conservation of mass condition. This is also true for chemical reactions involving electrons.

Conclusions

It is generally believed that chemical equations must be balanced, i.e., that the number of atoms of each kind on each side of the equation must be the same. This condition, in fact, does not apply to charged-particle equations in general and accounts for the fact that the formation equation of electrons and holes is not balanced with respect to particles. This equation

is a legitimate equilibrium chemical equation. A consequence is that in chemical reactions, the hole acts as if it had a mass that is the negative of the mass of the electron. The "convenient abstraction" of the hole has two masses. In chemical thermodynamic equilibrium reactions, it is the negative of the free electron mass; in physical dynamic processes, it is the effective mass, a positive number, the order of magnitude of the mass of a free electron.

ABSTRACT

Decomposition of trimethylgallium (TMG) and triethylgallium (TEG) in hydrogen and nitrogen atmospheres was studied by a quadrupole mass analyzer. The decomposition reactions of TMG in H_2 and in N_2 and of TEG in H_2 and in N_2 take place in the temperature ranges $370^\circ\text{--}460^\circ$, $450^\circ\text{--}570^\circ$, $220^\circ\text{--}330^\circ$, and $270^\circ\text{--}380^\circ\text{C}$, respectively. The reaction mechanisms are hydrogenolysis for TMG in H_2 , homolytic fission for TMG in N_2 , and β elimination for TEG in both H_2 and N_2 . The hydrogenolysis of TMG follows homogeneous first-order kinetics on TMG concentration.

Almost two decades have passed since the use of metal-organics as source materials for chemical vapor deposition (CVD) was first described in the preparation of III-V materials (1). Now, the metalorganics which spread throughout the periodic table of elements have been used for growth of III-V compounds (2-4) and II-VI compounds (5), doping to III-V compounds (6-8), microdeposition of metals (9), and so on. The nature of decomposition reaction of these metalorganics has also been studied (5, 10-13). It is important to investigate the reaction of metal-organics further to find the optimum condition for the growth, especially for the low temperature CVD of semiconductors, metals, and insulators.

The purpose of this paper is to describe mass spectrometric study of trimethylgallium (TMG) and triethylgallium (TEG) decomposition reaction in hydrogen and nitrogen atmospheres. The mass spectroscopy is of great advantage to both identification of species and quantitative analysis (14).

Experimental

An experimental apparatus made with a hot-wall reactor and an ANELVA AGA-360 quadrupole mass analyzer is shown in Fig. 1. The inner diameter of the reactor was 55 mm. The organometallics (TMG and TEG) were introduced into the reactor through a 65°C water-cooled quartz tube. Gas flow of hydrogen or nitrogen from the opposite side kept the reactor wall at the low temperature region clean, and its flow rate was 600 sccm (standard cubic centimeter per minute) throughout the experiment. Sampling of the reacted gas was done downstream at a temperature less than 100°C by means of a quartz pinhole adjusted to accomplish the pressure of 1×10^{-5} torr in the mass analyzer. Upstream from the sampling pinhole, quartz wool was set to prevent the pinhole being choked with higher paraffins ($C \geq 5$) produced from the TMG and the TEG. In the beginning of this experiment, the sampling was done in the reaction region and the pinhole was choked with liquid gallium. In contrast to the reaction in a hydride system (14), the decomposition reaction of TMG and TEG is frozen under a critical temperature, and this temperature was found to be higher than 200°C

in this study. Therefore, post sampling reaction (14, 15) is not a problem here. The sampled gas entered the ion source of the mass analyzer passing through a 3/32 in. id, 2m-long stainless tube at room temperature. Argon was added into the gas flow to compensate the signal intensity for changing condition of the ion source and the ion collector by taking the relative ion current to the ion current of mass 40.

Results and Discussion

Mass spectra of TMG and TEG in H_2 at room temperature are shown in Fig. 2(a) and 2(b). The flow rates of hydrogen (without the opposite flow) were 700 sccm in (a) and 670 sccm in (b). Those of TMG, TEG, and Ar were 7.7, 1.2, and 1.2 sccm, respectively. In Fig. 2(a), parent peaks of TMG are at masses 114 and 116, corresponding to a natural $^{69}\text{Ga}/^{71}\text{Ga}$ ratio of 3/2. Between Ga^+ and $\text{Ga}(\text{CH}_3)_3^+$, GaCH_3^+ and $\text{Ga}(\text{CH}_3)_2^+$ -related fragment peaks are observed. The peaks at masses 40 and 20 show the argon. Methyl ion at mass 15 reacts with H_2 , and CH_4^+ is formed in the ion source. Figure 2(b) shows parent peaks of TEG at masses 156 and 158. Between Ga^+ and $\text{Ga}(\text{C}_2\text{H}_5)_3^+$, GaC_2H_5^+ and $\text{Ga}(\text{C}_2\text{H}_5)_2^+$ are observed. The peaks of $\text{Ga}(\text{CH}_3)_2^+$ at masses 99 and 101 are higher than those of GaC_2H_5^+ . The fragments of GaCH_3^+ and $\text{Ga}(\text{C}_2\text{H}_5)\text{CH}_3^+$ are also observed. The signal of $\text{Ga}(\text{C}_2\text{H}_5)_2\text{CH}_3^+$ is very weak and not seen in the spectrum. Ethyl ion at mass 29 reacts

Fig. 1. Schematic of experimental apparatus

Fig. 2. Room temperature spectra of TMG and TEG in H_2

with H_2 , and $C_2H_6^+$ is formed in the ion source. No ethane was produced in the reactor at room temperature.

The relation between the normalized ion current ratio of mass 69 to mass 40 (unreacted TMG or TEG concentration normalized by that at room temperature) and the reaction temperature is shown in Fig. 3. The flow rates of H_2 , N_2 , TMG, TEG, and Ar were 670, 670, 4.6, 1.2, and 1.2 sccm, respectively. The pressures in the mass analyzer were 8×10^{-6} torr for H_2 and 1×10^{-5} torr for N_2 . The decomposition of TMG in H_2 took place at temperatures over $370^\circ C$ and was completed at $460^\circ C$. Those of TMG in N_2 , TEG in H_2 , and TEG in N_2 took place around temperature ranges of $450^\circ-570^\circ$, $220^\circ-330^\circ$, and $270^\circ-380^\circ C$, respectively. The temperature ranges of the TMG decomposition in both H_2 and N_2 agree with the study by infrared spectroscopy (13). TEG decomposed at lower temperatures than TMG, and the difference between H_2 and N_2 atmospheres in the TEG decomposition was less than that in the TMG decomposition.

The difference in the temperature range in which the decomposition reaction takes place means the difference in the reaction mechanism. To discuss this point, note is taken of hydrocarbons produced by the TMG and TEG decomposition. Figures 4(a) and (b) show mass spectra of TMG in H_2 at $450^\circ C$ and of TMG in N_2 at $550^\circ C$ in the mass range of 10-60. Figures 5(a) and (b) show those of TEG in H_2 and of TEG in N_2 at $300^\circ C$. In these measurements, the argon for the intensity reference was excluded to simplify the spectra.

Figure 4(a) shows that the TMG decomposition in H_2 produces methane (mass 12-16) and a small amount of ethane (mass 24-30). Propane (mass 37-44) and butane

Fig. 3. Relation between normalized ion current ratio of mass 69 to mass 40 and reaction temperature.

Fig. 4. Spectra of (a) TMG in H_2 at $450^\circ C$ and (b) TMG in N_2 at $550^\circ C$ in the mass range of 10-60.

(mass 50-58) observed in the spectrum were within background level of the analyzer. In contrast to TMG in H_2 , the TMG decomposition in N_2 produces methane, ethane, and propane, as shown in Fig. 4(b). Intense peaks at masses 14, 28, and 29 show $^{14}N^+$, $^{28}N_2^+$, and $^{29}N_2^+$. The peak at mass 30 equivalent to those at 26 and 27 in height shows ethane formation well. Therefore, it is concluded that the TMG decomposition in H_2 is hydrogenolysis which forms methane. The decomposition in N_2 is real pyrolysis, in which methyl radical formed by homolytic fission reacts with itself (forming ethane), TMG (forming methane or ethane), and products (forming propane and higher paraffins). The hydrogenolysis takes place at lower temperatures than the homolytic fission. The homolytic fission of TMG in H_2 also occurs as a subreaction. The radical mainly reacts with hydrogen forming methane, and a small amount of ethane is formed by radical-radical or radical-TMG reaction.

In Fig. 5, a noticeable feature in spectra is that the peak at mass 30 is small compared to the peaks at 26 and 27.

Fig. 5. Spectra of (a) TEG in H_2 and (b) TEG in N_2 at $300^\circ C$ in the mass range of 10-60.

Fig. 6. Plot for logarithm of normalized ratio of ⁶⁹Ga⁺/⁴⁰Ar⁺ vs. inverse of total flow rate.

This feature means that the TEG decomposition in H₂ and N₂ produces not ethane, but ethylene. Therefore, the reaction mechanism of the TEG decomposition in both H₂ and N₂ is not ethane forming hydrogenolysis or homolytic fission. The mechanism is β elimination (16) forming ethylene. The β elimination mechanism makes the decomposition temperature fairly lower. Probably, the peak at mass 30 comes mainly from the reaction between ethyl ion and H₂, or ethyl ion and TEG in the ion source. The slight difference in the decomposition temperature between TEG in H₂ and TEG in N₂ needs further discussion.

Figure 6 shows a plot for logarithms of the normalized ratio of ⁶⁹Ga⁺/⁴⁰Ar⁺ vs. inverses of the total flow (excluding the opposite flow) rate. The decomposition of TMG in H₂ at 450°C was measured. It should be noted that the increase in the total flow rate by 4.6 times, by means of adding H₂ flow, only shifted the high temperature region downstream without changing the value and the width of the reaction-temperature profile. That means the residence time for the reaction is proportional to the inverse of the total flow rate. Then, the linearity in Fig. 6 shows first-order reaction mechanism $-d[\text{TMG}]/dt = k[\text{TMG}]$. Over the total flow rate of 2200 sccm, the unreacted ratios of TMG (normalized ⁶⁹Ga⁺/⁴⁰Ar⁺ ratio) were larger than those on the linear relation, probably because the gas flow passed through the reaction region without perfect mixing at the high flow rates. Expansion of the quartz surface by 30 times, by means of putting 3g quartz wool (~8 μm φ) in the reaction region, caused only a slight shift (~10°C) of the curve for TMG in H₂ (in Fig. 3) to the higher temperature side. Therefore, it is concluded that the TMG decomposition in H₂ follows homogeneous first-order kinetics on TMG concentration.

The result gives suggestion for low temperature CVD of GaAs using TMG and TEG. The low temperature CVD of GaAs using TMG in H₂ (17-19) must also be limited by the decomposition of TMG.

Summary

The decomposition reactions of TMG in H₂ and in N₂ and TEG in H₂ and in N₂ take place in the temperature ranges 370°-460°, 450°-570°, 220°-330°, and 270°-380°C, respectively. The reaction mechanisms are hydrogenolysis for TMG in H₂, homolytic fission for TMG in N₂, and β elimination for TEG in both H₂ and N₂. The hydrogenolysis of TMG follows homogeneous first-order kinetics on TMG concentration.

Secondary Electron Effect on Electric Potential of Insulator Surface during Ion Implantation

Masahiro Yoshizawa, Masayasu Miyake, Hiroyuki Harada,* Kazuhide Kiuchi, and Satoshi Tazawa

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839, Ono, Atsugi-shi, Kanagawa Pref., 243-01, Japan

ABSTRACT

The effects of secondary electrons on the electric potential of a thick SiO₂ surface during ion implantation are studied by measuring the potential using MOSFET's. Secondary electrons emitted from electrodes on an ion-implanted SiO₂ layer reduce its potential. The potential decreases as the implantation energy increases, because secondary electron emission yield increases with implantation energy. The potential distribution is trapezoidal for a SiO₂ layer with secondary electron emission electrodes, while the distribution is parabolic for a SiO₂ layer without electrodes. The potential is slightly dependent on beam current when a large number of secondary electrons are emitted. The potential is proportional to $I^{0.68}$, where I is the beam current, if the secondary electron emission is negligible. A potential reduction method, which involves applying a negative voltage to a Faraday tube, is proposed for practical use.

Ion implantation has been widely and effectively used in LSI fabrication. Its basic disadvantage is that the electric potential on an insulator increases because of charging. The increase in potential can cause problems, such as the breakdown of the insulator layer, which results in gate leakage in MOSFET's.

A few studies have been reported on the potential or electric properties of an insulator during ion implantation (1, 2). Wada *et al.* (1) observed current paths for ion implantation into a quartz wafer and reported that the substrate current, the current which flowed through the substrate, was dominant when the insulator thickness was less than the projected range of the implanted ions. Mori *et al.* (2) studied the potential in a thick insulator layer in which the substrate current did not flow. In these previous studies (1, 2), the effect of secondary electrons has not been studied. It is well known that a metal emits a greater number of secondary electrons than incident ions during ion implantation (3, 4). These secondary electrons have a great influence on potential.

This paper reports on effects of secondary electrons on potential during ion implantation, particularly on the potential distribution in a SiO₂ layer and the potential dependence on beam current. First, secondary electron emission yield is examined. Then, the effect of secondary electrons on the potential is studied. Finally, a method of potential reduction using secondary electrons is described.

Experimental Procedure

Sample preparation.—A silicon dioxide layer on a silicon wafer was used as an insulator layer. The oxides used were grown on a 30 ~ 50 Ω-cm <100> p-type 3 in. silicon wafer to a thickness of 7500Å by wet O₂ oxidation or 1000Å by dry O₂ oxidation. A 1000Å dry oxide layer was prepared only for measuring potential when the substrate current was dominant. An unpatterned 1 μm-thick aluminum or 0.45 μm-thick arsenic-doped polysilicon electrode was deposited on the SiO₂ layer for secondary electron emission yield measurement. For the potential distribution measurement, aluminum stripe patterns were fabricated on the SiO₂ layer using photolithographic techniques.

A medium current ion implanter with an electrostatic scanning system was used. The vertical scan frequency was about 1 kHz and the horizontal scan frequency was 100 Hz. Potential dependence on the scan frequency was studied, and it was confirmed that the potential was independent of horizontal scan frequency above 30 Hz.

Potential measurement.—The potential of the electrode during ion implantation was measured using a MOSFET. Figure 1 shows the potential measurement method. This measurement method causes no disturbance of the poten-

tial distribution because of the high input impedance. The electrode for measurement is connected to the FET gate. A positive voltage (V_s) is applied to the FET source in order to protect it from breakdown. Bias voltage (V_D) is initially applied so that the drain current does not flow, then V_s is decreased till the suitable drain current flows. The difference between V_s and the electrode potential is determined from the drain current of the FET.

The SiO₂ surface potential was only about 1V when 150 keV boron ions were implanted into a 1000Å SiO₂ layer at a beam current of 5 μA. In this case, the projected range of the ions is larger than the thickness of the SiO₂ layer (5), and substrate current was confirmed to be dominant. Therefore, problems related to the induced potential would only occur when the insulator layer thickness was so thick that substrate current would not flow. It was confirmed that substrate current does not flow for boron implantation with less than 100 keV energy into a 7500Å SiO₂ layer at a beam current of 5 μA. The measurements of potential were performed mainly for a boron implantation energy of 50 keV into a 7500Å SiO₂ layer, so as to distinguish the effects of secondary electrons (SE's) from those of the substrate current.

Secondary electron yield measurement.—An unpatterned aluminum or polysilicon electrode was deposited on a 7500Å SiO₂ layer. The method of measuring the secondary electron yield is illustrated in Fig. 2. The implantation area is limited to the hatched area (3.5 × 3 cm²) in order to eliminate the effect of SE's emitted from an aluminum wafer holder. The ion implanter Faraday cup is used as a secondary electron collector, which collects SE's emitted from the electrode. The Faraday cup con-

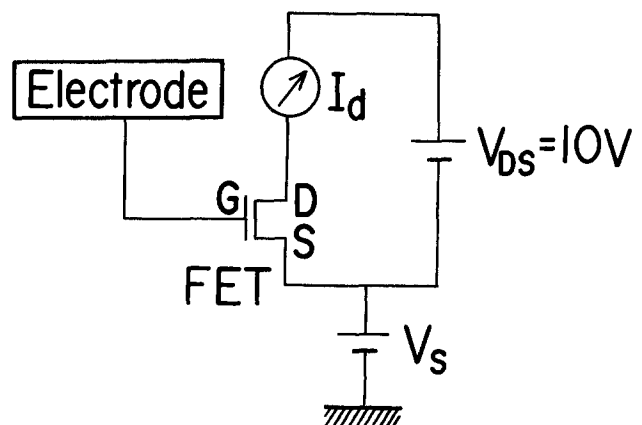

Fig. 1. The measurement method of the electrode potential using an FET. A bias voltage is applied to the FET source to protect it from breakdown. The difference between the electrode potential and the applied voltage is measured from the drain current of the FET.

*Electrochemical Society Active Member.

Fig. 2. The method of measuring the secondary electron yield. A Faraday cup is used for a secondary electron collector tube. A bias voltage (V_b) can be applied to the tube. A suppression voltage of $-300V$ is applied in front of the Faraday tube.

sists of the wafer holder and a tube (the tube is called a Faraday tube hereafter). A $-300V$ electron suppression voltage is applied to the suppression electrode in front of the Faraday tube in order to keep the SE's in the Faraday tube. Collector current (I_c) is due to the SE's, whereas electrode current (I_e) is due to both the incident ions and the SE's. Beam current (I_i) can be obtained as the sum of I_c and I_e . The secondary electron yield (γ) is defined by the ratio of I_c to I_i : $\gamma = |I_c/I_i|$. Secondary electron emission yield dependences on boron and arsenic ion implantation energy were measured for aluminum and polysilicon electrodes.

Potential distribution measurement of an insulator with secondary electron emission.—The potential distribution was measured using aluminum patterns with 7 stripe electrodes. Figure 3 shows two kinds of electrode patterns for measuring the effects of SE's on potential distribution. Pattern (a) has two secondary electron emission electrodes (S), which have wide areas, while pattern (b) does not have them. Stripe electrode width is 0.1 mm, and the distance between them is 1 mm. The electrodes (E) are earth electrodes, and the distance between electrodes (S) and (E) is 2 mm. The wafers were set so that the electrodes were parallel to the vertical scanning direction. The implantation area is limited to the hatched area ($3 \times 2.5 \text{ cm}^2$), so as to eliminate the SE effects from a wafer holder. Implantation area of electrodes (S), which emit SE's, is about 60% of the total implantation area. The potential distribution of the insulator is obtained by measuring the potentials of electrodes 1, 2, and 3 in patterns (a) and (b). The effects of SE's on the potential distribution were studied by comparing the potential of pattern (a) with that of pattern (b). Since the width of the potential measurement electrode is small, it is expected that the effects of SE's on potential distribution are negligible for pattern (b).

Fig. 3. The electrode patterns for measuring the effect of secondary electrons. Pattern (a) has secondary electron emission electrodes (S). Pattern (b) does not have them. Electrodes (E) are the earth electrodes. Stripe electrode width is 0.1 mm, and the distance between them is 1 mm. The distance between electrodes (S) and (E) is 2 mm.

Results and Discussion

Secondary electron yield.—Implantation energy dependences of secondary electron yields for aluminum and polysilicon are shown in Fig. 4. From this figure, it is found that (i) secondary electron (SE) yield increases with implantation energy, (ii) the yield for boron implantation is larger than that for arsenic implantation, (iii) the yield of the aluminum electrode is more than that of the polysilicon, and (iv) the number of SE's emitted from aluminum or polysilicon electrodes is more than, or about the same as, the number of incident ions. It was also confirmed that SE collector current (I_c in Fig. 2) was not observed when ions were implanted into a SiO_2 layer without an electrode.

It has been reported that kinetic emission is dominant in the velocity range above 10^7 cm/s , and the yield of the kinetic emission increases with incident ion velocity and decreases with work function of the material (3, 6). The velocity of a 25 keV arsenic ion is $6.6 \times 10^7 \text{ cm/s}$, which is the slowest velocity in the present work. Thus, secondary electrons are mainly due to the kinetic emission for the energy shown in Fig. 4. The difference between the yield of the boron ions and that of arsenic ions is caused by the velocity of boron ions being greater than that of arsenic ions at the same implantation energy. The yield difference between aluminum and polysilicon is caused by the difference of the work functions.

Secondary electron effects on insulator potential.—Potential distributions were obtained from potential measurements of electrodes 1, 2, and 3 in patterns (a) and (b) in Fig. 3. Figure 5 shows the potential distributions, where boron implantation was performed at 50 keV with a beam current of $0.5 \mu\text{A}$. The center electrode potential for pattern (a) is about 10 times less than that for pattern (b). The potential distribution for pattern (a) with secondary electron emission electrodes is trapezoidal, whereas that for pattern (b) without the electrodes is parabolic.

The potential distribution, when the effects of SE and those of substrate current are negligible, is parabolic as shown in the following equation (2)

$$V(X) = -\frac{iR_s}{2}(X-L)^2 + \frac{iR_sL^2}{2} \quad [1]$$

where R_s is the sheet resistance of the insulator layer, L is the distance between the earth electrodes, i is the beam density, and X is the distance from the earth electrode. The sheet resistance of the implanted SiO_2 layer is obtained by substituting the peak potential shown in Fig. 6 into Eq. [1]. The sheet resistance obtained is $6.5 \times 10^9 \Omega/\square$. A broken line in Fig. 5 was calculated using Eq. [1] and setting $R_s = 6.5 \times 10^9 \Omega/\square$. The difference between the po-

Fig. 4. Implantation energy dependences of secondary electron emission yield. Samples are grounded. Beam current is $1 \sim 1.5 \mu\text{A}$.

Fig. 5. The potential distribution on a SiO_2 layer for 50 keV. Boron implantation is performed at 50 keV with a beam current of $0.5 \mu\text{A}$. (a) Pattern with secondary electron emission electrodes (S). (b) Pattern without electrodes (S). The broken line is calculated using $R_s = 6.5 \times 10^9 \Omega/\square$ in Eq. [1].

tential distribution for pattern (b) and the calculated parabolic potential distribution is within 6%. Thus, it was confirmed that the SE effect was negligible for pattern (b).

Figure 5 indicates that a large number of SE's emitted from the aluminum electrodes decrease the potential and result in a trapezoidal potential distribution, since the number of SE's attracted to the insulator surface increases with surface potential.

Figure 6 shows center electrode potential dependence on the beam current. The potential for pattern (a) is less than one-tenth of that for pattern (b). The slope of the potential vs. beam current curve in pattern (b) is 0.68, and that in pattern (a) is 0.09. The potential for pattern (b) is greatly dependent on the beam current, whereas the potential for pattern (a) is slightly dependent on it. This difference is caused by the presence or absence of SE emission electrodes. Since the number of SE's increases with the beam current, potential dependence on the beam current is small for pattern (a) with SE emission electrodes.

Fig. 6. Beam current dependence of potential for a 50 keV B implant. (a) Pattern with electrodes (S), which emit many secondary electrons. (b) Pattern without electrodes (S).

Then, it was confirmed that SE's emitted from metal electrodes decreased the potential and resulted in a slight dependence of the potential on beam current.

The potential dependence on beam current for pattern (b) is mainly caused by a sheet resistance dependence on beam current, since the SE effect on potential is negligible for pattern (b). The obtained sheet resistance is in the order of $10^9 \Omega/\square$ and is proportional to $I^{-0.32}$, where I is the beam current. The electron hole pairs generated in the SiO_2 layer by ion beam irradiation increase with the beam current, which causes an increase in SiO_2 conductivity.

Method for potential reduction.—The number of SE's repelled back to a wafer varies with the bias voltage applied to the Faraday tube: a negatively biased tube repels the SE's to the wafer, and the positively biased tube attracts them. This variation of the number of SE's causes the insulator surface potential variation. Figure 7 shows bias voltage dependence of the potential of the center electrode 1 shown in Fig. 3(a). Boron ions were implanted in the pattern (a) at 50 keV with $5 \mu\text{A}$. An increase in V_b leads to an increase in the potential, since the number of SE's repelled back to the wafer decreases. Potential decreases with a decrease in the bias voltage and it has a minimum value at a bias voltage of about -10V . This fact indicates that the potential of a wafer can be reduced by applying a negative voltage to the Faraday tube.

Secondary electrons emitted from the secondary electron emission electrodes have three trajectories as shown in the upper left side of Fig. 7. In trajectory 1, the SE's are attracted to the Faraday tube. In trajectory 2, the SE's are attracted to their own electrodes. In trajectory 3, the SE's are attracted to the SiO_2 layer on the wafer. The potential of the SiO_2 surface is decreased by the trajectory-3 SE's. The number of SE's of trajectories 1, 2, and 3 are represented by n_1 , n_2 , and n_3 , respectively. The effective number of SE's emitted from the electrodes is $n_1 + n_3$. The potential has a minimum value as shown in Fig. 7. This fact indicates that n_3 has a maximum value. The reason for the presence of maximum value in n_3 is considered as follows. In the high positively biased region, n_3 becomes 0, since all SE's are attracted to the Faraday tube. In the high negatively biased region, n_3 also becomes 0, since SE's are no longer emitted from the electrodes, owing to high electric field. Since n_3 becomes 0 in both the limiting regions (the high positively and negatively biased regions) and has positive finite value in other regions, n_3 has a maximum value.

Secondary electron emission electrodes were fabricated in a wafer in the present experiment. Secondary electrons emitted from a wafer holder can be utilized for potential reduction in practical use, since the wafer holder is exposed to the ion beam by over scan.

In order to examine the effects of this potential reduction method, the potential of the insulated electrode at

Fig. 7. Potential dependence on bias voltage applied to a Faraday tube. The potential of electrode 1 for pattern (a) shown in Fig. 3 is measured.

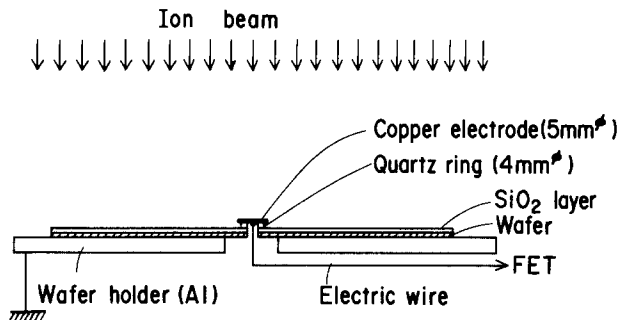

Fig. 8. The experimental arrangement for measuring potential of an insulated electrode at the wafer center. A center electrode made of copper is insulated by a quartz ring.

the wafer center was measured as illustrated in Fig. 8. A 7500Å oxide layer is grown on a 3 in. silicon wafer. The aluminum wafer holder area is $8 \times 8 \text{ cm}^2$, which is equal to the implantation area. The center electrode made of copper is insulated from the wafer by a quartz ring. The diameter of the ring is 4 mm, and that of the electrode is 5 mm. The SiO_2 layer area masked by the electrode, which is not irradiated by the ion beam, is not conductive. The potential of the wafer center is maximum in the wafer during ion implantation, because the distance between wafer center and wafer holder is maximum and only the SE's emitted from the holder can reduce the potential.

If we assume that no secondary electrons are emitted, the potential of a 3 in. wafer center with a SiO_2 layer can be estimated to be over 1000V using Eq. [1] and the order of $10^9 \Omega/\square$ sheet resistance. Further, the potential of the insulated electrode will become higher than 1000V. Figure 9 shows the insulated electrode potential dependence on the beam current as a function of implantation energy. Bias voltage was not applied to the tube. The potential is less than 30V and decreases with an increase in implantation energy, and slightly increases with the beam current. The fact that the resulting potential was less than the estimated value shows that the potential was decreased by the secondary electrons emitted from the wafer holder. The reason for this potential decrease with the implantation energy is an increase in SE emission from the wafer holder with the increase in implantation energy.

The potential becomes still smaller for practical ion implantation, since electrodes are not usually isolated from the SiO_2 layer and metal electrodes in the wafer emit SE's. However, it is necessary to reduce the SiO_2 surface potential even more to avoid problems such as gate leakage in MOSFET's. Figure 10 shows the insulated electrode potential dependence on the bias voltage applied to the Faraday tube, where boron ions were implanted at 50 keV with $5 \mu\text{A}$. The potential has a minimum value at a

Fig. 9. Potential dependences of beam current as a function of implantation energy for the insulated electrode at a 3 in. wafer center.

Fig. 10. Potential reduction by applying a negative voltage to a Faraday tube. Bias voltage dependence of the potential for the electrode illustrated in Fig. 8 is shown.

bias voltage of about -10V and slightly increases with a decrease in the bias voltage. This indicates that there is an optimum bias voltage to reduce the potential. The potential in Fig. 10 is more sensitive to bias voltage than that in Fig. 7, since the distance from the Faraday tube to the wafer holder is smaller than the distance to the secondary electron emission electrode in Fig. 7. This potential reduction method is advantageous in that the low potential can be maintained even when the ion beam is unstable, because the secondary electrons reduce the dependence of the potential on beam current.

Summary

The effects of secondary electrons on the electric potential of an insulator surface, during ion implantation, have been studied for an electrostatic scanning ion implanter. Results are summarized as follows.

1. Secondary electrons emitted from metal electrodes or a wafer holder during ion implantation decrease the insulator potential and result in a trapezoidal potential distribution. Secondary electrons also result in a slight dependence of the potential on beam current.

2. The potential distribution on an SiO_2 layer surface is parabolic, when the effect of the secondary electrons is negligible. In this case, the potential is in proportion to $I^{0.68}$, where I is the beam current. The sheet resistance of SiO_2 during ion implantation is on the order of $10^9 \Omega/\square$ in the beam density range of $0.01 \sim 1 \mu\text{A}/\text{cm}^2$.

3. The maximum potential of an insulated electrode on a 3 in. wafer is measured in the $1 \sim 30 \mu\text{A}$ beam current range when ion implantation is performed with overscan. The potential is less than 30V and decreases with the implantation energy, owing to the secondary electrons emitted from a wafer holder.

A potential reduction method, which employs applying a negative voltage to a Faraday tube, is proposed for practical use. This potential reduction method is advantageous in that low potential can be obtained even when the beam current is unstable, because the secondary electrons result in only a weak dependence of insulator potential on beam current.

ABSTRACT

The photocurrent increase as a function of the illumination time of a CdS film in contact with basic aqueous solutions, in the absence and in the presence of cysteine 1M, is correlated to the intensity of the X emission of Cd and S in XRFS and of O in LEEIXS. The evolution of the photocurrent spectra is also examined. This correlation and the comparison of the X emission spectra of O of illuminated CdS with those of CdO and Cd(OH)₂ indicate that the CdS photosensitivity increase is due to hydroxylated intermediates of the CdS photocorrosion. CdO, an end product of the photodegradation, is responsible for the slow photocurrent decrease, which occurs after longer irradiation times of the junction.

The photoanodic behavior of CdS electrodes in contact with different redox electrolytes has been extensively studied (1). The main limiting factor for these systems is the CdS photocorrosion (2). The authors have studied previously the photoelectrochemical behavior of amorphous and polycrystalline CdS films in contact with basic aqueous solutions of sulfur organic reducing agents (3). Although the photocorrosion is not inhibited by these reductants, an interesting characteristic was observed with cysteine (3a, b): as a function of the illumination time of the CdS-solution junction under a constant applied bias, the photocurrent increases by a factor of 3-4, reaches a maximum, and then decreases slowly. XPS analyses of the electrode surface showed that this photosensitivity increase is not related to the photoelectrochemical attachment of cysteine on the surface (3b). The comparison of the photoelectrochemical behavior of the amorphous CdS films in H₂O/NaOH alone and in H₂O/NaOH/cysteine 1M suggested that the chemical modification of the electrode would originate from the accumulation of oxygen derivatives of Cd on the surface (3b). However, no direct experimental evidence had been obtained in favor of specific oxygenated compounds. In this paper, in order to determine the chemical species responsible for the photosensitivity increase, the illuminated electrodes are analyzed by complementary techniques, such as x-ray fluorescence spectrometry (XRFS), XPS, and low energy electron-induced x-ray spectrometry (LEEIXS), and the results are correlated with the photocurrent evolution.

Experimental

Photoelectrochemistry.—CdS film preparation by chemical precipitation and photoelectrochemical methodology have been described previously (3a, b). The CdS film thickness is of the order of 1.8 μm. The amorphous CdS precipitates on a conducting SnO₂ layer of 0.32 μm deposited on a glass support. The surface analyses are

performed on electrodes illuminated during different times, with a 2000W quartz-halogen lamp (Osram 64788) and under an applied bias of 0V (SCE). Only a part of the beam is focused on the samples. The light intensities are measured with a solarimeter Kipp & Zonen CM 5/6. After irradiation, the electrodes are washed in H₂O/NaOH pH 14, rinsed with tridistilled water, dried in a dessicator, and analyzed by the various techniques.

The photocurrent spectra, after different polychromatic illumination times, are recorded with a high intensity Bausch & Lomb monochromator and a quartz-halogen lamp with dichroic mirror (Philips 13117). They are corrected, taking into account the emission spectrum of the lamp.

The thermal treatment of CdS to form CdO has been examined in the literature (4). In this case, the CdS electrodes are put in an oven at 110°C during variable times. This treatment leads to a bathochromic shift of the absorption spectrum of the film. Subtraction of the spectra before and after the treatment gives an absorption spectrum with a λ_{max} around 500 nm. The CdS absorption spectrum shifts bathochromically as a function of the heating time in the oven. After 10h, however, the bathochromic shift has reached its maximum value of 15 nm.

LEEIXS.—A detailed description of the LEEIXS instruments has been given elsewhere (5-9). Only the basic principles of such an apparatus will be mentioned here. It consists of a wavelength-dispersive x-ray fluorescence spectrometer equipped with a cold cathode tube (CCT). This gas-discharge tube is an open-window device which operates directly in the primary vacuum of the spectrometer. Normal operating vacuum is 1.5 × 10⁻² torr. The CCT is used to bombard the sample surface with a monoenergetic electron beam selectable over the range 0.5-5 keV. The beam spot size at the surface is limited by the aperture of the anode. Typically, this spot is 1 cm in diameter. For a given accelerating voltage, the current is stabilized by an automatic pressure regulator in the range from

*Electrochemical Society Active Member.

0 to 2 mA. Both voltage and current are digitally controlled during the experiment. The soft x-ray spectrometer employed in the present measurements uses flat analyzing crystals or pseudocrystals. The detector is a flow-proportional counter with an ultrathin ($0.5 \mu\text{m}$) polypropylene window and an argon-methane (P-10) flow gas at atmospheric pressure. The bombarding electron-beam incidence angle is 70° and the takeoff angle for x-rays is 35° .

The effective analysis depth of LEEIXS is determined by the material thickness at which characteristic x-rays are produced within the sample. Obviously, this depends on the target material, the energy and the incidence angle of the electron beam, and the x-ray takeoff angle. Typically, the information depth is in the range of some hundred angstroms.

XRFS.—X-ray fluorescence is the conventional x-ray emission technique. This simple spectrochemical technique is usually regarded as a bulk analytical method. Actually, it is also a near-surface analysis technique when the x-rays, emitted and detected, originate from a near-surface layer of finite thickness. The instrument employed in this work (Philips PW 1540) is a flat-crystal spectrometer equipped with a flow-proportional counter using the P10 gas flow. The x-ray tube used has a chromium target.

XPS.—The XPS measurements are performed with a vacuum generators-CLAM 100 ESCA spectrometer using nonmonochromatic $\text{AlK}\alpha$ radiations (1486, 6 eV). The carbon C1s binding energy of contamination (285 eV) is used for calibration. Measurements are carried out at a pressure of less than 2×10^{-9} torr in the spectrometer vessel. Sample etching is performed in a preparation chamber by 5 keV argon ions. The density of the ion current is approximately $10 \mu\text{A}\cdot\text{cm}^{-2}$ at the sample surface.

Results and Discussion

Figure 1 shows the photocurrent density as a function of the polychromatic illumination time, at a bias of 0V (SCE), with $\text{H}_2\text{O}/\text{NaOH}$ alone and with $\text{H}_2\text{O}/\text{NaOH}/\text{cysteine}$ 1M. Eight electrodes per photocurrent-time curve, all prepared in the same precipitation bath, have been illuminated, each one in the same conditions but during different times, and analyzed by XRFS, XPS, and LEEIXS.

XRFS.—Because the thickness analyzed by XRFS is of the order of a few micrometers to a few millimeters, this technique gives information on the elementary chemical composition of the CdS film and of the SnO_2 coating the glass support (see Experimental section). Figures 2 and 3 show the results of the XRFS analyses of electrodes irradiated in $\text{H}_2\text{O}/\text{NaOH}$ alone and in $\text{H}_2\text{O}/\text{NaOH}/\text{cysteine}$ 1M. The $\text{CdL}_{\beta}/\text{SnL}_{\alpha}$ emission ratios decrease in both cases as a function of the irradiation. This corresponds to a slight

Fig. 1. Photocurrent density as a function of the polychromatic illumination time with (A) $\text{H}_2\text{O}/\text{NaOH}$ and (B) $\text{H}_2\text{O}/\text{NaOH}/\text{cysteine}$ 1M.

Fig. 2. Intensity ratio of $\text{CdL}_{\beta}/\text{SnL}_{\alpha}$ and $\text{SK}_{\alpha}/\text{CdL}_{\beta}$ in XRFS for the electrodes illuminated in contact with $\text{H}_2\text{O}/\text{NaOH}$ pH 14.

Fig. 3. Intensity ratio of $\text{CdL}_{\beta}/\text{SnL}_{\alpha}$ and $\text{SK}_{\alpha}/\text{CdL}_{\beta}$ in XRFS for the electrodes illuminated in contact with $\text{H}_2\text{O}/\text{NaOH}/\text{cysteine}$ 1M, pH 14.

decrease of the CdS film thickness, which indicates that the electrode photodegradation is not inhibited by cysteine, as already found (3a). The $\text{SK}_{\alpha}/\text{CdL}_{\beta}$ ratio decreases on irradiating in the absence of reductant, whereas it remains quasi constant with cysteine. This is incompatible with a production of sulfur S^0 from the photoanodic decomposition and indicates that the sulfur is further oxidized into sulfate (3b, c, d) and solubilized. A Cd enrichment of the film in contact with NaOH alone could be responsible for the $\text{SK}_{\alpha}/\text{CdL}_{\beta}$ decrease. The Cd^{2+} ions liberated from the lattice would thus remain in the film as $\text{Cd}(\text{OH})_2$ or CdO. On the other hand, the addition of cysteine solubilizes the Cd^{2+} into cadmium cysteinate, very soluble in basic solution (3a, b), which explains the constancy of the $\text{SK}_{\alpha}/\text{CdL}_{\beta}$ ratio in this case.

XPS.—The XRFS data are not inconsistent with the formation of $\text{Cd}(\text{OH})_2$ or CdO in the film as a function of the illumination with NaOH alone. This could also be the case with cysteine; however, the oxygenated cadmiums would be formed to a lesser extent through the film and still not detected by XRFS. The detection of some chemical changes more localized near the surface requires XPS analyses which allow investigation of about 5 nm of the film.

The electrodes supposedly most modified chemically, i.e., the ones which have reached the maximum photocurrent with cysteine, were thus examined by XPS. The characteristics are studied as a function of depth, thanks to an ion sputtering. Figures 4 and 5 show the modifications of the Cd 3d and S 2p photopeaks, respectively, as a function of the sputtering time. The occurrence of a Cd 3d $_{5/2}$ binding energy splitting can result from two factors acting either separately or simultaneously: a chemical effect due to a modification of the cadmium atom environment or a charging effect resulting from the isolating nature of one of the chemical species. In order to eliminate this ambiguity, the study of the Auger parameters (10) can be useful. An Auger parameter for a given atom is equal to the difference between the kinetic energy of the Auger line and the photoelectron peak

Fig. 4. Evolution of the Cd 3d signals in XPS as a function of the sputtering time of the CdS electrode illuminated in contact with cysteine 1M.

energy; it allows determination of the sample chemical nature during an in-depth profiling, independently of the charging effects. The Cd 3d5/2 and S 2p binding energy differences and the oxygen Auger parameters ($O_{1s} - O_{KLL}$) for different standards and for the CdS electrode, at different ion sputtering times, are listed in Table I. These values have been measured from data obtained within a minimum x-ray irradiation time (less than 150s) to prevent or minimize any possible x-ray damage of the sample (11). For the CdS electrode, the binding energy of the main Cd 3d5/2 photopeak (≈ 404 eV) is associated with the sulfide. Figure 5 and Table I show the presence at the electrode surface of cadmium sulfide, cadmium sulfate in small amount, and cadmium hydroxide. After a 5 min sputtering, the CdSO₄ disappears and the Cd(OH)₂ and CdS remain present within the total sputtered layer.

Consequently, even with cysteine, a new Cd species, Cd(OH)₂, is formed.

LEEIXS.—Because Cd(OH)₂ and probably CdO occur on the films, the OK_α emission in LEEIXS of all the illuminated samples was analyzed. With this technique, for the OK_α signal and for an incident electron-beam energy of 3.5 eV, about 120 nm of the CdS film is analyzed.

The identification by LEEIXS of an oxygenated product at the surface must be performed by comparison with spectra of reference products. Therefore, the oxygen X emission spectra of CdO and Cd(OH)₂ have been recorded (Fig. 6). For CdO, the OK_α band is fairly symmetric, whereas the one for Cd(OH)₂ is characterized by a low energy shoulder (518 eV). Furthermore, Fig. 6 shows also that Cd(OH)₂ is unstable under the electron beam and that it changes rather quickly into CdO. The cadmium hydroxide decomposition into cadmium oxide is obviously associated with a OK_α intensity decrease. The OK_α spectra for electrodes illuminated in the presence of the reductant are shown in Fig. 7; they are similar to the ones for electrodes illuminated in absence of the reductant. They present the characteristics of the Cd(OH)₂ spectrum, *i.e.*, the shoulder at low energy and its disappearance as a function of the analysis time. The illuminated electrode surfaces are thus enriched in a Cd(OH)₂ type compound.

Then examined was the correlation between the intensity of the OK_α line and the changes of photocurrent *vs.*

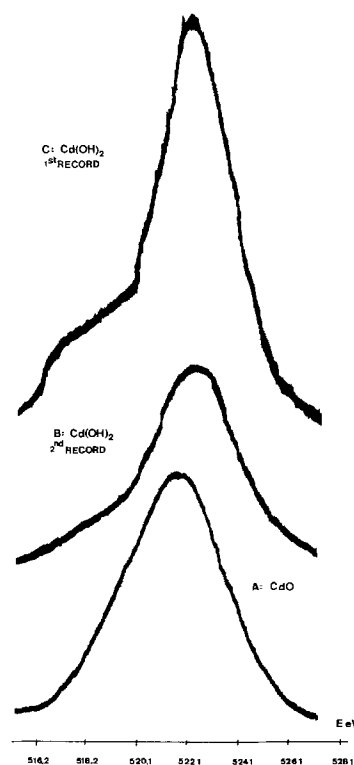

Fig. 6. Oxygen K_α emission spectra in LEEIXS for CdO and Cd(OH)₂ samples. (A) CdO. (B) Cd(OH)₂, second record. (C) Cd(OH)₂, first record.

time, without and with cysteine. Figures 8 and 9 show the evolution of the OK_{α} line intensity as a function of the illumination time, with $H_2O/NaOH$ alone and with cysteine, respectively. The curves a, b and c correspond to three successive countings of 20s. In both figures, the photocurrent increase corresponds to an intensity increase of the OK_{α} line; however, the photocurrent decrease does not correspond to any decrease of the OK_{α} signal. With NaOH alone, the OK_{α} intensity is more or less constant

Fig. 8. Three successive countings of 20s (a, b, c) of the OK_{α} signal in LEEIXS as a function of the illumination time of CdS in contact with NaOH alone. Dotted line: photocurrent evolution as a function of the illumination time, with NaOH alone.

Fig. 9. The same as Fig. 8, but as a function of the illumination time with cysteine 1M.

for successive countings, with differences of 12% at most at the times near the maximum photocurrent. On the other hand, with cysteine, the OK_{α} line decreases with the successive countings, with a difference as high as 50% at times close to the maximum photocurrent. This shows that $Cd(OH)_2$, unstable under the electron beam, would be present on the electrodes illuminated with cysteine, whereas CdO, stable under the electron beam, would correspond to the main species formed on the electrodes irradiated with NaOH alone.

If we compare Fig. 8 and 9, it is observed that for the illuminations with NaOH alone, corresponding to lower photocurrents, the OK_{α} intensities are higher and, as mentioned above, they do not vary as the photocurrent. For the illuminations with cysteine, it is clear also that the photocurrent does not follow the OK_{α} signal, but increases with the variations of the OK_{α} intensities in the successive countings. Consequently, the photocurrent increase would be related to the increase of a $Cd(OH)_2$ -type compound on the surface. This would be an intermediate component formed during the CdS photoanodic decomposition, which is present in greater amount with cysteine than with NaOH alone. On the other hand, the higher stability of the OK_{α} signal would be correlated to the photocurrent decrease and, thus, to the formation of CdO.

Photocurrent spectra.—We confirmed the conclusions from the XRFs, XPS, and LEEIXS by *in situ* analyses of the interface, such as photocurrent spectra. The evolution of the photocurrent spectra as a function of the polychromatic illumination does not depend very much on the presence of cysteine 1M. During the photocurrent increase, under white light, the photocurrent spectra recorded from 400 to 550 nm increase also in intensity, more so with cysteine than with NaOH alone. When they are normalized at 450 nm for short illuminations, only the disappearance of a slight absorption around 515 nm is observed (see further); otherwise during the photocurrent increase there are no important changes from one spectrum to the other. This indicates that the CdS photosensitivity enhancement is not related to the formation on the electrode of a product which absorbs in the visible region. This is in agreement with the LEEIXS analyses indicating the occurrence of a $Cd(OH)_2$ type compound which is colorless.

As shown by Fig. 10, near the maximum photocurrent and during the photocurrent decrease, the normalized spectra change: the photocurrents decrease at shorter wavelengths, with a bathochromic shift of the absorption edge. The changes are the same with cysteine, though to a

Fig. 10. CdS action spectra normalized at 450 nm as a function of the polychromatic illumination time at 0V (SCE). The analyzed samples are indicated on the curve photocurrent vs. the illumination time (4, 5, 6).

lesser extent. The bathochromic shift and the increase of the electron-hole recombinations at the surface, responsible for the photocurrent decreases at short wavelengths, could be attributed to the occurrence of CdO in the CdS lattice. The CdO bandgap differs throughout the literature [e.g., 590 nm (12); 500 nm (13)]. The authors obtained for a CdO powder an absorption λ_{max} of 540 nm. Because the gap of the CdS powder corresponds to about 510 nm, the formation of CdO in the CdS is thus compatible with these spectral data and in agreement with the LEEIXS conclusion.

In order to characterize better the CdS films enriched in CdO, thermally oxidized CdS (see Experimental) was prepared and its photoelectrochemical behavior was studied. The photocurrent spectra in NaOH, before any illumination, show that the thermal treatment shifts bathochromically the absorption edge (Fig. 11). The subtraction of the spectrum of the untreated electrode from the one of the treated CdS gives an absorption maximum around 515 nm which increases with the duration of the thermal treatment. Figure 12 shows for a thermally oxidized film the action spectra before illumination and after an irradiation corresponding to the maximum photocurrent. The evolution of the spectra is similar to that described for the untreated CdS. The absorption initially present at 515 nm, characteristic of the thermally generated CdO, disappears after illumination. Moreover, the longer the thermal treatment, the lower is the initial photocurrent in the first seconds of the polychromatic illumination, indicating some blocking of the electrode by CdO.

The experiments with thermally oxidized CdS films clearly indicate that the thermal CdO is different from the one formed photoelectrochemically. The thermal CdO probably forms a superficial film on the CdS, which disappears photoelectrochemically during the CdS photocorrosion. Besides, as mentioned above, this CdO film is also detected on the untreated electrode, before the polychromatic illumination. On the other hand, the photoelectrochemical CdO would form a mixed CdS-CdO lattice which penetrates deeper into the film and starts inhibiting the photoelectrochemistry.

Conclusion

The surface chemical analyses and photocurrent spectra lead to the conclusion that the photocurrent enhancement as a function of the illumination time, under a bias of 0V (SCE), is due to the accumulation of an intermediate species of the CdS photodegradation, which favors the electron transfer at the semiconductor-liquid interface. This species corresponds to Cd(OH)₂ or derivatives

Fig. 11. Action spectra normalized at 450 nm of CdS in contact with H₂O/NaOH pH 14. (a) reference CdS; (b) CdS treated 30 min at 110°C; (c) CdS treated 22h at 110°C.

Fig. 12. Action spectra normalized at 450 nm of CdS in contact with H₂O/NaOH/cysteine 1M, pH 14, treated 22h at 110°C. (a) spectrum before the polychromatic illumination; (b) spectrum when the photocurrent under white light at 0V (SCE) has reached the maximum value

of hydroxylated cadmium which are converted into a final product: CdO. The accumulation of CdO within the CdS lattice leads to the slow photocurrent decrease. The greater amount of oxygenated cadmium in the samples illuminated in NaOH alone, as evidenced by LEEIXS, is mainly due to CdO, responsible for the lower photocurrents in NaOH compared to those with cysteine. It has to be noted that elemental sulfur has not been detected by XPS and LEEIXS during the blocking of the electrode surface.

The nature of the CdS chemical modification is not influenced by cysteine. However, this reductant does play a role. Indeed, in its presence, the photocurrent increase is more pronounced and more Cd(OH)₂-type species are formed. The reductant would thus stabilize the degradation intermediate responsible for the photosensitivity increase, or in other words, would decrease the rate of formation of CdO from Cd(OH)₂ within the CdS lattice. If Cd²⁺ ions are liberated from the lattice during the photocorrosion, in the presence of cysteine 1M, these ions would rather solubilize into cadmium cysteinate than precipitate on the electrode as Cd(OH)₂. However, the greater amount of Cd(OH)₂-type species with cysteine than with NaOH alone would suggest that the hydroxylated species look more like hydroxylated cadmiums still belonging to the CdS lattice than like precipitated Cd(OH)₂.

There are two possible explanations for the photosensitivity increase due to hydroxylated cadmiums: (i) as already proposed previously (3a, b), a passivation of surface states related to cadmium's dangling bonds, by reaction with OH⁻ ions, similar to Heller's interpretation (14) for Ru³⁺ on GaAs; and (ii) a higher rate of photo-oxidation of cysteine on an hydroxylated CdS surface.

Sidewall Tapering in Reactive Ion Etching

A. G. Nagy

Motorola, Incorporated, SPS, Process Technology Laboratory, SRDL, Phoenix, Arizona 85008

ABSTRACT

This paper reports for the first time the existence of a sidewall tapering phenomenon in reactive ion etching (an oxide process in a commercially available hex-type system) which is akin to that seen in sputter etching or ion milling. A facet forms in the photoresist mask because of an angular dependence of the resist loss rate. The facet angle is about 16° off vertical, and its downward propagation rate is more than twice the vertical etch rate of the resist. If this facet is allowed to reach the etching material during the course of the etch, it will replicate significantly into this material. When an initially vertical unmasked silicon step is exposed to the same oxide etch process, an identical facet is formed. However, when a bare silicon dioxide step is exposed to the process, no faceting is seen.

Close examination of the profiles of certain samples after silicon dioxide etching in a conventional reactive ion etching (RIE) system has shown a taper of slightly more than 15° off vertical (75° sidewall angle). This paper will examine some of the possible causes of this tapering.

In the past, slight tapering of a feature etched by RIE was not considered a serious problem, and indeed may even aid subsequent step coverage. However, current interest in processes such as selective epitaxy (1), and schemes where a sidewall mask is needed, such as sidewall masked isolation (SWAMI) (2) and self-aligned silicide processes (3), all of which require vertical sidewalls, demands that the causes of RIE-induced tapering be investigated.

In reactive ion etching, the chemical etch process is assisted by ion bombardment normal to the substrate, such that the resulting etch rate is higher than would be expected from simply superimposing a physical sputtering mechanism onto the chemical etch process (4). This bombardment-assisted mechanism, which is believed to be responsible for most of the anisotropy in RIE, leads one to expect vertically etched profiles, contrary to what has been observed here.

Tapering has been observed in ion milling or sputter etching (in which material removal is by physical sputtering only) when initially vertical steps are milled at normal incidence (5), and tilting a sheet film relative to the ion beam at the sidewall taper angle usually gives the highest milling rate. It has never been reported whether the ion-assisted process in RIE shows a similar angular dependence.

Three possible causes of the observed tapering were investigated: an initially tapered mask profile reproducing itself into the etching film, a lateral pull-back of the mask during the course of the etch, and replication into the etching film of a facet (akin to that seen in ion milling) formed in the mask during the course of the etch. The first two causes are well known and have, in fact, been

used in RIE to generate tapered vias for improved step coverage (6).

The tapering phenomenon was studied in a hex-type RIE system using photoresist, silicon, and silicon dioxide samples. An explanation of the phenomenon is presented, and a solution is proposed.

Equipment, Samples, and Experimental Methods

A fluorine-based ($\text{CHF}_3 + \text{O}_2$) oxide etch process in a hex-type reactor was used in this work because it is in this system that the tapering was first seen. The hex-type configuration gives a very large anode-to-cathode area ratio, resulting in a high degree of ion bombardment. The oxide etch rate in this process is 550 Å/min, the silicon etch rate is 110 Å/min, and the photoresist loss rate is 170 Å/min.

Tapering in positive photoresist, single-crystal silicon, and thermal oxide samples was studied. The degree of tapering was determined through the use of cross-sectional photos taken with a scanning electron microscope, and some of the processes were modeled using SAMPLE (7), a computer program which simulates dry etch processes and prints the resulting profiles.

Results and Discussion

The following three sections examine in turn each of the possible causes of tapering mentioned in the introduction. A solution to the problem is proposed. In the third section, a mechanistic explanation of the phenomenon based upon the fundamental differences between silicon dioxide, silicon, and organic etching is presented.

Initial mask taper replication.—It is well known that conventional photolithography does not produce vertical resist edge profiles. Figure 1a shows a rather extreme example of a tapered resist profile, approximately 1.0 μm of patterned resist sloped about 45°, masking a 1.5 μm thick thermal oxide film. Figure 1b shows the film after etch-

Fig. 1. a(top): $1.0\ \mu\text{m}$ photoresist over $1.5\ \mu\text{m}$ thermal oxide prior to oxide etch. 45° resist taper. b(bottom): Above wafer after 50 min oxide etch, resist removed. Approximately 16° oxide taper.

ing in the reactor for 50 min (mask has been stripped). The sidewall taper is about 16° off vertical.

To help determine if mask taper replication is a major cause of feature sidewall tapering, the etching of an oxide film beneath a tapered mask was modeled using SAMPLE for the following conditions: oxide thickness of $1.5\ \mu\text{m}$; resist thickness of $1.0\ \mu\text{m}$; opening width at base of mask of $1.25\ \mu\text{m}$; oxide vertical etch rate of $550\ \text{\AA}/\text{min}$; oxide lateral etch rate of $0\ \text{\AA}/\text{min}$; resist vertical loss rate of $170\ \text{\AA}/\text{min}$; resist lateral loss rate of $0\ \text{\AA}/\text{min}$; mask selectivity of 3:1; etch time of 50 min; and resist taper of 45° .

Figure 2 shows the printout of this modeling. The oxide taper after etch is 15° . Figure 3 shows the profile which results when a more realistic resist taper of 30° is used in the modeling with all the other parameters held constant. The sidewall taper is now 10° .

Selectivity of the etching film relative to the mask was also suspected to be a major factor in mask taper replication, so a selectivity of 6:1 was next substituted for the 3:1 value in the modeling. Figure 4 shows that the resultant sidewall angle is now 7.5° . This illustrates that there is a strong relation between the final etch profile and the selectivity, and, indeed, that under ideal conditions, the final taper angle in the film is simply the mask taper angle divided by the selectivity value.

Consequently, a large mask selectivity may be expected to give relatively vertical etch profiles, even if the mask is severely tapered. SAMPLE modeling of the etch of an oxide film masked with 45° tapered resist assuming a (unrealistic) 20:1 selectivity revealed virtually vertical oxide sidewalls.

Though vertically etched sidewalls can, in principle, be produced by using a highly selective etch, it is usually

Fig. 2. SAMPLE modeling of 50 min etch of $1.5\ \mu\text{m}$ oxide masked with $1.0\ \mu\text{m}$ resist, tapered 45° . Selectivity: 3:1. Final oxide taper: 15° .

Fig. 3. SAMPLE modeling of 50 min etch of $1.5\ \mu\text{m}$ oxide masked with $1.0\ \mu\text{m}$ resist, tapered 30° . Selectivity: 3:1. Final oxide taper: 10° .

Fig. 4. SAMPLE modeling of 50 min etch of $1.5\ \mu\text{m}$ oxide masked with $1.0\ \mu\text{m}$ resist, tapered 45° . Selectivity: 6:1. Final oxide taper: 7.5° .

very difficult to make large changes in selectivity within the framework of an established process. Therefore, the possibility that tapered etching can be eliminated by using a mask with vertical sidewalls, a modification which at least in principle is feasible, was next studied. A $1.5\ \mu\text{m}$ thermal oxide film, patterned with approximately $1.0\ \mu\text{m}$ of resist using a standard tri-level technique (8) to ensure vertical resist profiles (Fig. 5) was etched for 50 min in the reactor. Figure 6 shows that a 15° taper, which SAMPLE does not predict, forms in the oxide. This implies that initial resist taper, while it is a factor, is not nec-

Fig. 5. $2.0\ \mu\text{m}$ tri-level resist patterned over bare silicon

essarily the dominant cause of tapered etch profiles, and that some other mechanism is clearly operating.

Lateral resist loss during etching.—Lateral erosion of the resist mask during anisotropic oxide etching could plausibly result in tapered sidewalls. Fluorine is believed to catalyze the surface reaction of oxygen with organic materials (9), which could lead to lateral resist loss.

Figure 7 shows a SAMPLE-generated profile of a $1.5 \mu\text{m}$ thick oxide film patterned with $1.5 \mu\text{m}$ of vertical-walled resist with a $100 \text{ \AA}/\text{min}$ isotropic loss rate, meaning that both the vertical and horizontal resist loss rates were equal. The resist thickness and loss rate were chosen rather arbitrarily, as was the $500 \text{ \AA}/\text{min}$ oxide etch rate. A 10° oxide sidewall taper results.

An experiment was next performed to determine if significant lateral resist loss was occurring during the oxide etch process. $2.0 \mu\text{m}$ thick resist was patterned on bare silicon using the tri-level technique. The sample was then exposed to the etch process for 105 min. Figure 8 shows that, instead of a uniform lateral pull-back of the resist, a tapered profile results. The resist taper angle is 16° , and that of the underlying silicon is slightly greater (about 19°). Given the silicon and resist etch rates in this process, the relation between the resist and silicon taper angle is not surprising.

The above results show that the resist loss process is not isotropic, meaning that lateral resist erosion is not the cause of tapered etching.

Faceting in the mask.—The resist taper shown in Fig. 8 looks very much like that seen in ion milling, in which tapered profiles result in the film being milled if the facet produced in the mask is allowed to reach this film during the course of the run (5). An analogous phenomenon has apparently occurred in Fig. 8, as evidenced by the taper in the underlying silicon.

To cure the tapering problem in ion milling, the mask thickness and run time are chosen such that the facet does not reach the underlying material during the run. The result of etching a tri-level patterned resist-over-

Fig. 7. SAMPLE modeling of $1.5 \mu\text{m}$ oxide masked with $1.5 \mu\text{m}$ vertical-walled resist. Resist lateral loss rate = resist vertical loss rate = $100 \text{ \AA}/\text{min}$. Mask selectivity: 5:1. 10° final oxide taper.

Fig. 8. Tri-level patterned resist over silicon after 105 min exposure to oxide etch process. Final resist taper: 16° . Silicon taper: 19° .

Fig. 9. Tri-level patterned resist over silicon after 50 min exposure to oxide etch process. Facet propagation rate: $310 \text{ \AA}/\text{min}$.

silicon sample for 50 min is shown in Fig. 9. The facet has not propagated all the way through the mask, leaving a vertical sidewall to protect the underlying silicon.

Knowing how far the facet has moved through the resist allows the facet downward propagation rate to be easily determined: $310 \text{ \AA}/\text{min}$, nearly twice the vertical etch rate. At this point, it should be mentioned that the high measured facet propagation rate explains the magnitude of the taper seen when etching an oxide film masked with vertical resist in relation to the apparent mask selectivity. While the ratio of the oxide etch rate to the vertical resist loss rate is about 3:1, which SAMPLE predicts should prevent serious mask taper replication into the etching film, substituting the resist facet propagation rate for the simple vertical loss rate gives an actual mask selectivity of only 1.8:1, producing the larger-than-expected oxide taper angle.

Now that the facet propagation rate in the photoresist was known, the tapering occurring in oxide etching could be eliminated by choosing an appropriate resist thickness and etch time: $1.0 \mu\text{m}$ thick thermal oxide samples were patterned with $1.0 \mu\text{m}$ of resist (tri-level), and the oxide was etched for 22 min, which only allowed the facet in the resist to propagate $0.68 \mu\text{m}$ downward through the mask. Figure 10 shows the wafer after the resist was removed. Vertical oxide sidewalls are seen.

Tapering mechanism.—In ion milling, the angular dependence of the milling rate leading to faceting is present regardless of the type of material being milled. To determine if the faceting observed in RIE is also common to all etchable materials, or if the fundamental differences in the mechanisms leading to material removal in photoresist, silicon, and silicon dioxide RIE might yield different profiles, unmasked vertical steps in silicon and oxide

Fig. 10. μm oxide step masked with tri-level resist, etched for 22 min. Mask has been stripped.

were next exposed to the oxide etch process and checked for tapering.

Figure 11a shows a $1.5\ \mu\text{m}$ high step etched into single-crystal silicon, and Fig. 11b shows a cross section of the same step after exposure to the oxide etch process for 2h. The same facet as in photoresist was observed, with a 16°

Fig. 11. a (top): $1.5\ \mu\text{m}$ high single-crystal silicon step. b(bottom). Wafer in Fig. 11a after 2h exposure to oxide etch process. 16° final silicon taper. Facet propagation rate: $180\ \text{\AA}/\text{min}$.

taper angle. The facet propagation rate is $180\ \text{\AA}/\text{min}$, again nearly twice the vertical etch rate.

Interestingly, however, when the vertical oxide steps produced as described above were exposed to the oxide etch process (for 8 min) after the mask was stripped, no faceting was seen (Fig. 12).

An explanation for the above observations is next presented.

Coburn and Winters have proposed that the following sequence of steps takes place during plasma etching (10): (i) nondissociative adsorption of gas-phase species at the surface of the solid being etched, (ii) dissociation of this adsorbed gas (*i.e.*, dissociative chemisorption), (iii) reaction between adsorbed atoms and the solid surface to form an adsorbed product molecule, *e.g.*, $\text{SiF}_4(\text{ads})$, (iv) desorption of the product molecule into the gas phase, and (v) the removal of nonreactive residue (*e.g.*, polymer) from the surface.

The key to tapering seems to be whether the rate-determining step in the etch mechanism of the particular material is strongly dependent upon purely physical sputtering, which is known to proceed more rapidly at preferential angles. Steps *iv* and *v* above are the only two which depend upon sputter ejection of material, so if either of these steps is dominant in a particular etch, an angular dependence would be expected.

Coburn and Winters concluded that the rate-limiting step in the etching of SiO_2 is step *iii*, the formation of the product molecule. The means by which ion bombardment may promote the reaction include damage-enhanced diffusion, knock-on collisions, and bond breaking (10). Sputter ejection and its corresponding angular dependence (11) do not come into play.

In silicon etching, Coburn and Winters proposed that step *ii*, the dissociative chemisorption of the etch species, is the rate-limiting step. This step would also appear not to be related to sputtering. However, step *v*, residue removal, may well be important. In Coburn and Winters' experiments, in which a XeF_2 beam and an ionized Ar beam were coincidentally directed at the surface (10), no polymer formation or residue (*e.g.*, carbon) deposition was possible. This is certainly not the case in the oxide etch process chemistry used here. Indeed, the anisotropy of the silicon and resist etching in the reactor could conceivably be aided by a polymer sidewall protection mechanism, as has been reported for other systems (12). If physical sputtering is the mechanism responsible for polymer removal from the top of features, as has been proposed (13), this would explain the observed angular dependence of silicon and photoresist RIE, provided the polymer deposition/removal process is a rate-limiting step. In oxide etching, oxygen released during the course

Fig. 12. Initially vertical oxide step exposed to oxide etch process for 8 min.

of the etch results in only a negligible buildup of polymer on the oxide surface (15). Consequently, a polymer deposition/removal mechanism is unlikely to occur in oxide RIE.

Conclusions

The tapered profile seen after etching a film which is known to etch anisotropically, such as oxide masked with vertical-walled photoresist, may now be explained. A facet forms in the resist mask, probably due to the angular dependence of the physical sputtering responsible for the removal of the polymer from the top of the resist. The facet propagates downward through the resist at a rate of approximately 310 Å/min, at an angle of slightly less than 20° off vertical. The resist facet starts to replicate into the oxide when it reaches the resist/oxide interface, because from this point on the oxide is no longer protected by a vertical mask.

To obtain vertically-etched sidewalls, then, one needs (i) a fairly vertical mask profile, (ii) good selectivity between the etching film and the mask material, and (iii) a mask thickness and etch time chosen such that at no time during the etch does the facet in the mask reach the interface between the mask and the etching film.

Faceting is also seen when bare vertical silicon steps are exposed to the same oxide etch process because of the angular dependence of polymer removal (sputtering) from the silicon surface. No faceting occurs when bare oxide steps are exposed to the process, however, because the oxygen liberated during oxide etching does not allow an appreciable amount of polymer to form on the oxide surface. The rate-limiting step in oxide etching, the formation of the adsorbed product molecule, SiF₄(ads), is not dependent upon sputter ejection.

Czochralski Silicon Crystals Grown in a Transverse Magnetic Field

Kinji Hoshi, Nobuyuki Isawa, Toshihiko Suzuki, and Yasunori Ohkubo

Sony Corporation, Semiconductor Group, Atsugi, Kanagawa 243, Japan

ABSTRACT

Turbulent convection in silicon melts used in the Czochralski crystal-growth method was found to be effectively suppressed by applying a transverse magnetic field over 2000G. When turbulent convection is suppressed, it was found that the oxygen concentration in the resulting silicon crystals could be precisely controlled within a range of $0.5\text{-}12 \times 10^{17} \text{ cm}^{-3}$. The oxygen concentration distribution in the crystals is more uniform than that obtained by the conventional Czochralski method. As-grown n-type silicon crystals with a resistivity as high as 5000 Ω-cm were obtained. Resistivity distribution along the radius of the crystals is more uniform than that produced by the floating zone method. Silicon crystals with low oxygen concentration prepared by the present method have few thermal-induced defects, which cause the degradation of generation lifetime. The characteristics and yield of p-i-n photodiodes and planar-type GTO's are superior to that obtained in wafers prepared by the floating zone method. We conclude that the Czochralski method using a transverse magnetic field is an effective method of producing high quality silicon crystals which can improve the characteristics of semiconductor devices and their production yield.

Crystal growth in a magnetic field is a relatively new notion and only a few studies had been carried out until 1980.

InSb crystals grown in a horizontal boat in a magnetic field were reported by Chedzey *et al.* (1) and Utech *et al.* (2) in 1966. They reported the suppression of temperature fluctuations in the InSb melt and the decrease of growth striations in the crystal. In 1970, Witt *et al.* (3) reported InSb crystal growth by the Czochralski method in a transverse magnetic field. The temperature difference in the melt was enhanced, and the resulting striations adversely affected the crystal properties. In 1980 and 1981, we reported a silicon crystal grown in a transverse magnetic field by the Czochralski method (MCZ method) (4, 5). The MCZ method can produce crystals with a specific oxygen concentration within a range of $0.5\text{-}12 \times 10^{17} \text{ cm}^{-3}$, and reduce convection-generated (nonrotational) growth changes in the crystal, inhibit defect generation, and reduce warping during heat-treatment.

Since then, the method has received much attention and several studies have been carried out (6-10).

Experimental Procedure

Figure 1 shows an outline of the pulling machine used. The device has almost the same structure as that used in the conventional Czochralski method. A transverse magnetic field of up to 3700G is applied to the silicon melt between a pair of pole pieces with a diameter of 70 cm and a gap of 60 cm. The pulling machine is mostly made of nonmagnetic stainless steel. DC power, with a ripple component of less than 4%, is applied to the graphite heater to prevent the heater from vibrating in the magnetic field.

The diameter of the crystal was controlled by the weighing method reported by Hoshi *et al.* (11). The pulling operation is the same as that used in the conventional CZ method except for the application of a transverse magnetic field to the silicon melt. The magnet was

Fig. 1. Schematic cross section of MCZ apparatus

turned on after the charged silicon had melted. A silicon crystal with a diameter of 7.6 cm was grown from a melt of 4.5 kg in argon gas kept at 1 atm, and a silicon crystal with a diameter of 10 cm was grown from a melt of 20 kg in argon gas kept at about 10 torr. The pulling rate ranged from 0.9 to 1.1 mm/min, the crystal rotation rate from 0 to 30 rpm, and the crucible rotation rate from 0 to 20 rpm. The magnetic field strength ranged from 0 to 3700G. The magnetic field did not affect the automatic diameter control.

The resistivity was measured by the four-point probe method and the spreading resistance method.

Oxygen concentration was measured by the infrared absorption method using a beam spot size of 5 mm. All samples used were cut perpendicular to the growth axis and polished on both sides to yield a sample 2 mm thick. Oxygen concentration was calculated by using an infrared absorption coefficient of 2.45×10^{17} at. cm^{-3} (ASTM F121-80).

The carrier generation lifetime was measured by the MOS C-t method reported by Zerbst *et al.* (12).

Copper decoration was carried out to observe the crystal defects. A polished wafer was immersed in a dilute solution containing 1 ppm of copper ions and annealed in a furnace at 900°C for 30 min, after which it was polished, etched by Wright etchant, and inspected with an optical microscope.

Photoluminescence was measured by using a grating monochromator of SPEX Company, Limited, with an argon laser emitting at a wavelength of 5145Å as the light source. Photoluminescence intensity was converted into the corresponding impurity concentration in accordance with the working curve given by Tajima (13).

When wafer warping was less than 30 μm , the measurement was carried out by using a Model LSF-500 flatness tester of Canon Company, Limited, which employs the reflection and interference of laser beams. When wafer warping was more than 30 μm , the measurement was done in accordance with ASTM F657-80.

Results and Discussion

Stability of the melt surface.—In order to investigate the stability of the melt surface, a transverse magnetic field was applied to the silicon melt of 4.5 kg and the melt surface was observed without crucible rotation while the magnetic field strength was gradually increased. To more easily observe the vibration of melt surface, a mo-

lybdenum ring was set above the melt surface to act as a visual reference. Figure 2a shows the silicon melt surface at zero magnetic field, and Fig. 2b shows the surface at 3700G. Figure 2a indicates that the melt surface strongly vibrates at zero magnetic field due to thermal convection. Thermal convection and surface vibration decrease with the application of a magnetic field. Thus, at about 1000G, the reduction in vibration is apparent, although there are still some waves caused by vibration on the melt surface. Continuous vibration essentially ceased in a magnetic field of 1500G, at which point the ring edge could clearly be seen reflected on the melt surface. No significant change was observed over 1500G. Intermittent vibrations occurring at intervals of several seconds, however, were still observed on the melt surface. These intermittent vibrations might have some other cause than thermal convection, such as the Marangoni flow, which is caused by the difference in surface tension of points with different temperatures in the melt surface, or the melt flow caused by the wetting of the silicon melt to the quartz crucible.

Temperature fluctuation and temperature distribution in the silicon melt.—The following experiment was carried out to investigate the relations between vibrations on the melt surface, temperature fluctuations within the melt, and the speed of melt flow due to thermal convection. A Pt-Rh(13%) thermocouple with a diameter of 0.5 mm, protected by a quartz tube of 6 mm od, was placed 1 cm beneath the unseeded melt surface at the center of the 4.5 kg melt. The temperature was then measured at magnetic fields from 0 to 3700G without crucible rotation.

Figure 3 shows that the temperature fluctuations within the melt start decreasing at or near 1500G, and they are minimized at about 2000G. No significant change occurs in magnetic fields over 2000G. When the

Fig. 2. Silicon melt surface. a(top): The melt vibrates due to thermal convection under 0G. b(bottom): The melt has a mirror-like surface at about 3700G.

Fig. 3. Effect of magnetic field on temperature fluctuations in silicon melt, measured at 10 mm below the melt surface of the crucible center.

magnetic field strength was changed stepwise, some spike noises were recorded on the chart, possibly caused by the induction current caused by the change in the field strength.

Utech *et al.* (14) measured the speed of flow in tin melts caused by thermal convection. No speed-of-flow measurement has been reported for silicon melt used in the CZ method. Two sets of Pt-Rh thermocouples were inserted into the 2.5 kg silicon melt, and were respectively placed at 10 (point a) and 20 mm (point b) beneath the melt surface with a clearance of about 10 mm from the crucible wall. Figure 4 shows the temperature fluctuations at points a and b at zero magnetic field. As the melt flows upward from point b to point a, the temperature at point a follows that at point b in the melt after a short period of time. One can calculate the speed of upward flow caused by thermal convection by measuring the time which has elapsed between X and X' shown in Fig. 4. The speed thus calculated was from 3.9 to 5.8 mm/s. When the 4.5 kg melt was used, the speed was calculated to be from 5 to 25 mm/s. In a magnetic field of 2000G, the upward flow was too slow to measure.

To measure the temperature distribution, three sets of thermocouples were placed about 20 mm beneath the surface at points A, B, and C, as is shown in Fig. 5. The temperature difference between point B and C was 0.5°C at 0G and 2.5°C at 3700G. This suggests that an increase in the magnetic field increases temperature gradients in the melt. Witt *et al.* (3) have previously reported similar increases of temperature differences in a magnetic field in a InSb melt used in the CZ method.

Temperature distribution is less of a problem than temperature fluctuations caused by thermal convection, be-

Fig. 4. Temperature fluctuations in 2.5 kg silicon melt measured at 10 mm (a) and 20 mm (b) below the melt surface at 10 mm from the crucible wall. Crucible is 200 mm diam. The speed of upward flow due to thermal convection was calculated by subtracting pen offset from the distance between X and X'. The recording direction is from right to left.

MAGNETIC FIELD (gauss)	TEMPERATURE (°C)			
	A	B	C	B - C
0	1423	1431.5	1432	0.5
3700	1422	1429	1431.5	2.5

cause temperature distribution can be made more even by rotating the crystal and crucible in the CZ and MCZ method.

Growth striations and dopant concentrations.—Figure 6 shows the smooth surface of the crystals obtained by the present method.

Figure 7 shows a photograph of growth striations in a crystal cut along the growth axis, together with a graph of

Fig. 6. MCZ silicon crystals with a diameter of 10 cm and a length of 100 cm grown in a transverse magnetic field of 3500G.

Fig. 7. Dopant concentration and growth striations in a crystal cut along a growth axis. Note that the magnet on region shows a uniform dopant distribution.

the corresponding phosphorus dopant concentrations measured at 10 μm steps using the spreading resistance method. This crystal, which has a diameter of 7.6 cm, was pulled into an orientation $\langle 111 \rangle$ without seed rotation at a growth rate of 1.1 mm/min. Irregular growth striations and an irregular phosphorus concentration were observed in the area grown without a magnetic field. In the area grown in the magnetic field of 3700G, growth striations were absent and phosphorus concentration distribution was uniform and about 33% greater than in the area grown without magnetic field. When a crystal was pulled with seed rotation, growth striations with a regular interval were observed in the crystal grown in a magnetic field, and complicated growth striation patterns were observed in the crystal grown without a magnetic field. Crystals grown with seed rotation also showed increases in phosphorus concentration of 38.1% at a seed rotation rate of 1 rpm, of 7.5% at 10 rpm, and of 0.13% at 30 rpm. Similar results were obtained with antimony-doped crystals, which were grown with and without a magnetic field (5). The effect of magnetic fields on rotational striations is now under investigation.

The increase of dopant concentration may be attributed to the increase of diffusion boundary-layer thickness caused by the suppression of turbulent convection and forced convection by a magnetic field.

Control of oxygen concentration.—Figure 8 shows the oxygen concentration in a crystal grown in a magnetic field of 0-3500G. The crystal, 7.6 cm diam and 30 cm long, was pulled at a rate of 0.9 mm/min from the 4.5 kg melt into an $\langle 100 \rangle$ direction at a crystal rotation rate of 30 rpm and a crucible rotation rate of 0.3 rpm. The oxygen concentration gradually decreases as the magnetic field increases to about 1500G, at which point it levels off and thermal convection almost disappears. This suggests that

Fig. 8. Typical oxygen concentration in silicon crystal grown at various magnetic fields. Oxygen concentration does not depend on the magnitude of the magnetic field over 2000G at which point the thermal convection in the silicon melt almost disappears.

Fig. 9. Oxygen concentration along the growth direction. The oxygen concentration can be controlled by setting the crucible rotation rate in a magnetic field. Note the variation in oxygen concentration in the crystal grown at rotation rate of 20 rpm.

thermal convection plays an important role in the incorporation of oxygen atoms into the growing crystals.

Figure 9 shows the oxygen concentration in the growth direction of crystals grown with various crucible rotation rates. When a crystal is grown at a constant rate, the oxygen concentration decreases from top to bottom. When a magnetic field is applied to the melt, the level of oxygen concentration strongly depends on the crucible-rotation rate, the oxygen concentration decreasing as the rate decreases. At a high crucible-rotation rate of 20 rpm, the oxygen concentration in a crystal was found to increase to $1.2 \times 10^{18} \text{ cm}^{-3}$, while it remained at $7.8 \times 10^{17} \text{ cm}^{-3}$ without a magnetic field.

We have reported that oxygen concentration decreases as the distance between the crystal periphery and crucible wall increases in a magnetic field (5). The lowest oxygen concentration we obtained was $5 \times 10^{16} \text{ cm}^{-3}$ with a distance between the crystal periphery and crucible wall of 69 mm with no crucible or crystal rotation at 3500G.

Figure 10 shows variations in oxygen concentration along the radial direction in crystal grown by CZ and MCZ with crystal-rotation rate as a parameter. Crystals with a diameter of 7.6 cm were pulled at a growth rate of 1.0 mm/min from crucibles with a diameter of 19 cm. It is evident that the magnetic field does not degrade radial uniformity in crystals grown at a high rotation rate of 30 rpm. Crystal rotation, with or without magnetic field, improves the radial uniformity of oxygen as well as dopant impurity concentration. With the CZ method, the crystal-rotation rate is closely related to the oxygen concentration; that is, a high rotation rate gives a high oxygen concentration, even at a low crucible rotation rate. With the MCZ method, however, the oxygen concentration is kept low even at high crystal-rotation rates, and it can be effectively controlled by adjusting the crucible rotation rate. In this way, crystals with a good uniformity in the radial direction can be easily obtained in a wide range of oxygen concentration.

Crystal defects and lifetime.—We investigated the effect of oxygen concentration on stacking fault density within

Fig. 10. Oxygen concentration along the radial direction of crystals grown with and without a magnetic field. MCZ used a field strength of 3500G.

a bulk crystal and on generation lifetime. Samples were cut from the center of boron-doped <100> crystals with a resistivity of 10-15 Ω-cm and an oxygen concentration in the range of $1 \times 10^{17} \text{ cm}^{-3}$ to $1 \times 10^{18} \text{ cm}^{-3}$. One sample with an oxygen concentration of $1 \times 10^{18} \text{ cm}^{-3}$ was prepared by the CZ method, and another was by the MCZ method.

Figure 11 shows the stacking fault density and the generation lifetime obtained by the MOS C-t method after samples were annealed at 1100°C in dry oxygen for 36h. The generation lifetime is inversely proportional to the stacking fault density and to the oxygen concentration. A remarkable change occurs near an oxygen concentration of $5 \times 10^{17} \text{ cm}^{-3}$.

Table I summarizes the generation lifetime after annealing at 1100°C in dry oxygen, using samples with an oxygen concentration in the range of $3.4\text{-}9.2 \times 10^{17} \text{ cm}^{-3}$. Ten test MOS capacitors were made from each sample. As the table shows, the generation lifetime decreases as the annealing time increases. The rate of decrease in the generation lifetime is related to the oxygen concentration.

High resistivity silicon crystals.—Undoped <100> silicon crystals were grown using an n-type polycrystalline silicon charge of resistivity of 1000 Ω-cm or more produced by High Silicon Company, Limited, and a quartz crucible of Toshiba Ceramics Company, Limited, containing a boron content of 10 ppb or less. Pulling conditions were at a crystal rotation of 10 rpm, a crucible rotation of 0.1 rpm, and at 3500G. n-Type crystals with a resistivity of up to 5000 Ω-cm and an oxygen concentration of $1.5 \times 10^{17} \text{ cm}^{-3}$ were obtained. Photoluminescence measurements showed that these crystals contained phosphorus of $7.6 \times 10^{12} \text{ cm}^{-3}$ and boron of 3.9×10^{12}

Table I. Generation lifetime after annealing at 1100°C in dry oxygen. MCZ-T and MCZ-B indicate the top and bottom of the crystal, respectively

Sample	Oxygen concentration (10^{17} cm^{-3})	Generation lifetime (μs)		
		As grown	1h	16h
CZ	8.2-9.2	1650-1700	450-580	175-310
MCZ-T	3.4-3.9	1240-1400	1060-1260	680-870
MCZ-B	5.2-5.5	1160-1450	960-1200	820-1000

Fig. 11. The effect of oxygen concentration on stacking fault density and on generation lifetime after heat-treatment. Wright etchant was used to reveal the stacking faults.

cm^{-3} , the former mainly coming from the polycrystal and the latter from the quartz crucible.

As the suppression of thermal convection by a magnetic field reduces the quantity of oxygen and boron from the quartz crucible, the MCZ method can provide high resistivity silicon crystals with a low oxygen concentration, leading to low thermal donor generation.

Figure 12 shows resistivity distribution in the periphery of CZ and floating zone (FZ) phosphorus-doped wafers with a resistivity of about 80 Ω-cm. Resistivity was measured in 10 μm steps by the spreading resistance method. Resistivity within the measured range varied 2.6% for a

Fig. 12. Micro distribution of resistivity in MCZ and FZ wafers, measured at in 10 μm steps using the spreading resistance method.

MCZ wafer and 19.2% for an FZ wafer, presumably because the thermal convection and surface tension gradient-induced convection (Marangoni convection) which occurs in FZ crystal growth can cause a fluctuation in growth rates, resulting in variations in dopant concentration.

Wafer warpage caused by heat cycle.—The degree of warpage caused by heat cycles was found to be related to the oxygen concentrations in wafers, as is shown in Fig. 13 and 14. Samples with an oxygen concentration of 7.6×10^{17} , 2.5×10^{17} , and less than $1 \times 10^{16} \text{ cm}^{-3}$ were cut from three types of $\langle 100 \rangle$ boron-doped silicon crystals grown by CZ, MCZ, and FZ methods, respectively. Mirror-polished wafers of 5.0–5.2 cm diam and $380 \mu\text{m}$ thick were used. Heat cycles between room temperature and 1100°C were applied to the wafer, keeping the wafers at each temperature for 30 min. The transition time between room temperature and 1100°C was 6s. FZ wafers showed the largest warpage, as is shown in Fig. 13. After the heat-cycle test, the largest number of slip lines were observed in FZ wafers. FZ wafers contain too low an oxygen concentration to cause SiO_2 precipitation, which can prevent dislocations from moving and multiplying in the crystals during the heat cycles.

Figure 14 shows the effect of preannealing on warpage. The samples were preannealed at 1050°C for 100h, then heat cycled. At this point, CZ wafers showed the largest warpage. In the present experiment, it was seen that oxygen in CZ wafers can easily precipitate to form SiO_2 , because the oxygen concentration exceeds the solubility limit of oxygen in silicon at this preannealing temperature.

Figure 15 shows x-ray Lang topographs of CZ and MCZ wafers with oxygen concentrations of 7.6×10^{17} and $2 \times 10^{17} \text{ cm}^{-3}$, respectively. The wafers were thermally oxidized in dry oxygen at 1100°C for 16h. Dislocations caused by precipitated SiO_2 were in much evidence in the CZ wafer while there were few in the MCZ wafer. Dislocations

Fig. 13. Wafer warpage after heat cycle. The initial warpage was subtracted from warpage after heat cycle.

Fig. 14. Preannealing effect on wafer warpage after heat cycle. The initial warpage caused by preannealing was subtracted from the warpage after heat cycle. The initial warpages were almost the same in the three types of crystals.

punched out due to precipitated SiO_2 have been found to cause strains in wafers (15), suggesting that a high density of precipitated SiO_2 can cause warping in silicon wafers.

Application to devices.—A high sensitivity photodiode with a chip size of $3 \times 3 \text{ mm}$ was fabricated by using n-type MCZ and FZ wafers with a resistivity of 1000 $\Omega\text{-cm}$. The MCZ wafers had an oxygen concentration of $1.5 \times 10^{17} \text{ cm}^{-3}$, and the FZ wafers less than $1 \times 10^{16} \text{ cm}^{-3}$. Phosphorus was diffused into the wafers at 1280°C

Fig. 15. X-ray Lang topographs of MCZ and CZ wafers after heat-treatment.

Fig. 16. Defects observed by optical microscopy. The samples were decorated with copper after completing the device processes.

for 155h before device fabrication to reduce the series resistance of the device, then one surface was polished to remove the phosphorus diffusion layer. The wafers, after being subjected to a course of heat-treatment, were diffused with copper, then polished to obtain a mirror surface. Wright etching was carried out to observe the defects in the wafers. Dislocations and microdefects were found in the order of 10^5 cm^{-2} in FZ wafers, but only microdefects were found in the order of 10^2 cm^{-2} or less in MCZ wafers, as is shown in Fig. 16. These microdefects may be caused by precipitation of metal coming from the furnace tube, heater elements, or carrier gas during the phosphorus-diffusion process.

Dark currents were measured at a bias voltage of 30V, at which the depletion layer width in the diode was about 80 μm . The dark current is lower and more concentrated in MCZ wafers than in FZ wafers, as is shown in Fig. 17. The dark current magnitude and distribution seem to be closely related to the density of the defects generated in the wafers during the phosphorus diffusion process and the course of heat-treatment.

Figure 18 shows the relationship between the resistivity and the breakdown voltages of planar-type GTO's fabricated using phosphorus-doped $\langle 111 \rangle$ MCZ and FZ wafers. Gold was diffused into the wafers to reduce the turn-off time. Figure 18 shows that the devices prepared using

Fig. 17. Dark current of high sensitivity photodiodes fabricated using n-type MCZ and FZ wafers with a resistivity of 1000 $\Omega\text{-cm}$. The dark current is lower in MCZ wafers, showing more concentrated values than those in FZ wafers.

Fig. 18. Relationship between the resistivity and the breakdown voltages of the planar-type GTO's fabricated using n-type $\langle 111 \rangle$ MCZ and FZ wafers.

an MCZ wafer have more uniform and higher breakdown voltages than those prepared using an FZ wafer.

Summary

Turbulent convection within a silicon melt used in the CZ method is effectively suppressed and temperature fluctuations in the melt are reduced to 0.1°C or less by applying a transverse magnetic field over 2000G to the melt. As a result, the crystal is grown with higher thermal stability and less contamination from the crucible as compared to a crystal grown using the conventional CZ method.

Silicon single crystals prepared by the present method have the following advantages.

1. The oxygen concentration within the crystal can easily be controlled within the wide range of $0.5\text{-}12 \times 10^{17} \text{ cm}^{-3}$.
2. High resistivity crystals with up to 5000 $\Omega\text{-cm}$ can be obtained.
3. Resistivity along the radius of the crystals is more uniform than that of crystals produced by the FZ method.
4. Nonrotational growth striations are few.
5. The change in carrier lifetime after heat-treatment is small.
6. Oxygen precipitation and defect generation are reduced in crystals with a low oxygen concentration.
7. The degree of wafer warpage after heat cycles is small.
8. High sensitivity photodiodes and planar-type GTO's with very uniform device characteristics can be obtained.

These advantages indicate that this new method provides silicon wafers which produce devices of higher production yield than the FZ method. In addition, this method can provide wafers which satisfy the strict requirements for producing the very high speed integrated circuits (VHSIC), which will be needed soon. To realize VHSIC, low temperature processing is required in order to make possible the fine patterning techniques. Low temperature processing requires wafers with little precipitation of oxygen atoms and thermal donor generation. Precipitation notably occurs at 900°C or lower and leads to defect generation. Thermal donor generation which leads to a change in resistivity in the wafer is also a problem in low temperature processing. Thus, a crystal with a precisely controllable oxygen concentration should be used as a starting material. However, it should be noted that the silicon wafers with a low oxygen concentration do not contain any intrinsic gettering region in the wafer; therefore, extrinsic gettering technology is required for the high temperature processes currently in use.

ABSTRACT

Growth of two-dimensional patches of photosensitive layered transition metal dichalcogenides (MoSe_2 , WSe_2 , MoTe_2) from tellurium melts is reported. The material exhibits a substantially different morphology compared to vapor-transported crystals. Single-crystalline hexagons grow together along their edges and can form larger polycrystalline films with relatively few surface defects. No rosette-type growth is observed. The first electrochemical solar cells made with these materials did not yield conversion efficiencies exceeding 1%. Scanning laser spot analysis on smooth crystals reveals deficiencies concerning doping profile, stoichiometry, and impurity content. Better control of the growth process promises the development of high quality thin films.

The optical and electronic properties of layered Group VI transition metal dichalcogenides make these semiconductors promising candidates for efficient solar energy conversion (1, 2). With low energy indirect transitions followed by highly absorptive direct transitions ($\alpha \approx 10^5 \text{ cm}^{-1}$) at photon energies around 1.5 eV (WSe_2 , MoSe_2) and minority carrier diffusion lengths of about $2 \mu\text{m}$ (3, 4), it appears possible to convert solar to electrical energy efficiently in thin film structures. Investigations in semiconductor/liquid junction solar cells revealed that, although exceptional stability against photocorrosion is obtained with these semiconductors (5), large differences and irreproducibilities in photocurrent (i_{sc}), photovoltage (V_{oc}), and fill factor (ff) are observed (6). These differences have been attributed to variations in surface morphology (7-9) and deviations in stoichiometry (10). In particular, it turned out that steps on the surfaces of layered compounds are deleterious for the solar cell performance and that doping profiles can result in p- and n-conducting areas on the same crystal.

Extensive materials preparation work, however, resulted in the development of a photoelectrochemical solar cell with n- WSe_2 , which converts solar to electrical energy with an efficiency of 10% (11). Such crystals, grown by chemical vapor deposition (CVD), have to be selected with respect to their surface texture and doping profiles since this preparation method lacks reproducibility and

uniformity of the crystals. In addition, only relatively small polycrystalline material (50 mm^2) is obtained with CVD.

Fig. 2. X-ray fluorescence spectrum of Te-grown MoSe_2 indicating impurities of Te, Si, and transition metal.

Hence, considerable effort has been made to improve the performance of samples with a highly textured surface (11-14). An alternative possibility is given by changing the growth process of these semiconductors. Recently, Te has occasionally been used as melt for the growth of semiconducting crystals. Both the synthesis of II-VI compounds (15) and of transition metal dichalcogenides (16) have been successful. Whereas these studies emphasized improved quality and size of crystals, the present work focuses on the possibility of predominantly lateral growth at a melt/vapor interface.

The technical realization of large grain polycrystalline thin films of MoSe_2 and WSe_2 would be highly attractive

for the development of practicable, alternative solar energy converting devices.

Material Preparation

Powdered transition metal diselenide is added to double distilled Te (Koch-light no. 8698 h, 5N purity) in a ratio of 1:100, respectively. To 10g of this mixture, 100 mg of Se (Koch-light no. 8982-60, 5N) are added for better control of the desired reaction. The starting material is then encapsulated in a quartz tube (20 mm diam) evacuated and heated to 1050°C. Subsequent cooling is done with a gradient of 4°-5°C/h (16). During the cooling process, transition metal dichalcogenide crystals begin to nucleate in the bulk of the liquid as well as at the melt/vapor interface. A mechanism involving convection and surface tension (see below) appears to facilitate crystallization along the Te/vapor interface (Fig. 1), although the density of the semiconducting material exceeds the density of the melt. After termination of the growth process, the Te melt is eliminated by sublimation.

Fig. 5. Photo- and dark current-voltage characteristics of Te-grown MoSe_2 ; electrolyte 0.1M H_2SO_4 .

Fig. 6. Power output characteristic of Te-grown MoSe_2 electrode in $1\text{M KI}/0.1\text{M I}_2$ redox solution. Illumination by Solar Simulator (Oriental Corporation) under $\sim\text{AM 1}$ conditions.

MoSe_2 , MoTe_2 , and WSe_2 have been prepared. Crystal sizes range from typically $20\ \mu\text{m}$ up to $6\ \text{mm}$ diam with a thickness of approximately $0.3\ \text{mm}$. The transition metal diselenides obtained with the above described procedure had the stoichiometry $\text{MeSe}_{2-x}\text{Te}_x$ ($\text{Me} = \text{Mo}, \text{W}$) with $x \leq 0.1$. The Te content of the crystals could be reduced by heating the samples in Se atmosphere to 650°C . The MoSe_2 material investigated in this publication still showed detectable amounts of Te and some Si (Fig. 2).

All prepared materials were photoactive; MoSe_2 and MoTe_2 were n-type and WSe_2 showed p-type conductivity. The semiconductors exhibited photocurrent densities of several milliamperes per square centimeter at simulated AM 1 conditions. MoSe_2 was chosen for investigation because of its higher photopotential. It is of interest to note that large melt-grown layer-type MoS_2 crystal plates are found in pegmatitic deposits (17).

Results and Discussion

Compared to vapor transport grown and synthesized crystals, our samples show strong lateral attachment of hexagonal crystallites along their edges. The morphology of two differently and quite heavily structured MoSe_2 samples is displayed in Fig. 3. No rosette-type growth is observed, but the crystallites appear to be partially superposed, resulting in the formation of steps. These defects, however, do not appear to be predominantly responsible for the still moderate photoactivity of the material as compared to selected high quality vapor-grown crystals. This is evident from scanning laser spot experiments

Fig. 7. Photo- and dark current-voltage characteristics of Te-grown MoSe_2 under $900\ \text{mW}/\text{cm}^2$ illumination in I^-/I_2 redox solution.

(Fig. 4) on optically smooth MoSe_2 electrodes which show pronounced variations in photoresponse across the surface. This could result from lateral differences in stoichiometry, impurity concentration, and doping level and has also been observed on vapor grown material (10).

Figure 5 shows current-voltage (*i*-*V*) characteristics of a structured MoSe_2 electrode in the dark and under simulated AM 1 illumination. In presence of the I^-/I_2 redox couple energy conversion is possible. As can be seen in Fig. 6, a relatively low photocurrent, a fill factor *ff* of ~ 0.25 , and a photovoltage of approximately $0.3\ \text{V}$ is obtained in a two-electrode solar cell experiment. The relatively low performance is obviously associated with a high density of states within the forbidden energy region which mediate electron transfer from iodide to the conduction band in the dark as shown in Fig. 7. In this case, higher photocurrents and photovoltages can only be reached under intense illumination. These defects could arise partly from the impurities found in the material as shown in Fig. 2 which could be reduced by better control of growth parameters, cleaning procedures, and annealing processes.

Fig. 9. Scheme illustrating surface accumulation of crystals for lateral growth due to the Marangoni effect. σ : Surface tension. F_x : Resulting force. $\Delta T/\Delta x$: Temperature gradient.

The preparation of large area smooth crystalline thin films of transition metal dichalcogenides appears to be possible by the described method. Different possibilities for separation of the Te from the crystallized phase are schematically shown in Fig. 8. A better understanding of the physical chemistry of crystal growth by this method is essential. It has to be emphasized that the mechanism involved is not trivial; the density of the nucleated layered crystallites exceeds that of the Te melt. In view of the experimental geometry, it appears plausible to assume a Marangoni type (18) of mechanism (Fig. 9): the surface tension which is a critical parameter for nucleation does not only depend on the concentration of a mixture but also on the temperature. A temperature gradient in the surface layer results in a force parallel to the surface, F_x , whose origin is the difference in surface tension. A convection results which transports nucleation centers from the bulk of the melt to the surface at the higher temperature site of the tube with subsequent transport of the slowly growing crystals along the interface. The larger crystallites at the sites with higher surface tension do not follow the convection path of the melt since the increased

surface tension probably inhibits their sinking. Further studies in well-designed crystal-growth vessels are necessary to test this hypothesis quantitatively.

Acknowledgment

We are indebted to Dr. S. Fiechter for providing us with information on the Marangoni effect.

ABSTRACT

Chemical vapor deposition of the nonstoichiometric zirconium carbide is computed by minimization of the Gibbs free energy of the system. Analytical expressions for the Gibbs free energy of formation of Zr_xC_{1-x} f.c.c. solid and liquid phases are set up, and the deposition diagram with "isostoichiometric curves" is presented as a function of ZrCl₄, CH₄, and H₂ pressures in the input gas mixture.

For several years, thermodynamic computations based on the minimization of the total free energy of a complex chemical system involving a gas phase and several condensed species have been developed in order to predict the conditions of deposition. They were essentially applied to pure solid phases and/or stoichiometric compounds such as intermetallic oxides and carbides.

In recent years, such an approach has been enlarged in order to determine the deposition conditions of nonstoichiometric refractory solid solutions such as titanium carbides or nitrides and titanium carbonitrides.

In order to obtain CVD coats of ZrC having a well-defined stoichiometry, previously published activity values for Zr were fit by a model based on the Redlich-Kister formalism. The variation of Zr activity with composition, based on the model, was used to calculate the optimum conditions for producing Zr_xC_{1-x} from a mixture of CH₄, ZrCl₄, and H₂.

Thermodynamics of the Phase Zr_xC_{1-x}

Zirconium carbide has an f.c.c. structure with a large homogeneity range due to carbon vacancies (1, 3-8). Very few studies are concerned with the thermodynamic properties of Zr_xC_{1-x} over its homogeneity domain. The only high temperature thermodynamic data available are the measurements of the activity of zirconium over the whole range of homogeneity of Zr_xC_{1-x}, referred to liquid zirconium, made by Storms and Griffin (1) for temperatures between 1700 and 2000 K.

These values, referred to b.c.c. Zr, allow the calculation of the activity of carbon (referred to graphite) by integration of the Gibbs-Duhem equation and, consequently, the determination of the Gibbs free energy of formation of Zr_xC_{1-x} (f.c.c.) from graphite and Zr (b.c.c.), namely

$$\Delta G_{\text{Zr}_x\text{C}_{1-x}}^{\text{f.c.c.}} = X_{\text{Zr}} RT \ln a_{\text{Zr}} + X_{\text{C}} RT \ln a_{\text{C}}$$

$$\text{ref. } \left| \begin{array}{l} \text{C graphite} \\ \text{Zr b.c.c.} \end{array} \right.$$

When using the Redlich-Kister formalism to represent the Gibbs free energy of formation of the f.c.c. solid solution Zr_xC_{1-x}, it is easier to fit the experimental results with the elements referred to the same structure, that is, to consider the reaction

whose Gibbs free energy is related to the former by

$$\Delta G_{\text{Zr}_x\text{C}_{1-x}}^{\text{f.c.c.}} = \Delta G_{\text{Zr}_x\text{C}_{1-x}}^{\text{f.c.c.}} - X_{\text{Zr}} [\Delta G_{\text{Zr}}^{\text{f.c.c.}} - \Delta G_{\text{Zr}}^{\text{b.c.c.}}]$$

$$\text{ref. } \left| \begin{array}{l} \text{C f.c.c.} \\ \text{Zr f.c.c.} \end{array} \right. \quad \text{ref. } \left| \begin{array}{l} \text{C graphite} \\ \text{Zr f.c.c.} \end{array} \right. - X_{\text{C}} [\Delta G_{\text{C}}^{\text{f.c.c.}} - \Delta G_{\text{C}}^{\text{graphite}}]$$

where $\Delta G_{\text{Zr}}^{\text{f.c.c.}} - \Delta G_{\text{Zr}}^{\text{b.c.c.}} = -961.4 + 3762 T$ (J/mol) corresponding to the free energy (2) of the reaction Zr_{b.c.c.} →

*Electrochemical Society Active Member.

Zr_{f.c.c.} and $\Delta G_{\text{C}}^{\text{f.c.c.}} - \Delta G_{\text{C}}^{\text{graphite}} = 138,523 - 14.6 T$ (J/mol) corresponding to the free energy (2) of the reaction C graphite → C f.c.c. Then the Gibbs energy as a function of the concentration may be expressed in the following form

$$\Delta G_{\text{Zr}_x\text{C}_{1-x}}^{\text{f.c.c.}}(T) = X_{\text{Zr}} \cdot X_{\text{C}} [A(T) + B(T)(X_{\text{C}} - X_{\text{Zr}})]$$

$$\text{Ref. } \left| \begin{array}{l} \text{C f.c.c.} \\ \text{Zr f.c.c.} \end{array} \right.$$

$$+ C(T)(X_{\text{C}} - X_{\text{Zr}})^2 + RT[(X_{\text{C}} \ln X_{\text{C}} + X_{\text{Zr}} \ln X_{\text{Zr}})] \quad [1]$$

$$\text{where } A(T) = -6.962 \cdot 10^5 + 73.6 \times T \\ B(T) = 8.561 \cdot 10^4 - 12.4 \times T \\ C(T) = 14.793 \cdot 10^5 - 243.3 \times T$$

in J/mol of Zr_xC_{1-x}.

Fig. 1. Experimental (*) and calculated Zr activity vs. composition at 1900 K. *: Storms and Griffin (1).

Fig. 2. Experimental (*) and calculated Zr activity vs. composition at 2200 K. *: Storms and Griffin (1).

Using Eq. [1], the activity of Zr can be calculated and compared to the measured a_{Zr} by Storms and Griffin (1) as shown in Fig. 1 and 2, and Gibbs free-energy values can be determined for $Zr_{0.5}C_{0.5}$, which are in good agreement with the values published in the literature, as illustrated in Table I.

The model can be used to calculate a tentative Gibbs energy for the liquid phase. Although this quantity was not needed in this paper, it may provide useful information for other studies. However, it cannot be used to calculate the phase diagram with a precision any greater than is currently available from published measurements.

After use of different optimization computer programs, the following expression was selected

$$\Delta G_{(Zr_xC_{1-x})}^{(l)} = X_{Zr}X_C[A(T) + B(T)(X_C - X_{Zr}) + C(T)(X_C - X_{Zr})^2] + RT[X_C \ln X_C + X_{Zr} \ln X_{Zr}] \quad [2]$$

ref. $\left\{ \begin{array}{l} \text{C liquid} \\ \text{Zr liquid} \end{array} \right.$

where $A(T) = -3.46 \cdot 10^5 + 30.0 \times T$
 $B(T) = 2.15 \cdot 10^4 - 5.5 \times T$
 $C(T) = 9.82 \cdot 10^4 - 3.8 \times T$

in J/mol of liquid ZrC.

Table I. Comparison between different values of the Gibbs free energy for $Zr_{0.5}C_{0.5}$ fcc phase

CVD Diagram of Zr_xC_{1-x} from a CH_4 - $ZrCl_4$ - H_2 Gaseous Mixture

Thermodynamic calculations based on the minimization of the total free energy of a complex chemical system have been used by others to determine conditions for chemical vapor deposition (10-12). In the present case, the conditions for deposition of zirconium carbide have been calculated as a function of the input gas pressures ($P_{ZrCl_4}^\circ$, $P_{CH_4}^\circ$, $P_{H_2}^\circ$) at 1400 and 1900 K, under a total pressure of 1 atm.

Fig. 4. "Isostoichiometric curves" as function of the input gas composition: $T = 1400 \text{ K}$; $P_{CH_4}^\circ + P_{ZrCl_4}^\circ + P_{H_2}^\circ = 1$.

The calculation requires thermodynamic data for all the chemical species which may be present: Zr_xC_{1-x} solid solutions, Zr and C, which are considered as pure condensed phases, and the gaseous species Zr, Cl, Cl_2 , $ClZr$, Cl_2Zr , Cl_3Zr , Cl_4Zr , CCl_4 , C_2Cl_2 , C_2Cl_4 , H, H_2 , HZr , CH, CH_2 , CH_3 , CH_4 , C_2H , C_2H_2 , C_2H_4 , ClH , $CClH$, $CClH_3$, CCl_2H_2 , CCl_3H , and C_2ClH .

The previously determined relation (1) Gibbs integral energy of mixing is used as input thermodynamic data for Zr_xC_{1-x} .

The various deposits and their deposition fields as a function of input gas composition are presented in Fig. 3 and 4. Isostochiometric curves are also reported in the deposition domain of the pure Zr_xC_{1-x} solid solution. This very large domain is limited by the boundary associated with $Zr_{0.5}C_{0.5}$ on the $ZrC + C$ side and by the boundary associated with $Zr_{0.62}C_{0.38}$ on the $ZrC + Zr$ side.

For equilibrium, the deposited phase ($ZrC + C$, ZrC , $ZrC + Zr$) and the composition of the pure solid solution may be easily varied by adjusting the input partial pressure of CH_4 for a constant $ZrCl_4$ feed.

At 1900 K, the field of interest is located in the following range (atm units)

$$5 \cdot 10^{-3} < P_{CH_4} < 10^{-2} \text{ and } 6 \cdot 10^{-2} < P_{ZrCl_4} < 10^{-1}$$

In conclusion, diagrams of this type allow specification of the gas composition, leading to the deposition of a zirconium carbide phase of controllable stoichiometry under equilibrium conditions. Work is in progress to estimate more precisely the thermodynamic properties of this nonstoichiometric monocarbide by use of a sublattice model to provide a better fit of the measured activities and the phase boundaries. Preliminary results indicate that the calculated CVD diagram is not changed greatly.

Experimental Study of Equilibrium Conditions in the Si-H-Cl System

David W. Woodruff* and Rony A. Sanchez-Martinez

Corporate Research and Development, General Electric Company, Schenectady, New York 12345

ABSTRACT

Thermodynamic studies of the Si-H-Cl system are widely available. The results of these studies vary due to differences in the number of gas-phase components used and differences in the basic thermodynamic data employed. This work describes the first experimental study to determine the equilibrium Si/Cl ratio as a function of Cl/H and temperature. The experimental results fall near those which are calculated, though they do not uniquely support any one of the theoretical studies. Computational studies make the assumption that the Cl/H ratio is constant for the silicon CVD reaction. It is shown in this study that this is not always the case, particularly when there is substantial condensation of polychlorosilanes.

There have been a number of thermodynamic studies (1-5) of the Si-H-Cl system with specific application to the CVD of silicon. The results of such studies vary depending on which of the possible gas-phase components are included in the calculation and on the source of the primary thermodynamic data. Herrick and Sanchez-Martinez (1), for example, used 18 gas-phase components in their calculation; Hunt and Sirtl (2, 3) used 14, and Lever (4) used 9. These investigators also used different values of the enthalpy of formation for many of the components that their studies shared in common. These differences manifest themselves not only in the calculated partial pressures of the components at the solid surface, but also in the equilibrium Si/Cl ratio. Figure 1 shows the dependence of the Si/Cl ratio on the Cl/H ratio at 1350 K as calculated by the three sets of investigators mentioned above (1, 2, 4).

Experimental verification of these calculations is inadequate. Most comparisons (6-9) are from experiments done under conditions not designed to bring the bulk of the reactant gases to equilibrium with solid silicon. This

work describes the results of an experiment specifically designed to measure the equilibrium value of the Si/Cl ratio as a function of the Cl/H ratio and the temperature at atmospheric pressure.

An important feature of any equilibrium experiment is the assurance of achieving the equilibrium state. One way to assure this is to approach the equilibrium Si/Cl ratio starting with both higher and lower values of the initial Si/Cl ratio. Accordingly, this work presents results of both silicon deposition and silicon etching experiments. Another important assurance that equilibrium has been achieved is the independence of the results with reaction time. This independence has been demonstrated.

One of the premises of the thermodynamic calculations described above is that the Cl/H ratio remains constant for the silicon CVD reaction. This premise is based on the assumption that solid silicon is the only condensed material to be formed in this reaction thus leaving the amounts of Cl and H unchanged. This assumption ignores the formation of polychlorosilane materials which also condense and in doing so change both the Si/Cl and Cl/H ratios. The extent to which this reaction can occur has been observed experimentally and is presented herein.

*Electrochemical Society Active Member.

Fig. 1. Dependence of equilibrium Si/Cl on Cl/H as calculated by three investigators (1, 2, 4) at 1350 K and 1 atm total pressure.

Experimental

The equilibrium experiments were conducted in a horizontal hot-wall reactor consisting of a 0.64 cm-id, 1.22m-long quartz tube supported by an alumina tube in a three-zone furnace (see Fig. 2). The furnace hot zone was 0.61m long. Silicon deposition or etching occurred on the inside surface of the quartz tube. Trichlorosilane (TCS) and silicon tetrachloride (TET) were introduced from separate saturators with hydrogen carrier gas. HCl and additional hydrogen were fed directly from gas cylinders. The gases were mixed prior to delivery to the furnace.

The apparatus had two basic flow modes. The first allowed straight flow-through of the gases from the mixer through the furnace to the scrubber. This mode was used both to establish the concentration of reactant gas along the entire flow path and to put an initial deposit of silicon on the quartz tube. The second mode allowed recirculation of the gases through the furnace. The recycle was driven by a small, Teflon bellows pump. Gas samples were taken in 75 ml stainless-steel gas sampling cylinders, which by valving could be either included or excluded from the flow path. Gas analysis was performed on a gas chromatograph equipped with a gas sampling valve and a thermal-conductivity detector. By making multiple injections of each sample and averaging the results, the Si/Cl and Cl/H ratios were determined to an accuracy of $\pm 3\%$.

The experiments presented here were accomplished in three to five distinct steps. The first step was to establish an atmosphere of pure hydrogen in the entire flow circuit. This was done by evacuating and refilling, first four times with nitrogen, then four times with hydrogen. Following this, the system was purged with a constant hydrogen flow while the reactant gas flow was established to the scrubber.

Step two was the establishment of the reactant gases in the furnace flow circuit. The reactant flow was switched to the furnace line for 60 min, during which the flow was

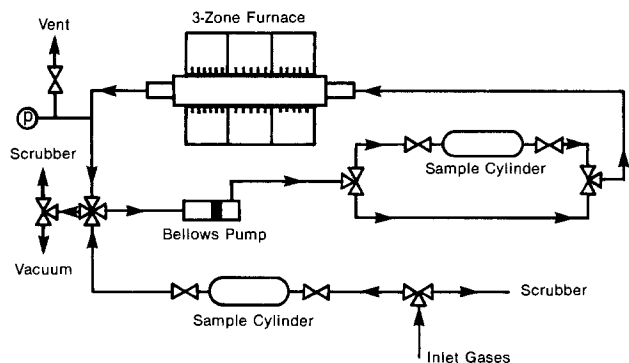

Fig. 2. Schematic diagram of the apparatus

Fig. 3. Comparison of experimental data with theoretical data (1, 2) at 1250 K and 1 atm total pressure. Recycle time was 15 min.

directed straight through the tube to the scrubber with no recycle. This procedure not only established the desired concentration in the lines, but also built an initial deposit of silicon on the reaction-tube inner wall.

The equilibration of the reactant gases was the third step. The valving was switched so that the bellows pump recycled the gases through the sample cylinders to the furnace and then back. The recycling was generally done for 15 min, though some tests were performed to determine the extent of reaction as a function of recycle time. 15 min was more than adequate to reach equilibrium under these conditions.

Steps four and five were used only for those tests where etching was performed. Step four was a hydrogen purge to remove the deposition gases followed by a procedure similar to step two where the hydrogen/HCl mixture was introduced to the flow circuit. After the etching mixture flowed for 15 min, the valve was switched for recycle (step five). Because the etching step was slower than deposition, this recycle step was run for 2h, during which equilibrium was established.

Results and Discussion

The primary result of the experiments described herein is the dependence of the equilibrium Si/Cl ratio on the temperature and Cl/H ratio, pressure being constant. Experiments were conducted at temperatures of 1250, 1350, and 1450 K and covered a range of 0.01-0.6 in the Cl/H ratio. The results are presented in Fig. 3-5 along with calculated results using the data from Herrick and Sanchez-Martinez (1) and from Hunt and Sirtl (2). The experi-

Fig. 4. Comparison of experimental data with theoretical data (1, 2) at 1350 K and 1 atm total pressure. Recycle time was 15 min.

Fig. 5. Comparison of experimental data with theoretical data (1, 2) at 1450 K and 1 atm total pressure. Recycle time was 15 min.

Fig. 6. Time dependence of experimental results compared with Fig. 3. All results were at 1250 K and 1 atm total pressure.

mental results follow closely the general shape of the calculated results. They do not, however, coincide with one or the other of the calculations at all conditions tested. The results of experiments at 1250 K coincide closely with the calculated results of Ref. (2), whereas at 1350 and 1450 K, the experimental data fall between the two calculated curves.

One test of the extent to which this experimental system reached equilibrium is the comparison of results from both etching with HCl and deposition from a variety of chlorosilane sources. The results of both 1250 and 1350 K coincide regardless of the reactant gas used for deposition. The etching and deposition results also agree well. At 1450 K, the results from depositions using TCS were slightly different from depositions using TET. Because of excessive formation of polychlorosilanes, etching experiments at 1450 K were not directly comparable to the deposition results.

Another test of the achievement of equilibrium is to compare results obtained using a variety of recycle times. Results for experiments with sufficient recycle times should all fall on the same locus of points. In Fig. 6, results are shown for recycle times of 5, 10, 15, and 30 min, all of which fall on the same curve. Also shown are the results of a test where samples were taken of the inlet gas, of gas which made only one pass through the oven (no recycle), and of the normal 15 min recycle run (these are connected by dashed lines). These results taken together show that the recycle is necessary to achieve equilibrium and that 5 min is sufficient recycle time to reach equilibrium for this particular set of conditions. These tests were repeated for each of the temperatures of interest, with the same results.

The comparison of results between no recycle and 15 min recycle also points out a major misconception in the understanding of the silicon CVD reaction. Note that not only does the Si/Cl ratio change over the course of the reaction, but the Cl/H ratio does as well. This observation has never been reported before, but was very consistent throughout these tests. It indicates that Cl is being removed from the gas phase in addition to the silicon. Because the chlorosilanes would not condense at the temperatures and pressures present in this apparatus, it is concluded that the change comes about because of the condensation of polychlorosilanes, a family of polymeric compounds with the general formula $(\text{Si-Cl}_x\text{-H}_{2-x})_n$. An oily substance of this type was observed at the outlet end of the reactor tube. This condensation would reduce all

three of the atomic species to various degree, depending on the amounts and degrees of chlorination of these materials. The formation of the polychlorosilanes could explain the differences seen in the results at 1450 K. It is expected that different reaction systems would form polychlorosilanes to varying degrees, depending on the amount of time the gases are held at reaction temperature. Because of this change in the Cl/H ratio, the results are presented using the outlet value of Cl/H as the independent variable, the condition at which the gases come to equilibrium.

Conclusions

This work has shown, for the first time, experimental results of the equilibrium Si/Cl ratio as a function of Cl/H ratio and of temperature. That the results are true equilibrium values was supported by the time invariance of the results and by the coincidence of results from various chlorosilane deposition sources as well as from HCl etching experiments. Experimental results also show that the Cl/H ratio is not necessarily constant for the silicon CVD reaction due to the condensation of polychlorosilanes. The experimental results fall near those which are calculated, though they do not uniquely support any one of the theoretical studies.

ABSTRACT

We describe a new hotwall-C.S.V.T. deposition system, GREG, which is especially suitable for high temperature deposition of large grained, high quality layers of II-VI compounds on common substrates. High growth rates and large deposited area are among the advantages claimed for this technique, which produced layers of CdTe and CdS with good crystalline orientation and large grain size.

The close-spaced vapor transport (C.S.V.T.) method has been utilized as a useful technique for epitaxial deposition of II-VI and III-V compound semiconductors (1-5). The advantage of the C.S.V.T. method (it allows deposition to be carried out at relatively high substrate temperatures, with a small temperature gradient between source and substrate, thus approaching equilibrium crystal growth conditions) makes the use of this, or improved techniques, attractive.

It is the aim of this report to present details of a deposition system, GREG (gradient recrystallization and growth), which is suitable for the deposition of semiconductor layers (especially of II-VI compounds, though not restricted to them) on a variety of common low cost substrates such as Pyrex glass slides, metals, and ceramics. The main improvement is the incorporation of a hotwall chamber that surrounds the source and reaches up to the substrate, so that the evaporant species is continuously surrounded by a high temperature envelope, such that the temperature gradient maintained during growth of the layer is uniform from source to substrate. The hot wall helps to maintain a high partial pressure of the condensing species adjacent to the substrate (23). The following are the salient features of the method.

1. The hotwall chamber, constructed of conductive graphite, maintains the required distance between source and substrate. In contrast with the C.S.V.T. method, which uses small spacings (0.1-1 mm), we use several tenths of a centimeter (0.3-0.8) as a spacing between source and substrate.

2. The surrounding ambient which is Argon gas at a low pressure, from 1 to 0.1 torr, maintains the delicate balance between the deposition and evaporation from the substrate; at the same time, the low pressure reduces collision events and decreases loss of incident energy of evaporant material by thermalization.

3. Large grained (30-50 μ) layers can be obtained rapidly with the GREG technique even on glass substrates at temperatures between 500° and 600°C. The very short deposition times required to obtain an appreciable thickness of the deposit allow Pyrex or other glass substrates to be used without much deformation.

A summary of the advantages claimed for the GREG method follows.

1. Ability to obtain well-oriented (see x-ray data), large grained layers (of CdTe, CdS, ZnSe) on low cost, commonly available glass substrates.

2. Large area of deposition, because of the use of a hotwall chamber which surrounds both source and substrate in a temperature gradient. Layers of 30-40 cm² can be grown with the existing GREG system.

3. Rapid growth rates (6-10 μ /min) make the method especially suitable for applications requiring thick layers, such as for thermoelectric modules, on large area substrates.

4. Ease of doping the layers using the GREG cycling mode (17) where a very thin film of dopant metal (*e.g.*, Al or Ag) is first deposited onto the substrate. By reversing the temperature gradient repeatedly, the dopant can be incorporated into the layer.

The GREG system, as suggested by its name, can also be used for the gradient recrystallization of previously grown films lacking in crystalline structure. The application of a temperature gradient during recrystallization improves the layer quality, as seen from data in Fig. 3(b). Thus the GREG system has two main applications: growth of semiconductor layers from suitable sources and recrystallization of random or structureless layers of films to obtain better layer characteristics.

On single-crystal CdTe (111) or (100) substrates, good quality epitaxial layers were obtained even though the growth rate was about 7-8 μ m/min (20).

The GREG system consists of three graphite blocks shown in schematic view in Fig. 1. The lower block (A) is termed the source block and the upper one (B) is the substrate block. The third and important element of this design is the hotwall chamber (C). The use of a hotwall chamber in high vacuum evaporation has been described by Behrnt and Moreno (8) for ZnTe, by López-Otero (9), and by Menezes (10) for CdTe, but has not so far been used in C.S.V.T. systems. Thermocouples are provided in each of the three blocks to monitor temperatures, which are controlled by S.C.R. controllers.

Although diffusion seems to play an important role in the transport mechanism (19), the deep etching, in regular planes of the source material (when single-crystal material is used), indicates that thermal etching of the source in the presence of argon may also be important.

Experimental

The general procedure for deposition of CdTe, CdS, and ZnSe using the GREG technique is as follows.

The substrates were thoroughly cleaned (11) using TCE, acetone, and a final rinse in an ultrasonic cleaner with alcohol. The hotwall chamber was loaded with the sub-

Fig. 1. Schematic of the GREG deposition system. The following labels refer to components of interest: (A) source block; (B) substrate block; (C) hotwall with chambers for source material; (L.T.1) low tension supply for substrate heater; (L.T.2) low tension supply for source heater.

Fig. 2. (bottom) Photomicrograph of a CdTe layer deposited at 600°C on a glass substrate ($\times 600$). (top) Electron micrograph of a CdTe layer deposited by the GREG system at 650°C on a glass substrate ($\times 3000$).

strates and the source block with the evaporant (CdTe). The chamber was then evacuated to a pressure of less than 10^{-5} mm. Argon gas was introduced till a steady

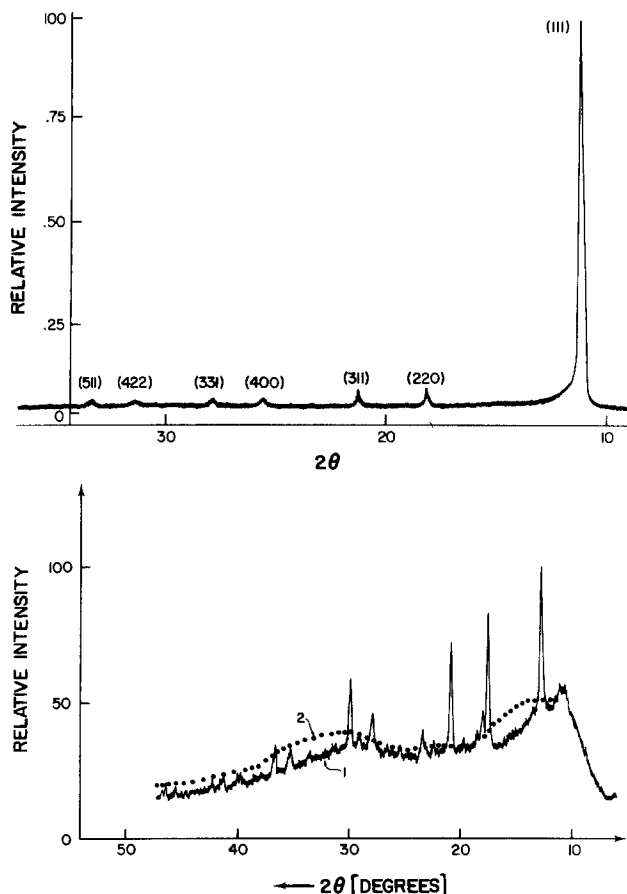

Fig. 3. (top) X-ray diffractometer trace of a CdTe layer deposited at 500°C substrate temperature and 625°C source temperature. (bottom) Recrystallized layer (1) and original amorphous layer (2).

pressure of 500-700 mtorr was obtained in the chamber. The pressure was monitored by a thermocouple vacuum gauge.

The deposition temperature was in the range 400°-600°C for the substrate block and 470°-650°C for the source block. Since the substrate is in intimate contact with the substrate block, we assume only a negligible temperature difference between the substrate and the substrate block heater whose temperature is continuously measured.

Characterization of Layers

Electron and photomicroscopy.—Figure 2 (bottom) shows a photomicrograph of a CdTe layer deposited at 500°C on a glass substrate. Figure 2 (top) shows an electron micrograph taken with a scanning electron microscope of a GREG-deposited CdTe layer which was deposited at 650°C on a glass substrate. The clean facets of the cubic CdTe crystals are clearly seen in the photograph. The (100) and (111) planes can be clearly distinguished in the picture.

X-ray diffraction.—All CdTe layers deposited by the GREG method show a cubic structure with the (111) plane being more usually the oriented plane. Most layers showed highly oriented crystal structure with the (111) plane being the principal plane of orientation. Figure 3 (top) shows a typical trace taken on an x-ray diffractometer of a specimen of CdTe deposited by the GREG technique with 75°C gradient.

Energy of activation.—In Fig. 4, we have plotted the log transport ratio ($\text{mg}/\text{cm}^2\text{-min}$) against temperature of source. The lower activation energy (34 K cal/mol) for deposition may be due to the geometry of the GREG system and the lower argon ambient pressure.

Thermoelectric power.—Preliminary thermoelectric power measurements were carried out on some specimens of CdTe deposited by the GREG method. Using the technique described by Arnoldussen (12), we obtained carrier concentrations of $\sim 10^{13}/\text{cm}^3$ for undoped specimens of CdTe and of $10^{16}\text{-}10^{17}/\text{cm}^3$ for aluminum and indium doped specimens. These values were in good agreement with the known doping concentration of the source material.

Electroreflectance.—Electroreflectance spectra taken for specimens of CdTe on conducting glass substrates show the characteristic line shape for CdTe (13). The measurements confirm the optical bandgap of the deposited CdTe to be 1.45 eV at room temperature (14).

Fig. 4. Log transport ratio vs. temperature of source

Photoluminescence.—CdTe layers deposited by the GREG method showed strong photoluminescence. The photoluminescence spectrum of CdTe on ordinary glass showed an interesting structure which is very similar to that obtained with single crystals (15). Photothermal deflection spectroscopy was also used, to study the stoichiometry characteristics of these layers (16). Strong photoluminescence was also obtained with ZnSe and ZnS layers produced by the GREG method (21, 22).

Conclusions

We have demonstrated an improved hotwall-C.S.V.T. growth technique (GREG) which can also be used for gradient recrystallization of previously grown films. The advantages are: the use of commonly available substrates, large grain size and lower grain boundary concentration, large area, growth conditions approaching equilibrium as compared to high vacuum deposition, fast deposition rate without loss of layer quality, and applicability to many semiconductor materials. On single-crystal substrates, good quality epitaxial layers can be produced at a fast growth rate. CdTe layers have been used in experimental solar cells in a simple process (18).

Acknowledgments

Thanks are specially due to Dr. Richard Bube and Dr. A. F. Fahrenbruch for discussion and several useful suggestions in the course of this work. We also wish to thank my colleagues Dr. Feliciano Sánchez Sinencio, Dr. Ciro Falcony, Dr. Alfonso Lastras, and Dr. Julio Mendoza. Special thanks are due to Mr. Orlando Zelaya Angel, who carried out many of the depositions and made measurements of the thermoelectric power, optical absorption, and x-ray diffraction. This work was supported by a grant from the CONACYT and NSF (International Programs) and by O.A.S.

ABSTRACT

Transient properties of Eu^{3+} emitting levels $^5\text{D}_2$, $^5\text{D}_1$, and $^5\text{D}_0$ in an yttrium oxysulfide matrix have been studied at various activator concentrations and under different excitation modes. Eu^{3+} was excited either to the charge-transfer state (CTS) by UV light or selectively to the $^5\text{D}_1$ levels by laser. At low Eu^{3+} concentrations, the results can be explained by a step process, $^5\text{D}_2 \rightarrow ^5\text{D}_1 \rightarrow ^5\text{D}_0$; the values calculated from rate equations are in agreement with the measured ones. The decrease of the lifetimes of $^5\text{D}_2$ and $^5\text{D}_1$ with increasing Eu^{3+} concentration can be explained by a cross-relaxation process between the Eu^{3+} ions. The lifetime of $^5\text{D}_0$ level decreases linearly with concentration when excited to CTS or with cathode rays; with selective excitation, the lifetime of $^5\text{D}_0$ is constant. The quenching of $^5\text{D}_0$ seems to be more complex than energy transfer to a sink and is possibly connected to the presence of Eu^{3+} ions excited into CTS, or is caused by the electronic structure of $(\text{YO})_2\text{S}$. In Tb^{3+} -activated oxysulfides, no step process $^5\text{D}_3 \rightarrow ^5\text{D}_4$ was observed. $(\text{GdO})_2\text{S}:\text{Tb}^{3+}$ compounds contained Eu^{3+} as an impurity, and an effective energy transfer $\text{Tb}^{3+}(^5\text{D}_4) + \text{Eu}^{3+}(^7\text{F}_0) \rightarrow \text{Tb}^{3+}(^7\text{F}_4) + \text{Eu}^{3+}(^5\text{D}_0)$ was noticed.

The fluorescence-decay studies of luminescent materials have been used to determine parameters such as energy-transfer rates, as well as radiative and nonradiative transition probabilities [e.g., Ref. (1), (2)]. On the other hand, many applications of inorganic phosphors have

specific requirements for the lifetime of luminescence. For instance, the afterglow of the phosphor cannot be too long in cathode-ray tubes. The measurement of the lifetime thus belongs to the quality control of commercial phosphors.

The dependence of intensity on Eu^{3+} and Tb^{3+} concentrations in rare-earth oxysulfides has been extensively studied, mainly under cathode-ray excitation (3-7), but also under ultraviolet light (4, 8, 9). Different aspects of the interaction mechanisms between the host lattice and the activator ion, or even between different activator ions, have been clarified. The characteristics of the Eu^{3+} emission *vs.* temperature in rare-earth oxysulfides have also been investigated by Struck *et al.* (10, 12). These experiments have shown the importance of the charge-transfer state (CTS) in the thermal quenching of Eu^{3+} luminescence. A crystal-field analysis of an Eu^{3+} spectrum in oxysulfides has been performed by Sovers (13).

The present study is a continuation of our previous one on the lifetimes of Eu^{3+} emission lines in an yttrium oxysulfide matrix and on the concentration dependence of lifetimes (14). In comparison with our previous observations under cathode-ray excitation, we present here detailed measurements under pulsed laser beam excitation. Ultraviolet light emitted by the nitrogen laser permits excitation into the CTS, whereas the use of tunable dye laser allows selective excitation into the $^5\text{D}_j$ levels of Eu^{3+} . The study of temporal evolution of Eu^{3+} emission in these different cases thus gives a better insight into the various phenomena occurring in the luminescence process which is the aim of the present work. The lifetime studies are also extended to other activator-matrix combinations than $(\text{YO})_2\text{S}:\text{Eu}^{3+}$, *viz.*, $(\text{GdO})_2\text{S}:\text{Tb}^{3+}$.

Experimental

The preparation of the rare-earth oxysulfide samples has been described elsewhere (14, 15). The europium and terbium concentrations varied between 0.1 and 12 mole percent (m/o). The purity of the host oxides was 99.99% and that of activators was 99.9%. This means that at higher activator concentrations, the trace elements of activator may play a role in the luminescence measurements. Particularly, Eu, Gd, and Tb can contain each other as impurities because they are the successive elements in the periodic system. Therefore, in $(\text{GdO})_2\text{S}:\text{Tb}^{3+}$ (10%), *e.g.*, the europium concentration can be several ppm.

The cathode-ray equipment has been described earlier (14). The photonic excitation was performed either by a JOBIN-YVON pulsed nitrogen laser ($\lambda = 3370\text{\AA}$, corresponding excitation into the CTS of Eu^{3+}) or by a JOBIN-YVON pulsed dye laser (selective excitation into the $^5\text{D}_j$ levels of Eu^{3+}). A schematic representation of the equipment used is shown in Fig. 1. The pulse duration is about 8 ns and the repetition rate is 10 Hz. The dye laser is tunable

within a wavelength range characteristic for the dye; its linewidth is 0.2\AA at 5800\AA .

The luminescence spectra were measured through a Jarrel-Ash monochromator of 1m focal length. The rising and decay curves were analyzed in a Boxcar integrator (ATNE) connected to a photomultiplier via an amplifier. The signal was digitalized and stored in a minicomputer (COMMODORE CBM 3032). The intensity fluctuations of the laser beam were corrected by the use of a photodiode reference. The signal/noise ratio was improved by summing over several pulses, generally 10 pulses.

The determinations of τ were made by the computer either by linear regression of $\log I(t)$ for exponential decays or by computing the mean duration $T_m = \int_0^\infty I(t)tdt / \int_0^\infty I(t)dt$. The uncertainty is experimentally estimated to be 3% for measurements with the same excitation and mode of computation.

Results and Discussion

Several points have to be specified before discussing experimental results. The positions of the Eu^{3+} energy levels in oxysulfide and the different notations used in the following are presented in Fig. 2. Let us first consider the case where ion-ion interactions (here, $\text{Eu}^{3+}-\text{Eu}^{3+}$) are not effective, *i.e.*, low europium concentrations. An excited level (say, $^5\text{D}_2$) may relax radiatively ($^5\text{D}_2 \rightarrow ^7\text{F}_j$ emission) and nonradiatively ($^5\text{D}_2 \rightarrow ^5\text{D}_{j<2}$) by a multiphonon process or quench via the CTS (10-12). The emission intensity $I(t)$ for a given level i is proportional to $n_i(t)$, the number of ions excited at time t . $n_i(t)$ follows the general evolution (16)

$$n_i(t) = \sum_{j=1}^k A_j^i e^{-t/T_j} \quad [1]$$

where i and j refer to given levels within the k -levels system. A_j^i are determined by the initial conditions and T_j are the inverse decay (radiative + nonradiative) probabilities. The reverse transitions $i \rightarrow j$ are neglected, which in the particular case of oxysulfide matrices implies working at low temperature to avoid $^5\text{D}_1 \rightarrow \text{CTS} \rightarrow ^5\text{D}_j$ processes. Although exact solutions do exist for the equations system (1), the relation between the decay function of one given level and the various individual probabilities are too complex to be of physical use when $k > 4$, and several approximations are then necessary. Even without searching for exact solutions, Eq. [1] shows that decay functions differ with the excitation mode. In the case of ultraviolet excitation of Eu^{3+} into the CTS (level 5), for example, $n_i(t) = f(P_{51}, P_{41}, P_{31}, P_{21}, P_{10})$, whereas under selective excitation, $n_i(t) = f(P_{i0}) = n_i(t_0)e^{-t/\tau_i}$.

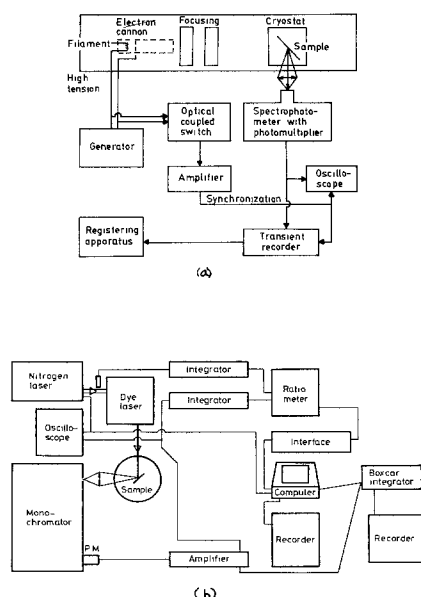

Fig. 1. Schematic representation of the equipment: (a) cathode-ray excitation; (b) pulsed-laser excitation.

Fig. 2. Schematic representation of Eu^{3+} levels from Ref. (11) and notations used in the text.

In the low concentration limit, the so-called rate equations may apply. The simple case of a three-level system is treated in the Appendix with reference to the Eu³⁺ ⁵D₁ (*i* = 2), ⁵D₀ (*i* = 1), and ⁷F₁ (*i* = 0) levels. It is shown that the consideration of the "mean duration of luminescence"

$$T_m = \int_0^\infty tI(t)dt / \int_0^\infty I(t)dt \quad [2]$$

permits one to discuss in a simple quantitative way the validity of rate equations in a given experimental case. The final equations ([A-8], [A-9]) can be verified only by using selective excitation. *T*₂ and *T*₁ are the ⁵D₁ and ⁵D₀ lifetimes measured successively under the ⁵D₁ and ⁵D₀ excitations. (*T*_m's are equal to 1/*e* lifetimes.) *T*_{1m} is the mean ⁵D₀ duration under ⁵D₁ excitation.

Equation [A-8] applies for any given three-level system, provided that the appropriate *T*'s are known. For instance, in the case of ⁵D₂ (*i* = 3) and ⁵D₁ (*i* = 2) levels, *T*_{2m} = *T*₂ + *T*₃ where *T*₂ and *T*₃ are determined under selective excitation of ⁵D₁ and ⁵D₂, respectively; *T*_{2m} refers to ⁵D₁ emission under ⁵D₂ excitation.

When the activator concentration increases, ion-ion interactions become more effective and the equations above are no longer valid. Eu³⁺-Eu³⁺ interaction causes ⁵D₂ and ⁵D₁ emission quenching by cross-relaxation processes like (17)

The emptying of upper levels causes the feeding of lower levels, and the overall effect is that *P*₂₁ and *P*₃₂, which include Eu-Eu energy-transfer probabilities, increase with concentration. In this case, as explicitly formulated by Inokuti and Hirayama (18), the decay function of donor luminescence is not exponential and

$$n_2(t) \sim \exp[-t/T_0 - \Gamma(1 - 3\theta)(c/c^*)(t/T_0)^{3/\theta}] \quad [3]$$

where *T*₀ is the (*i* = 2) radiative lifetime at low concentration, *Γ* a function of argument unity, *c* the dopant ion concentration, and *c** the critical activator concentration. *θ* defines the index of multipolar interaction. Experimental determination of *θ* has been made for numerous rare-earth-doped systems [see, e.g., Ref. (19) and references therein].

The above formulation (Eq. [3]) is still an approximation because the diffusion between identical levels without energy degradation has not been considered. When the diffusion of energy is very effective, the donor ion system (Eu³⁺ excited on ⁵D₁ level, for instance) exhibits a simple exponential decay and rate equations analogous to Eq. [A-2] and [A-3] apply. The intermediate case of diffusion-limited relaxation has been evidenced, for example, by Weber for Eu³⁺-Cr³⁺ doped samples (20).

The recent investigations, where emission from selected activator pairs has been monitored, give new information from ion-ion energy transfer (21-24). There are, however, many problems when these results are applied to the real samples.

Europium-activated yttrium oxysulfide (Y_{1-x}Eu_xO)₂S.—Figure 3 shows the concentration dependence of the lifetime of excited ⁵D₂ and ⁵D₁ levels of Eu³⁺ in (YO)₂S, excited with two different modes into the CTS of Eu³⁺ (3370Å). The shapes of the curves are similar in both excitation modes, but the lifetime values depend on the excitation mode. The lifetimes measured with UV excitation are shorter in the cases of ⁵D₁ and ⁵D₂ than those obtained by cathode ray excitation. Ozawa (3, 5) has given evidence that relaxation mechanisms are different when exciting luminescence by cathode ray or by photons (into CTS or ⁵D levels), which may explain the differences in *T*_m. Moreover, the pulse duration of electron beam (~1 ms) is much longer than the laser pulse, so the initial conditions for Eq. [A-3] should be modified (*N*₁⁰ ≠ 0); this leads to a different expression for *n*₁(*t*).

The lifetime (*T*_m) vs. Eu³⁺ concentration curves are nearly exponentially decreasing in the ⁵D₁ and ⁵D₂ cases. When the europium concentration is increased from 0.1 to

Fig. 3. Comparison of the lifetime vs. Eu³⁺ concentration curves of ⁵D₁ and ⁵D₂ levels when excited by both cathode rays and nitrogen laser (*λ* = 3370Å) at 300 K.

6%, the lifetimes are decreased from 180 and 110 μs to 50 μs and from 130 and 120 μs to 40 and 20 μs for ⁵D₁ and ⁵D₂ cases with both cathode ray and UV excitation, respectively. With higher europium concentrations, the intensity of these levels is so low that the lifetime measurements were impossible.

In our previous work (14), we reported the linear decay of *T*_m(⁵D₀) vs. Eu³⁺ concentration in the range 2-10% Eu³⁺. However, the experimental determination of *T*_m according to Eq. [2] has proven to be a simple and more precise method for the determination of activator concentrations. Figure 4 shows the evolution of *T*_m(⁵D₀) at 300 K vs. concentration for cathode ray, UV, and dye laser selective excitations. Most striking is that under direct selective excitation, *T*_m(⁵D₀) remains almost constant in the range 0.5% ≤ *x* ≤ 10% (*T*_m = 470 ± 20 μs) and suddenly falls at *x* = 12% (*T*_m = 400 μs). The observed discrepancies will be discussed in the following.

Fig. 4. The effect of excitation mode on the lifetime vs. concentration curves of ⁵D₀ of Eu³⁺ at 300 K: Cathode-ray excitation; pulsed nitrogen-laser excitation into the CTS level (3370Å); selective laser excitation into the ⁵D₀ level (5832Å).

We have investigated in detail the emission properties at relatively low dopant concentrations ($x = 0.005$). Because the phosphor characteristics are changed with temperature (10), the sample is immersed in liquid nitrogen and then has a constant temperature of 77 K. The main observations are the following.

Practically no differences were observed in the rise and decay curves when Eu^{3+} was excited into CTS (3370Å) or $^5\text{D}_2$ (4767Å), and $^5\text{D}_{2-0}$ emission was monitored. According to Struck and Fonger (10-12), at this composition and temperature, CTS excitation feeds instantaneously the $^5\text{D}_2$ and $^5\text{D}_1$ levels by passing $^5\text{D}_3$ and higher levels. This is in agreement with the observation of the same transient characteristics for both excitations. Selective excitation into $^5\text{D}_3$ level ($\lambda = 4130\text{Å}$) (13) at 77 K has proven to be impossible. Instead we observed the same weak fluorescence signal when tuning the laser between 4100 and 4150Å. On the other hand, Eu^{3+} is selectively excited with $\lambda = 3970\text{Å}$ corresponding to an upper 4f state observed but unidentified (11). This excitation mode leads to the same characteristics as did UV and $^5\text{D}_2$ excitation. The levels situated above $^5\text{D}_2$ have decay times too short to influence the lifetimes of the lower lying levels.

Under direct selective excitation, the decay curves of $^5\text{D}_2$, $^5\text{D}_1$, and $^5\text{D}_0$ levels are exponential within our experimental precision. The values are reported in Table I. By exciting $^5\text{D}_1$ ($i = 2$) and monitoring the evolution of $^5\text{D}_0$ ($i = 1$) fluorescence with time, we may discuss the applicability of Eq. [A-8]. The curve is presented in Fig. 5 and clearly shows a delayed buildup when compared with direct excitation. The numerical values are $T_1 = 1/P_{10} = 458 \mu\text{s}$, $T_2 = 1/(P_{21} + P_{20}) = 160 \mu\text{s}$, and $T_{1m}(\text{calc.}) = 618 \mu\text{s}$ instead of experimental $553 \pm 17 \mu\text{s}$. In the same way, we may study the values T of $^5\text{D}_2$ ($i = 3$) and $^5\text{D}_1$ ($i = 2$) under respective direct excitations as $1/(P_{32} + P_{31} + P_{30}) = 151 \mu\text{s}$ and $1/(P_{21} + P_{20}) = 160 \mu\text{s}$ giving $T_{2m}(\text{calc.}) = 311 \mu\text{s}$. The corresponding experimental value is $263 \mu\text{s}$.

The maximum $^5\text{D}_1$ intensity is reached experimentally at $\Delta t = 200 \mu\text{s}$, and by applying Eq. [A-4], the maximum is at $\Delta t(\text{calc.}) = T_2 T_1 / T_2 - T_1 \ln T_1 / T_2 = 258 \mu\text{s}$. The measured values are then 10%-20% lower than the theoretical ones. The difference is appreciably greater than our experimental uncertainty. Nevertheless, the general trend is that successive $^5\text{D}_2 \rightarrow ^5\text{D}_1 \rightarrow ^5\text{D}_0$ cascade process is effective at a Eu^{3+} concentration of 0.5% and that the order of magnitude of these measured mean lifetimes justifies the use of so-called rate equations at this Eu^{3+} concentration (and of course at smaller concentrations). The possible reasons for the observed discrepancies will be discussed in the following. On the contrary, at higher concentrations (6% Eu^{3+}), Eq. [A-8] gives $T_{1m}(\text{calc.}) = 595 \mu\text{s}$ instead of the $495 \mu\text{s}$ obtained experimentally. For this concentration, the observed T_{1m} are equal for any excitation mode, although upper levels have a non-negligible decay time ($100 \mu\text{s}$ for

Fig. 5. Comparison of the transient properties of the $^5\text{D}_0$ level in $(\text{YO})_2\text{S}:\text{Eu}^{3+}$ (0.5%) at 77 K when excited by different methods: (1) into the CTS level; (2) $^5\text{D}_1$ level; and (3) $^5\text{D}_0$ level. ΔT_1 is the risetime of $^5\text{D}_0$.

$^5\text{D}_1$, Table I). This clearly shows that at this concentration, Eq. [A-2] and [A-3] are no more applicable due to ion-ion interactions which seem to be effective above the activator concentration of 1%.

Terbium-activated gadolinium oxysulfides ($\text{Gd}_{1-x}\text{Tb}_x\text{O}_2\text{S}$).—The behavior of the $^5\text{D}_4$ level of terbium was studied with the transition $^5\text{D}_4 \rightarrow ^7\text{F}_5$ (5440Å). The excitation wavelengths used were 3370 and 4897Å. The first value hits an f-f transition of Tb^{3+} and the second corresponds to the selective excitation of $^7\text{F}_6 \rightarrow ^5\text{D}_4$. The exponential decay curves are independent of the excitation way.

Yamamoto *et al.* (7) have observed the $^5\text{D}_3 \rightarrow ^5\text{D}_4$ step process in cathodoluminescence of Tb^{3+} at concentrations as low as 0.1%. In the present measurements, no delayed buildup of $^5\text{D}_4$ level was observed under any excitation condition with Tb^{3+} concentrations between 1% and 10%. This means that the cross-relaxation process $\text{Tb}^{3+}(^5\text{D}_3) + \text{Tb}^{3+}(^7\text{F}_6) \rightarrow \text{Tb}^{3+}(^5\text{D}_4) + \text{Tb}^{3+}(^7\text{F}_6)$ (25) is effective and that above 1% of Tb^{3+} the rate equations do not apply.

The concentration quenching of $^5\text{D}_4$ level in $(\text{GdO})_2\text{S}:\text{Tb}^{3+}$ samples is presented in Fig. 6. The shapes of the lifetime vs. Tb^{3+} concentration curves are similar in both excitation modes. Strong quenching was observed: the measured lifetime with 10% of Tb^{3+} was approximately 80% shorter than that with 1% of Tb^{3+} . In literature, the quenching of $^5\text{D}_4$ level in oxysulfide matrices has been reported to begin at concentrations of about 5%-6% (9, 26). In other high purity Tb^{3+} -activated compounds, a weak $^5\text{D}_4$ quenching has been observed (27, 28). The shortening of T in these compounds has been only about 10% when the Tb^{3+} amount varied between 0.1% and 100%.

In the present oxysulfide samples, at least a part of the additional quenching is due to the presence of a significant amount of Eu^{3+} , estimated to be 0.05%-0.1%. Europium probably originates from the impurities of gadolinium oxide. The fluorescence spectra of these compounds exhibit both Tb^{3+} and Eu^{3+} emissions. The relative intensities of the emissions vary with the excitation mode (Table II).

In $\text{Tb}^{3+}\text{-Eu}^{3+}$ interaction, the enhancement effect of Eu^{3+} emission by a small amount of Tb^{3+} in oxysulfide phosphors (7, 29) is well known. Yamamoto *et al.* (7) point out, however, that the simple multipolar energy transfer is not preponderant, at least for cathode ray excitation. On the contrary, this mechanism seems to be effective in experi-

Table I. Measured lifetimes (μs) for $(\text{Y}_{1-x}\text{Eu}_x\text{O})_2\text{S}$ samples at 77 K. (a) Direct selective excitation ($T_e = T_m$); (b) indirect excitation (T_m).

Fig. 6. Lifetime of 5D_4 vs. Tb^{3+} concentration in $(GdO)_2S$ matrix when excited with wavelengths 3370 Å (○) and 4897 Å (●) at 300 K. Note that the samples contain a small amount of europium as impurity.

mental conditions employed in the present work. The excitation spectra recorded between 4800 and 5000 Å for ${}^5D_4 \rightarrow {}^7F_5$ of Tb^{3+} at 5440 Å and ${}^5D_0 \rightarrow {}^7F_2$ of Eu^{3+} at 6165 Å show exactly the same shape with a line at 4897 Å corresponding to ${}^7F_6 \rightarrow {}^5D_4$ transition of Tb^{3+} (Fig. 7). This indicates that the energy transfer occurs via process $Tb^{3+}({}^5D_4) + Eu^{3+}({}^7F_0) \rightarrow Tb^{3+}({}^7F_4) + Eu^{3+}({}^5D_0)$. However, this process is probably not the only one in this system, as shown in Ref. (7). In particular, the results from the relative fluorescence intensities of Tb^{3+}/Eu^{3+} presented in Table II show that the intensity ratio is strongly dependent on the excitation mode, indicating complex interaction phenomena.

Discussion

We will now discuss in more detail the Eu^{3+} -activated oxysulfides. As shown in the previous paragraph, our Tb^{3+} -activated samples are in fact codoped with Eu^{3+} ions; thus there is a risk that the results on Tb^{3+} concentration quenching are altered by the Tb^{3+} - Eu^{3+} ion-ion interactions which we are not dealing with in this paper.

Let us consider the results collected in Fig. 4. By comparing the data measured under UV and direct selective excitation at room temperature, it can be seen that at very low Eu^{3+} concentrations (0.25% and 0.5%), the mean duration T_{im} of 5D_0 luminescence is longer under UV excitation, due to the slow buildup of 5D_0 when Eu^{3+} is excited into higher energetic levels. For $x = 1\%$, the values are equal, whereas for higher concentrations, T_{im} becomes shorter under UV excitation. The difference between the two values increases with x . This indicates that excitation of 5D_0 via the CTS provides an additional pathway for 5D_0 nonradiative relaxation, which becomes more and more effective for higher Eu^{3+} concentrations. Several investi-

Fig. 7. Excitation spectra of transition ${}^5D_4 \rightarrow {}^7F_5$ (5440 Å) of Tb^{3+} (full line) and transition ${}^5D_0 \rightarrow {}^7F_2$ (6165 Å) of Eu^{3+} (dashed line) between 4800 and 5000 Å.

gations of 5D_0 concentration quenching have been reported. Generally they present the 5D_0 fluorescence yield under UV or cathode ray excitation. The 5D_0 quenching does not occur via the usual ion-ion multipolar interactions, because the ${}^5D_0 \rightarrow {}^7F_5$ energy gap cannot be matched by a transition within the 7F_5 multiplet. According to van Uitert (19), the 5D_0 self-quenching is related to exchange between identical Eu^{3+} ions: energy migrates until it reaches a sink. The nature of such sinks is very difficult to disclose, and there may be another rare-earth ion present in the sample as impurity, or the sample may contain crystal defects or grain boundaries.

Another type of concentration-related quenching mechanism proposed in Ref. (19) is more-efficient ion-phonon coupling for paired Eu^{3+} ions. This mechanism may well be the origin of the observed overall diminution of 5D_0 radiative lifetime at 300 K (520 μs for $x = 0.25\%$ vs. 400 μs for $x = 12\%$), but it has no reason to be more effective under CTS than under 5D_0 excitation. Another way to depopulate 5D_0 is up-conversion. Imanaga *et al.* (8) have observed a decrease in Eu^{3+} 5D_1 decay times with strong excitation into the CTS by pulsed nitrogen laser. Their observations are qualitatively in agreement with ours because, moreover, the shortening is stronger for higher Eu^{3+} concentrations. The nonradiative relaxation of 5D_1 states is attributed in Ref. (8) to interactions between Eu^{3+} (5D_1) and Eu^{3+} (CTS). In the absence of more experimental data, we cannot exactly define the mechanism responsible for additional 5D_0 quenching under UV and cathode ray excitation. It is obvious from experimental data, however, that it is directly linked to the presence of CTS-excited Eu^{3+} ions.

At moderately high Eu^{3+} concentrations (6%), rate equations are not available and the differential equations governing even the simple (5D_1 , 5D_0 , 7F) three-level system have not been established. The decay observed for the 5D_1 (donor) system is exponential within the experimental precision so that a donor time evolution following the Inokuti-Hirayama formulation (Eq. [3]) does not apply. The ${}^5D_1 \rightarrow {}^5D_0$ energy transfer occurs instantaneously because no 5D_0 delayed buildup is observed under 5D_1 excitation. Such apparent inconsistencies would probably be resolved only by establishing a correct set of differential equations for $n_i(t)$ and by fitting with experimental results.

Conclusion

Previous measurements dealing with lifetimes or quantum yields of Eu^{3+} -excited levels in $(YO)_2S$ under different excitation modes led to apparently incoherent results. In

Table II. Relative fluorescence intensities of Tb^{3+} and Eu^{3+} in $(Gd_{1-x}Tb_xO)_2S$ samples excited with different modes

particular, the 5D_0 -level lifetime evolution vs. concentration seemed abnormal.

In this work, we have tried to study in some detail the $\text{Eu}^{3+}({}^5D_{j=0-2})$ temporal time evolutions in $(\text{YO})_2\text{S}$. This was made possible by selectively exciting each of the 5D_j levels by means of a pulsed dye laser. The so-called decay time for a given level (i) is not strictly the inverse radiative probability of this level, but is a complex function $T = f(P_{ij})$ which depends on the initial conditions (excitation mode) and the concentration (quenching). At low concentrations (experimentally $< 1\%$ Eu^{3+}), we have shown that the time evolutions of excited levels' populations follow in first approximation the differential equations (rate equations) described in the literature. The function $T = f(P_{ij})$ differs following the way of calculating [mean duration or linear regression of $\log I(t)$]. Only the experimental case of a real three-levels system (observed under selective excitation) leads to a simple relation between T and the P_{ij} 's. For higher Eu^{3+} concentrations, the differential equations' systems describing the excited levels' populations are not known. Experimentally we have drawn the 5D_j fluorescence time evolution and computed the mean durations T_m vs. concentration.

The present study thus complements our previous measurements of T_m under cathodic excitation. In that work, it is shown that the experimental linear evolution of T_m (5D_0) vs. Eu^{3+} concentration is an indirect way of determining the activator concentration in oxysulfide matrices within the usual range $2\% \leq x \leq 10\%$. In the present study, we have observed approximately the same evolution of T_m (5D_0) vs. concentration when excited through the charge-transfer state CTS by means of UV nitrogen laser light. On the other hand, by direct 5D_0 selective excitation a quite different evolution is observed, namely, an almost constant T_m value over the composition range $0.5 \leq x \leq 10\%$. The physical reason for this additional 5D_0 quenching under CTS excitation as well as cathode ray has till now not been elucidated and may be linked to the particular electronic structure of $(\text{YO})_2\text{S}:\text{Eu}^{3+}$. Nevertheless, these comparative measurements prove that the 5D_0 quenching phenomenon is more complex than simple energy migration toward sinks and necessitates further investigation to be fully understood.

For terbium-activated gadolinium oxysulfide, we have evidenced the presence of Eu^{3+} as impurity in the samples as a cause for the 5D_4 concentration quenching. In these compounds, we observe no difference for 5D_4 and 5D_3 time evolution when excitation is made by UV light or selectively within each of the 5D_j levels.

The present work has clearly shown that the use of dye laser selective excitation permits clarifying to some extent the problem of transient properties of Eu^{3+} emission in the yttrium oxysulfide matrix by measuring reliable T_m (mean durations of luminescence) numerical values. Further investigation is, however, needed mainly at relatively high Eu^{3+} concentrations to establish the differential equations ruling the system. In this first step, we have evidenced that the excitation mode (cathode ray, CTS, or direct 5D_j) as well as the mathematical definition for the so-called lifetime have to be carefully defined before comparing different sets of experimental data.

Preliminary report was given at the 16th Rare Earth Research Conference, Tallahassee, Florida (31).

APPENDIX

The time evolutions of Eu^{3+} 5D_1 and 5D_0 levels follow the general formulation (see Fig. 2 for notations)

$$\begin{matrix} n'_0 & = & 0 & P_{10} & P_{20} & n_0 \\ n'_1 & = & 0 & -P_{10} & P_{21} & n_1 \\ n'_2 & = & 0 & 0 & -(P_{20} + P_{21}) & n_2 \end{matrix} \quad [\text{A-1}]$$

The solution is

$$n_2(t) = N_2^0 \exp [-(P_{21} + P_{20})t] \quad [\text{A-2}]$$

$$n_1(t) = \left(N_1^0 + \frac{P_{21}N_2^0}{P_{21} + P_{20} - P_{10}} \right) \exp(-P_{10}t) - \left(\frac{P_{21}N_2^0}{P_{21} + P_{20} - P_{10}} \right) \exp [-(P_{21} + P_{20})t] \quad [\text{A-3}]$$

N_2^0 and N_1^0 are initial values of n at $t = 0$. In case of pulsed excitation, $N_2^0 = N_2$ and $N_1^0 = 0$ can be assumed. P_{ij} is the $i \rightarrow j$ transition probability. From Eq. [A-2] and [A-3] the following conclusions can be obtained.

1. The emission intensity at level 1 shows an initial rise and then a decay formed in general by the sum of two exponentials. However, when $P_{10} \ll P_{21} + P_{20}$, the slope of $\ln [n_1(t)] = f(t)$ gives $T_e = 1/P_{10}$, the 5D_0 radiative lifetime.

2. $n_1(t)$ is at maximum at time

$$t = \frac{1}{P_{10} - P_{21} - P_{20}} \ln \frac{P_{10}}{P_{21} + P_{20}} \quad [\text{A-4}]$$

3. When $N_1^0 = 0$, Eq. [A-4] can be written

$$n_1(t) = \frac{P_{21}N_2^0}{P_{21} + P_{20} + P_{10}} [\exp(-P_{10}t) - \exp(-(P_{21} + P_{20})t)] \quad [\text{A-5}]$$

if $K = \frac{P_{21}N_2^0}{P_{21} + P_{20} - P_{10}}$

$$\int_0^\infty t n_1(t) dt = K \left[\left(\frac{1}{P_{10}} \right)^2 - \left(\frac{1}{P_{21} + P_{20}} \right)^2 \right] \quad [\text{A-6}]$$

and

$$\int_0^\infty n_1(t) dt = K \left(\frac{1}{P_{10}} - \frac{1}{P_{21} + P_{20}} \right) \quad [\text{A-7}]$$

taking T_m from Eq. [2] follows

$$T_{1m} = \frac{\int_0^\infty t n_1(t) dt}{\int_0^\infty n_1(t) dt} = \frac{1}{P_{10}} + \frac{1}{P_{21} + P_{20}} \quad [\text{A-8}]$$

Experimentally, P_{10} may be measured as $1/T_1$, and $(P_{21} + P_{20})$ may be measured as $1/T_2$ under selective excitation.

Then

$$T_{1m} = T_1 + T_2 \quad [\text{A-9}]$$

In many rare-earth systems, the decay times of the levels are very different so that various approximations can be employed. For example, if $T_2 \ll T_1$ in Eq. [A-8], $T_{1m} = T_1$ and may be determined as the 1/e decay time. In the case of Eu^{3+} , however, the 5D_0 lifetime is only about twice the lifetimes of 5D_1 and 5D_2 , which are almost equal. So the above approximation cannot be used.

Comparative Study of Sensitization of the Luminescence of Trivalent Rare Earth Ions by Ce³⁺ in LaOBr

Li You Mo,¹ F. Guillen, C. Fouassier, and P. Hagemmuller

Laboratoire de Chimie du Solide du CNRS, Université de Bordeaux I, 33405 Talence Cedex, France

ABSTRACT

Energy transfer from cerium to the Pr³⁺, Nd³⁺, Tb³⁺, Dy³⁺, Ho³⁺, and Er³⁺ ions has been observed in LaOBr. Comparison of the effect of the activator ions on the cerium emission intensity suggests that transfer occurs mainly by an exchange mechanism, after migration of the excitation among donor ions. With increasing cerium concentration, the ³P₀ praseodymium, ⁵S₂ holmium, and ⁴S_{3/2} erbium emissions are quenched, the energy difference between the transition to the next lowest level and the ²F_{5/2} → ²F_{7/2} cerium transition being sufficiently small for energy transfer. The cerium emission is quenched at room temperature by the Sm³⁺, Eu³⁺, Tm³⁺, and Yb³⁺ ions without sensitization of the activator as a result of the formation of a charge-transfer (Ce⁴⁺-divalent activator ion) state.

The use of rare earth phosphors in lamps has developed in recent years. Only two rare earth elements, europium and terbium, are used as activators. Both of them are expensive, so it is worthwhile investigating the possibility of using other lanthanides. Several reasons account for the remarkable properties of Eu³⁺ and Tb³⁺: (i) Eu³⁺ can be made (by high concentration) to emit dominantly from ⁵D₀ with the favorably placed ⁵D₀ → ⁷F₁, ⁷F₂ most prominent, and, similarly Tb³⁺ can be made to emit dominantly from ⁵D₄ with the favorably placed ⁵D₄ → ⁷F₅, ⁷F₄, ⁷F₃ most prominent; (ii) the large gap between the emitting level and the next-lowest excited state precludes nonradiative losses by multiphonon processes; (iii) the UV excitation radiation can be strongly absorbed, since Eu³⁺ shows a charge-transfer band and Tb³⁺ allowed f → d transitions around 250 nm; the Tb³⁺ emission can also be efficiently excited through a sensitizer like Ce³⁺; and (iv) concentration quenching is weak (no cross relaxation). Most other trivalent rare earths do not possess allowed transitions above 250 nm, so a high efficiency requires a sensitizer. Although the Ce³⁺ → Tb³⁺ transfer has been extensively studied, transfer from cerium to other luminescent rare earth ions has drawn much less attention. However, the importance of Ce → Ce migration for avoiding concentration quenching of the Sm³⁺ or Dy³⁺ ions has been emphasized (1, 2).

For cations like Ho³⁺ or Er³⁺ whose energy levels are closely spaced, a high probability for radiative emission in the visible requires weak phonon energies or weak coupling to phonons. This is the case for lanthanum oxybromide, LaOBr. Hölsa (3) has recently published the visible emission spectra of the trivalent rare earths in this host lattice. The emitting levels under UV excitation are indicated in Fig. 1 for some of those ions.

Ce³⁺ shows an intense blue emission peaking at 435 nm at room temperature (5-7). Rabatin and Sieger (8), Hölsa *et al.* (7), and H. Wang *et al.* (19) have shown that energy transfer from Ce³⁺ to Tb³⁺ occurs in LaOBr. However, despite the presence of several f-f absorption lines in the wavelength range of the cerium emission, no sensitization

of the samarium, holmium, dysprosium, or thulium emissions was observed (8).

For determining the parameters which govern the efficiency of the transfer from Ce³⁺ to other trivalent rare earth ions we have undertaken an investigation of the luminescence of the Pr³⁺, Nd³⁺, Sm³⁺, Eu³⁺, Tb³⁺, Dy³⁺, Ho³⁺, Er³⁺, and Tm³⁺ ions in the presence of this ion.

Experimental

The starting rare earth materials (Rhône-Poulenc) were La₂O₃ (99.99%), preheated for removing H₂O and CO₂, CeO₂ (99.99%), and other trivalent oxides (>99.9%). They were ground in an agate mortar with 30% excess of the calculated amount of NH₄Br and 0.3M KBr for 1M rare

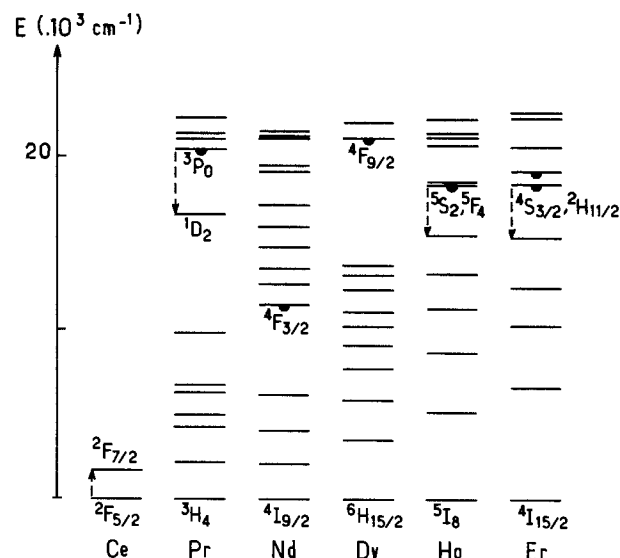

Fig. 1. Lower energy levels of Ce³⁺, Pr³⁺, Nd³⁺, Dy³⁺, Ho³⁺, and Er³⁺ (4). The half-circles point out the emitting levels of these ions in LaOBr for UV excitation. The arrows show the transitions responsible for quenching by cerium ions.

earth oxide, then fired at 900°C in a stream of nitrogen for 1h. After cooling, the flux is washed away with water.

Excitation and emission spectra were corrected for variation of lamp flux and detector response, respectively. A 6 ns pulsed nitrogen laser was used for determination of the fluorescent lifetimes. The signal was fed into a box-car averager (PAR Model 162).

Results

Energy migration among Ce³⁺ ions.—Figure 2 shows the emission spectra of Ce³⁺ in LaOBr at 300 and 90 K. Previous authors mention the existence of one band at room temperature. As a matter of fact, for low cerium concentrations, a shoulder on the short wavelength side can be clearly distinguished. When cooling, the high energy component becomes the most intense one. The two bands correspond to the transitions from the lowest 5d states to the ²F_{5/2} and ²F_{7/2} 4f levels. The decrease of the 5d → ²F_{5/2} 4f component intensity with cerium concentration indicates energy migration (9). Broadening of the absorption and emission bands with rising temperature results in increased overlapping, leading also to decrease of the high energy component. At low concentration, the luminescence shows weak thermal quenching at 300 K, as expected from the rather small Stokes shift (3400 cm⁻¹) (ratio of the integrated *I*(*hν*) curves: *I*_{300 K}/*I*_{90 K} = 0.92).

The high efficiency at room temperature and the existence of energy migration are two characteristics favorable for use of cerium as a sensitizer.

Effect of the incorporation of other trivalent rare earth ions on the cerium emission.—Figure 3 shows the cerium emission dependence on the activator concentration at 300 K in the La_{0.995-x}Ce_{0.005}A_xOBr compounds (A = Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er, Tm, Yb). For each activator, the cerium emission intensity decreases rapidly with *x*. The effect of the incorporation of samarium and thulium is particularly strong since the cerium emission is nearly entirely quenched for *x* = 0.002.

Influence of cerium on the activator emission.—A = Pr, Nd, Tb, Dy, Ho, Er.—Figure 4 compares the excitation spectra of some of these ions in LaOBr- and Ce-doped LaOBr samples. As observed for Tb³⁺ by Hölsa *et al.* (7), the excitation spectra of Pr³⁺, Nd³⁺, Dy³⁺, Ho³⁺, and Er³⁺ in the cerium-doped samples contain the Ce 4f → 5d bands, indicating energy transfer.

Figure 5 shows the influence of the cerium concentration on the visible emission intensity of levels indicated in Fig. 1 for Pr, Dy, Ho, Er, excited through the f-d Ce bands. While, in the case of dysprosium, the intensity increases up to high cerium concentration, for praseodymium, holmium, and erbium, it reaches a maximum for a low content (*x* ≈ 0.01 for Pr, 0.005 for Ho and Er), then rapidly decreases. Such a dependence was also reported for terbium by Rabatin (8) and Hölsa *et al.* (7). However, as observed for dysprosium, the ⁴F_{3/2} infrared neodymium emission increases with cerium concentration.

Fig. 2. Emission spectrum of La_{0.99}Ce_{0.01}OBr at 90 and 300 K for excitation into the 5d bands.

Fig. 3. Effect of the incorporation of other rare earths (A) on the cerium emission intensity for the La_{0.995-x}Ce_{0.005}A_xOBr series.

A = Sm, Eu, and Tm.—The excitation spectra of the Sm³⁺, Eu³⁺, and Tm³⁺ ions displayed in Fig. 6 show that the emission of these ions is not sensitized by Ce³⁺. The energy of photons absorbed by cerium ions is lost, so for excitation in the UV the presence of this element has a detrimental effect.

Discussion

Quenching of the Ce³⁺ emission by Sm³⁺, Eu³⁺, Tm³⁺, and Yb³⁺.—Blasse and Brill (1) have investigated the energy

Fig. 4. Excitation spectra of the Pr³⁺, Dy³⁺, and Er³⁺ emissions in LaOBr and Ce-doped LaOBr at 300 K (Compositions: La_{0.99}Pr_{0.01}OBr and La_{0.985}Pr_{0.015}Ce_{0.005}OBr, La_{0.99}Dy_{0.01}OBr and La_{0.985}Dy_{0.015}Ce_{0.005}OBr, La_{0.99}Er_{0.01}OBr and La_{0.985}Er_{0.015}Ce_{0.005}OBr. Emission wavelengths: Pr-501, Dy-568.7, Er-542 nm.)

Fig. 5. Dependence of the visible emission intensity of the acceptor on cerium concentration for excitation into a f-d Ce band in the $\text{La}_{0.99-x}\text{Ce}_x\text{A}_{0.01}\text{OBr}$ ($\text{A} = \text{Dy}, \text{Ho}, \text{Er}$) and $\text{La}_{0.98-x}\text{Ce}_x\text{Pr}_{0.02}\text{OBr}$ series. The excitation wavelength lies near the maximum of the most intense f-d band in a region where the acceptor shows little absorption: $\lambda = 348 \text{ nm}$ for Pr, Ho, Er; $\lambda = 353 \text{ nm}$ for Dy. The measured intensity corresponds to transitions below 680 nm originating from the levels indicated in Fig. 1.

transfer from Ce^{3+} to Sm^{3+} or Eu^{3+} in borate and phosphate host lattices and in YOCl . In samples doped with europium, the cerium emission was quenched without sensitization of the activator. With samarium, sensitization was observed in the oxides but not in the oxychloride. In oxide glasses, Reisfeld *et al.* (17, 18) have observed energy transfer from Ce^{3+} to Tm^{3+} . The absence of sensitization for Sm^{3+} and Eu^{3+} was ascribed by Blasse *et al.* (i.c.) to the weak energy difference between the states ($\text{Ce}^{3+} + \text{A}^{3+}$) and ($\text{Ce}^{4+} + \text{A}^{2+}$) with $\text{A} = \text{Sm}, \text{Eu}$. The present study shows that the oxidizing character of the

(Compositions: $\text{La}_{0.99}\text{Sm}_{0.01}\text{OBr}$ and $\text{La}_{0.985}\text{Sm}_{0.01}\text{Ce}_{0.005}\text{OBr}$, $\text{La}_{0.98}\text{Eu}_{0.04}\text{OBr}$, $\text{La}_{0.9595}\text{Eu}_{0.04}\text{Ce}_{0.0005}\text{OBr}$ and $\text{La}_{0.955}\text{Eu}_{0.04}\text{Ce}_{0.005}\text{OBr}$, $\text{La}_{0.99}\text{Tm}_{0.01}\text{OBr}$ and $\text{La}_{0.985}\text{Tm}_{0.01}\text{Ce}_{0.005}\text{OBr}$. Emission wavelengths: Sm-609 nm, Eu-618 nm, Tm-460 nm.)

Fig. 7. Reflectance spectra of the lanthanum oxybromide doped with samarium, europium, thulium, and ytterbium (composition: $\text{La}_{0.99}\text{A}_{0.10}\text{OBr}$).

Tm^{3+} and Yb^{3+} ions in LaOBr is also sufficiently high for causing quenching of the cerium emission by such a mechanism. The tendency to reduction to the divalent state for the Sm^{3+} , Eu^{3+} , Tm^{3+} , and Yb^{3+} ions is given by the position of the band corresponding to electron transfer from a ligand in the $\text{A}_x\text{La}_{1-x}\text{OBr}$ phases. Owing to the weak electronegativity of bromine, the charge-transfer band for these four cations lies above 200 nm. As expected, its energy varies according to the sequence $\text{Eu} < \text{Yb} < \text{Sm} < \text{Tm}$ (Fig. 6 and 7). The strong effect of the acceptor on the cerium emission implies energy transfer between Ce^{3+} ions to a $\text{Ce}^{3+}\text{-A}^{3+}$ pair.

Figure 8 shows that in samarium- and thulium-doped samples the cerium emission reappears at low temperature. Such a thermal dependence was not observed for the Ce-Eu and Ce-Yb samples. Two mechanisms can be considered for interpreting the strong variation with temperature of the cerium emission in the samples containing samarium or thulium.

As shown by the changes in the shape of the cerium emission spectra (Fig. 2), Ce-Ce migration decreases at low temperature, reducing the probability of transfer to acceptor ions. This has been observed for instance for the $\text{Ce}^{3+} \rightarrow \text{Tb}^{3+}$ energy transfer in LaPO_4 (10). However, this process cannot account for the different behavior of the Ce-Eu and Ce-Yb samples.

Another explanation is that the reaction $\text{Ce}^{3+}(5d) + \text{A}^{3+} \rightarrow \text{Ce}^{4+} + \text{A}^{2+}$ ($\text{A} = \text{Sm}, \text{Tm}$) requires an activation energy

Fig. 8. Thermal dependence of the cerium emission in $\text{La}_{0.993}\text{Ce}_{0.005}\text{Sm}_{0.002}\text{OBr}$ and $\text{La}_{0.993}\text{Ce}_{0.005}\text{Tm}_{0.002}\text{OBr}$.

E_A , the trivalent states being more stable for samarium and thulium than for europium and ytterbium. From the thermal dependence of the cerium emission a value of about 900 cm^{-1} can be derived for E_A . The similarity of the thermal quenching curves for $A = \text{Sm}$ and Tm is surprising since thulium is less oxidizing than samarium. However, the variation of the equilibrium interatomic distance after the change of oxidation states may lower the charge-transfer state more strongly in the case of thulium than in that of samarium. It is known that when a lanthanide ion is substituted for a larger cation, the number of phonons emitted after absorption in the charge-transfer band increases with the difference in size (11).

The effect of the incorporation of other lanthanides on the cerium emission was similar when GdOCl was used as the host lattice. In a recent paper, Blasse (12) shows that in the $(\text{Y}, \text{Gd})\text{F}_3$ fluoride the europium emission can be sensitized by Ce^{3+} , owing to an energy transport of the type $\text{Ce}(\text{Gd})_n\text{-Eu}$. Such a transfer is not possible in chloride or bromide compounds since the $5d$ cerium levels are lowered below the first excited gadolinium level (${}^6\text{P}_{7/2}$) by the nephelauxetic effect.

$\text{Ce}^{3+} \rightarrow \text{Pr}^{3+}, \text{Nd}^{3+}, \text{Tb}^{3+}, \text{Dy}^{3+}, \text{Ho}^{3+}, \text{Er}^{3+}$ energy transfers.—The quenching of the Ce^{3+} emission increases in the sequence $\text{Tb} < \text{Pr} < \text{Er} < \text{Ho} < \text{Nd} < \text{Dy}$. Radiative transfer occurs since the Ce emission band shows dips corresponding to the f - f absorption lines of the acceptor (Fig. 9). However the magnitude of the quenching does not correlate with the variation of the oscillator strengths in the wavelength range of the donor emission; thus the effect of the incorporation of Pr^{3+} which possesses intense absorption lines around 450 nm is much less pronounced than that of Dy^{3+} and Nd^{3+} which show weaker absorption properties in this region. For the same reason, nonradiative transfer by multipolar interactions cannot be the primary cause of the quenching of the cerium emission.

According to Blasse and Brill (1), energy transfer from Bi^{3+} or Ce^{3+} to Sm^{3+} , Eu^{3+} , Tb^{3+} , Dy^{3+} in YOCl occurs mostly by exchange interaction. The probability of such a transfer is given by the formula derived by Dexter (13)

$$P = \frac{2\pi}{h} Z^2 \int f_s(E) F_A(E) dE$$

where Z is an exchange integral and $f_s(E)$ and $F_A(E)$ represent the normalized shape of the emission band of the sensitizer and the absorption band of the acceptor. Z cannot be derived from optical experiments. Blasse has suggested that the transfer probability is enhanced by mixing of anionic and cationic orbitals. The mixing is related to the energy necessary to promote an electron from the ligand to the $4f$ orbitals. Charge-transfer transitions have been recently observed in wide-gap sulfides for neodymium, dysprosium, holmium, and erbium (14).

Fig. 9. Emission spectrum of cerium in $\text{La}_{0.985}\text{Ce}_{0.005}\text{Ho}_{0.010}\text{OBr}$ ($\lambda_{\text{exc}} = 362 \text{ nm}$) at 300 K .

Their energy increases according to the sequence $\text{Dy} < \text{Ho} < \text{Nd} < \text{Er}$; from the Jorgensen's spin-pairing theory (20), the charge-transfer bands of Pr^{3+} and Tb^{3+} are expected at higher energy ($\text{Pr} < \text{Tb}$). This is in nearly complete agreement with the influence of these ions on the cerium emission in LaOBr , the only difference being the relative positions of Nd and Ho . The results, therefore, support the mechanism proposed by Blasse.

The dependence of the activator emission intensity on cerium concentration shown in Fig. 5 can be related to the possibility of deexcitation of the emitting level by energy transfer to cerium ions. The separation between the ${}^2\text{F}_{5/2}$ and ${}^2\text{F}_{7/2}$ cerium levels is 1650 cm^{-1} . Measurements of the activator emission intensity for excitation into its $4f$ levels show that quenching occurs when the energy gap between the emitting level and the next-lower level, ΔE , is lower than 4000 cm^{-1} , i.e., for praseodymium, holmium, and erbium ions (Fig. 1). The activator ion decays to the next-lower level, while, simultaneously, cerium ions are excited from ${}^2\text{F}_{5/2}$ to ${}^2\text{F}_{7/2}$, the excess energy being given up to the lattice. Such a mechanism was proposed for explaining the quenching of the ${}^3\text{P}_0$ emission of praseodymium by cerium in LaF_3 (15, 16). As a consequence, at high cerium concentration in the oxybromide, the ${}^1\text{D}_2$ Pr^{3+} emission becomes predominant. The emission of dysprosium and neodymium for which ΔE amounts to about 7000 and 5000 cm^{-1} , respectively, is not affected by the incorporation of cerium. While no change was detected in the decay of the dysprosium fluorescence for $0 < x_{\text{Ce}} < 0.05$, Fig. 10 shows that over this composition range the erbium decay is strongly influenced by cerium concentration.

For dysprosium, despite the absence of nonradiative process involving the ${}^2\text{F}_{5/2}$ and ${}^2\text{F}_{7/2}$ cerium levels, at 300 K for the optimum composition the quantum yield of the visible emission for excitation into the cerium absorption bands is only about 10%. Neglecting the infrared transitions and concentration quenching cannot account for such a low value. The efficiency of the transfer increases with decreasing temperature: for the $\text{La}_{0.98}\text{Ce}_{0.01}\text{Dy}_{0.01}\text{OBr}$ composition, the intensity is multiplied by 5 at 85 K . An explanation may be the existence of nonradiative losses due to the mechanism proposed for Sm^{3+} , Eu^{3+} , Tm^{3+} , Yb^{3+} ions since Dy^{3+} is the most oxidizing of other rare earth cations (like these four elements dysprosium can occur in halides in the divalent state) (21).

Conclusions

From the present study, the following conclusions can be drawn.

Fig. 10. Decay of the ${}^4\text{S}_{3/2}$, ${}^2\text{H}_{11/2}$ erbium emission in $\text{La}_{0.99-x}\text{Ce}_x\text{Er}_{0.01}\text{OBr}$ oxybromides at 300 K .

1. Ce-doped LaOBr is an efficient phosphor. Owing to the importance of energy migration between cerium ions, a high purity of the starting materials is required to avoid quenching by transfer to impurities. The presence of samarium and thulium is particularly detrimental.

2. Ce³⁺ cannot sensitize the emission of the most oxidizing Ln³⁺ ions (Sm³⁺, Eu³⁺, Tm³⁺) when incorporated in host lattices containing chloride or bromide ions.

3. Energy transfer from Ce³⁺ to Pr³⁺, Nd³⁺, Tb³⁺, Dy³⁺, Ho³⁺, and Er³⁺ occurs in LaOBr. However, when the energy gap between the emitting level and the next-lower level is less than 4000 cm⁻¹, the efficiency of the acceptor emission is affected by nonradiative losses due to an energy transfer involving the ²F_{5/2} → ²F_{7/2} cerium transitions.

Dye-Laser Spectroscopy of Commercial Y₂O₃:Eu³⁺ Phosphors

R. G. Pappalardo* and R. B. Hunt, Jr.

GTE Laboratories, Physical Electronics Technology Center, Waltham, Massachusetts 02254

ABSTRACT

Commercial Y₂O₃:Eu phosphors, formulated at constant europium content, exhibit under 254 nm excitation plaque-brightness variations of up to 10%. Several working models are proposed to explain this variation in emission brightness, and their physical implications on the spectral behavior of the Y₂O₃:Eu materials under discussion are explored by means of the techniques of low temperature, time-resolved emission and excitation spectroscopy, following dye-laser excitation. The following physical models were considered, as affecting the emission brightness of the Y₂O₃:Eu phosphors: sample-specific, nonradiative deactivation of the ⁵D₀ level; preferential site occupation (C₂ or C₃) by Eu³⁺; and the presence of secondary crystalline phases, or sites, of low emission efficiency. None of these models satisfactorily explains the variation in emission brightness for 254 nm excitation. However, a variety of spectral observations suggest that the Eu³⁺ content is lower in Y₂O₃:Eu materials of reduced brightness. This conclusion has been confirmed by high sensitivity, visible-reflectance spectroscopy on the phosphor powders.

The emission properties of Eu-doped Y₂O₃:Eu³⁺ were first reported in 1964 by Wickersheim and Lefever (1) of GTE Laboratories. Shortly afterward, this material (and its oxy-sulfide analog, Y₂O₃S) found extensive commercial application as efficient red emitting phosphors in CRT picture tubes (2, 3).

In the early 1970's, researchers at Philips extended to the area of low pressure fluorescent lamps a scheme familiar in color television technology: namely, the creation of a high efficacy white field by combining the narrow-band emission from three rare earth-activated phosphors (4, 5) emitting in the spectral regions of maximum sensitivity of the human color receptors. One such phosphor was Y₂O₃:Eu³⁺, chosen for its narrow emission in the red, at ≈612 nm and for its high emission-efficiency under 254 nm excitation. Later, this concept was extended to the development of higher brightness deluxe fluorescent lamps, again coated with phosphor blends (6) containing Y₂O₃:Eu³⁺.

Since both the Y₂O₃ host matrix and the Eu activator are very expensive chemicals, a large volume utilization of such materials in a mass-production item, such as the fluorescent lamp, entails high production costs and ultimately a great strain on the market availability of these materials. In many industrial laboratories, these cost considerations are presently the driving force behind efforts

aimed at: (i) replacing the Y₂O₃:Eu³⁺ phosphor with a less expensive material capable of comparable performance, (ii) reducing the yttrium content in the host lattice by partial substitution with a cheaper cation, (iii) ensuring the optimum utilization of the expensive Eu activator, and (iv) maintaining phosphor performance while reducing the Eu³⁺ content.

The present article is concerned in particular with point (iii) of the above listing, in view of observed variations in plaque brightness under 254 nm excitation, for commercial phosphors formulated at constant Eu. Working models to explain these observations were tested using mainly the techniques of pulsed dye-laser spectroscopy. The models in question were: (i) preferential occupation by Eu³⁺ of one of the two cation sites, (ii) enhanced nonradiative deactivation of the dominant (⁵D₀) emitting level of Eu³⁺ in the low brightness materials, and (iii) segregation of Eu³⁺ in distorted sites, or in secondary phases of low emission efficiency.

Results on the dye-laser spectroscopy of the Y₂O₃:Eu phosphors are reported and discussed in what follows, to assess the validity of such models.

Experimental Details

Phosphor samples and their preparation.—A variety of samples were studied in the course of the present investigation. All the samples had 4.7 mole percent (m/o) nomi-

*Electrochemical Society Active Member.

nal Eu^{3+} content. Phosphors fired under similar conditions often showed considerable variations (more than 10%) in plaque brightness for excitation at 254 nm.

Some of the materials studied were supplied by the GTE Products Corporation (Towanda, Pennsylvania), and were prepared there according to procedures perfected by Chenot and Kasenga (7). Their recommended procedure was also followed by Peters of GTE Laboratories in the preparation of some additional phosphors, as described next.

The required quantities of luminescent-grade Y_2O_3 and Eu_2O_3 , with total approximate weight of 25g, were dissolved in hot 10.5M nitric acid. Mixed oxalates were subsequently co-precipitated from the nitrate solutions by means of oxalic acid. After washing and drying, the oxalate precipitate was decomposed in a 1h-1000°C air firing, and the final luminescent materials were developed in a second firing in air at 1600°C for 4h.

Spectral instrumentation.—The powder samples were excited by the output of a Molelectron nitrogen-laser-pumped dye laser, Model UV24 and DL-II respectively. Time-detection of the luminescence relied on PAR boxcar integrators; measurements of the emission spectra, excitation spectra, and decay kinetics were performed under computer control, using APL language software, as described elsewhere (8). Steady-state spectral measurements were performed using a Perkin-Elmer spectrofluorimeter MPF-44A, while a Tektronix J16 photometer was used for plaque-brightness measurements.

For spectral measurements at room temperature the powder samples were pressed into circular cavities milled in anodized aluminum disks. For measurements at low temperature (to 4 K), the powders were deposited onto nickel disks from acetone slurries, and were then mounted on the cold finger of an Air Products Helitran cryostat (8).

Energy Levels of Eu^{3+} in Y_2O_3

A preliminary interpretation of the observed spectra of Eu^{3+} in the condensed phase, in terms of the excited en-

ergy levels of the $4f^6$ configuration, can be found, for instance, in Dieke's book (9). A more detailed spectral investigation of the energy levels of Eu^{3+} in Y_2O_3 was reported by Chang and Gruber (10), with emphasis on transitions involving C_2 sites (see below).

From x-ray diffraction studies (11), it is known that the point symmetry at the cation sites of Y_2O_3 is either C_2 or C_{3i} , the latter site possessing a center of inversion. Early work on rare earth-activated Y_2O_3 single crystals and powder materials (10, 12) established that both cation sites in Y_2O_3 are occupied by the $4f^6$ rare earth activators. The presence of a center of inversion at the C_{3i} site has far-reaching consequences, in the sense of greatly reducing the absorption cross section and the emission rate of the pertinent, forced-electric-dipole transitions, thus favoring the appearance of magnetic-dipole transitions, when the latter are allowed by the selection rules for the crystal-field wavefunctions (13, 14). A detailed energy-level scheme for the ${}^7\text{F}_0$, ${}^7\text{F}_1$, ${}^5\text{D}_1$, and ${}^5\text{D}_0$ levels of Eu^{3+} in Y_2O_3 , for both the C_2 and C_{3i} sites, was derived by Heber *et al.* (15) (Fig. 1) as a result of investigations on single crystals of Y_2O_3 containing Eu^{3+} (up to 5 m/o concentration). The details of the ${}^5\text{D}_1 \rightarrow {}^5\text{D}_0$ relaxation with $\text{C}_{3i} \rightarrow \text{C}_2$ energy transfer were also reported by Heber and Koebler (16). Extensive spectroscopic investigations of $\text{Y}_2\text{O}_3:\text{Eu}$ single crystals, using polarized light, have been recently reported by Dexpert-Ghys and Faucher (17).

The excited electronic states reached on exciting $\text{Y}_2\text{O}_3:\text{Eu}$ at 254 nm belong to a dense distribution of states associated with a charge-transfer process, involving the Eu^{3+} ions and the adjacent oxygen ions. The excitation energy then relaxes from the charge-transfer states to the excited levels of Eu^{3+} proper; hence, emission and nonradiative de-excitation from the ${}^5\text{D}$ term drive the electronic system of Eu^{3+} back to its equilibrium condition.

Spectral Results under UV Excitation

The values of the plaque brightness under 254 nm excitation for the phosphors investigated are collected in Table I. Inspection of the table shows that the plaque

^a In chronological order of preparation.

brightness of commercial materials formulated at constant Eu content (4.7 m/o) has gradually increased in time by more than 10%, as a result of improved synthesis procedures.

Emission after laser excitation in the UV.—Time-resolved detection of the emission after nanosecond-long excitation in the neighborhood of 254 nm shows, at delays of the order of a few microseconds after excitation, a large number of emission lines originating from upper levels of the 4f⁶ configuration. At later times ($\approx 100 \mu\text{s}$ after excitation), many of these lines are strongly reduced in intensity, or totally extinguished. Figures 2 and 3 show examples of emission curves in the spectral region 400-650 nm. The relative intensity of the various emission groups, at different detection times after excitation, gives an approximate measure of the lifetime of the relevant levels: namely, ⁵D₃, ⁵D₂, ⁵D₁, and ⁵D₀. The emission lifetime is of course longest for the low lying ⁵D₀ level (emission group from 580 nm to longer wavelengths) and decreases progressively for the ⁵D₁, ⁵D₂ levels, and for levels still higher in energy.

For our specific concerns, we would like to draw attention to the marked relative-intensity drop (between 10 and 100 μs) for the line at 588 nm, compared to the other emission components between 580 and 600 nm (Fig. 4; spectra individually normalized at the intensity of the 611 nm emission line). We attribute this intensity drop to the wavelength overlap between an emission line of ⁵D₀ and an intense emission line of ⁵D₁.

This wavelength overlap also affects the shape of the emission pattern measured in this spectral region under

Fig. 2. Overview of the time-resolved emission spectra from 400 to 650 nm, following nanosecond laser excitation at 260 nm. Sample YCX-6 at room temperature. a): Emission detected during the first 5 μs . b): Some, first 10 μs . c): Some, first 20 μs . All curves are normalized to the peak of the strong emission line at 611 nm, which is truncated in plotting to enhance the weaker emission lines.

Fig. 3. Detail of Fig. 2 over the spectral range 400-580 nm. The emitting levels responsible for the main emission groups are identified.

steady-state excitation. While sample-to-sample differences in this emission pattern in steady-state emission measurements are often construed as indicative of structural differences between samples, the time-resolved spectra show that the shape of the emission pattern is also determined by the relative contribution of the ⁵D₁ level.

Emission decays after UV excitation.—An overview of the emission kinetics of ⁵D levels of interest is given in Table II, which lists relevant parameters, such as temperature, wavelength, transition assignments, the time after excitation at which detection was started, the risetime, and the time for emission to reach 1/e of the peak value. All measurements refer to 5-10 ns long laser excitation.

Some comments on the entries of Table II are now appropriate, in the context of correlating plaque brightness and decay kinetics of the phosphors. In Fig. 5 are plotted the normalized decay curves for emission at 611 nm (from

Fig. 4. Detail of the time-resolved spectra from 520-620 nm, to emphasize the unusual intensity behavior with detection time in the emission group between 580 and 600 nm. Sample YCX-6 at room temperature, excited with nanosecond pulses at 268 nm. Detection times are, respectively, 10, 100, and 1000 μs . Spectra are individually normalized at the peak of the 611 nm line. Note the rapid, relative-intensity drop of the 588.8 nm line between 10 and 100 μs .

the 5D_0 level of the C_2 sites) for three different $Y_2O_3:Eu$ phosphors formulated with the same Eu content, but exhibiting a range of $\approx 10\%$ difference in plaque brightness under steady-state excitation at 254 nm (Table I). The normalized decay curves, resulting from dye-laser excitation at 265 nm, in the charge-transfer band of Eu^{3+} , were not appreciably different in the three materials. The decay was exponential, and its constant was measured as 1.1 ms (see Table II).

Fig. 5. Normalized emission decays at room temperature, measured at 611 nm for various $Y_2O_3:Eu$ samples, following laser excitation at 265 nm. See also Tables I and II.

The area under the actual emission-decay pulse of sample II-04A was measured as $\approx 89\%$ of the analogous quantity of YCX-6, in agreement with the relative brightness values of Table I. However, when we consider the areas under the curves (individually normalized at peak intensity), they differ by only 2%, the area for the dimmer II-04A being actually greater. Therefore, for UV excitation at room temperature no correlation appears to exist between 5D_0 emission lifetime and steady-state emission intensity at 611 nm (the dominant emission component). In other words, sample-specific nonradiative quenching of the 5D_0 population is apparently not responsible for the observed variation in steady-state plaque brightness for UV excitation.

In Fig. 6, the room temperature decays of the emission line at 533.8 nm are given for excitation at 265 nm of samples from lots YCX-6, II-04A, and W4117-54-1. By reference to the energy-level scheme of Fig. 1, this particular emission line is assigned to $^5D_1 \rightarrow ^7F_{11}$ transitions for C_2 sites.

Contrary to the case of the emission at 611 nm, a pronounced spread is observed in the emission decays of Fig. 6. The dimmest sample (II-04A; Table I) exhibited the slowest decay, with a decay constant of 49 μ s (to I_0/e intensity; Table II). Lowering of the sample temperature to 77 K produced a marked lengthening of the emission lifetime (92 μ s to I_0/e intensity for sample YCX-6) and a longer buildup time for emission to reach its maximum (≈ 20 μ s).

A trend in emission lifetimes similar to that of Fig. 6 is also observed, on a more compressed time scale, for emission from the 5D_2 manifold, as monitored at room temperature for the 467.8 nm emission line, the dominant transition of this group (see Fig. 2).

Of the three samples, the one with lowest steady-state brightness again exhibits the longest decay (*i.e.*, 6.5 μ s;

Fig. 6. Same as Fig. 5, but emission at 533.8 nm from C₂ sites of ⁵D₁. Sampling window 2 μs. The longest decay is observed for a sample of relatively low brightness for 254 nm excitation (see Table I).

Fig. 7). The decays were nonexponential, and the time required for the peak intensity to decay to its I₀/e value ranged in Fig. 7 from 4.5 to 6.5 μs (Table II). This time increased to ≈8 μs when the II-04A phosphor was cooled to 77 K.

Table II also lists the risetimes for emission, defined as the time between the 10% and 90% values of the emission intensity. A related quantity, namely the buildup time required for emission to reach its peak, was of the order of 10 μs for the ⁵D₁ emission resulting from UV excitation. The buildup time was definitely longer in the case of the ⁵D₀ emission at 611 nm, as a result of the gradual feeding of this level by higher lying levels; even at room temperature, the buildup time was of the order of 100 μs (Fig. 8; excitation at 265 nm), and it was appreciably longer for sample II-04A, in correlation with the ⁵D₁ lifetimes of the individual samples.

In summary, under UV excitation the emission decays at room temperature for the ⁵D₁ and ⁵D₂ manifolds (but not for ⁵D₀) were generally of longer duration for the low brightness II-04A material.

Fig. 7. Emission from the ⁵D₂ manifold at room temperature. Again, the longest decay is exhibited by the least bright material of the three.

Fig. 8. Detail of the initial portion of the normalized emission decay at 611.2 nm at room temperature, for excitation at 265 nm. The emission from sample II-04A has an appreciably longer buildup time to reach its peak (≈100 μs).

Spectral Results for Level-Selective Excitation

Emission and excitation characteristics of the ⁵D manifolds will be now reconsidered for the case of selective excitation into specific levels of the ⁵D term.

Emission spectra for selective excitation into ⁵D₀.—We refer now to the energy-level scheme of Fig. 1. On excitation at 580.8 nm, energy is absorbed in the ⁷F₀ → ⁵D₀ transition of the C₂ sites. The emission at 77 K in the case of the YCX-6 material (Fig. 9, dotted curve) is found to consist of the resonant line at 580.8 nm, a weaker line at 582.4 nm, followed by a triplet at 587.4, 593.0, and 599.7 nm, and the intense line at ≈611 nm used for normalization in plotting. There are, in addition, emission groups at wavelengths longer than 611 nm, not considered here.

The assignment of the emission lines to specific electronic transitions is shown in Fig. 9 (see also the energy-

Fig. 9. Emission spectra ⁵D₀ → ⁷F₀, ⁷F₁, ⁷F₂ for selective excitation into the ⁵D₀ level of sample YCX-6 at 77 K. a) C₂ excitation at 580.8 nm (⁵D₀ → ⁷F₀; dashed trace). b) C_{3i} excitation ⁵D₀ → ⁷F_{3i} at 582.4 nm (continuous trace). The emission spectra are normalized at the peak of the 611 nm emission line. Note the strong C₂-type emission lines, especially at 611 nm, even for C_{3i}-type excitation, and the additional structure on the long wavelength side of the ⁵D₀ → ⁷F_{1b} emission line of C_{3i} type. Sampling: 1 ms long, starting 0.2 ms after excitation.

level scheme of Fig. 1). Excitation into the C_2 site produces, as expected, the corresponding ${}^5D_0 \rightarrow {}^7F_0, {}^7F_1, {}^7F_2, {}^7F_3, {}^7F_4, {}^7F_5$ emissions for the C_2 site. In addition, as evidenced by the weak line at 582.4 nm [${}^5D_0(C_{31}) \rightarrow {}^7F_{1a}(C_{31})$], only a modest energy transfer takes place at this temperature from ${}^5D_0(C_2)$ to the ${}^5D_0(C_{31})$ level, higher in energy by $\approx 90 \text{ cm}^{-1}$ (see Fig. 1).

On excitation at 582.4 nm (C_{31} -site absorption), a mixture of emission lines of C_2 and C_{31} origin is observed (Fig. 9, continuous trace). Among the former is the anti-Stokes emission at 580.8 nm, and all the remaining ${}^5D_0 \rightarrow {}^7F_0, {}^7F_1, {}^7F_2$ transitions for the C_2 site, including the dominant line at 611 nm, which is used for the normalization of the emission spectrum resulting from C_{31} -type excitation. The emission lines for transitions originating from Eu^{3+} ions in the C_{31} -sites are: the resonant ${}^5D_0 \rightarrow {}^7F_{1a}$ line at 582.4 nm; and the ${}^5D_0 \rightarrow {}^7F_{1b}$ transition at ≈ 592.9 nm, accompanied by some additional structure, which we shall assume to be of vibronic nature, for the time being. The point we want to emphasize is the efficient energy transfer from C_{31} to C_2 sites, even at 77 K, in the sense that excitation energy pumped into the C_{31} subsystem of 5D_0 ends up predominantly as C_2 emission at 611 nm.

For the purpose of the discussion to follow, it should be noted that, in comparing the emission spectra at 77 K for YCX-6 and II-04A following C_{31} excitation at 582.4 nm, the resonant emission line at 582.4 nm was found to be relatively stronger in II-04A, after the emission spectra were individually normalized at the intensity of the 611 nm line.

No evidence of additional emission lines, diagnostic of Eu^{3+} in secondary crystalline phases, was found on contrasting the emission spectra for level-selective excitation of the two materials YCX-6 and II-04A of different plaque-brightness.

Emission decays from 5D_0 .—The intrinsic emission kinetics of the important 5D_0 level are considered next. In Fig. 10, the solid curve shows the measured decay at 5 K of the emission line at 611.5 nm for sample YCX-6, after C_2 -type excitation at 580.8 nm; the dotted curve corresponds to a normalized curve for single exponential decay with 0.92 ms constant. The agreement is seen to be excellent. A different low temperature run with the same sample at 4 K gave on fitting a decay constant of 0.93 ms (Table II). The decay of the 611.5 nm emission of sample II-04A was also measured at 5 K after C_2 -type excitation at

Fig. 10. Decay at 5 K of the emission at 611.5 nm from sample YCX-6 for C_2 -type excitation at 580.8 nm. The curve (normalized at its peak) was recorded with a $50 \mu\text{s}$ aperture, starting at $100 \mu\text{s}$ after excitation. By comparison, the dotted curve represents an exponential decay with a time constant of 0.92 ms. The overlap of the two curves is remarkably good.

580.8 nm. The decay was closely exponential with a decay constant of ≈ 0.97 ms, namely, longer than the 0.92-0.93 ms value for sample YCX-6.

In a separate series of measurements at various temperatures, we recorded the decay at 611.2 nm from sample YCX-6, after C_2 -type excitation at 580.0 nm (Fig. 11). Again, the decay was exponential at ≈ 4 K and at 300 K, but it had a more complex behavior at the intermediate temperature, presumably because at 77 K the upward energy transfer between C_2 and C_{31} sites, and back-transfer, become possible. Self-trapping of the emitted radiation could also play a role in the observed emission kinetics, especially at room temperature. The time associated with the first e folding of the emission (*i.e.*, to I_0/e) was 0.92 ms at 4 K and 1.2 ms at 300 K (see Table II).

Next, the decay curves for the main emission line at 611 nm were considered at room temperature both in the case of C_2 excitation at 580.6 nm and C_{31} excitation at 582.4 nm. In the former case, the decays of YCX-6 and W4117-54-1 were very similar, and were both somewhat longer than the decay of II-04A. In the latter case of C_{31} excitation, the decays were all generally longer, in view of the $C_{31} \rightarrow C_2$ transfer, and the decay constant of YCX-6 was measured as 1.58 ms, $\approx 5\%$ longer than for II-04A. Since the decay of YCX-6 was also longer than that of W4117-54-1 (Fig. 12), no correlation was found between plaque brightness for 254 nm excitation and decay time for C_2 emission resulting from C_{31} excitation in 5D_0 .

Excitation spectra for 5D_0 emission.—On monitoring the emission at 611.2 nm and scanning the excitation region corresponding to the ${}^7F_1 \rightarrow {}^5D_0$ absorptions in the YCX-6 material, peaks corresponding to both C_{31} and C_2 transitions are observed (Fig. 13). As the temperature is lowered, the short wavelength excitation peak of Fig. 13 (C_2 -transition ${}^7F_0 \rightarrow {}^5D_0$) increases in intensity at the expense of the remaining two lines, partly because of accumulation of population in the fundamental 7F_0 level.

As for the $C_{31} \rightarrow C_2$ transfer, as shown by the presence in the excitation spectra of lines corresponding to absorptive transitions within both C_{31} and C_2 sites, it continues even for temperatures as low as 55 K (Fig. 13; excitation line at 582.4 nm, namely ${}^7F_{1a} \rightarrow {}^5D_0$ transition for the C_{31} sites). When the temperature is further lowered to 4 K, the excitation pattern of Fig. 13 simplifies to one line at 580.8 nm, because the electronic population is effectively concentrated on the 7F_0 fundamental level, while the ${}^7F_{1a}$ level is depopulated.

In conclusion, since efficient $C_{31} \rightarrow C_2$ transfer occurs within 5D_0 at low temperatures, it can be expected to be

Fig. 11. Semilog plot of the emission decay for sample YCX-6 measured at 4, 77, and 300 K for C_2 -type excitation at 580 nm. The decay is exponential both at 4 and 300 K (definitely longer in the latter case), but nonexponential in its initial portion at 77 K.

Fig. 12. Emission decays at room temperature for C_{3i}-type excitation at 582.4 nm. C₂-type emission monitored at 611 nm. The decay for the YCX-6 sample appears to be consistently slower.

even more effective at room temperature, thereby coupling the population of the two cation subsystems.

Excitation spectra measured while monitoring the emission along the spectral contour of the dominant emission line at ≈ 611 nm, revealed no new excitation peaks in samples exhibiting lower brightness under UV excitation. In the particular case of the ${}^7F_0 \rightarrow {}^5D_0$ excitation line of C₂ sites, we did not observe either the broadening or the splitting that would arise from Eu³⁺ in distorted sites or in secondary phases.

Similarly, no evidence of additional emission lines, diagnostic of Eu³⁺ in secondary crystalline phases, was found on contrasting the emission spectra for level-selective excitation of the two materials YCX-6 and II-04A of different brightness.

Discussion

Emission brightness for UV excitation.—As already mentioned, several mechanisms could be invoked as rele-

Fig. 13. Excitation spectra at various temperatures for the 611.2 nm emission in sample YCX-6, in the spectral region for 7F_0 , ${}^7F_{1a} \rightarrow {}^5D_0$ transitions. The excitation line at 580.8 nm increases monotonically with the decrease in temperature, as a result of thermal population-redistribution in the ground manifold of levels. Contributions to the C₂ emission originating from C_{3i}-type absorption (excitation line at 582.4 nm) are noticeable even at temperatures as low as 55 K. Detection: 1 ms long, starting 0.2 ms after excitation.

vant to the question of sample-to-sample variation in plaque brightness for 254 nm excitation in Y₂O₃:Eu, and appropriate measurement techniques would have to be used to verify experimentally the implications of such models. In this context dye-laser spectroscopy is especially suitable for checking mechanistic models, whose operation affects the emission-decay kinetics and/or fine details of the emission spectra and of the excitation spectra. Among these, we have considered: (i) preferential occupation by Eu³⁺ of one of the two cation sites (C_{3i} or C₂), (ii) enhanced nonradiative deactivation of the emitting 5D_0 level of Eu³⁺ in the low brightness materials, and (iii) segregation of Eu³⁺ in distorted sites or in secondary phases of low emission efficiency.

These models are now assessed on the basis of the experimental information gathered in the present study.

Nonradiative deactivation of 5D_0 .—It was already noted in previous sections that the bulk of the emission intensity in Y₂O₃:Eu phosphors originates from the 5D_0 level, and that the emission-decay kinetics from 5D_0 , following room temperature UV excitation (Fig. 5) do not differ sufficiently from sample to sample (Table II) to account for the observed 10% brightness differential (Table I).

On the contrary, for selective excitation into the C_{3i} level at 582.4 nm (Fig. 12) a somewhat longer emission decay is observed for the YCX-6 material than for the material W4117-54-1 (and II-04A). The reasons for the different decay behavior under UV excitation and 5D_0 excitation are not clear at present.

However, even for level-selective excitation, no correlation was found between plaque-brightness (for 254 nm excitation) and emission lifetimes of the 5D_0 levels.

One of the reasons for the lack of correlation between 5D_0 decay kinetics and phosphor brightness is the coupling in 5D_0 between two systems of ions (in C_{3i} sites and in C₂ sites) decaying at different rates. In view of the efficient C_{3i} \rightarrow C₂ intersite energy transfer in 5D_0 at room temperature, slower decays for the 611 nm emission do not necessarily indicate the absence of deleterious nonradiative deactivation processes. Longer decays may simply reflect an oscillatory-type migration of excitation energy back and forth between the C_{3i} and C₂ sublattices. No correlation between plaque brightness for 254 nm excitation, and the duration of the 5D_0 , C₂-type decay is expected *a fortiori* for UV excitation of the materials, since the emission kinetics of the 611 nm line are further complicated by intersite transfer and nonradiative deactivation along the ladder of electronic levels funneling the excitation energy down to the 5D_0 level.

Preferential site occupation by Eu³⁺.—Another mechanism impacting the emission brightness was initially postulated to be the following: let us assume that Eu³⁺ is preferentially situated in the C_{3i} site of the host matrix. Then these effects would be anticipated: (i) the relative intensity of the "hypersensitive" (18) C₂-type emission line at 611 nm will be reduced, while an increase would be expected in the relative intensity of the emission lines of C_{3i}-type, ${}^5D_0 \rightarrow {}^7F_{1a}$ and ${}^5D_0 \rightarrow {}^7F_{1b}$ at ≈ 582 and ≈ 593 nm, respectively. In addition, the longer lifetime of the C_{3i}-type 5D_0 level would enhance the probability of its nonradiative deactivation, resulting in reduced emission brightness.

The spectral measurements on the materials in question have shown that efficient coupling between C_{3i} and C₂ sites occurs even at temperatures as low as 55 K. Evidently, the intersite exchange of excitation energy will be even more effective at room temperature. Even assuming that such site occupation actually occurs, it will not affect significantly the emission from 5D_0 , which is predominantly in the form of the hypersensitive line at 611 nm.

Crystalline sites (or phases) of low emission efficiency.—As another working model, one could envisage that some of the Eu³⁺ ions are present either in distorted sites of the Y₂O₃ host matrix, or segregated in secondary crystalline phases. Both effects are expected to lead to re-

duced emission efficiency at 611 nm, by arguments similar to those outlined in the previous section on C_{31} vs. C_2 site occupation.

Assuming the model to be correct, we expect to find changes in the excitation and emission spectra in comparing $Y_2O_3:Eu$ phosphors of different brightness. In particular, if the hypothetical distorted sites of Y_2O_3 were occupied by Eu^{3+} , one would anticipate either a broadening, or a multiplicity of excitation and emission lines associated, for instance, with the easily detectable ${}^7F_0 \rightarrow {}^5D_0$ and ${}^5D_0 \rightarrow {}^7F_0$ transitions for the C_2 sites. Neither expectation is validated by the observations of the present study.

As for the presence of secondary crystal phases, the evidence to this effect is inconclusive, either from the x-ray diffraction data or from the overall absence of additional spectral features in the emission and excitation spectra.

The question of the actual Eu^{3+} content.—We list now some differences observed in the spectral behavior of the YCX-6 material and the dimmer II-04A material.

1. On UV excitation, the room temperature emission decays from 5D_2 and 5D_1 were slower in II-04A.

2. Again in II-04A, a longer buildup time after UV excitation was observed at room temperature for the 611 nm emission to reach its peak.

3. Longer 5D_0 emission decay of C_2 -type was measured at 5 K in II-04A, for C_2 -type selective excitation at 580.8 nm.

4. On excitation at 77 K into the C_{31} levels of 5D_0 , the resonant, C_{31} -type emission ${}^5D_0 \rightarrow {}^7F_{1a}$ was relatively stronger in II-04A.

5. The emission from II-04A had a relatively weaker intensity in the long-wavelength structure of the dominant emission line at 611 nm.

Most of these effects can be viewed as being caused by a less rapid energy transfer in the excited states of II-04A, which we attribute to a lower Eu^{3+} content in II-04A. This conclusion is quite unexpected. Measurements of the Eu content in the three phosphor materials of main interest in this report were obtained from atomic-absorption measurements, and are listed in Table III. The analytical data reveal that, while the early-vintage YRO-6 sample of low brightness (Table I) has a definitely lower Eu content (and this would explain the reduced brightness value), there appears to be no significant difference (only a relative $\approx 4\%$) in Eu content between YCX-6 and II-04A.

For our purposes, we are interested rather than in the total Eu content, as listed in Table III, in the fraction of Eu that is actually present as the trivalent ion. Since the analytical data do not differentiate between these two quantities, we have resorted to high sensitivity reflectance spectroscopy to assess qualitatively the relative concentration of Eu^{3+} in the II-04A and YCX-6 materials. Examples of reflectance spectra in the long-UV and visible regions are given in Fig. 15 and 16. In both figures, we are plotting diffuse reflectance spectra of two $Y_2O_3:Eu$ samples, using the reflectance of a suitable standard (Eastman Kodak Reflectance Standard 6091) as the base line for the measurements. In order to discriminate reflectance from luminescence signals, two monochromators (locked at the same wavelength) were

Fig. 14. Same as Fig. 13, but comparing excitation spectra at 55 and 4 K. At the latter temperature only, the contribution from the C_2 -type ${}^7F_0 \rightarrow {}^5D_0$ transition at 580.8 nm is observed.

Fig. 15. Weak absorption lines contributed by Eu^{3+} , as detected from reflectance measurements at room temperature in the visible spectral region of sample YCX-6 and sample II-04A. Ordinates: difference reflectance spectra vs. the Eastman Kodak Reflectance Standard 6081. Absorption is in the direction of increasing ordinates.

scanned in tandem to supply the direct radiation and to detect the reflected radiation, respectively. The resulting spectra are plotted so that decreased reflectance (*i.e.*, increased absorbance) is in the direction of increasing values of the ordinates.

^c Relative quantum yield, from 254 nm reflectance and brightness values from Table I.

Fig. 16. Same as Fig. 15, but for samples W4117-54-1 and sample YRO-6.

Figure 15 shows a comparison of such spectra for samples II-04A and YCX-6, that have almost the same particle size (Table III). In spite of the comparable total Eu content, the Eu³⁺ content in II-04A seems lower, by almost a factor of two, judging from the reduced strength of the absorption lines. A similar comparison in Fig. 16 for W4117-54-1 and YRO-6, again with similar particle size (Table III), highlights the more intense Eu³⁺ absorption in the former, as expected simply from the difference in total Eu content.

Table III also lists the reflectance at 254 nm for the relevant samples. Here again, the objective of the measurement was to correlate UV absorbance with total Eu³⁺ content. Such correlation is apparently absent. Since the UV absorption at 254 nm is contributed not only by the charge-transfer transitions of Eu³⁺, but also by lattice defects/vacancies, a simple measurement of the reflectance at 254 nm may be insufficient for the stated aim. Instead, a careful study of the absorption throughout the entire UV spectral region would be required to separate the contributions to the absorption originating from Eu³⁺ and those caused by centers associated with lattice defects.

Conclusions

The present investigation on the dye-laser spectroscopy of commercial Y₂O₃:Eu phosphors has uncovered several spectral features of interest, associated with the excited state relaxation of Eu³⁺, and has clarified some effects observed in conventional optical spectroscopy of these materials. Such effects will now be summarized.

1. In the steady-state measurements of emission after 254 nm excitation, the intensity pattern of the line group from 580 to 600 nm is often observed to change from sample to sample. On the basis of the time-resolved emission spectra, we attribute these changes to variations in relative emission intensity from the upper ⁵D₀ level. In other words, these spectral effects are associated with changes in Eu³⁺ concentration.

2. Efficient coupling exists between the Eu³⁺ ions in the two C_{3i} and C₂ sublattices of the dominant ⁵D₀ emitting level. Differences from sample to sample in ⁵D₀ decay kinetics depend, via the Eu³⁺ concentration and the temperature, on the rates of the energy exchange back and forth between the C_{3i} and C₂ sublattices.

The following observations are pertinent to the specific question of plaque brightness for 254 nm excitation of the materials under consideration.

1. The decay time of the ⁵D₀ emission at room temperature does not correlate with emission brightness for 254 nm excitation.

2. No evidence was uncovered for secondary crystalline phases, or for Eu³⁺ sites of intrinsically low emission efficiency.

3. Dye-laser spectroscopy suggests that low-brightness materials contain lower concentrations of Eu³⁺.

4. High sensitivity reflectance spectroscopy confirms the model of a correlation of plaque brightness for 254 nm excitation and strength of the Eu³⁺ reflectance lines in the visible spectral region.

The techniques of dye-laser spectroscopy have been useful in suggesting a lower Eu³⁺ content in the sample of lower plaque brightness. Rather than the decay kinetics of the ⁵D₀ level, the key factors determining the emission brightness for 254 nm excitation in Y₂O₃:Eu appear to be: first, the actual Eu³⁺ concentration, as distinct from the total Eu content detected by analytical techniques; and, second, the nature of the short-UV absorptions in the materials in question: namely, whether they are contributed by Eu³⁺ charge-transfer processes or by absorbing centers that decay nonradiatively and do not transfer the absorbed UV radiation to Eu³⁺ emitting centers.

At this stage, the problem of plaque brightness under 254 nm excitation must be tackled by techniques other than dye-laser spectroscopy, with a shift to conventional excitation and reflectance spectroscopy in the UV, and high resolution reflectance spectroscopy in the visible region.

Acknowledgments

The authors wish to express their thanks to the following technical personnel of the GTE Corporation. From GTE Laboratories (Waltham, Massachusetts), M. Downey for the x-ray diffraction measurements; F. Durkin and C. Persiani for the analytical determination of the Eu content; T. Peters for the preparation of some of the phosphor samples and for many discussions on phosphor properties; and A. Vetrovs for assistance in the preparation of the phosphors. From GTE Products Corporation, Chemical and Metallurgical Division (Towanda, Pennsylvania), C. Chenot and A. Kasenga for providing the phosphor samples, for advice on procedures for the phosphor synthesis, and for discussions on the problem of emission brightness in Y₂O₃:Eu phosphors. From GTE Products Corporation, Lighting Products (Danvers, Massachusetts), E. Dale, for suggesting models relevant to the question of emission efficiency in Y₂O₃:Eu phosphors.

Technical Notes

Selective Reactive Ion Etching of TiW

P. M. Schaible and G. C. Schwartz*

IBM Corporation, General Technology Division, Hopewell Junction, New York 12533

TiW is used as a barrier to interdiffusion between aluminum or aluminum copper thin films (used as interconnections in integrated circuits) and silicon or PtSi contacts, thereby preventing junction short circuits (1). One method of defining VLSI interconnection patterns is by a lift-off technique. A stencil is defined (2), and after evaporation, the unwanted metal is removed with the stencil, leaving the interconnection metallization. However, TiW is most practically deposited by sputtering, which is not compatible with this method. If TiW were sputtered through a lift-off mask, the pattern would have sloped walls (3), and coverage of the walls of the lift-off stencil is a potential problem. A more practical process for the formation of patterns in TiW is subtractive etching, following lift-off formation of the aluminum or aluminum copper on top of a blanket layer of TiW. To insure the absence of undercutting, reactive ion etching (RIE) is used to etch the TiW.

Although TiW can be etched in a CF_4 plasma, the etch-rate ratios, $R(TiW)/R(SiO_2)$ and $R(TiW)/R(Si_3N_4)$, are unfavorable, so severe attack of the substrate occurs.

This note describes the optimization of an alternate TiW RIE process, first proposed by Kitcher *et al.* (4). The process, RIE in CCl_4/O_2 mixtures, results in a favorable etch-rate ratio with respect to the nitride (or oxide) substrate. An overlying pattern of aluminum or AlCu (formed by lift-off or by a previous RIE step in CCl_4) is not etched in the CCl_4/O_2 mixture. Al_2O_3 , grown during the TiW etch is easily removed by an *in situ* RF sputter clean prior to deposition of the next level of metal (5).

*Electrochemical Society Active Member.

Fig. 1. Etch rates of TiW, Si_3N_4 , AlCu, and Si vs. $\%O_2$ in CCl_4 at room temperature, 200W, 10 mtorr total pressure. The two curves in the AlCu data represent the minimum and maximum etch rates observed.

The reactor used in these experiments has been described previously (6). In order to achieve, in this system, the maximum etch rate and the maximum selectivity, we investigated (at small loads) the effect of gas composition, input RF power, system pressure, and cathode temperature. The temperature of the etching samples (thin films deposited onto silicon-wafer substrates) is not controlled; it will depend on the cathode temperature and the RF power density (7).

Figure 1 shows the dependence of the etch rates of TiW, AlCu, and Si_3N_4 on the concentration of O_2 in CCl_4 , $\{C(O_2) = P(O_2)/[P(O_2) + P(CCl_4)]\}$; the input RF power density was 0.4 W/cm^2 , the total pressure was 10 mtorr, and the cathode was not heated by an external source. The etch rates of SiO_2 are not shown. We had found in previous experiments that Si_3N_4 always etched at a higher rate than SiO_2 in these plasmas (8). In pure CCl_4 , AlCu etches about 3-4 times more rapidly than TiW and Si_3N_4 . As $C(O_2)$ is increased, the etch rate of AlCu decreases rapidly; the etch rate becomes equal to the sputter etch rate at $C(O_2) = 0.2$. On the other hand, the etch rate of TiW, $R(TiW)$, increases with increasing $C(O_2)$ and reaches a broad maximum at $C(O_2) = 0.2-0.3$. When $C(O_2)$ is increased beyond 0.3, $R(TiW)$ decreases rapidly. The etch rate of Si_3N_4 , $R(Si_3N_4)$, is independent of $C(O_2)$ for values of $C(O_2)$ less than about 0.4; above $C(O_2) = 0.4$, $R(Si_3N_4)$ decreases gradually. The maximum value of $R(TiW)/R(Si_3N_4)$ is approximately 5 and occurs at $C(O_2) = 0.2$. In this gas mixture, the etch

Fig. 2. Etch rates of TiW, Si_3N_4 , and ERR vs. RF power at room temperature, 2 mtorr $O_2/8$ mtorr CCl_4 .

Fig. 3. Etch rates of TiW, Si₃N₄, and ERR vs. pressure at room temperature, 20% O₂ in CCl₄, 200W.

Fig. 4. Etch rates of TiW, Si₃N₄, Al, AlCu, and Si vs. %O₂ in CCl₄ at 150°C, 200W, 10 mtorr.

rate of silicon is approximately 0.9 $R(\text{TiW})$, so that uncovered contacts would be attacked.

At a constant value of $C(\text{O}_2) = 0.2$, we investigated the dependence of $R(\text{TiW})$, $R(\text{Si}_3\text{N}_4)$, and $R(\text{TiW})/R(\text{Si}_3\text{N}_4)$ on RF power and total pressure. At constant pressure, an increase in input power causes an increase in both etch rates, but the etch rate ratio remains unchanged. At constant input power, an increase in total pressure results in a decrease in both etch rates, but again, the etch rate ratio remains unchanged. This is illustrated in Fig. 2 and 3.

As seen in Fig. 4, increasing the cathode temperature to 150°C results in increases in both $R(\text{TiW})$ and $R(\text{AlCu})$ but no increase in $R(\text{Si}_3\text{N}_4)$. Figure 5 shows that the maximum value of $R(\text{TiW})/R(\text{Si}_3\text{N}_4)$ is 7.5 and that it remains constant as $C(\text{O}_2)$ changes from 0.3 to 0.7; at these values of $C(\text{O}_2)$, $R(\text{AlCu})$ is negligible and $R(\text{Si}) = 0.5R(\text{TiW})$, which decreases the attack on uncovered contacts. It can also be seen that a further increase in cathode temperature produces no further increase in $R(\text{TiW})/R(\text{Si}_3\text{N}_4)$.

Substitution of Cl₂/O₂ or Cl₂/CO₂ for CCl₄/O₂ resulted in similar trends of $R(\text{TiW})/R(\text{Si}_3\text{N}_4)$ vs. $C(\text{O}_2)$, but the etch rate ratios were lower than in CCl₄/O₂.

Fig. 5. ERR (TiW/Si₃N₄) vs. %O₂ in CCl₄ as a function of temperature at 200W, 10 mtorr pressure.

It has been proposed that Cl, formed in a CCl₄ plasma, is responsible for etching aluminum and AlCu (9). Burton *et al.* have shown that addition of O₂ to a CCl₄ plasma increases the amount of atomic Cl in the plasma until the dilution effect predominates (10). Nevertheless, Tokunaga *et al.* (9) reported that increasing additions of O₂ to CCl₄ plasmas reduced the etch rate of aluminum until, finally, no further etching was observed. They suggested that the species responsible for etching aluminum oxide were consumed by the O₂ so that the aluminum surface was protected from etching. Another view of the role of oxygen is that it reoxidizes the aluminum surface as fast as it is exposed, thereby preventing attack by Cl. We assume that the TiW is not subject to passivation by the added oxygen; therefore, the higher concentration of atomic Cl results in a higher etch rate.

Use of a gas mixture of 40%-50% O₂ in CCl₄ and a cathode temperature of 150°C permits etching of TiW with minimal attack of Al or AlCu and SiO₂ or Si₃N₄. The etch rate of silicon is about one-half the etch rate of TiW.

In Situ Preparation of p-Type CdTe Thin Films by Cathodic Electrodeposition

R. N. Bhattacharya and K. Rajeshwar*

Department of Chemistry, The University of Texas at Arlington, Arlington, Texas 76019

R. N. Noufi*

Solar Energy Research Institute, Golden, Colorado 80401

Recent studies on n-CdS/p-CdTe heterojunction solar cells (1) have reported solar-to-electrical conversion efficiencies approaching the 10% benchmark. Thin films of CdTe required for these devices are fabricated by a variety of methods (e.g., vacuum deposition, screen printing, close-spaced sublimation). Electrodeposition is another candidate technique receiving scrutiny (1b, 2). Although earlier studies had prescribed conditions for cathodic deposition of both n- as well as p-type CdTe (3), more recent work reveals difficulties with electrodeposition of p-type layers from acidic baths [cf. Ref. (1g, 4)]. These difficulties have led to the need for post-deposition thermal treatment of electrodeposited films to induce n → p-type conversion. Preliminary evidence for p-type electronic conductivity in the as-deposited films was presented in previous communications (2c, 2d). These experiments, however, were conducted on deposition baths containing no intentionally added acceptor impurity (e.g., Cu). The purpose of this note is to present further evidence for p-type conductivity in CdTe thin films containing Cu as well as some data bearing on the direct applicability of these films to n-CdS/p-CdTe heterojunction fabrication.

Experimental

Procedures for bath preparation and electrodeposition have been described in previous papers from these laboratories (2d, 5). Glass slides coated with Sn-doped indium oxide (ITO) (nominal sheet resistance: 10 Ω/□) and Mo were used as substrates for electrodeposition. These were obtained from commercial sources; the surfaces of these substrates were ultrasonically cleaned prior to use in the electrochemical cell. For acceptor doping of the electrodeposited CdTe thin films, requisite amounts of CuSO₄ were added to the deposition bath.

Ohmic contacts or barrier metals on devices were fabricated in a high vacuum metallization chamber. The intervening CdS layer in the n-CdS/p-CdTe heterojunction devices was prepared by a solution-growth technique described in Ref. (6). This layer was subsequently annealed in H₂ atmosphere at 250°C for ca. 1h to lower its resistivity. Typical characteristics of the annealed samples were the following: van der Pauw resistivity of 1.09 Ω-cm; Hall mobility of 6 cm²/V-s; and donor concentrations of ~10¹⁸ cm⁻³.

The thickness of the electrodeposited CdTe layers was nominally in the range 0.5-4 μm. For heterojunction CdS/CdTe devices, CdS layers 1000-3000 Å thick were employed. Cross-sectional examination of these structures by electron microscopy reveal columnar CdTe grains atop a fine-grained layer of CdS.

Results and Discussion

Table I contains representative compositional data obtained by electron probe microanalyses (EPMA) for CdTe thin films fabricated on ITO and Mo substrates. Additionally, data on two samples of CdS on glass are also shown. The CdTe thin films on ITO invariably contain Te as a separate phase; this is reflected in the high Te: Cd ratio for these samples (cf. sample no. 87 and 17 in Table I). Evidence for the presence of Te is also obtained from

Table I. Representative compositional characteristics of CdTe and CdS thin films from EPMA

Sample no.	Substrate	Composition (atom percent) ^a			
		Cd	Te	Cu	S

^e Films prepared by solution growth method [cf. Ref. (6)].

x-ray diffraction analyses and is further confirmed by the tailing of the long-wavelength optical absorption response of these thin films. Precedence for formation of Te precipitates in CdTe is found in previous work (7). Excess Te is also implicated in device behavior wherein oxidative etching of the CdTe surface was employed (1f). In our experience, electrodeposition of device-quality CdTe thin films which are intrinsically p-type (i.e., those which contain interstitial Te in slight excess from the stoichiometric composition) is invariably accompanied by the formation of Te as a separate phase. In this regard, acceptor doping of CdTe during electrodeposition is a more viable approach as demonstrated below.

A typical Auger electron spectrum (differential form) and a depth profile for a doped thin film on Mo substrate are shown in Fig. 1a and 1b, respectively. Along with the ubiquitous C, S, and Cl are seen as impurities in Fig. 1a. The former is undoubtedly a consequence of SO₄²⁻ incorporation during film growth; a possible source for Cl⁻ ions is the internal solution of the saturated calomel reference electrode. A further point with acceptor doping is illustrated in Table I. The Cu uptake of the film increases with Cu²⁺ content in the bath as expected. However, the Cu content of the film is seen to be a sensitive function of the substrate material for a given Cu²⁺ loading of the bath (cf. Table I).

That our films thus prepared are indeed p-type in the as-deposited condition is shown by representative data shown in Fig. 2 and 3. Figure 2 shows the current voltage (i-E) characteristics of a Schottky barrier constructed from a CdTe film on ITO substrate. Indium [work function, φ = 3.97 eV, Ref. (8)] is a known Schottky barrier inducing contact on p-CdTe [electron affinity, EA: 4.28 eV, cf. Ref. (9)]. Consistent with this expectation, the i-E characteristics show good rectification on reverse bias of

*Electrochemical Society Active Member.

Fig. 1. (a): Auger electron spectrum of an electrodeposited CdTe/Cu thin film on Mo substrate. (b): Auger depth profile of an electrodeposited CdTe/Cu thin film on Mo substrate.

the junction. Figure 3 shows the behavior of a n-CdS/p-CdTe heterojunction fabricated from another Cu-doped CdTe thin film. In this case, note that the heavily doped ITO layer [$EA = \phi = 4.40$ eV, cf. Ref. (10)] functions as an ohmic contact for n-CdS [$EA = 4.50$ eV, cf. Ref. (9)], which is also heavily doped (see above). Gold [$\phi = 5.2$ eV, cf. Ref. (8)], however, forms an ohmic contact to p-type CdTe. Again, the high degree of rectification on reverse bias of the junction is consistent with p-type conductivity in the CdTe film and consequent formation of an n-CdS/p-CdTe heterojunction.

The absence of a buried n-CdTe/p-CdTe homojunction [cf. Ref. (1b)] in our ITO/CdS/CdTe/Au device structure is

Fig. 2. Current-voltage (i-E) characteristics of an ITO/CdTe/In Schottky barrier.

Fig. 3. Typical i-E characteristics of an ITO/CdS/CdTe/Au heterojunction device utilizing electrodeposited and Cu-doped p-CdTe layers. The two curves as shown denote scans in opposite directions.

shown by spectral response data. The short-wavelength cut-off and long-wavelength fall-off (ca. 500 and 850 nm, respectively) match the known absorption characteristics of CdS and CdTe. Additionally, measurement of the electron-beam induced current for the structure locates the photoactive junction at the CdS/CdTe interface.

Summary and Conclusion

The data presented in Fig. 1-3, when taken as a unit, are unequivocal evidence for the fact that our CdTe films are p-type when deposited under the conditions described above and in Ref. (5). We emphasize that these films show the typical behavior illustrated in Fig. 2 and 3 in the as-deposited condition; i.e., they received no thermal treatment to induce $n \rightarrow p$ conversion [cf. Ref. (1g)]. This may be an important advantage in the device fabrication stage given the extreme sensitivity observed for interfacial phenomena in comparable devices and the consequent deleterious effects in cell efficiencies on heat-treatment (11).

In conclusion, acceptor doping of electrodeposited CdTe thin films yield p-type films which show satisfactory rectification behavior when fabricated into CdTe/In Schottky barriers and CdS/CdTe heterojunctions.

Acknowledgments

This research was made possible by a subcontract (no. XL-3-03140-01) from the Solar Energy Research Institute (SERI). The authors (R. N. B. and K. R.) thank Satyen Deb and Gene Blakeslee of SERI for access to their laboratory facilities. EPMA and Auger electron spectroscopy were performed by Chuck Herrington and Amy Schwartzlander, respectively, at SERI. Solubility of α - Fe_2O_3 in Fused Na_2SO_4 at 1200 K

Y. S. Zhang and Robert A. Rapp*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

Iron-, nickel-, and cobalt-base alloys used at high temperatures are sometimes subjected to accelerated corrosion attack when covered by a thin layer of fused salt. This type of accelerated oxidation is called hot corrosion. Fused Na_2SO_4 , or a mixed alkali sulfate melt, is often responsible for this hot corrosion attack of metals. A knowledge of the solubilities of metal oxides, and the dependencies of the solubilities on acid/base melt chemistry assists in evaluating any oxide fluxing mechanism (1). The dissolution behavior of a metal oxide is also important for elucidating any electrochemical mechanism of hot corrosion in which soluble metal species are involved (1). Solubilities of the oxides NiO (2, 3), Co_3O_4 (2), Al_2O_3 (4), and Y_2O_3 (5) have been measured in fused Na_2SO_4 . In this work, the solubility of α - Fe_2O_3 at 1200 K and 1 atm oxygen has been measured as a function of the Na_2SO_4 melt basicity defined as $\log a_{\text{Na}_2\text{O}}$.

Experimental Procedure

About 0.5g of α - Fe_2O_3 powder (99.9% purity) and 25-30g of reagent-grade Na_2SO_4 were mixed and contained in an alumina crucible inside a closed-end cylindrical mullite chamber. Different compositions of catalyzed SO_2 - O_2 mixed gases were used to adjust the basicity of the Na_2SO_4 melt. Varying amounts of Na_2O_2 from 0.002 to 0.2 mole percent (m/o) Na_2O_2 were added to the melt to change its basicity in the basic direction from 9.5 to 7.3. As described in detail earlier (2, 4), the melt basicity was measured by two solid-state reference electrodes: a Na sensor and an oxygen probe. The Na sensor was composed of a Ag wire immersed in a fused Na_2SO_4 -10 m/o Ag_2SO_4 solution at the bottom of a Na^+ ion conducting mullite tube which was sealed at the top by ceramic cement. A Pt wire was welded to the Ag wire to serve as the lead wire. The oxygen probe was an internally platinized ZrO_2 (3.5 weight percent CaO) tube with a Pt lead wire. The internal electrode contacted air. The open-circuit potential between these two reference electrodes is given by (2)

$$E(\text{V}) = 1.4943 + 0.119 \log a_{\text{Na}_2\text{O}}(\text{melt}) \quad [1]$$

at 1200 K if the melt is in internal equilibrium (lacks concentration gradients). In addition, a Pt wire working electrode contacted the melt. Another Pt electrode was painted onto the outside surface of the zirconia tube just above the melt to monitor the P_{O_2} of the gas phase. After about two days, the P_{O_2} in the melt and above the melt became approximately equal and the melt basicity remained constant. Samples of the salt were taken by quenching some melt onto a cool alumina rod. The sampling rod did not contact either of the electrodes or the inside wall of the alumina crucible. The tip of the

sampling rod was kept 4-5 mm above the bottom of the crucible, so that no solid (dense) α - Fe_2O_3 powder was incorporated along with the salt sample. Each salt sample of about 0.2g was weighed to 0.1 mg accuracy and dissolved in 0.02N HCl to a volume of 100 or 1000 ml, depending upon the Fe concentration in the salt. The contents of soluble Fe were determined by using an atomic absorption spectrophotometer (Perkin-Elmer, Series 360) with a graphite furnace. The salt solutions introduced into the graphite furnace were limited to a 10 microliter volume, so that the Na_2SO_4 in the solutions did not affect the analytic results.

Results and Discussion

Figure 1 is the thermodynamic phase stability diagram for the Na-Fe-S-O system at 1200 K, which shows that α - Fe_2O_3 is stable at $8.1 < -\log a_{\text{Na}_2\text{O}} < 17.7$. Most of the data used for the construction of Fig. 1 are provided in

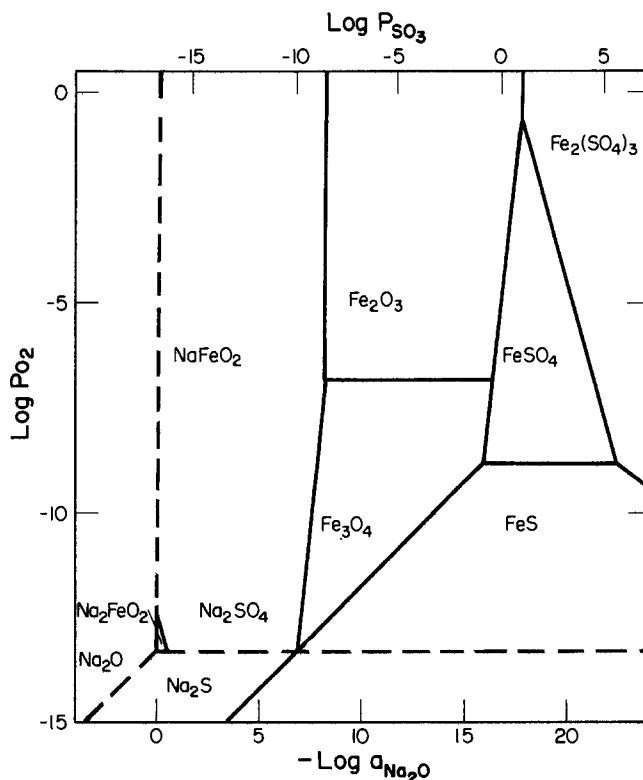

Fig. 1. Thermodynamic phase stability diagram for the Na-Fe-S-O system at 1200 K.

*Electrochemical Society Active Member.

Fig. 2. Solubility of α -Fe₂O₃ in fused Na₂SO₄ at 1200 K and $P_{\text{O}_2} = 1$ atm.

the succeeding note (4). The dual designations for the abscissa are valid only in the regime where Na₂SO₄ is stable. Additionally, for 1200 K, $\Delta G^\circ_{\text{Fe}_2\text{O}_3} = -512.2$ kJ/mol (6), $\Delta G^\circ_{\text{Fe}_3\text{O}_4} = -731.9$ kJ/mol (6), $\Delta G^\circ_{\text{FeS}} = -85.8$ kJ/mol (6), $\Delta G^\circ_{\text{Fe}_2(\text{SO}_4)_3} = -1216.9$ kJ/mol (6), $\Delta G^\circ_{\text{FeSO}_4} = -488.7$ kJ/mol (6), $\Delta G^\circ_{\text{NaFeO}_2} = -474.1$ kJ/mol (7), and $\Delta G^\circ_{\text{Na}_2\text{FeO}_2} = -527.2$ kJ/mol (7). The data points in Fig. 2 are the measured solubilities of α -Fe₂O₃ in molten Na₂SO₄ at 1200 K and 1 atm oxygen. Each data point in Fig. 2 represents the average analysis for a separate salt sample compared against a certified standard solution. The high precision of the solubility values is indicated by the reproducibility of the data. In basic dissolution, the Na₂O dependence of the solubility indicates that the solute species of Fe₂O₃ is FeO₂⁻. The dependence of the FeO₂⁻ concentration upon the melt basicity is consistent with the following dissolution reaction

$$\left\{ \frac{\partial (\log a_{\text{FeO}_2^-})}{\partial (-\log a_{\text{Na}_2\text{O}})} \right\} = -\frac{1}{2} \quad [2a]$$

The solubility plateau to the left of about $-\log a_{\text{Na}_2\text{O}} = 9$ is expected because the dissolution of the equilibrium

NaFeO₂ phase to form FeO₂⁻ ions does not involve O²⁻ ions in the reaction. The cross-hatched transition indicates the thermodynamic uncertainty in the location of the phase stability boundary.

For acidic dissolution of Fe₂O₃, the solute correlates to Fe³⁺. The dependence of the Fe³⁺ concentration on the melt basicity is consistent with the reaction

$$\left\{ \frac{\partial (\log a_{\text{Fe}^{3+}})}{\partial (-\log a_{\text{Na}_2\text{O}})} \right\} = \frac{3}{2} \quad [3a]$$

Close to 1 atm O₂, both the basic and acidic solutes of Fe₂O₃ involve trivalent iron. Because no oxidation step is involved in such dissolution reactions, no dependence of solute concentrations upon P_{O_2} is expected near $P_{\text{O}_2} = 1$ atm.

Figure 2 shows that the solubility minimum lies at $-\log a_{\text{Na}_2\text{O}} = 12.9$. Thus, α -Fe₂O₃ is an oxide considerably more acidic than Co₃O₄ and NiO (2) but more basic than α -Al₂O₃ (4). The activity coefficients of the soluble species NaFeO₂ and Fe(SO₄)_{1.5} were calculated by methods used previously (2, 4) to be 250 and 3.6×10^{-3} , respectively. But these values possess considerable uncertainties arising from the uncertainties in the thermodynamic data (6, 7) for $\Delta G^\circ_{\text{NaFeO}_2}$ and $\Delta G^\circ_{\text{Fe}_2(\text{SO}_4)_3}$.

In order to evaluate and test the P_{O_2} dependence of the solubilities of iron oxides, and to relate the data to the hot corrosion of iron-base alloys, the solubilities of iron oxides are being measured at lower oxygen pressures in a continuing study.

Solubility of α -Al₂O₃ in Fused Na₂SO₄ at 1200 K

P. D. Jose, D. K. Gupta, and Robert A. Rapp*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

Many alloys and coatings owe their resistance to high temperature oxidation to the slow growth of adherent Al₂O₃ scales. However, the dissolution of this protective oxide scale could represent an important step in the accelerated corrosion of engineering alloys in contact with a thin layer of fused salt. A number of salt films are known to cause such "hot corrosion." Because of its high stabil-

ity in oxidizing sulfur-bearing gases, sodium sulfate is particularly aggressive toward protective coatings in aircraft and marine gas turbines and in other engineering systems. A knowledge of the solubility of the protective oxide and its dependence on the fused salt chemistry may aid the interpretation of hot corrosion mechanisms and in the development of new protective materials.

Liang and Elliott (1) have reported a few values for the solubilities of Cr₂O₃, Al₂O₃, and NiO in Na₂SO₄ over a lim-

*Electrochemical Society Active Member.

ited range of salt compositions. Stroud and Rapp (2) reported solubilities for $\alpha\text{-Al}_2\text{O}_3$ and Cr_2O_3 in Na_2SO_4 at 1200 K as a function of P_{O_2} and $\log a_{\text{Na}_2\text{O}}$. However, their results were inconsistent with thermodynamic expectation, because the observed minimum in the oxide solubility occurred at too high a value for $a_{\text{Na}_2\text{O}}$. It now appears that because of a reaction of Na_2SO_4 with their platinum electrode in the Na_2SO_4 melts, a faulty potential was indicated for the Pt/melt electrode. The present study reports measurements for Al_2O_3 solubility using improved methods. Two solid electrolyte probes were used to infer the basicity of Na_2SO_4 melts as suggested by Watt *et al.* (3), and used by Gupta and Rapp (4) in a determination of the solubilities of NiO and Co_3O_4 in Na_2SO_4 at 1200 K. Deanhardt and Stern (5) have employed two pairs of such probes to determine the solubility products for NiO in Na_2SO_4 at 1200 K. Misra *et al.* (6) calculated the solubilities and the interaction energy parameters for the acidic solutes of NiO and Co_3O_4 by use of existing phase diagrams and a regular solution model. They found good agreement with experimental solubility results.

The acid-base character of Na_2SO_4 can be described by the equilibrium

in which Na_2O can be considered as the basic component and SO_3 the acidic component. The thermodynamic data listed in Table I were used to construct the Na-Al-S-O phase stability diagram of Fig. 1, which is analogous to the Pourbaix diagram of E vs. pH for aqueous solutions. The oxidation potential is plotted as the ordinate against the negative of salt basicity (defined as $\log a_{\text{Na}_2\text{O}}$) as the abscissa. The dashed lines show that liquid Na_2SO_4 is stable over a large area in this diagram. Alternate abscissa variables of $-\log a_{\text{Na}_2\text{O}}$, or else $\log P_{\text{SO}_3}$, can be used within the range of Na_2SO_4 stability at essentially unit activity. The diagram could provide quantitative values for the solubility of the metal oxide in the fused salt if the identity and the activity coefficients of the solute species were known. Conversely, if the solubility were known, the activity coefficients of the respective solutes in solution could be calculated. The reliability of activity coefficients obtained in this way depends greatly on the accuracy of the Gibbs energy of formation data for the soluble metal salts and the metal oxide and also on the accuracy of the experimental measurements. In the present study, the solubility of α -alumina in fused Na_2SO_4 at 1200 K was measured as a function of the thermodynamic activity of Na_2O for a fixed oxygen pressure of 1 atm. The results are related to the phase stability diagram and are used to infer the ionic solute species as well as the activity coefficients for the solute species of alumina.

Experimental Procedure

As in the preceding study by Gupta and Rapp (4), the voltage between two solid-state electrochemical probes was used to measure the basicity of the Na_2SO_4 melt. A closed-end mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) tube (McDanel MV30) with glassy grain boundaries is known to be an exclusive conductor of sodium ions at high temperatures. Within this tube, a small amount of liquid salt with composition 90 mole percent (m/o) Na_2SO_4 , 10 m/o Ag_2SO_4 contacted a Ag wire which was welded within the hot zone to a Pt lead wire. The working electrode for this cell was either a

Table I. Thermodynamic data relevant to Na-Al-S-O system

Fig. 1. Thermodynamic phase stabilities in the Na-Al-S-O system at 1200 K

Au or Pt wire contacting the Na_2SO_4 melt external to the mullite tube and remote from the gaseous environment; again, a Pt lead wire was attached. A closed-end 3.5 weight percent (w/o) CaO partially stabilized zirconia tube contacted the Na_2SO_4 melt. This zirconia tube was platinized on its aerated inside surface and provided with an internal Pt lead wire. The voltage between the zirconia electrode and the Au or Pt working electrode in the melt indicated the P_{O_2} of the melt (4). At 1200 K, the open-circuit voltage between the mullite and the zirconia electrodes is given by (4)

$$E(\text{V}) = 1.4943 + 0.119 \log a_{\text{Na}_2\text{O}} \quad [2]$$

Strictly speaking, the $a_{\text{Na}_2\text{O}}$ is measured at the $\text{ZrO}_2/\text{fused Na}_2\text{SO}_4$ interface (7), but this Na_2O value is valid for the entire melt under equilibrium conditions.

Excess amounts (30-40g) of $\alpha\text{-Al}_2\text{O}_3$ powder were added to 100g of sodium sulfate in an alumina crucible placed within the mullite reaction tube. After drying the salt for a few days at 200°C, the temperature was raised to 1200 K. Salt samples were taken after various times by freezing salt onto a cold alumina tube after the electrochemical probes indicated equilibrium for oxygen between the fused salt and the gas, and after the salt basicity became constant. The salt samples were weighed, dissolved in distilled water, and analyzed by atomic absorption spectroscopy (Perkin-Elmer, Series 360) using a graphite furnace. For neutral water at $\text{pH} = 7$, the solubility of $\text{Al}(\text{OH})_3$ is a factor of at least 150 times higher than the highest Al solute concentration from the dissolved salt.

Results and Discussion

Figure 2 presents the results of solubility measurements for $\alpha\text{-Al}_2\text{O}_3$ in fused Na_2SO_4 at 1200 K in $P_{\text{O}_2} = 1$ atm. Although only a few points were obtained for the acidic segment of the solubility curve, the plot is well described by lines for one basic solute, AlO_2^- , and one acidic solute Al^{3+} . The minimum solubility occurs at about $\log a_{\text{Na}_2\text{O}} = -15.4$ and 13 wt ppm dissolved Al. A single datum point from Liang and Elliott (1) is in good agreement after conversion of their measurement to a common value for $\Delta G_{\text{Na}_2\text{SO}_4}^\circ$ (reported in Table I).

For the dissolution of $\alpha\text{-Al}_2\text{O}_3$ as a basic solute

so that

Fig. 2. Solubility of α - Al_2O_3 in fused Na_2SO_4 at 1200 K and $P_{\text{O}_2} = 1$ atm

$$\left(\frac{\partial \log a_{\text{AlO}_2^-}}{\partial -\log a_{\text{Na}_2\text{O}}}\right) = -\frac{1}{2} \quad [4]$$

With the assumption of a constant activity coefficient for the dissolved NaAlO_2 in these dilute solutions, the same dependence is expected for the plot of log concentration vs. $-\log a_{\text{Na}_2\text{O}}$, as shown in Fig. 2. Correlation of the data with the theoretical slope is good, implying that only the AlO_2^- ion is formed in basic dissolution. Any pair of values of salt basicity and oxide solubility can be used to calculate the activity coefficient for the dissolved NaAlO_2 component through the equilibrium

For the presence of Al_2O_3 at unit activity

$$2 \log a_{\text{NaAlO}_2} - \log a_{\text{Na}_2\text{O}} = 8.10 \quad [6]$$

From Fig. 2, for $\log a_{\text{Na}_2\text{O}} = -13$ and therefore $a_{\text{NaAlO}_2} = 3.55 \times 10^{-3}$, the soluble mole fraction of NaAlO_2 (equal to twice the soluble Al_2O_3) equals 10^{-3} . Then, the activity coefficient for NaAlO_2 in dilute solution in Na_2SO_4 is given by

$$\gamma_{\text{NaAlO}_2} = \frac{a_{\text{NaAlO}_2}}{N_{\text{NaAlO}_2}} = 3.6 \quad [7]$$

Except for the indicated single solubility measurement from Liang and Elliott (1), previous measurements are not available for comparison.

For the dissolution of α - Al_2O_3 as an acidic solute

and

$$\left(\frac{\partial \log a_{\text{Al}^{3+}}}{\partial -\log a_{\text{Na}_2\text{O}}}\right) = +\frac{3}{2} \quad [9]$$

Only a few data for acidic dissolution are shown in Fig. 2, but they are consistent with the presence of a single Al^{3+} acidic solute. Acidic dissolution of Al_2O_3 in Na_2SO_4 can also be described in terms of an $\text{Al}(\text{SO}_4)_{1.5}$ solute

For the presence of Al_2O_3 and Na_2SO_4 at unit activities

$$(3/2) \log a_{\text{Na}_2\text{O}} + \log a_{\text{Al}(\text{SO}_4)_{1.5}} = -27.05 \quad [11]$$

For $\log a_{\text{Na}_2\text{O}} = -16$, $a_{\text{Al}(\text{SO}_4)_{1.5}} = 8.91 \times 10^{-4}$, and the measured solubility (equal to twice the molar Al_2O_3 solubility) is about $N_{\text{Al}(\text{SO}_4)_{1.5}} = 2.5 \times 10^{-4}$, so that

$$\gamma_{\text{Al}_2(\text{SO}_4)_3} = \frac{a_{\text{Al}(\text{SO}_4)_{1.5}}}{N_{\text{Al}(\text{SO}_4)_{1.5}}} = 2.3 \quad [12]$$

No previous values have been reported in the literature. Indeed, the uncertainty in each activity coefficient is large, as previously mentioned.

In this study, it has been shown that at 1200 K and $P_{\text{O}_2} = 1$ atm α - Al_2O_3 dissolves in fused Na_2SO_4 as one acidic and one basic solute species, with the minimum solubility occurring at $\log a_{\text{Na}_2\text{O}} = -15.4$. Because neither dissolution reaction involves a change in aluminum valence, the solubility plot of Fig. 2 should not depend upon P_{O_2} .

Experimental Determination of the Passive-Active Transition for Iron in 1M Sulfuric Acid

Philip P. Russel and John Newman
(pp. 547-553, Vol. 130, no. 3)

C. Gabrielli, M. Keddam, C. Rakotomavo, and H. Takenouti:¹ In this paper, the authors claim to have verified a previously developed model² concerning the active-passive transition of an iron electrode in 1M sulfuric acid solution first described by Epelboin *et al.*³ This model accounts for the Z-shaped polarization curve in terms of an ohmic drop overvoltage on an active disk whose radius r_p decreases as the passive state is approached (A-P configuration). A nearly parabolic I-E relationship in the transition region is used as a validity criterion of the model.

As a general criticism, a fitting of the experimental data to this law does not seem to us a very accurate way of testing the model, since, at least in the low current range, I-E plots are independent of the electrode diameter, as established in this paper, but also of the rotation speed Ω (see Fig. 6 of Epelboin *et al.*,³ reproduced in Fig. 1 of Law and Newman²), whereas the repartition of passive and active zones are dependent on Ω .³ Hence, whatever the elementary process involved to set the geometry of the dissolution and the ohmic drop, the parabolic law will fit the data satisfactorily.

Let us limit the discussion to more particular points.

1. It should be emphasized that the model is only consistent with the A-P configuration observed at high rotation speeds ($\Omega > 3600$ rpm) and high currents ($I \geq 180$ mA for 5 mm diam electrode). Have the authors really observed the A-P configuration to 1600 rpm?

2. It is extremely surprising that the paper deals with computed values of i_{avg} and r_p as presented in Table IV with no reference to direct measurements of r_p on the attacked surface [see (1) above]. It seems to us that a comparison of the data shown in Table IV with the real-life values of i_{avg} and r_p is of basic importance to substantiate the model and to establish definitely the increase of i_{avg} when I decreases in the transition range. It must be noted that our finding of i_{avg} decreasing with I is hardly questionable, since it is based on direct determinations of the active area, regardless of any model and hazardous assumptions on the electrode kinetics.

3. We agree with the authors that the ohmic drop may be the determining effect under extreme conditions where little mass-transfer limitation occurs (large Ω values, Fe-Ni alloy⁴). This is perfectly verified, as shown

in our Fig. 1 by complex impedance⁵ performed in the transition range under conditions where the model is likely to be valid (A-P). The diagram exhibits the usual shape related to a passivation process. The apparently positive polarization resistance (positive slope of the I-E curve) is entirely due to the electrolyte resistance shifting the diagram in the positive direction.

For lower rotation speeds, where a passive disk is always present at the center of the electrode (PAP or PA), impedance data reveal a more complicated behavior involving mass transfer in the Z-shaped feature.

This is also supported by recent estimations of the ohmic drop profiled along the disk radius by means of a Haber-Luggin capillary adapted to the rotating disk device.⁶ The AP configuration is the only case where the potential of the active area lies cathodic to the Flade potential.

It must be recognized that the general behavior of iron in the transition range from active to passive state involves some kind of coupling between mass transfer and passivation which remains to be incorporated in a more sophisticated form of the model.

Philip P. Russel⁶ and John Newman⁷ We appreciate the comments of Dr. Gabrielli and his co-workers. They are critical of the fact that we did not measure specifically the active area for use in the calculation of i_{avg} . We agree with their claim that our results would have been stronger if the active area had been measured instead of calculated. This statement is made in the conclusions section of our paper. However, we question the accuracy of

such a measurement, should one attempt to make it. Specifically, it is not clear that one may be able to determine that there is a central passive disk in a passive-active-passive configuration, as explained below.

First, consider a large central active area and an outer passive ring. The current density on the active area will approach a primary distribution for a sufficiently large active area.⁸ This will result in a high rate of dissolution near the periphery of the active region and a much smaller rate of dissolution near the center. We conclude that it may be difficult to differentiate between a low current density region in the center of the disk and a truly passivated central region in light of the $\pm 1 \mu\text{m}$ depth measurement accuracy given by Epelboin *et al.*³

As the active area decreases, the current density distribution will become more nearly uniform. This change is accompanied by a continuous decrease in the nonuniformity of the potential distribution. The maximum potential variation from the center to the edge of the passive zone is given as

$$\Delta\Phi_0 = 0.363 r_p i_{\text{avg}}/K \quad [1]$$

Assuming a value of 1 mm for the radius, 1.3 A/cm² for the average current density on the active portion, and a conductivity of 0.4 mho/cm, the potential may vary by up to 120 mV. The active dissolution kinetics of iron follow the Tafel law with a slope of 60 mV/decade.^{9, 10} This large difference in potential may produce much lower dissolution rates at the center of the disk even though the entire distribution is more uniform than it was in the nearly primary case. Again, this would make differentiation between a low dissolution rate and true passivation difficult in the small central region of the disk.

The high dissolution rates encountered on the peripheral area of the active zone provide additional complications in analyzing experimental results. The rapid recess of selected parts of the electrode surface will alter both the mass transfer and the ohmic potential drop in a manner that is difficult to quantify exactly. However, in the absence of this effect, the disk surface is uniform from a mass-transfer point of view, so that the current density distribution is controlled by the nonuniform potential field, which is directly related to the ohmic potential drop.

A Thermodynamic Theory of Electric Potential Generated on Crystallization of Electrolytes

R. P. Rastogi and S. A. Khan
(pp. 1327-1334, Vol. 130, no. 6)

B. N. Tripathi¹¹ In the above-mentioned and related paper,¹² Rastogi and Khan have presented an interesting theory of the development of electric potential on the precipitation and dissolution of electrolytes. In the paper under discussion, they tried to give a semiquantitative check of an inequality based on their thermodynamic theory. However, a quantitative check of their theory (Eq. [40]) can easily be made by substituting appropriate

values of transport numbers t_1^0 and t_2^0 . As already pointed out by the authors, the ions are dehydrated before they are added on to the crystal lattice. Therefore, it is quite reasonable to assume that the transport numbers t_1^0 and t_2^0 associated with the migration of ions from liquid/crystal interface to the crystal lattice are different from the conventional transport numbers. The supersaturated solution/crystal interface may be supposed to consist of mostly unhydrated cations and anions. Therefore, the layers closest to the crystal lattice may be supposed to behave like ionic melt. Hence, t_1^0 and t_2^0 should be equivalent to the transport numbers of bare ions in the molten salt. Therefore, we can make use of such transport numbers in order to have a theoretical estimation of $(\Delta\Phi)_{PP}$.

Rastogi and Khan have theoretically calculated the values of $(\Delta\Phi)_{PP}$ of KCl, KBr, and NaCl (Table II.) Their theoretical values (-284, -272, and -310 mV, respectively) are much higher in comparison to the experimental values (-54, -52, and -56 mV, respectively). However, the values of $(\Delta\Phi)_{PP}$ calculated on the basis of transport numbers of ions in the ionic melts of their respective salts (-67, -87, and -74 mV, respectively) are found to be in an excellent agreement with the experimental data.

R. P. Rastogi¹³ The significance of t_1^0 in the above paper has not been comprehended correctly by the above author. t_1^0 is not the conventional transport number since U_+^0 and U_-^0 are the mobilities of cations and anions on the crystal lattice. This is amply clarified by the paragraph preceding Eq. [40] in the paper under discussion. Hence, the mobilities of attachment of ions on the crystal lattice cannot be equated with the conventional mobilities of the bare ions in molten salt as such.

The theoretical values of precipitation potential in Table II of my paper are the expected upper limits of precipitation potential when t_1^0 is put equal to unity and $(\Delta H)^0$ is put equal to (i) $(\Delta H)_l$ and (ii) $-(\Delta H)_s$. Thus the meaning of the theoretical values has also not been correctly appreciated by the author. Such a calculation had to be devised since the mobilities of attachment of ions are not available in literature and only inequality [44] could alone be subjected to test.

Some calculated values of precipitation potential have been quoted by the author when t_1^0 and t_2^0 are put equal to the transport number of corresponding ion in the molten salt for which no theoretical justification has been given. It should be noted that this procedure does not provide excellent agreement as claimed, particularly when the recent experimental values¹⁴ obtained with microelectrode are considered. The agreement as regards order of magnitude is perhaps due to the fact that the mobilities of attachment of the ions on the crystal lattice is likely to be inversely proportional¹⁴ to ionic radii and that the mobilities of the ions in molten salt obey a similar relationship¹⁵ approximately. It is difficult to comment further on the values obtained by the author since neither the source nor the data on the transport number of bare ions in molten salts has been reported.

ERRATUM

In the paper by A. Reisman, C. J. Merz, J. R. Maldonado, and W. W. Molzen, Jr. [*This Journal*, **131**, 1404 (1984)], the authors discovered subsequent to the paper's publication that a calculation error had been made which in turn led to an erroneous conclusion. In evaluating 10 keV electron damage effects on thin IGFET gate insulators, we had calculated that the insulators had absorbed 3×10^6 (SiO₂) and 3×10^7 rad (SiO₂) in two experiments employing 20 and 200 μ C doses, respectively. Comparing the measured insulator damage at these assumed rad doses with those observed for x-rays at the same rad doses led to the conclusion that electron-induced damage is greater for a given rad dose than is x-ray damage. The comparisons were made with 1.5 and 8.03 keV x-rays.

The correct numbers for the electron rad doses should have been 4.9×10^7 and 4.9×10^8 rad, respectively. The original, incorrect, and present recalculated numbers were based on the use of the Terrill equation [Ref. (14)]. Use of the Snow *et al.* energy-loss equation [Ref. (2)], or the Everhart relationship [Ref. (14)], gives, within experimental limits, similar results to the recalculated ones. Finally, using

energy-loss statistics obtained with 2×10^4 electrons in a Monte Carlo calculation by M. Rosenfield (IBM, T. J. Watson Research Center), we obtained a number of 5.5×10^7 rad for the 20 μ C case, in good agreement with the other recalculated value. The Monte Carlo calculations were made using the program developed by Rosenfield for his thesis titled "Analysis of Backscattered Electron Signals for X-ray Mask Inspection" (1984), Department of Electrical Engineering and Computer Science, University of California, Berkeley, California.

If the recalculated data point, 4.9×10^7 rad, is placed in its correct location in Fig. 1 (positive charge), or Fig. 2 (neutral traps), it falls within the data band of the x-ray curves. The 4.9×10^8 rad data point cannot be plotted since it lies outside the rad dose range studied for x-rays.

Consequently, the conclusion that, at the same dose, electrons create more damage than x-rays is incorrect. It should be concluded that similar electron and x-ray rad doses appear to give rise to similar levels of fixed positive charge and neutral trap damage, when particle and photon energies are similar.

Macroscopic Mechanical Oscillation Associated with Electrochemical Periodic Variation

O. Teschke,* D. M. Soares, and F. Galembeck

Inst. de Física and Inst. Química, Universidade Estadual de Campinas, 13100 Campinas S. P., Brazil

A number of electrochemical systems display oscillatory behavior (1-8). One example is iron anode in dilute sulphuric acid (9,10), in which case current oscillations are concurrent with oxide/salt films formation and removal (11).

Now, we have found that the level of the liquid (dilute H_2SO_4) surrounding an (wire) iron anode moves up and down, in synchronism with the current oscillations. That means, electrochemical oscillations are associated to mechanical oscillations, in this case.

The experimental set-up used is in Figure 1. Reagent-grade chemicals were used without further purification. 0.3 mm-thick, 99.99% iron wire was from C. Erba. Iron tips cut normal to the wire axis, washed with methanol and rinsed with double-distilled water were used as the anodes. The iron electrode was grounded. Voltage was applied between the counter electrode (a piece of 9.999% platinum wire with a drowned area 20 times larger than the area of the iron tip) and a saturated calomel electrode (SCE). Operational amplifiers kept the electrode voltages at the desired level, independently of current changes; a constant + 300 mV was applied between the iron and calomel electrode. Current-time curves were recorded on a 7100 BM Hewlett Packard recorder and pictures of the liquid-air-iron contact line were taken with a Nikkon F-2 camera (fitted with approximation rings). Reproducible current-time curves could only be obtained following this routine: i) a fresh solution is placed in the apparatus; ii) an iron tip is introduced in the solution and polarized (- 300 mV) against the SCE, allowing electrolysis to proceed for 15 minutes; iii) the iron tip is replaced by a new tip; iv) this is polarized (+ 300 mV) against the SCE and positioned to contact the liquid

meniscus.

As soon as iron touched the liquid this ascended around the metal, by capillary action. After an induction period of a few minutes, mechanical oscillations of the liquid level could be observed. Their appearance was concurrent with that of current-time oscillations and they led to considerable geometric changes in the iron tip-liquid contact region, as shown in Figure 2. Figure 3 shows typical current-time oscillations. Peak maxima were affected by a number of factors: solution stirring rate, solution concentration, shape of the iron tip and its exact position at the liquid interface. In the experiments reported here the iron tip (cut normal to the wire axis) was positioned with micromanipulators just to touch the meniscus at its center.

It has been reported (11) that electrochemical oscillations in the iron-sulphuric acid system are associated with the cyclic formation and destruction of a hydrous iron sulphate deposit, over the electrode metal. Contact angles between the electrolyte - i) bare iron wire and ii) sulphate-covered iron wire were measured from enlarged pictures, and they are 83° and 30° , respectively. Consequently, wetting ability of the surface changes in phase with the observed chemical changes.

The observed steps may be identified in the overall process: i) iron is corroded; its surface is covered with hydrophylic corrosion products, and becomes rougher; ii) liquid moves up, in a more wettable surface than bare metal, assessing new, unattached regions and originating slow current increase; iii) liquid reaches a higher point; suddenly, the liquid column falls, together with solid particles and leaving the metal surface clean -

the strong current pulse is detected at this point; iv) the current falls quickly to a low value and starts to increase slowly as the liquid moves up again.

It seems that the main factor leading to the oscillatory behavior are the iron surface wettability changes and the poor adhesion between iron, iron sulphate and aqueous solution, which at a point is unable to sustain the ascending liquid column. We believe that a better understanding of electrochemical-mechanical coupled oscillations depends on the evaluation of the involved adhesion forces.

Diffusion Coefficient of Dopants in Polyacetylene

Fritz G. Will*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

INTRODUCTION

There have been few attempts so far to establish the diffusion coefficient of dopants in polyacetylene (1-3), and published values show a ten order of magnitude discrepancy with values ranging from 4×10^{-18} to 2×10^{-8} cm²/sec. The low value is an estimate based on the open circuit voltage decay of polyacetylene electrodes following doping with Li or ClO₄ (1). The high value was determined from the I₂ uptake of polyacetylene films in organic I₂ solutions (2). In fact, however, one would expect the diffusion coefficient of various dopant molecules to be of the same order of magnitude.

In this communication, we report the diffusion coefficient of BF₄ in polyacetylene from electrochemical current pulse measurements and show that simultaneous determination of the solution-wetted surface area of the polyacetylene is mandatory to arrive at correct values. The wetted surface area was unknown in previous studies (1,2), and we demonstrate that different degrees of wetting of the microporous fibrous structure of polyacetylene readily accounts for the widely differing literature values.

EXPERIMENTAL

Polyacetylene film of 89 μ thickness had been prepared by the Rohm and Haas Company, using the standard Shirakawa technique. Details regarding the preparation have been published elsewhere (4). The film had 48% of theoretical density, the void space being comprised of interstices of several hundred Angstrom dimensions between polyacetylene fibers of 200 to 400 Å diameter. The specific surface area was determined by low temperature N₂ adsorption as 40 m²/g. Circular electrodes of 2 cm² area were prepared by sputtering 1000 Å Au films on one side and making pressure contact to a coiled Au wire. Experiments were

performed at room temperature in a PTFE cell employing a Li counter and reference electrode. The electrolyte was a 30% b.w. solution of LiBF₄ in sulfolane. Galvanostatic pulses were applied to electrodes pre-doped with approximately 7 mole% BF₄.

RESULTS AND DISCUSSION

Fig. 1 shows anodic and cathodic polarization-time transients, corresponding to p-doping and undoping with 100 sec current pulses of 1 mA. Both the wetted surface area and the diffusion coefficient can be determined from these transients.

The slope $d\eta/dt$ at $t=0$ yields the double layer capacity $C_D = I/d\eta/dt = 22 \mu\text{F}$. Such a value is only compatible with solution wetting the exterior surface, comparable in size to the projected area of 2 cm². If the large interior surface of 4000 cm² were wetted, then the capacity would have the unreasonably small value of 0.005 μF/cm². Based on the relevant solute and dopant concentrations, an estimate of the double layer capacity on the solution side of the polyacetylene and of the capacity associated with the space charge region within the polyacetylene yields values in the range of 10 to 50 μF/cm² for each. The total predicted capacity is therefore 5 to 25 μF/cm² of wetted area. Hence, the observed value of 22 μF corresponds to between 1 and 4 cm² of wetted area.

In the present case of only one exterior surface wetted by solution and pulse times short compared to the time constant for diffusion through the entire film thickness, semi-infinite diffusion analysis applies. Accounting for slow interface reaction (I₀), the solution (5) for small polarizations η is

$$\eta = (RT/F)(I/I_0 + 2I\sqrt{t}/\sqrt{\pi F c_0 A D}), \quad (1)$$

where t = time, c_0 = initial dopant concentration, A = wetted area, D = diffusion coefficient

Key Words: Polymers, Electrode, Kinetics

Manuscript received Nov. 19, 1984.

cient, I_0 = exchange current, I = applied current, F = Faraday, R = gas constant, T = temperature. A straight line should result in a plot of η vs \sqrt{t} with slope proportional to $1/\sqrt{D}$. Fig. 2 shows that this is indeed the case, and a value of 6×10^{-12} cm²/sec is determined from the slope from either anodic or cathodic transient. The fact that the extrapolated straight lines do not intersect the origin is due to the finite rate of charge transfer through the polyacetylene-solution interface (3).

It is important to note from Eq. (1) that identical transients are observed for identical values of $A\sqrt{D}$. Hence, D cannot be determined unless the wetted surface area A is known. Kaufman et al. (1) estimated 4×10^{-18} cm²/sec for the diffusion coefficient of Li and ClO₄ in polyacetylene, based on open circuit voltage decay measurements. Without knowing the wetted surface area, they assumed complete wetting of the interior surface. However, if one assumes only wetting of the exterior surface, the diffusion coefficient becomes 10^{-12} cm²/sec, in good agreement with the value determined in this study. Beniere et al. (2) derived diffusion coefficients of 2×10^{-10} to 2×10^{-8} cm²/sec for I₂ diffusion in polyacetylene, based on I₂ absorption from dilute I₂ solutions in pentane. They assumed wetting of the exterior surface only. If 0.1 to 1% of the interior surface were wetted, then the data of Beniere et al. would result in a diffusion coefficient of 6×10^{-12} cm²/sec.

In conclusion, we have established the diffusion coefficient of BF₄ dopant in polyacetylene as 6×10^{-12} cm²/sec and have shown that simultaneous determination of wetted surface area is mandatory. Grossly disparate literature values can be reconciled if allowance is made for different wetted surface areas.

Multichannel Optical Analysis for the Study of Rapid Film Growth

Application to the Anodic Oxidation of Titanium

S. Djemai-Gadi, M. Froelicher, and A. Hugot-Le Goff

Laboratoire "Physique des Liquides et Electrochimie" du C. N. R. S., Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

The multichannel optical analysis is now a means to investigate rapid phenomena, for instance the beginning of growth of an anodic oxide. Here, we will study the potentiostatic oxidation of the titanium in a sulfuric acid solution. We will show that the growth law during the first seconds is different from a classical high field law.

EXPERIMENTAL

The synopsis of the equipment is shown on figure 1. The titanium sample (E) has been mechanically and electrolytically (1) polished to be proper for optical studies, and it is polarised in 1N H₂SO₄ by a high power potentiostat (2) which allows passage of the large transient currents present at the beginning of the polarisation. The sample is illuminated by a 150 W Xenon source (S), focused by (L). After reflection, two other lens (L) focus the light on an entry slit (FE). The grating disperses the light between 200 and 800 nm, and the Reticon diode array detector (CAMERA) receives a plane scattered spectrum having a width of 25 mm. The array consists of 1024 diodes, each of them having a width of 25 μ m. Each diode can be read in 64 μ s, and the complete spectrum can be obtained in 64 ms.

Fig. 1 : Synopsis of the equipment

Key Words : multichannel optical analysis, anodic oxidation, titanium

The beginning of the spectrum acquisition is synchronised with the beginning of the oxidation by an electronic trigger. A new spectrum can be taken immediately after the end of the first acquisition, and one can then obtain a reflectance spectrum of the titanium sample under oxidation every 64 ms.

RESULTS

In figure 2 are plotted some reflectance spectra obtained at different oxidation times for a 7 V potential. One sees the appearance of an interference minimum (λ_{m1}), which shifts towards the higher wavelengths when the oxidation time (and, then, the film thickness) increases. We have previously (3) determined the relation between the wavelength of the minimum and the film thickness. Then we can obtain the growth law of the oxide from the positions of the minimum.

Fig. 2 : Reflectance spectra during an oxidation at 7 V ; -- : 64 ms ; — : 1.97 s ; -.- : 12 min.

When the thickness is greater than about 50-70 nm, one has to deal with the second interference minimum (λ_{m2}), as shown in figure 3 for a 50 V potential.

Plotting the values of thickness as function of the oxidation time, at a serie of voltages between 7 and 50 V, one observes two different growth laws, one after about 0.4 s,

Fig. 3 : Reflectance spectra during an oxidation at 50 V. -- : 64 ms ; — : 0.38 s ; -.-. : 6.50 min.

and the other during the first hundred ms. The beginning of the growth is not dependent on the electric field since, as shown in figure 4, it is the same at every voltage. The growth rate is very high ; about one monolayer of oxide is built in 1 ms. The demand for material at the interface is great and needs a rapid transport of anions towards this interface. The transport processes in the electrolyte phase control the beginning of the growth.

In the second time range, as seen in figure 5, where the values of d/V are plotted in function of $\log t$, all the experimental points fall on the same straight line. We have fitted by least square this line, and found :

$$d/V = 2.19 + 0.217 \log t \text{ nm.V}^{-1}$$

One can write also $\delta d/\delta t = 0.217 \text{ V}/t$

Fig. 4 : Beginning of the growth law of films. x : 7 V ; ● : 8 V ; + : 10 V ; o : 20 V ; ∇ : 30 V ; Δ : 50 V.

The thickness increment by time unit is proportional to the voltage, and in inverse ratio with the time. In this case, the growth of film is merely controlled by the electric field at the interface.

An Improved Interrupter Circuit for Battery Testing

A Function Generator for the Resistance-Free Recording of Current/Voltage Curves

J. Gsellmann and K. Kordesch*

Technische Universität Graz, A-8010 Graz, Austria

ABSTRACT

The use of current interrupter circuits for the determination of the "resistance-free potential" of a cell under load condition is a well-known practice. One of the authors (K. K.) and A. Marko (1) designed a line-frequency (50/60 Hz) pulse-current circuit (2-4), which has been widely used since the 1960's. In the meantime, many electronic components have been improved and miniaturized. A new measuring circuit, which can be used in combination with any potentiostat or galvanostat, has been designed and tested in our laboratory.

Current/voltage characteristics of single electrodes, cells, and batteries are measured routinely in order to study the electrochemical processes occurring in galvanic systems. For this purpose, a potentiostat or galvanostat is used in combination with a function generator, which produces a triangular (smooth-ramp) or a saw-tooth voltage pattern, the latter determined by a certain frequency and showing the desired potential steps. The resulting electrode or cell voltages and corresponding currents can be obtained simultaneously and plotted by an X/Y recording system.

Such chronopotentiometric diagrams are "voltammograms." The obtained curves are usually showing the combined effects of several electrochemical processes, following the different physical chemical laws of thermodynamic or kinetic nature, like polarization or mass-transport phenomena. The limiting process will always dominantly show its characteristic parameter.

Superimposed on all these processes, expressed by the shape of the potential or current curves is the relationship between voltages and currents, given by Ohm's law: $U = IR$, whereby U stands for the potential, I for the current, and R for the resistance or the ohmic part of the impedance of the system. The purely ohmic value of R has its origin in no electrochemical reaction and sometimes completely overshadows the electrode system's response to the potentiostatic or galvanostatic test circuit. For that reason, it is often necessary to eliminate the ohmic components from all the test data before they can be properly evaluated.

However, in many technical cell systems, great significance is given to the ohmic resistance, it should be as small as possible, for a high electrical output, but especially to minimize the heat (I^2R) losses. Large electrolyte spaces or bad external or internal electronic contacts (*e.g.*, between particles) can result in a very poor cell performance and this may be blamed wrongly on electrochemical inefficiencies. Therefore, one needs to know at least the total of the values of the ohmic resistance components. Also, the influences of cell operating parameters, such as temperature, pressure, etc., must be known, but separated from the effects on the electrochemical processes.

In the electrochemical literature, the voltage difference caused by the current flow was named "polarization" or, as the effect is called more recently, "overvoltage." The terminology divides the phenomena further, in "resist-

ance overvoltage," into "chemical polarization" and "concentration polarization," etc. The direction of the current (charging or discharging a cell) determines if the voltage drops below, or rises above, the open-circuit voltage, as a result of the polarization of the electrodes, causing the overvoltage.

In this paper, we distinguish between the instantly (with electronic speed) occurring voltage step caused by the current flow through the ohmic resistance components of the cell and the slow (mass-transport determined, equilibrium seeking) voltage changes caused by the electrochemical reactions or physical processes at the interface or in the electrodes. "Resistance overvoltage" and "chemical (kinetic) polarization" have, therefore, principally different properties related to the speed at which they appear as soon as the current is switched on. Furthermore, the chemical (kinetic) polarization stays constant (in fuel cells) or increases slowly (in batteries) while the current continues to flow.

Methods to Eliminate the Ohmic Resistance Overvoltage

The resistance can be measured with an alternating current bridge-circuit while the cell is discharged or charged. With separate probes, it is possible to locate the partial resistances of, *e.g.*, the electrolyte, certain layers, or components. The effects of temperature or pressure can be determined similarly. The correction of the current/voltage curves obtained from the X/Y recorder is only a matter of calculating the resistance-free voltages, using Ohm's law, and redrawing the curves with the new voltage values.

Resistance can be measured with separate current and voltage leads (four-point ac measurements). This method is very accurate across metallic or good conductive carbon electrodes. Difficulties arise with less good conductive materials, *e.g.*, conductive plastic sheets, where the current may go another path than the voltage probe is measuring. Area averaging measurements are helpful; sometimes surface films give very different measurements in dry conditions and in electrolyte-wetted situations. Measuring the resistance overvoltage across electrode/electrolyte interfaces in operating cells requires the use of Luggin capillaries as close as possible to the electrode. In critical cases (with a low conductivity electrolyte), one must extrapolate to the distance zero.

Effects of the ohmic resistance can be eliminated by providing a "negative ohmic resistance" compensation. Such a negative impedance converter (NIC) can be built

*Electrochemical Society Active Member.

into the electronic measuring circuit of test instruments. One of the disadvantages is that the NIC can only compensate the ohmic resistance of the whole cell; another is that the value is only approximated because the circuit has a tendency to oscillate near the compensation point.

The ohmic portion of the overvoltage can be very accurately determined by the use of pulse measurements. The simplest way to do it galvanostatically is as follows: first, set the current through the cell at the desired constant level and then apply a negative voltage pulse to the control input of the same galvanostat so that the current drops to zero. At the end of the negative pulse, the previous control setting establishes the current flow again. The voltage of the cell is measured during the short time period when the current is zero. The voltage measurement can be made in different ways. A storage or delay oscilloscope may be used, or the trace of the pulse on the screen can be photographed and evaluated.

It is also feasible to use an analog storage circuit consisting of a condenser and a periodically operating mechanical (5), electronic (6), or thermal switch (7). The simplest circuit producing high current pulses periodically consists of a transformer and a diode. In order to obtain the voltage between the pulses, a diode bridge-circuit which is opened and closed by the opposite-phase voltage is very practical (1).

The pulse measurement method described above can be automated by establishing a certain timing control sequence (with an electronic timer or with a computer program) for the current interruptions. The current flowing from or into the cell can also be changed according to a test program profile. The result is current/voltage curves which are free of the voltage difference caused by the ohmic resistance. Simultaneously, of course, the terminal voltages can be recorded. The difference can be very indicative, especially if reference electrodes are employed.

Automatic Current Interrupter Devices

Potentiostatic and galvanostatic circuits are well known in the electrochemical test practice and are commercially available. The principal diagram of a V/I control circuit is shown in the left part of Fig. 1. A potentiostat is a direct current (dc) amplifier which works as a voltage following circuit. It has a differential input; if the (-) input is connected to the output, then the amplifier will act in such a way as to reduce the voltage difference between (+) and (-) to zero (inverting mode). If the test cell, in Fig. 1 consisting of a counterelectrode CE and a working electrode WE, is put into the circuit between output and ground G, then a current will be driven through the cell; it may flow in the charge or discharge direction, depending on the test purpose. This current is controlled by the voltage supplied from a constant source (CP) and adjusted by means of the variable resistor VR (a precision ten-turn potentiometer) between (+) and the ground. The (-) input

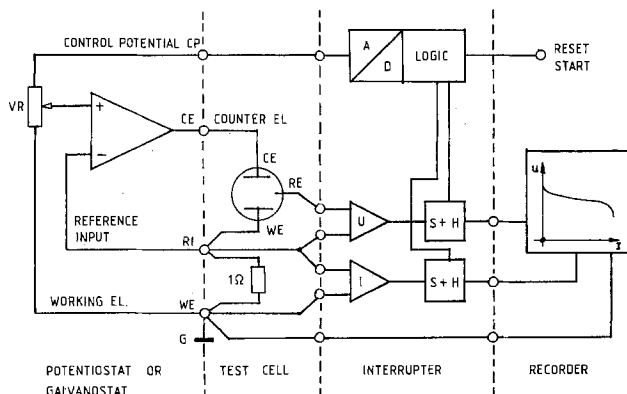

Fig. 1. Principal circuit for the "resistance-free" voltage measurements by the interruption method. CE: Counterelectrode. WE: Working electrode. RE: Reference electrode. RI: Reference input. terminal (reference input RI) follows this voltage, impressed on the circuit via the variable resistor VR and holds it (potentiostat).

Arranging a 1.0Ω resistor between ground G and allowing the potentiostat to control the voltage difference across this constant 1.0Ω resistor, one obtains the characteristic behavior of a "galvanostat." Controlling to a $1.0V$ differential corresponds to a current flow of $1.0A$.

The characteristic features of a potentiostat are maximum current output, voltage range, actual control accuracy, which is determined by the stability of the electronic circuits, and the noise level. The reference voltage source must also be considered in respect to its true accuracy and reproducible long-time stability.

The achievable steepness of the voltage step (expressed in volts per microsecond) for the case of an ideal square pulse is of special importance for the design of interrupters. The speed of the response (risetime) determines how fast the current will be able to go to zero. The time needed is usually in the range of microseconds (μs). This time is negligible compared with the time requirements of electrochemical reactions and faradic transport processes, which do show differential changes (mV) in milliseconds (ms) but may reach final equilibria only in seconds to minutes.

Figure 2 shows graphically how the current, which flows through the test cell, drops from the value i to zero. Design calculations indicated that a time period of $100\mu s$ is sufficient for the measurement of the potential while no current is flowing. The "resistance-free" voltage obtained that way may have an uncertainty of less than 1% if one does not want too severe requirements with respect to precision and cost of the circuit components. Only electrodes which have a strong tendency to form passive surface films (magnesium, for example) need special attention.

In order to measure potentials independent of the ground connections, so-called "instrument amplifiers" are used. The counterelectrode and the reference electrode of the cell to be measured are not connected to ground. Good instrument amplifiers are commercially available; if they have to be made from single components, care must be taken to adjust resistors to very close tolerances in order to achieve a high "common mode rejection." The literature describes the selection of suitable components (8, 9).

Similar considerations are applicable to the current amplifiers. Exchanging the (+) and (-) input terminals makes it possible to adapt the recorded curves to the corresponding quadrant of the X/Y recorder.

The circuit diagram shown in Fig. 3 pictures the now-available (10) complete Sample and Hold Integrated Cir-

Fig. 2. Current/time diagram: trace of the current going from the constant value I to zero and back. This profile shows the slopes of the I/T lines due to the limitations imposed by the switching speed.

Fig. 3. Principal diagram of the sample and hold integrated circuit LF398 by National Semiconductor Corporation.

circuit designated S&H-IC-LF 398 which we used. The potential of the cell to be measured is first applied to the Fet input of an impedance converter with a very high resistance input and a low resistance output. In this way, a condenser can be charged very fast to the level of the cell voltage ("sample" mode). The capacitor can be separated from the charging circuit by means of a very high resistance electronic switch and exists then in the "hold" mode. A second impedance converter with a high resistance input and a low resistance output supplies the condenser voltage to the output terminal. The impedance converters are coupled with a feedback resistor to reduce possibilities for faulty operation. The electronic switch is actuated by an operational amplifier with differential input in order to be flexible in the choices of voltages and polarities to operate the switch.

The condenser charge current is limited by a 300Ω resistor. The charge time $T = RC$; therefore, we know the necessary charge time with a given capacity. A compromise must be chosen for the ratio of charge time (that is, the acquisition time in the sample mode) and the self-discharge time in the hold mode, which must be small compared to the intervals between the pulses. A frequency of, e.g., 1 pulse in 10s, needs already a two-stage

sample and hold circuit in which the first S&H uses a small capacitor and needs an extremely short time for being charged, but keeps the voltage accurately enough for about 100 μs for charging the following, perhaps a hundred times larger capacitor. The quality of the capacitors (type of dielectric) is very important.

The integrated circuit ADC-MC8BC is used as the digital/analog converter (11). It is an 8 bit converter with built-in counter and a reference potential source of 2.55V. The unit can be utilized in two ways: the pulses reaching the input of the counter are registered as dual value and converted into an analog voltage. Vice versa, 8 bit data can be supplied as input and converted into analog voltages. The counter can be set back with the reset input.

The buffer amplifier is a sensitive component; it must have a very small drift at zero input if the temperature changes and should have a low noise level at low frequencies. We chose an LF 13741 amplifier (12), but there are higher-quality IC's available (13).

Discussion of the Complete Measuring Instrument

Figure 4 is a flow diagram of the circuits to be shown in more detail later (in Fig. 6). The numbers correspond to the IC blocks discussed. 1 is a square wave generator, using an LM 555 to produce 256 Hz oscillations (12). The next IC, 2, is a 14-step binary divider. Its steps are used to provide the following frequencies: 64, 32, 16, 8, 4, 2, 1, 0.5, 0.25, 0.125, 0.0625, 0.03125, and 0.015625 Hz. In this way, we can obtain curves with a time axis of 4s-34 min. The various frequencies are selected with the step switch S-1. The switch has also an open position in which no pulses are transmitted. The selected pulses go to three parallel, monostable (MS-IC) multivibrators (no. 3, 4 and 5), each containing an RC circuit which triggers the MS-IC timers with the negative edge of the pulses. The delay times are adjusted with an oscilloscope to the following values: no. 3, 100 μs; no. 4, 90 μs; and no. 5, 10 ms. The output pulse of no. 3 is connected to the counter input of the D/A converter (IC no. 6) via the Nand gate IC-8. The same pulses are also reaching the CMOS Gate 74C00, in which a double conversion is made in order to operate the semiconductor switch CD4066, marked as no. 9, in the correct phase relation, required at that time.

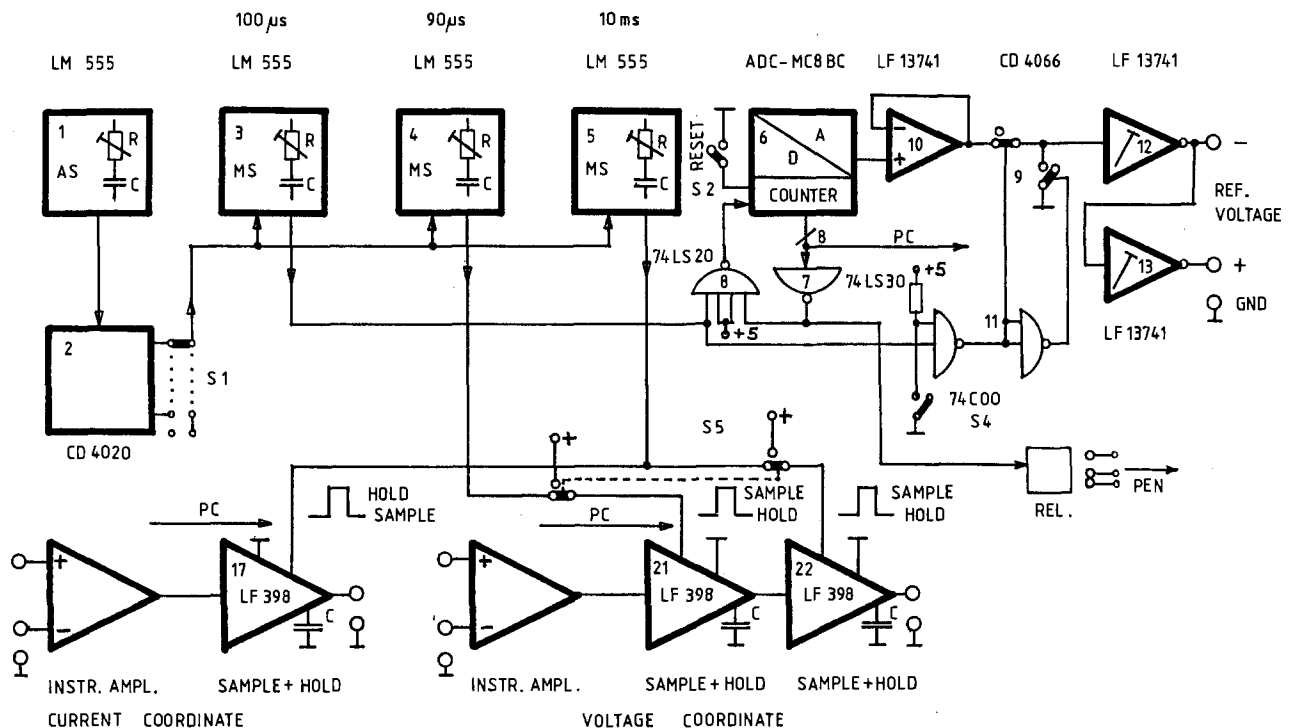

Fig. 4. Flow diagram of the frequency-controlled current interrupter circuit and voltage sensing system. The numbers in the circuit blocks correspond to the IC numbers in Fig. 6.

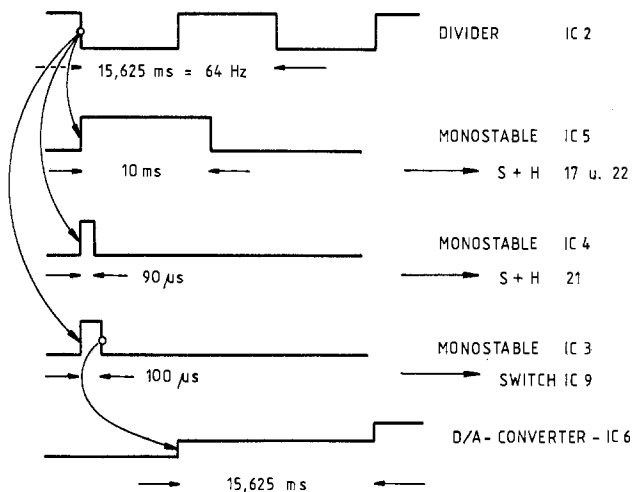

Fig. 5. A comparative diagram, showing the durations of the pulses and their timing sequences. The notations for the IC's corresponds with the numbers in Fig. 4 and 6.

As long as the Reset-Input of the D/A converter is on ground, no change occurs in the state of the counter and the output voltage is zero. As soon as S-2 is opened, the counter starts and a stepwise rising potential appears at the output. Once the counter reaches its highest decimal value (255), all eight data outputs go into the high state. The eight values are then going to a Nand gate with eight inputs and the outputs of the gate go into low state, locking the gate IC-8 for further pulses and storing the maximum values in the counter. Now the reference voltage for stationary measurements is available.

IC-12 and IC-13 amplify (and invert) the voltage to the desired value, so that the output terminals of the instrument can supply a buffered reference potential in positive and negative directions for the input of the galvanostat. Switch S-4 can prevent the pulses from going to IC-9 and the circuit measures the cell voltage with the ohmic resistance included. The output of gate IC-7 controls also a relay for the lifting of the recorder pen, as soon as the counter reaches 225.

Figure 5 is a comparative diagram, showing the durations of the pulses (the length of milliseconds in relation to microseconds is not drawn to scale!) and their timing sequences. The notations for the IC's correspond with the numbers in Fig. 4 and 6. The binary divider (IC-2) produces (in the 64 Hz position) pulses of 15,625 ms length. MS timer IC-5 controls one S&H circuit in the current circuit (17), and the second S&H in the voltage circuit (22) with pulses of 10 ms length. It should be noted that at high pulse, the S&H in the current circuit is in hold mode and the S&H in the voltage circuit is in sample mode. IC-4 controls the first S&H in the voltage circuit (21) with a 90 μ s sample period.

Figure 6 shows the power supply for the whole instrumentation. IC-6, IC-7, and IC-8 are operated with 5V and all others with 10V, split in +5 and -5V against ground. That is the reason why the input of IC-8, which gets the 10V pulses, must be connected to ground with a diode/resistor combination for the case that there is a negative voltage.
